Main Matter

Chapter 1 Introduction **3**
1.1 The Scale Moment 5
1.2 From Single Node to Fleet 12

1.3 AI Scaling Laws . . . 17
1.4 Constraints of Scale . . . 27
1.5 The C^3 Taxonomy and Foundations of Scale . . . 31
1.6 The Fleet Stack and the Lighthouse Archetypes . . . 40
1.7 The Structure of This Textbook . . . 43
1.8 Fallacies and Pitfalls . . . 44
1.9 Summary . . . 45

Part I: The Fleet

Fleet Principles **51**

Chapter 2 Compute Infrastructure **57**
2.1 The Infrastructure Walls . . . 59
2.2 The Accelerator . . . 60
2.3 The Memory Wall . . . 73
2.4 Sustained Compute and Precision . . . 86
2.5 The Node . . . 90
2.6 The Rack . . . 105
2.7 The Pod . . . 121
2.8 Accelerator Selection for Fleet Workloads . . . 125
2.9 Infrastructure Technologies That Move the Walls . . . 131
2.10 Fallacies and Pitfalls . . . 133
2.11 Summary . . . 136

Chapter 3 Network Fabrics **141**
3.1 The Synchronization Backbone . . . 143
3.2 How ML Networking Inverts Data-Center Assumptions . . . 146
3.3 Level 1 Wire and Link . . . 151
3.4 Level 2 Transport and the Performance Model . . . 155
3.5 Level 3 Switch and Topology . . . 163
3.6 Level 4 Fabric Behavior, Congestion, and Routing . . . 176
3.7 Level 5 Cluster Design and Case Studies . . . 186
3.8 Network Virtualization . . . 188
3.9 Monitoring and Debugging . . . 189
3.10 Network Technologies That Move the Ceiling . . . 192
3.11 Fallacies and Pitfalls . . . 195
3.12 Summary . . . 196

Chapter 4 Data Storage **199**
4.1 The Fuel Line . . . 201
4.2 How ML Workloads Invert Storage Assumptions . . . 203
4.3 The ML Storage Hierarchy . . . 207
4.4 The Data Pipeline Equation . . . 232
4.5 GPUDirect Storage and the CPU Data-Copy Bypass . . . 244

4.6 Checkpoint Storage . . . 249
4.7 Versioned Data and Commit Boundaries . . . 256
4.8 Storage Economics . . . 260
4.9 Storage for Serving . . . 264
4.10 Storage Technologies That Move Tiers . . . 266
4.11 Fallacies and Pitfalls . . . 267
4.12 Summary . . . 270

Part II: Distributed ML

Distributed ML Principles **275**

Chapter 5 Collective Communication **281**
5.1 From Parallelism to Communication Patterns . . . 283
5.2 The Physics of Data Movement . . . 285
5.3 Parallelism Strategies and Their Traffic . . . 287
5.4 Collective Operation Primitives . . . 289
5.5 Pricing Collectives by Rounds and Chunks . . . 294
5.6 AllReduce Algorithms and Topologies . . . 297
5.7 Hierarchical Communication . . . 312
5.8 AllToAll Exchanges at Scale . . . 320
5.9 Gradient Compression Under Bandwidth Scarcity . . . 326
5.10 Communication-Computation Overlap . . . 335
5.11 Communication Libraries and Runtimes . . . 340
5.12 Fallacies and Pitfalls . . . 342
5.13 Summary . . . 345

Chapter 6 Distributed Training **349**
6.1 Why Distribution Is Necessary . . . 351
6.2 The Parallelism Design Space . . . 354
6.3 Data Parallelism . . . 358
6.4 Scaling Efficiency and Convergence . . . 375
6.5 Model Parallelism . . . 393
6.6 Hybrid Parallelism . . . 414
6.7 Multi-Model Training for Alignment and RLHF . . . 421
6.8 Parallelism Strategy Comparison . . . 427
6.9 Frameworks and Runtime Contracts . . . 430
6.10 Fallacies and Pitfalls . . . 431
6.11 Summary . . . 434

Chapter 7 Fault Tolerance **437**
7.1 Failure Analysis at Scale . . . 439
7.2 The Mathematics of Inevitable Failure . . . 440
7.3 Failure Taxonomy . . . 445
7.4 Hardware Faults at Fleet Scale . . . 452

7.5 Check-and-Verify Defenses Against Silent Data Corruption 458
7.6 Software Faults 462
7.7 The Cost of Failure 464
7.8 Checkpointing and Progress Preservation 467
7.9 Failure Detection and Recovery 478
7.10 Elastic Recovery 490
7.11 Serving Fault Tolerance 495
7.12 Graceful Degradation 502
7.13 Distributed Debugging and Observability 507
7.14 Fault Injection Tools and Frameworks 513
7.15 Case Studies 514
7.16 Fallacies and Pitfalls 516
7.17 Summary 519

Chapter 8 Fleet Orchestration **523**
8.1 The Scheduling Problem 525
8.2 Distributed Scheduling Complexity 528
8.3 Scheduling Objectives and Their Conflicts 532
8.4 Core Allocation Constraints 535
8.5 Orchestration Paradigms 544
8.6 Topology-Aware Scheduling 555
8.7 Elastic Scheduling 563
8.8 Cost Optimization 569
8.9 Custom ML Schedulers 578
8.10 Serving Capacity in the Shared Fleet 582
8.11 Multi-Tenancy and Quotas 589
8.12 Debugging Cluster Utilization 593
8.13 Fallacies and Pitfalls 598
8.14 Summary 600

Part III: The Fleet in Production

Fleet-in-Production Principles **605**

Chapter 9 Fleet Efficiency **611**
9.1 Where Fleet Capacity Goes 613
9.2 ML Goodput 615
9.3 Measuring Goodput 625
9.4 Scheduling Goodput 636
9.5 Runtime Goodput 642
9.6 Program Goodput 649
9.7 Recovering Program Goodput 660
9.8 The Whole Fleet 671
9.9 Trading Between Factors 676
9.10 Fallacies and Pitfalls 688

9.11 Summary . . . 692

Chapter 10 Serving at Scale **695**
10.1 Inference Cost and Serving Architecture . . . 697
10.2 Limits of Single-Machine Serving . . . 699
10.3 SLO Goodput and the Serving Tax . . . 701
10.4 Serving Cost Dominance in Production . . . 703
10.5 Serving Workloads and the Serving Hierarchy . . . 705
10.6 Batching Strategies at Scale . . . 708
10.7 Memory and Decode-Time Management . . . 731
10.8 Prefill and Decode . . . 748
10.9 Weight Quantization for Serving . . . 755
10.10 Model Sharding for Inference . . . 761
10.11 Load Balancing and Request Routing . . . 773
10.12 Multi-Tenancy and Isolation . . . 784
10.13 Autoscaling and Capacity Control . . . 789
10.14 Global Inference Infrastructure . . . 794
10.15 Case Studies . . . 801
10.16 Fallacies and Pitfalls . . . 810
10.17 Summary . . . 813

Chapter 11 Edge Intelligence **815**
11.1 The Edge Learning Paradigm . . . 817
11.2 Why Learn on the Device . . . 820
11.3 Design Constraints . . . 824
11.4 Model Adaptation . . . 840
11.5 Data Efficiency . . . 854
11.6 Federated Learning Algorithms . . . 862
11.7 Federated Learning Systems at Scale . . . 868
11.8 Continual Adaptation Under Edge Budgets . . . 882
11.9 Integrating the Edge Intelligence Pillars . . . 884
11.10 Production Integration . . . 888
11.11 Engineering Challenges and Mitigations . . . 894
11.12 Fallacies and Pitfalls . . . 899
11.13 Summary . . . 901

Chapter 12 ML Operations at Scale **905**
12.1 Why a Model Fleet Needs a Control Plane . . . 907
12.2 The N-Models Problem . . . 908
12.3 Governance of State and Change . . . 922
12.4 Feature Store Operations . . . 931
12.5 CI/CD for ML at Scale . . . 942
12.6 Monitoring at Scale . . . 972
12.7 Production Debugging and Incident Response . . . 985
12.8 Platform Engineering . . . 994

12.9 Fleet Economics and Utilization . . . 1000
12.10 Organizational Operation and Learning . . . 1030
12.11 Case Studies . . . 1033
12.12 Fallacies and Pitfalls . . . 1035
12.13 Summary . . . 1037

Part IV: The Responsible Fleet

Responsible Fleet Principles **1043**

Chapter 13 Security & Privacy **1049**
13.1 The Expanded Attack Surface . . . 1051
13.2 Security and Privacy Foundations . . . 1052
13.3 Learning from Security Breaches . . . 1056
13.4 Systematic Threat Analysis and Risk Assessment . . . 1059
13.5 Model-Specific Attack Vectors . . . 1066
13.6 Fleet-Internal Trust Boundaries . . . 1091
13.7 Hardware-Level Security Vulnerabilities . . . 1095
13.8 Comprehensive Defense Architectures . . . 1105
13.9 Differential Privacy . . . 1129
13.10 Selecting and Sequencing Defenses . . . 1143
13.11 Fallacies and Pitfalls . . . 1147
13.12 Summary . . . 1149

Chapter 14 Robust AI **1153**
14.1 The Silent Failure Problem . . . 1155
14.2 Real-World Robustness Failures . . . 1158
14.3 A Unified Framework for Robust AI . . . 1161
14.4 Environmental Shifts . . . 1167
14.5 Adversarial Attacks . . . 1183
14.6 Adversarial Defenses . . . 1188
14.7 Data Poisoning Defenses . . . 1196
14.8 Robustness of Generative Models . . . 1203
14.9 System-Level Faults . . . 1205
14.10 Fallacies and Pitfalls . . . 1208
14.11 Summary . . . 1210

Chapter 15 Sustainable AI **1213**
15.1 The Energy Ceiling . . . 1215
15.2 The Scale of Environmental Impact . . . 1218
15.3 Exponential Growth vs. Physical Constraints . . . 1220
15.4 Energy Measurement and Modeling . . . 1225
15.5 Carbon Footprint Calculation . . . 1237
15.6 Data Center Energy and Resource Consumption . . . 1250
15.7 Training vs. Inference Energy Analysis . . . 1258

15.8 Hardware Lifecycle and E-Waste . . . 1270
15.9 Mitigation Strategies . . . 1277
15.10 Policy, Regulation, and the Path Forward . . . 1292
15.11 Fallacies and Pitfalls . . . 1296
15.12 Summary . . . 1298

Chapter 16 Responsible AI **1301**
16.1 The Governance Imperative . . . 1303
16.2 The Governance and Assurance Lifecycle . . . 1305
16.3 Core Principles and the ML Lifecycle . . . 1309
16.4 Architectural Trade-Offs . . . 1310
16.5 Fairness and Bias Mitigation . . . 1316
16.6 Privacy and Data Governance . . . 1341
16.7 Explainability and Transparency . . . 1349
16.8 AI Safety, Robustness, and Generative Controls . . . 1358
16.9 Accountability, Governance, and Sociotechnical Dynamics . . . 1368
16.10 Governing Responsible AI at Fleet Scale . . . 1380
16.11 Fallacies and Pitfalls . . . 1392
16.12 Summary . . . 1394

Synthesis

Chapter 17 Conclusion **1401**
17.1 Distilling Distributed ML Systems . . . 1403
17.2 Six Principles of Distributed ML Systems . . . 1404
17.3 The Complete Production System . . . 1410
17.4 Competencies Mastered . . . 1415
17.5 Where the Binding Constraint Moves Next . . . 1416
17.6 Fallacies and Pitfalls . . . 1417
17.7 Summary . . . 1418

Author's Note

When a new model is announced, the world looks at the model. It almost never looks at the fleet. Behind many frontier models, however, stand thousands of accelerators held in lockstep across a network where one slow link can stall the whole run, cooled by systems that move megawatts of heat, kept alive by protocols that treat failure not as an exception but as a scheduled event. None of this fits in the announcement. The model gets the paper. The fleet gets a footnote, if that.

This book is an argument that the fleet deserves more than a footnote. We have built vast distributed systems before, but none quite like this one, because none of the others had to be right about two things at once. The telephone network had to stay available; it never had to converge. The internet had to deliver the packet; it never had to preserve the gradient inside it. A fleet has to do both. It must move data the way any distributed system does, and it must keep the mathematics of learning intact while it moves. A node that drops out does not only cost capacity; it can break the synchronization a training step depends on and force a rollback that wastes work since the most recent checkpoint. That double obligation, computational and statistical, sustained at the scale of a small campus, is the engineering this book makes visible.

The obligation does not end when training does. A model that cannot be trained is an idea, not a system. A model that cannot be served is a research result, not a product. A model that cannot be governed is a liability, not an asset. At every stage, from the first allocated node to the last served request, the fleet decides what is possible and what remains imagined.

The problem under every chapter is easy to state and hard to solve: what it takes to build not one machine learning system but a thousand, make them work as one, and run them responsibly. I believe that is a defining engineering problem of this generation, and that the people who take it on, the ones who rarely get the headline, deserve a book that treats it as one.

Preface

Who This Book Is For

This book is for anyone who understands machine learning on a single machine and now faces the challenge of making it work at scale. The problems of scale are not the problems of a single node, only bigger. They are qualitatively different: networks partition, hardware fails as a statistical certainty, and the societal impact of every design decision is amplified by millions of users.

The assumed foundation is what an introductory ML systems course or equivalent experience supplies, with no particular prior textbook required. The advanced scope here is the transition from that single node to a coordinated fleet. That scope ranges from designing the physical substrate of an AI data center, to scaling training beyond the limits of a single accelerator, to reasoning about what happens when a production fleet serves a global user base. Throughout, the focus is on the physics of distribution, the invariants that govern every fleet-scale ML system regardless of the framework, the model, or the era.

Prerequisites

Readers should bring the following background:

- **Single-machine ML systems**: Understanding of ML workflows, neural network training, model optimization, and deployment on a single machine. Readers should be comfortable reasoning about memory hierarchies, computational graphs, accelerator execution, and hardware-software interactions. Appendix A recaps the single-machine performance model (the iron law, arithmetic intensity, and the Roofline Model), the memory hierarchy, training memory per parameter, and transformer compute that later chapters assume.
- **Programming**: Fluency in Python, including functions, classes, and data manipulation with NumPy. Familiarity with at least one ML framework (PyTorch, TensorFlow, or JAX).
- **Mathematics**: Comfort with linear algebra, basic calculus, and probability at the undergraduate level. Section E.1.1 restates the probability results that the failure analysis uses, and section F.1.1 develops the queuing results that serving analysis uses.

The following background is helpful but not required:

- **Distributed systems**: Familiarity with networking concepts (TCP/IP, bandwidth, latency), parallelism, and basic distributed computing deepens understanding of the fleet infrastructure and training chapters.
- **Cloud infrastructure**: Experience with containerization and orchestration (Docker and Kubernetes) or cluster schedulers (Slurm) provides useful operational context.
- **Production engineering**: Understanding of monitoring, observability, and site reliability practices will enrich the deployment and operations chapters.

Why a Fleet-Level Textbook

In 2012, training AlexNet took five to six days on two GPUs (Krizhevsky et al. 2012). By 2023, public GPT-4-class estimates placed frontier training at roughly 25,000 GPUs running for about three months (Patel and Wong 2023); OpenAI did not disclose the actual hardware configuration (OpenAI et al. 2023). This is not the same engineering problem at a larger scale. It is a categorically different engineering problem.

On a single machine, performance is governed by the memory wall, the gap between processor speed and memory bandwidth. In a distributed cluster, a new limit emerges. Bisection bandwidth, the total bandwidth across the narrowest cut that divides the cluster into two halves, caps the throughput of any traffic that must cross that cut. Data no longer moves through local hierarchies alone; it traverses optical fabrics governed by the speed of light between racks and across continents. Hardware failures, rare enough on a single machine to be treated as exceptions, become routine statistical events at fleet scale. Long training runs must plan for interruptions rather than rely on every component remaining available until completion.

These are not operational annoyances. They are physical constraints, as fundamental and as permanent as the memory wall, Amdahl's Law, or the energy cost of data movement. They require their own engineering discipline, built on the invariants this book develops:

- **The Empirical Scaling Law**: Within empirically validated regimes, model loss falls as a power law in training compute, data, or parameters, so each further improvement demands multiplicatively more resources. This is the pressure that moves machine learning from single machines onto fleets.
- **The Bisection Bandwidth Theorem**: For communication patterns that must cross the minimum bisection, throughput is bounded by that bisection bandwidth.
- **The Fleet Law**: Under fixed-work scaling, reduced per-node computation competes with communication and coordination costs, so adding workers does not guarantee proportional speedup.
- **The Young-Daly Checkpoint Interval**: The optimal checkpoint interval balances the cost of writing state against the expected cost of lost work due to failure.

- **Serving Cost Dominance**: For high-traffic production models, cumulative inference operational expenditure can exceed the one-time training cost, making serving efficiency a lifecycle optimization target.
- **The Fairness Impossibility Theorem**: With unequal group base rates and imperfect prediction, risk scores cannot satisfy groupwise calibration and equal mean scores across groups within both outcome classes simultaneously. Thresholded error-rate parity and demographic parity are distinct requirements with their own trade-offs.

If single-machine ML systems engineering asks *"what can one machine build?"*, then fleet-scale ML systems engineering asks *"what can a thousand machines build together, and at what cost to reliability, efficiency, and society?"* That final clause is what sets fleet-scale engineering apart. A single machine affects its user; a fleet affects everyone its outputs touch, across millions of decisions per second. At that scale, reliability, efficiency, and fairness stop being features and become engineering constraints as binding as bandwidth or power. A system that scales but cannot be trusted has not been engineered. It has only been enlarged.

This book develops that discipline. It follows the Hennessy and Patterson pedagogical model, extending the quantitative, principles-first approach to the distributed scale (Hennessy and Patterson 2011; Hennessy and Patterson 2019, 2017). Just as their work taught a generation to reason about processor performance from first principles, this book teaches the reader to reason about fleet performance, replacing intuition about distributed systems with measurement, and ad hoc scaling with engineering.

The architectural priorities and operational failure modes explored in these chapters did not originate in an academic vacuum. They were gathered directly from practitioners in industry, through technical exchanges at conferences, engineering meetups, and conversations with colleagues. These colleagues generously made the time to explain what breaks when scaling models across thousands of accelerators and what practicing systems engineers must understand.

Single-node foundations supply the bricks of those systems: tensors, kernels, memory hierarchies, and optimization loops. What breaks at fleet scale is rarely an individual brick, because a fleet is closer to an orchestra than to a larger wall. An orchestra is not simply many musicians playing at once. It needs a conductor, a score, precise synchronization, and the ability to recover when a player drops out, none of which governs a solo performer. A training cluster, a serving fleet, and an edge deployment are vastly different systems, but beneath them sit the same building blocks: parallelism strategies, collective communication primitives, checkpoint protocols, scheduling algorithms, and the trade-offs between throughput, latency, fault tolerance, and cost.

What This Book Covers

This book focuses on the machine learning fleet: coordinated machines that jointly train, serve, or maintain ML models. Warehouse-scale training clusters are one form; geographically distributed serving replicas and heterogeneous edge devices

are others. Across these forms, communication and coordination couple local execution to fleet behavior, while reliability, resource budgets, and governance constrain the design. The scope is the fleet as it exists today and the governance of operating it at scale. Research-frontier topics such as fully autonomous fleet management, next-generation interconnects, neuromorphic computing at scale, and formal verification of fleet-level safety properties lie beyond it.

The content is organized into four parts:

- **Part I: The Fleet** builds the physical substrate of the AI data center from the ground up: the silicon and cooling of compute infrastructure, the network fabrics that connect thousands of accelerators, and the scalable data storage that feeds training pipelines.
- **Part II: Distributed ML** establishes the logic of distribution beyond a single machine: the collective communication primitives that synchronize gradients, the parallelism strategies (data, tensor, and pipeline) for training models too large for single devices, the fault tolerance mechanisms that ensure reliability when failure is routine, and the orchestration systems that manage the fleet.
- **Part III: The Fleet in Production** takes the trained model from the cluster to the world: fleet efficiency, which measures how much of a fleet's capacity becomes useful work, serving at scale for millions of concurrent requests, edge intelligence across heterogeneous and federated devices, and the operational lifecycle required to manage production fleets.
- **Part IV: The Responsible Fleet** confronts the forces that determine whether the fleet serves its users or harms them: security and privacy, robust system design, environmental sustainability, and responsible engineering as constraints as fundamental as power density or bisection bandwidth.

These four parts trace a path through the fleet stack, a layered abstraction that organizes an ML system at distributed scale, from the physical facility up to its governance. The stack has eight rows grouped into four bands, and each band is one part of the book. At the base, the Infrastructure band (Part I) holds **Facility & Accelerators** and **Fabric & Storage**, the physical substrate. On top of that hardware, the Distribution band (Part II) adds **Distributed Execution** and **Reliability & Control** to manage parallel work, communication, scheduling, and recovery. Once a model can be trained reliably, the Serving band (Part III) provides **Runtime & Serving** and **Operations** to take models to users and manage the production lifecycle. At the top, the Governance band (Part IV) layers **Assurance** (security, privacy, and robustness) and **Governance & Sustainability** to turn trust, risk, policy, and environmental cost into engineering constraints. Each row provides an abstraction to the row above and consumes the row below. Engineering decisions in the Infrastructure band constrain what is possible in the bands above it, while governance requirements constrain choices throughout the stack. Privacy, acceptable risk, and environmental budgets enter the design from the beginning; Part IV

develops their enforcement mechanisms after the infrastructure and operational dependencies are available.

Where the fleet stack locates responsibility, a second framework diagnoses cost. The C^3 taxonomy divides the wall-clock time of distributed execution into Compute, Communication, and Coordination, and the Fleet Law turns that division into an equation for distributed step time. Every chapter applies this lens to its own layer of the stack. Three recurring workloads, the archetypes, keep the analysis concrete: a large dense language model (Archetype A), a recommendation model with very large embedding tables (Archetype B), and a model trained by federated learning across phone-class devices (Archetype C). Each stresses a different part of the fleet, and the chapters return to whichever one exposes their central constraint.

Each part builds on the previous one, so sequential reading is recommended. The reading paths below offer alternatives for readers with specific goals.

Suggested Reading Paths

The chapters are ordered so that each can draw on everything before it, but not every chapter consumes the one immediately before it. A dependency map derived from the chapters' own cross-references records which chapters build directly on which (figure P.1). An arrow in the map means the later chapter uses a model, mechanism, or constraint that the earlier one establishes. Two features of the map guide the choice of path. First, every chapter lies on a route to chapter 17, whose six principles cite every chapter of Parts I through IV, so no chapter is a dead end. Second, several dependencies cross part boundaries: distributed training builds on both the storage pipeline of chapter 4 and the collectives of chapter 5, and fleet efficiency (chapter 9) builds on chapter 8. Consecutive chapters without an arrow mark a change of thread rather than a gap. Chapter 5, for example, builds on the fabric model of chapter 3 rather than on the storage chapter that precedes it.

Each path below begins with the introduction, assumes the single-machine prerequisites listed earlier in this preface, and keeps every chapter that its destination depends on in the map:

- **The Complete Path** (all chapters, in sequence): Follows the causal chain of constraints that governs the ML fleet from first principles of distribution. After the introduction, progress through Parts I, II, III, and IV.
- **The Infrastructure Path** (physical fleet and orchestration): Focuses on Part I (chapter 2, chapter 3, chapter 4), then chapter 8. Before orchestration, use the collective traffic patterns in chapter 5, the workload partitioning in chapter 6, and the checkpoint/recovery model in chapter 7 to establish what the scheduler must place, connect, and preserve.
- **The Scaling Path** (distributed training depth): Establishes the memory-capacity, network-bandwidth, and storage-throughput models in Part I before focusing on chapter 5, chapter 6, chapter 7, chapter 8, and chapter 9. Readers already comfortable estimating those limits can use Part I as a reference.
- **The Production Path** (deployment and operations): Uses Part I for fleet capacity and network constraints. It then establishes collective communi-

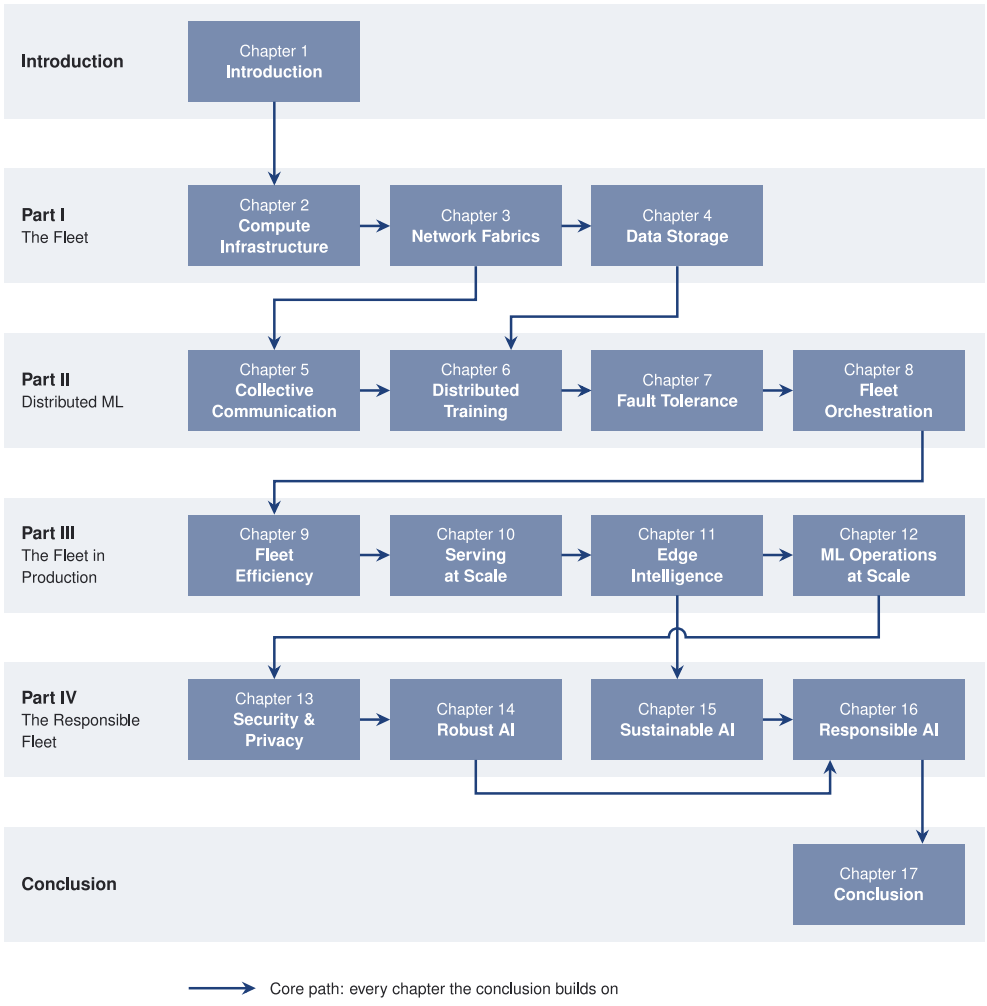

Figure P.1: Chapter Dependency Map: Each arrow points from a chapter to a later chapter that builds on its results, derived from the book's cross-references with transitive links omitted. Every chapter lies on the core path the conclusion builds on, so the map draws no optional branch. Book order is one valid reading order; a missing arrow between consecutive chapters means the later chapter does not directly consume the earlier one's results.

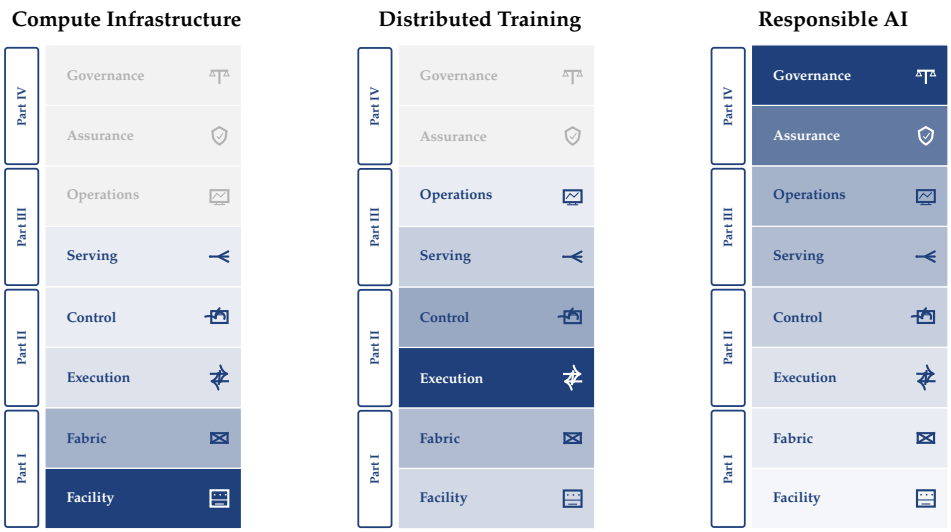
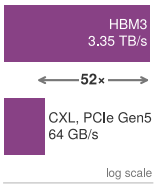
cation in chapter 5, model partitioning in chapter 6, failure and recovery in chapter 7, placement and isolation in chapter 8, and how much of the fleet's capacity becomes useful work in chapter 9. Continue through chapter 10, chapter 11, chapter 12, and Part IV (chapter 13, chapter 14, chapter 15, and chapter 16).



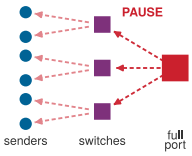
How to Read This Book

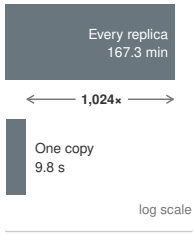
Across any of those reading paths, recurring visual cues in the margins orient the reader within the fleet stack. At every chapter opening, a margin figure highlights which rows of the stack the chapter addresses. The full stack below shows each row with its scope, grouped into the four parts of the book:

The Roman numerals (I–IV) mark those four parts, while the row intensity marks emphasis. The stack uses one accent color throughout so that shade, not hue, carries the chapter-focus signal.

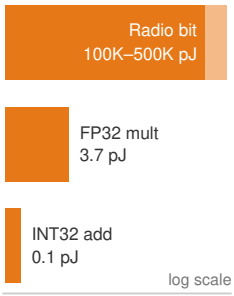


In the margin figures throughout the book, the intensity of each row reflects how strongly the chapter engages it. Brighter (higher intensity) marks the chapter's primary focus; dimmer (lower intensity) marks contextual relevance as constraints propagate upward. Consider three chapters that illustrate how the emphasis shifts:





In Compute Infrastructure, the bottom row dominates because the chapter is about silicon, power, cooling, and physical deployment. In Distributed Training, **Distributed Execution** is brightest while **Reliability & Control** remains visibly relevant because large training runs depend on scheduling and recovery. In Responsible AI, **Governance & Sustainability** is primary while **Assurance** stays strong because accountability depends on measurable trust and risk controls. The



same stack tells three different stories, and in each one a decision made in one row ripples through the rows above and below it.

Small visual notes sit in the margins wherever a relationship is fastest to grasp by eye. They are reading aids, not figures to cite later. At fleet scale, this visual grammar makes bandwidth gaps, failure blast radius, checkpoint ratios, and edge-energy trade-offs visible without interrupting the argument. When a miniature uses a log scale, it says so inside the image.

Alongside these visual miniatures, the margins carry unnumbered **marginal navigation pointers** that trace architectural dependencies across the fleet without interrupting the reading flow of the prose:

- ↩ **Backward pointer:** Directs the reader back to the earlier chapter where a physical limit, hardware contract, or analytical model was established.
- ↪ **Forward pointer:** Directs the reader ahead to the later chapter, or to the appendix, where the current idea is developed, measured, or enforced.
- ⇄ **Contrast:** Marks a place where two chapters treat the same problem differently, so the comparison is visible at a glance.

A pointer only orients. When a sentence depends on another chapter, the reference stays in the text.

The appendices are the last reading aid. Beyond the single-machine recap in Appendix A, they collect the diagnostic tables, the communication, reliability, and serving models, and the reference numbers the chapters use.

Conventions

This book uses a small set of typographic conventions to mark what each piece of prose is doing.

Bold marks first definitions

A term in **bold** within body prose is its formal first introduction in the book. Each term receives this treatment exactly once. Subsequent appearances are unbolded; by then the term is part of the working vocabulary the chapter carries forward.

> The **Fleet Law** decomposes the time of one distributed step into local computation, exposed communication, and synchronization.

The bold is a contract: register this term because it will recur. A matching index entry in the back of the book points to the defining occurrence (under the `definition` subentry), providing a way to return to it. Key technical terms are also compiled in the glossary.

Bold also appears in a second, structural role: as a functional label at the start of an item inside a callout box or a summary bullet, for example **Recommendation**, **Trade-off**, or **Result**. In that context, the bold is scaffolding rather than a first definition.

Italics mark specific distinctions

Italics are not used for general emphasis. Every italic span in this book performs one of five specific jobs:

- **Direct opposition**: *training* vs. *inference*, *allocated* vs. *productive* accelerator time.
- **Impossibility, stated as physical, mathematical, or logical law**: "a synchronous step *cannot* finish before its slowest worker does."
- **Word used as word**: "the term *gradient* refers to a vector of partial derivatives."
- **Titles of works**: *Computer Architecture: A Quantitative Approach*.
- **Thesis punchline**: A single italicized sentence that captures the controlling insight of a section, for example, *At scale, failure is the normal operating condition.*

An italicized word is performing one of these jobs. A word that is not italicized carries no implicit emphasis.

Callouts have visual identities that match their job

Callout boxes are not decoration. Each type signals a specific kind of content, so the visual identity tells the reader what the box contains before they read it.

Callout	Contains
Definition	Formal definition of a key term, with its significance, distinction from the nearest neighbor concept, and a common pitfall
Example	Historical case or concrete scenario, structured as context, insight, and systems lesson
Systems Perspective	Analytical observation or mathematical nuance that enriches the surrounding argument
Napkin Math	Worked calculation walked through step by step, with values computed inline from the book's constants; intermediate tables and equations are the math itself
Checkpoint	Self-check questions to verify understanding of the preceding section
War Story	Documented engineering incident with a sourced failure mode, structured as context, failure, consequence, and lesson

Callout	Contains
Lighthouse	Recurring workloads characterized by a profile (parameters, FLOPs, dominant constraint), used as anchored case studies across multiple chapters
Principle	Canonical book principle or invariant referenced from later chapters
Theorem	Formal, equation-backed result or bound, stated with its conditions and applied in later quantitative analysis
Key Takeaways	Four to seven most important results from a chapter, in summary form
Learning Objectives	Skills and concepts that readers should be able to explain or apply after completing the chapter
What's Next	Bridge from the chapter just ended to the chapter beginning, naming the open question the next chapter addresses

When a callout contains a table, figure, or equation, that artifact is part of the callout's pedagogical unit, not decoration. A lighthouse's profile *is* its characterization. A napkin math box's intermediate tables *are* the worked math. Reading these as separated artifacts loses the teaching arc. Standalone reference tables, by contrast, sit between paragraphs as numbered artifacts the reader returns to through cross-references. Both forms are valid; the visual marker (callout vs. standalone) tells the reader which one they are looking at.

Companion Resources

Whichever path readers choose, this book is part of a broader learning ecosystem. The complete text, interactive notebooks, lecture slides, exercises, hands-on labs, and supplementary materials for every chapter are available online at **mlsysbook.ai**.

This book is built in the open. Its full text, figures, and build system are public, and contributions from readers worldwide have sharpened every chapter. Visit **mlsysbook.ai/git** to report an issue, suggest an improvement, or contribute directly.

Using This Book in a Course

This book grew out of CS249r at Harvard University and the TinyML edX professional certificate program. That teaching reinforced an insight that shapes the curriculum here: bandwidth, energy, and failure set the limits on a microcontroller and on a data center alike, and what changes with scale is which limit binds. Because the physics is continuous while the engineering changes at each scale boundary, the book is structured to support a one-semester advanced course covering the full distributed ML systems stack, while allowing instructors to select individual parts for shorter modules:

- **Parts I–II** (The Fleet and Distributed ML) suit an advanced half-semester on distributed training infrastructure.
- **Parts III–IV** (The Fleet in Production and The Responsible Fleet) suit an applied half-semester on production ML at scale. Such a module should first

review chapter 5 and chapter 8, which fleet efficiency and serving build on (figure P.1).

For survey courses or executive programs, the four part introductions provide a condensed map of the constraints that govern fleet-scale ML systems. Their principle statements are previews; the chapters supply the assumptions, worked reasoning, and mechanisms needed to apply them.

Slides, assignments, and instructor materials for courses that use this book are available at **mlsysbook.ai**.

Acknowledgments

Origins

Earlier teaching on TinyML grew out of the realization that the constraints governing milliwatt devices are the same constraints governing data-center accelerators. This book grew out of a different realization, one that came from working on ML Fleet Efficiency as a visiting researcher at Google. Peter Mattson, who had been a collaborator on MLPerf, made that opportunity possible. What I encountered there changed how I think about ML systems: the engineering required to coordinate thousands of accelerators into a single coherent system is a discipline unto itself, and that discipline had no textbook.

That work introduced me to the ML Productivity Goodput (MPG) metric, fleet-level heterogeneity at a scale I had not seen before, and the daily reality of failure as a statistical certainty rather than an exception. The gap between what practitioners knew and what was written down was enormous. The researchers who built these systems published individual results, but the connective tissue between those results, the principles that made them cohere into a discipline, existed only in the heads of the people doing the work. This book is an attempt to document that connective tissue.

Collaborators and Colleagues

I learned most of what I know about fleet-scale systems from the ML Fleet Efficiency team at Google: Arissa Wongpanich, Tayo Oguntebi, Jose Baiocchi Paredes, Yu Emma Wang, Phitchaya Mangpo Phothilimthana, Ritwika Mitra, and Zongwei Zhou. Naveen Kumar led that effort, and the way he thought about fleet-level optimization shaped how I think about it still. Robert Hundt pushed my understanding of performance engineering at scale. Together, Naveen and Robert showed me what fleet-level efficiency looks like from the inside. David Kanter continued the MLPerf collaboration, and our discussions on benchmarking distributed systems sharpened the quantitative methodology that runs through every chapter. Greg Diamos provided invaluable perspective on scaling laws and their origins at Baidu, where some of the earliest work on large-scale distributed training took shape.

The researchers whose papers fill the bibliography of this book deserve particular acknowledgment. The principles taught here were not invented for this textbook; the practitioners and researchers who built the systems, measured the failures, and published what they learned discovered them. This book synthesizes their work into a coherent narrative. The debt is to them.

Support

The Harvard Data Science Initiative, Harvard Extension School, and the National Science Foundation supported this work. The Edge AI Foundation and ICTP supported educational outreach and scholarships, while our industry partners provided the infrastructure and tooling that enabled practical experimentation.

At MIT Press, Susan Hartman believed in this project from the beginning and guided it from an open-source experiment to a published textbook. Her editorial judgment and support made this book real. I am equally grateful to MIT Press for agreeing to keep this book available as open access. A textbook about a discipline shaped by the open-source community should be accessible to everyone in it.

For the complete and most up-to-date list of all GitHub contributors, please visit the online version at mlsysbook.ai. For those interested in contributing, please consult our GitHub repository.

Every GitHub star is a signal that someone cares about this material, is learning from it, and believes the work matters. The online community of learners, with their questions, their curiosity, and their willingness to engage with an unfinished textbook, kept this project moving when the scope felt overwhelming.

Finally, I thank my wife and my children. I wrote this book in the hours that belonged to them: weekends that disappeared into revisions, evenings that stretched past midnight, mornings when I was present but not quite there. They never complained. They asked how the writing was going, brought me coffee, and gave me the space to finish. Whatever merit this book has, their patience and their support made it possible.

A Note on AI Assistance

Every chapter of this book was researched, written, and rewritten by me. I also used artificial intelligence tools throughout the process. What follows is more than the disclosure MIT Press requires of authors who use AI. It is an honest statement of how AI assisted in navigating fleet-scale systems engineering, and the rigorous human verification standard applied to the result.

In an era of generative AI, defining what authorship really means has become genuinely difficult. When tools can draft prose, crunch cluster arithmetic, unearth research papers, and generate visual sketches, where does the machine end and the author begin?

In developing this text, AI tools served as an accelerator across computation, literature review, and drafting. On the infrastructure side, this involved extending the MLSysIM infrastructure modeling engine from single-node execution to the fleet level: modeling 3D parallelism (tensor, pipeline, and data parallel strategies), collective communication fabrics, cluster network topologies, and fault-tolerance protocols. AI helped formulate complex cluster-level equations, write executable Python cells, and implement automated pre-commit checks.

AI proved especially valuable in digging into the vast literature of distributed systems, unearthing seminal, classical papers and historical foundations that modern AI literature often overlooks. In the writing itself, I used AI to draft initial chapter outlines, generate preliminary explanations, and synthesize dense research papers into first-pass text, which I then evaluated, restructured, and substantially rewrote to ensure conceptual rigor.

Beyond code and prose, AI fundamentally shifted how I developed the book's visual language. In previous work, sketching architectural diagrams was a slow, manual bottleneck. For this book, I used generative AI to produce initial conceptual drafts and rough schematics of cluster topologies. While these AI-generated sketches were far from publication-ready, they served as an effective conceptual boilerplate, helping clarify and communicate the architectural concepts and communication patterns for the ongoing illustration and refinement process.

Yet mechanical computation, literature synthesis, and AI-assisted drafting are only the starting point. The most critical and time-intensive phase of writing this book was human validation. To ensure that the analytical models reflect the reality of warehouse-scale computing rather than idealized abstractions, I conducted extensive one-on-one review meetings with domain experts: distributed systems researchers, ML fleet operators, and hardware architects. In these sessions, we

walked through chapters, stress-tested assumptions, scrutinized performance equations, and debated design trade-offs. This human feedback loop is the longest and most demanding part of the authoring process, but it is indispensable. Without that expert review, a systems book risks teaching clean abstractions that fail on real silicon.

Writing a textbook is an act of synthesis, not a claim of personal invention. The fundamental breakthroughs in distributed systems and hardware architecture belong to the researchers and engineers cited throughout these chapters. My name appears on the cover not out of ego, but because authorship is the assumption of human responsibility. It is the demanding process of vetting these ideas against real-world hardware, and it means providing a single human being whom readers, students, and engineers can hold accountable, someone to reach out to for clarifications, debates, and corrections.

Machine learning systems cannot be certified the way deterministic logic can. That verification gap applies to AI-assisted authoring with equal force. The standard held here is the standard we must demand of every fleet we build: **the tool can propose, but only the human engineer can ratify and take responsibility.**

Notation

To a machine learning researcher, B denotes batch size, while to a network engineer, B denotes bandwidth. In distributed systems, N represents the count of worker accelerators, whereas in statistics, N denotes sample count. In high-performance computing, P is commonly used for processor count, but in deep learning, P is reserved for model parameter count. Similarly, in this book's communication models, α denotes per-message network latency and β denotes link bandwidth, whereas in statistical learning, α represents a power-law scaling exponent and β represents optimizer momentum.

These collisions arise because machine learning at scale combines three fields that developed their mathematical conventions independently: machine learning, distributed systems, and high-performance data center networking. Training and serving modern foundation models requires orchestrating workloads across thousands of accelerators connected by high-speed networks, which places symbols from all three fields into the same equation.

This book establishes a unified mathematical notation for distributed machine learning systems. The conventions defined below eliminate ambiguity across scaling laws, collective communication algorithms, parallel execution schedules, and cluster reliability models.

The Governing Equations of Distributed Performance

A distributed training step or serving request spends time both inside each accelerator and across the network that connects them, so performance modeling follows a two-tier hierarchy: the single-device execution foundation and its fleet-wide composition. The subsections that follow state each governing equation and define the symbols that appear in its terms.

The single-device foundation (the iron law of ML systems)

Every distributed training step or inference pass builds on local execution on individual accelerators. For serialized execution phases on a single accelerator, the **iron law of ML systems** decomposes execution time into memory access, arithmetic computation, and latency overhead:

$$T = \underbrace{\frac{D_{\text{vol}}}{\text{BW}}}_{\text{Memory Time}} + \underbrace{\frac{O}{R_{\text{peak}} \cdot \eta_{\text{hw}}}}_{\text{Compute Time}} + \underbrace{L_{\text{lat}}}_{\text{Latency Overhead}}$$

Each symbol was chosen deliberately to preserve machine learning conventions while maintaining architectural precision. The table below records the definition, physical unit, and collision-avoidance rationale for each term:

Symbol	Definition	Unit	Notes
T	**Execution Time**	seconds	Total serialized execution time in the iron-law performance decomposition.
BW	**Bandwidth**	bytes/s	**Avoids collision with B (Batch Size)**. Systems literature often uses B for bandwidth, while ML literature often uses B for batch size. The notation preserves the ML convention.
D_{vol}	**Data Volume**	bytes	**Avoids collision with D (Dataset Size)**. In scaling laws, D means training tokens. Here we need bytes moved through memory. The subscript disambiguates.
η_{hw}	**Efficiency**	—	Hardware utilization $(0 \leq \eta_{\text{hw}} \leq 1)$. Avoids collision with learning rate (η).
L_{lat}	**Latency**	seconds	**Avoids collision with L (Loss)**. Fixed overhead time (kernel launch, network RTT). The subscript distinguishes from the loss function.
O	**Operations**	FLOPs	Total floating-point operations. Clean in equations (vs. "Ops").
R_{peak}	**Peak Rate**	FLOP/s	**Avoids collision with P (Parameters)**. Roofline presentations often use P for performance, while ML literature commonly uses P for parameter count. The notation preserves the ML convention.
Θ	**Asymptotic Tight Bound**	Operator	Asymptotic tight bound: grows at the same rate as its argument, up to constant factors.
$D_{\text{vol}}^{(\text{batch})}$	**Batch Data Volume**	bytes	Bytes of input data one batch carries to the accelerator.
f	**Clock Frequency**	hertz	Rate at which a processor's clock ticks, setting how many switching cycles occur per second.
Δ	**Finite Change**	Operator	Finite change in the quantity it prefixes, between two states, configurations or points in time.
µ	**Micro Unit Prefix**	Operator	SI unit prefix micro, one millionth, written before a unit such as seconds.
b	**Numeric Bit Width**	Integer	Number of bits used to represent one numeric value, such as an arithmetic operand or a quantized weight or activation.
$T_{\text{pipelined}}$	**Pipelined Execution Time**	seconds	Execution time of a workload whose data movement and computation overlap, set by the slower of the two plus fixed latency.

Symbol	Definition	Unit	Notes
$T_{\text{sequential}}$	**Sequential Execution Time**	seconds	Execution time when data movement, computation and fixed overhead run one after another with no overlap, the sum of the iron-law terms.
T_{IO}	**Step I/O Time**	seconds	Time the input pipeline needs to read, decompress, decode and stage the data for one training step.
$\text{BW}_{\text{storage}}$	**Storage Bandwidth**	bytes/s	Sustained rate at which the storage system delivers bytes to the input pipeline.
T_{step}	**Training Step Time**	seconds	Wall-clock time of one training step, bounded below by the slower of compute and input I/O.
k	**Unit Alias Multiplier**	Dimensionless	Number of base units in one unit alias, the conversion multiplier of a unit-conventions table row.

Why these choices matter

Without careful notation, statements about distributed systems become ambiguous. Consider a typical unsubscripted claim:

> *"Reducing D improves performance."*

In distributed machine learning, this could mean reducing the dataset size (fewer training samples), shrinking the data-parallel degree N_{DP}, or reducing the data volume D_{vol} moved across the memory bus through quantization. With our notation, we distinguish them precisely:

> *"Reducing D_{vol} through FP8 quantization cuts memory traffic across the interconnect while D (training tokens) and N_{DP} remain unchanged."*

Subscripted variants

The root symbol names the fundamental physical quantity, while an upright subscript specifies the precise domain or measurement point. Three recurring families illustrate this convention across this book:

- $\text{BW}_{\text{memory}}$, $\text{BW}_{\text{network}}$, $\text{BW}_{\text{interconnect}}$: bandwidth across distinct tiers of the distributed memory and fabric hierarchy.
- D_{vol}, R_{peak}, L_{lat}, η_{hw}: single-node iron-law terms, held clear of shared ML symbols.
- E_{move}, E_{compute}, E_{total}: energy budget components across distributed compute nodes.

The subscript therefore carries part of the claim. Memory and network bandwidth differ by orders of magnitude, so a figure is reproducible only when the subscript says where it was measured.

The Fleet Law (distributed step time)

When scaling a model across a fleet of $N = N_{\text{GPU}}$ accelerators, single-device compute time is distributed across workers, while communication and synchronization overheads are introduced. Under partitioned execution of fixed work, the governing equation is the **Fleet Law** (the distributed step-time model, equation 1.3):

$$T_{\text{step}}(N) = \frac{T_{\text{compute}}}{N} + T_{\text{comm}}(N) + T_{\text{sync}}(N) - T_{\text{overlap}}$$

Symbol	Definition	Unit	Notes
N, N_{GPU}	**Number of Devices**	Integer	Accelerator count in a distributed job, the core's N_{GPU} ($N = N_{\text{GPU}}$); also the rank count of a collective. *(Not parameters, use P.)*
G_{node}, N_{nodes}	**Accelerators per Node, Node Count**	Integer	Hierarchical collectives split the fleet as $N = G_{\text{node}} N_{\text{nodes}}$. *(Bare G is the LogGP gap per byte.)*
$T_{\text{step}}(N)$	**Distributed Step Time**	seconds	Wall-clock time for one training step at scale N.
T_{compute}	**Single-Device Compute Time**	seconds	The core's compute term for one training step (forward + backward pass) on one device.
$T_{\text{comm}}(N)$	**Communication Time**	seconds	Time for collective operations (AllReduce, AllGather); depends on payload, topology, and N.
T_{overlap}	**Overlapped Time**	seconds	Communication hidden behind computation. Reduces effective overhead.
$T_{\text{sync}}(N)$	**Synchronization Time**	seconds	Total nonoverlapped synchronization or coordination cost per step at scale N.
ρ	**Communication-Computation Ratio**	Dimensionless	$\rho = T_{\text{comm}}(N)/(T_{\text{compute}}/N)$. Values near or above 1 indicate communication-bound scaling.
CI	**Communication Intensity**	bytes/FLOP	Network bytes moved per local FLOP, $\text{CI} = M/O$; the fleet analogue of arithmetic intensity I.
C_2	**Communication Axis**	Set	Communication axis of the C^3 taxonomy, data movement across the network fabric, viewed as the set of techniques it covers so that axis intersections name zones of the taxonomy.
C_1	**Compute Axis**	Set	Compute axis of the C^3 taxonomy, local arithmetic and memory within a node, viewed as the set of techniques it covers so that axis intersections name zones of the taxonomy.

Symbol	Definition	Unit	Notes
C_3	**Coordination Axis**	Set	Coordination axis of the C^3 taxonomy, synchronization, failure recovery and scheduling across the fleet, viewed as the set of techniques it covers so that axis intersections name zones of the taxonomy.
C	**Operational Dimension**	Record	One of the three operational dimensions of the C^3 taxonomy, indexed 1 to 3 as compute, communication and coordination.

Scaling laws of foundation models

Scaling laws anchor the book's account of why machine learning moved onto fleets. The single-resource power law and the dense-transformer compute rule are:

$$\mathcal{L}(X) = A_{\mathcal{L}} X^{-\alpha_{\text{scale}}} + C_{\mathcal{L}}, \qquad O_{\text{train}} \approx 6PD$$

Symbol	Definition	Unit	Notes
X	**Scaled Resource**	varies	Training compute, parameter count P, or training tokens D, depending on the fitted law.
α_{scale}	**Scaling Exponent**	Dimensionless	Fitted power-law exponent; valid only within the regime in which it was measured. *(Not network latency α.)*
$A_{\mathcal{L}}$	**Scale Coefficient**	loss units	Task-dependent fitted constant.
$C_{\mathcal{L}}$	**Irreducible Loss**	loss units	Loss floor that added resources do not remove within the fitted regime.
O_{train}	**Training Compute**	FLOPs	About $6PD$ for a dense transformer: $2P$ per token forward and $4P$ backward.
B_{base}	**Base Batch Size**	Integer	Reference batch size at which the base learning rate was tuned.
η_{base}	**Base Learning Rate**	Dimensionless	Learning rate tuned at the reference batch size before linear scaling.
N_{epochs}	**Epoch Count**	Integer	Number of full passes a training run makes over its dataset.
B_{new}	**Scaled Batch Size**	Integer	Batch size a training recipe is scaled to under the linear scaling rule.
η_{new}	**Scaled Learning Rate**	Dimensionless	Learning rate used at a new batch size under the linear scaling rule.
$\mathcal{L}$	**Scaling Law Loss**	Function	Loss a trained model reaches as a function of the resource scaled, such as parameters, training tokens or compute, in an empirical power-law scaling law.

The distributed energy corollary

At data center scale, energy and power delivery are primary system constraints. For N devices that each move the same D_{vol} bytes and execute the same O FLOPs over a workload interval, effective per-byte data-movement costs and per-operation compute costs give the following fleet energy model. Here the work and traffic terms are per-device quantities, so multiplying by N sums the device contributions:

$$E_{\text{total}} \approx N \times \left(D_{\text{vol}} \times E_{\text{move}} + O \times E_{\text{compute}} \right)$$

Symbol	Definition	Unit	Notes
E_{move}	**Energy per Byte Moved**	joules/byte	Effective movement cost; total energy also depends on bytes moved and operations executed.
E_{compute}	**Energy per Operation**	joules/FLOP	Energy cost of a single arithmetic operation.
E_{total}	**Total Energy**	joules	Total energy consumed by an ML workload, decomposed into data-movement and compute terms.
i	**Accelerator Supply Current**	amperes	Electrical current an accelerator draws from its power supply.
P_{active}	**Active Inference Power**	watts	Average power an accelerator draws while actively running inference.
P_{avg}	**Average Power**	watts	Power drawn averaged over a stated period.
E_{transmit}	**Cloud Offload Energy**	joules	Energy a device spends transmitting an input to the cloud for remote inference.
P_{thermal}	**Coolant Heat Load**	watts	Heat per unit time that a liquid cooling loop must carry away from a rack, the load that sets its coolant mass flow.
$\dot{m}$	**Coolant Mass Flow Rate**	kg/s	Mass of coolant, liquid or air, passing through a cooling loop per second.
T	**Coolant Temperature**	kelvin	Temperature of the liquid or air coolant in a cooling loop, whose finite change is its rise from inlet to outlet.
P_{device}	**Device Power**	watts	Electrical power one device draws.
P_{dynamic}	**Dynamic Power**	watts	Power a chip draws switching its transistors, proportional to switched capacitance, supply voltage squared and clock frequency.
R	**Electrical Resistance**	ohms	Electrical resistance of a circuit or winding.
$\dot{Q}_{\text{remove,max}}$	**Facility Heat Removal Capacity**	watts	Largest rate at which an installed facility and cooling configuration can remove heat.

Symbol	Definition	Unit	Notes
P_{facility}	**Facility Power**	watts	Total electrical power a data center facility draws from the grid, its IT load plus cooling, power conversion, lighting and other overhead.
$\rho_{\text{energy,general}}$	**General-Purpose Energy Productivity**	FLOP/J	Useful floating-point operations general-purpose silicon delivers per joule on a given workload.
α_{duty}	**Inference Duty Cycle**	Dimensionless	Fraction of time an accelerator actively runs inference rather than waiting in standby.
$\dot{Q}_{\text{IT}}$	**IT Heat Load**	watts	Rate at which a facility's information technology equipment (servers, accelerators, network gear) produces heat.
P_{IT}	**IT Power**	watts	Electrical power delivered to a data center's IT equipment: servers, accelerators, storage and networking.
I_{leak}	**Leakage Current**	amperes	Current that leaks through a chip's transistors when they are not switching.
P_{leakage}	**Leakage Power**	watts	Static power a chip dissipates through leakage current regardless of switching.
E_{local}	**Local Inference Energy**	joules	Energy a device spends running one inference on its own hardware.
E_{network}	**Network Energy**	joules	Energy the network fabric, its switches, links and adapters, consumes over a stated interval.
$L_{\text{parasitic}}$	**Parasitic Loop Inductance**	henries	Unintended inductance of the current loop that feeds an accelerator's core rail, which turns current slew into voltage droop.
$\rho_{\text{energy,specific}}$	**Specialized Energy Productivity**	FLOP/J	Useful floating-point operations specialized, domain-specific silicon delivers per joule on a workload suited to its design.
c_p	**Specific Heat Capacity**	J/(kg K)	Heat needed to raise one kilogram of a coolant by one kelvin at constant pressure.
P_{idle}	**Standby Power**	watts	Power a device draws in standby, when it is not running inference.
V	**Supply Voltage**	volts	Supply voltage that powers a digital circuit, the quantity dynamic voltage and frequency scaling lowers.
C	**Switched Capacitance**	farads	Capacitance of the wires and gates a circuit charges when it switches.
α	**Switching Activity Factor**	Dimensionless	Average fraction of a chip's gate capacitance that switches each clock cycle.

Symbol	Definition	Unit	Notes
P_{total}	**Total Chip Power**	watts	Total power a chip dissipates, the sum of dynamic switching power and static leakage power.

Network Communication Models and Collectives

Collective communications (AllReduce, AllGather, ReduceScatter, AllToAll) move payloads across the network fabric, following ring or tree schedules over topologies such as the fat tree. The models below price those transfers by separating fixed per-message latency from bandwidth-proportional transmission time.

The α-β communication model

In the standard first-order model, network communication time decomposes into fixed message startup latency and bandwidth-dependent transfer. For a single point-to-point message, transfer time is the sum of those two terms:

$$T(n) = \alpha + \frac{n}{\beta}$$

The model keeps its literature's letters as aliases of core concepts: α is the per-message L_{lat} and β is a link's BW, written in α-β form. Inside α-β formulas, write α and β; elsewhere, write L_{lat} and a subscripted BW.

Symbol	Definition	Unit	Notes
$T(n)$	**Point-to-Point Transfer Time**	seconds	Wall-clock time to transmit one message of size n across one link.
n	**Point-to-Point Message Size**	bytes	Size of one message in $T(n)$.
α	**Per-Message Latency**	seconds	The core's L_{lat} for one message, in α-β form: the fixed startup cost. *(Not significance level or Rényi order, which carry subscripts.)*
β	**Link Bandwidth**	bytes/s	The core's BW for one link (BW_{link}), in α-β form: effective throughput per link.
n^*	**Crossover Point**	bytes	$n^* = \alpha \cdot \beta$. Below n^*: latency-bound. Above: bandwidth-bound.
M	**Collective Payload Size**	bytes	Per-rank gradient, model-state, activation, or compressed payload that a collective moves. Not a memory footprint (those are M_{total}, M_{weights}, and so on) and not the core's GEMM dimension M, which appears only in GEMM shape statements.

Symbol	Definition	Unit	Notes
M_{coll}	**Collective Tensor Size**	bytes	Full tensor acted on by Broadcast, Reduce, or AllReduce, reconstructed by AllGather, or partitioned by ReduceScatter. An equally sharded AllGather starts with M_{coll}/N bytes per rank; AllToAll uses the per-rank payload M.
T_{ring}, T_{tree}	**Collective Completion Time**	seconds	AllReduce time under the ring or tree algorithm in α-β form, for example $T_{\text{ring}} = 2(N-1)\alpha + 2\frac{N-1}{N}\frac{M}{\beta}$. $T_{\text{allreduce}}$ names an AllReduce whose algorithm the text leaves open.
$M_{\text{crossover}}$	**Ring-Tree Crossover Payload**	bytes	Payload at which $T_{\text{ring}} = T_{\text{tree}}$; approximately $N\alpha\beta/\log_2 N$ for large N.
$T_{\text{allreduce}}$	**AllReduce Completion Time**	seconds	Time to complete one AllReduce collective over a group of devices, whatever algorithm implements it.
T_{alltoall}	**AllToAll Completion Time**	seconds	Time to complete one AllToAll collective, in which every device exchanges a distinct share of its payload with every other device.
$\text{BW}_{\text{bisect}}$	**Bisection Bandwidth**	bytes/s	Total bandwidth across the narrowest cut that divides a network's nodes into two equal halves.
i	**Local Rank Index**	Integer	Position of an accelerator within its node, its local rank, which in a rail-optimized fabric also names the rail it attaches to.
$\text{BW}_{\text{network}}$	**Network Bandwidth**	bytes/s	Sustained rate at which a network path delivers bytes between machines.
M	**Network Traffic Volume**	bytes	Bytes one worker moves across the network over a stated interval, such as one training step.
m	**Rank Count Binary Exponent**	Dimensionless	Integer exponent for which the rank count equals two raised to it, the condition algorithms such as butterfly AllReduce require.
i	**Rank Index**	Integer	Position of one rank, a device or worker, within a collective communication group, counted from zero.
BW_{link}	**Single Link Bandwidth**	bytes/s	Bandwidth of one network link in one direction, written in the core bandwidth notation outside alpha-beta formulas.
k	**Switch Radix**	Integer	Number of ports on one network switch, its radix.

N	**Topology Endpoint Count**	Integer	Number of endpoints, accelerators or hosts, that one network topology connects, the size variable of its scaling relations.

The LogGP extension

LogGP refines the α-β model by separating network transit latency, processor initiation overhead, and long-message injection gaps. The book uses descriptive subscripts for the highest-collision terms; the bare letters g and G keep their LogGP meanings inside this model only.

Symbol	Definition	Unit	Notes
$T_{\text{long}}(n)$	**LogGP Long-Message Time**	seconds	Transfer time for an n-byte long message. Reuses n from the α-β model.
L_{LogGP}	**LogP/LogGP Network Latency**	seconds	Network transit time of one message, the part of the core's L_{lat} that excludes processor overhead, so $\alpha \approx o_{\text{send}} + L_{\text{LogGP}} + o_{\text{recv}}$. The subscript avoids bare L collisions.
o_{send}	**Sender Overhead**	seconds	Processor/NIC overhead to initiate a message.
o_{recv}	**Receiver Overhead**	seconds	Processor/NIC overhead to complete a message. Symmetric LogP writes $o = o_{\text{send}} = o_{\text{recv}}$, so one message costs $2o$.
g	**Message Injection Gap**	seconds	Minimum interval between consecutive message injections. *(Gradients are bold,* **g***.)*
G	**Long-Message Gap per Byte**	seconds/byte	Per-byte long-message gap; distinct from β link bandwidth. *(Accelerators per node are* G_{node}*.)*
o	**Symmetric Message Overhead**	seconds	Processor time spent initiating or completing one message in the symmetric LogP model, where sender and receiver overheads are equal, during which the processor cannot compute.

Compression cost and savings

Gradient and activation compression trade local computation for reduced network traffic. The resulting models compare codec overhead against the communication time saved by shrinking the payload:

Symbol	Definition	Unit	Notes
T_{transfer}	**Transfer Time for Payload**	seconds	Communication time for an x-byte payload: $T(x)$ for one link, or the relevant collective time.

Symbol	Definition	Unit	Notes
$T_{\text{compressed}}$	**Compressed Communication Time**	seconds	Total time after encode, transfer of M/r_{comp}, and decode.
T_{encode}	**Codec Encode Time**	seconds	Local compression overhead before transfer.
T_{decode}	**Codec Decode Time**	seconds	Local decompression overhead after transfer.
b_{block}	**Quantization Block Size**	Integer	Number of tensor elements in one block of block-wise quantization, all sharing one scale.
s	**Quantization Scale**	Varies	Real-valued step between adjacent integer levels of a uniform quantizer.
K_{top}	**Retained Gradient Element Count**	Integer	Number of largest-magnitude gradient elements top-k sparsification keeps and transmits.

Parallelism Dimensions and Scaling Efficiency

Scaling large foundation models requires combining multiple parallelism strategies across device dimensions. The notation below tracks how devices are partitioned across those dimensions and how efficiently the combined schedule converts added hardware into speedup.

Parallelism dimensions

A single parallelism strategy rarely scales across an entire cluster without hitting memory or bandwidth limits. To stay within both bounds, 3D parallelism partitions the training workload across three orthogonal dimensions:

$$N = N_{\text{DP}} \times N_{\text{PP}} \times N_{\text{TP}}$$

Symbol	Definition	Unit	Notes
N_{DP}	**Data-Parallel Degree**	Integer	Number of model replicas. *(Bare d stays the core's hidden dimension.)*
N_{PP}	**Pipeline-Parallel Degree**	Integer	Number of physical pipeline stages in model-depth partitioning.
N_{TP}	**Tensor-Parallel Degree**	Integer	Degree of intra-layer partitioning (model width). *(Bare t stays time or a step index.)*
m	**Microbatch Count**	Integer	Number of microbatches used to fill and drain the pipeline.
b_{pipe}	**Pipeline Bubble Fraction**	Dimensionless	Fraction of pipeline GPU-time spent idle, $b_{\text{pipe}} = (N_{\text{PP}} - 1)/(N_{\text{PP}} - 1 + m)$; avoids bare b.

Symbol	Definition	Unit	Notes
V	**Virtual Pipeline Stages per Device**	Integer	Number of interleaved virtual chunks assigned to each physical pipeline stage. *(The attention value matrix is bold,* $\mathbf{V}$*.)*
τ_{stale}	**Gradient Staleness**	steps	Number of parameter updates between the parameters a gradient was computed on and the parameters it updates; $\tau_{\text{stale}} = 0$ is synchronous training.
k	**Accumulation Step Count**	Integer	Number of micro-batches whose gradients are accumulated before one optimizer update.
k	**Client Index**	Integer	Position of one client among the clients of a federated round or secure aggregation.
C_{cap}	**Expert Capacity Factor**	Dimensionless	Multiplier on an expert's uniform share of token assignments that sets how many assignments it may accept per step.
N_{experts}	**Expert Count**	Integer	Number of expert subnetworks in one mixture-of-experts layer.
R	**Federated Round Count**	Integer	Number of communication rounds a federated training run performs, or needs to reach a quality target.
B_{global}	**Global Batch Size**	Integer	Number of examples one synchronous optimizer update averages over across all data-parallel workers.
$\mathbf{g}$	**Local Gradient**	Vector	Gradient vector one data-parallel worker computes from its local batch in one step, its contribution to the gradient collective.
B_{micro}	**Microbatch Size**	Integer	Number of examples in one micro-batch, the unit run through a single forward and backward pass.
N_{clients}	**Participating Client Count**	Integer	Number of clients whose updates one federated round aggregates.
k_{experts}	**Routed Expert Count**	Integer	Number of experts a mixture-of-experts router sends each token to.
p_{gate}	**Router Gate Probability**	Dimensionless	Probability a mixture-of-experts router assigns to the expert it selects for a token.

Scaling efficiency

Adding accelerators to a job increases communication and synchronization overhead alongside raw compute capacity. Scaling efficiency measures the resulting realized speedup relative to ideal linear scaling:

$$\eta_{\text{scaling}} = \frac{T_1}{N \times T_N}$$

Symbol	Definition	Unit	Notes
η_{scaling}	**Scaling Efficiency**	Dimensionless	Ratio of measured speedup to ideal linear speedup. 1.0 is the ideal linear baseline, not a hard upper bound.
T_1	**Single-Device Time**	seconds	Baseline wall-clock time for the same productive work on one device.
T_N	**N-Device Time**	seconds	Wall-clock time for the same productive work on N devices; excludes operational downtime counted by η_{runtime}.
r	**Serial Fraction**	Dimensionless	Share of a fixed workload's single-device execution time that does not shrink when the work is spread across devices, the serial term of Amdahl's law.

Cluster Reliability, Fault Tolerance, and Checkpointing

At cluster scale, hardware component failures are standard operating conditions rather than rare anomalies. The symbols in this section quantify failure rates, checkpoint intervals, recovery overheads, and their net effect on fleet goodput.

Fault tolerance and reliability

When a job requires many components to remain healthy simultaneously, individual failure hazards compound across the fleet. Assuming independent components with exponential failure distributions, system reliability across N components is:

$$R_{\text{system}}(t) = e^{-N\lambda t}$$

The aggregate exponent uses the system-level rate $N\lambda$, where λ is the per-component failure rate under the independent, identical-component assumption. The exponent $N\lambda t$ is dimensionless, so the elapsed time t must use the same time unit as λ (hours, when λ comes from the FIT-derived rates below).

Checkpointing too frequently wastes wall time writing state to storage, whereas checkpointing too rarely loses long stretches of training work when a node fails. The optimal checkpoint interval balances that I/O overhead against recomputation rework:

$$T^*_{\text{ckpt}} = \sqrt{2 \cdot T_{\text{write}} \cdot \text{MTBF}_{\text{system}}}$$

The formula uses the *system-wide* mean time between failures (the failure interval for the whole job), not a *component* lifetime; substituting the per-component value would overestimate T^*_{ckpt} by $\sqrt{N}$. For dimensional consistency, T_{write} and $\text{MTBF}_{\text{system}}$ must be in the same time unit. Industry-standard MTBF is reported in hours; to combine it with seconds-scale write times, multiply the hour value by 3600. The result T^*_{ckpt} then carries the time unit chosen for the inputs.

Symbol	Definition	Unit	Notes
$R_{\text{system}}(t)$	**Reliability Function**	Probability	Probability of no failure across the whole system before time t. One component has $R_{\text{single}}(t) = e^{-\lambda t}$.
λ	**Per-Component Failure Rate**	failures/hour	Per-component failure rate, written λ_{fail} wherever another rate shares the passage; the system-wide rate is $N\lambda$ under independent, identical components. The industry-standard reporting unit is FIT (failures per 10^9 device-hours): $\lambda_{\text{hour}} = \text{FIT} \times 10^{-9}$. *(Other rates carry subscripts, such as the core's arrival rate λ_{arr}.)*
$A_{\text{component}}$	**Component Availability**	Probability	Probability that one component is up at a given instant. A job that needs all N components at once has availability $(A_{\text{component}})^N$ under independent, identical components.
N	**Required Component Count**	Integer	Components (accelerators, hosts, NICs, switches) the job needs up at the same time. Not N, which counts accelerators only.
MTBF	**Mean Time Between Failures**	hours	Average time between consecutive failures of a repairable, composed system. $\text{MTBF}_{\text{system}} = 1/(N\lambda) = \text{MTTF}_{\text{component}}/N$.
$\text{MTBF}_{\text{system}}$	**System MTBF**	hours	Mean time between failures that interrupt the whole job, equal to the per-component MTTF divided by N under independent, identical components. It is the input to the Young-Daly interval. Same time unit as T_{write} when combined with it.
MTTF	**Mean Time To Failure**	hours	Per-component lifetime constant derived from FIT rates, $\text{MTTF}_{\text{component}} = 1/\lambda$. Distinct from system-level MTBF when repair/replacement cycles are modeled.
MTTR	**Mean Time To Repair**	hours	Average recovery time after a failure.
T_{ckpt}	**Checkpoint Interval**	seconds	Useful compute time between consecutive checkpoints.
T^*_{ckpt}	**Optimal Checkpoint Interval**	seconds	The T_{ckpt} that minimizes total wasted time; Young-Daly formula.
T_{write}	**Checkpoint Write Time**	seconds	Time to persist model state to storage.
T_{load}	**Checkpoint Load Time**	seconds	Time to read the latest checkpoint state from storage back into accelerator memory during recovery.

Symbol	Definition	Unit	Notes
$\mathbf{MTTF_{component}}$	**Component Mean Time to Failure**	hours	Mean time to failure of one component, the reciprocal of its constant failure rate.
R_{single}	**Component Reliability**	Dimensionless	Probability that one component of a system runs without failure up to a given time, its survival function.
d	**Erasure Data Fragment Count**	Integer	Number of data fragments an erasure code splits an object into, any that many of the stored fragments recovering the original.
m	**Erasure Parity Fragment Count**	Integer	Number of parity fragments an erasure code adds to the data fragments of an object.
T_{detect}	**Failure Detection Time**	seconds	Time from a hardware or process fault until the system classifies it as a failure.
T_{recovery}	**Failure Recovery Time**	seconds	Time from a failure until useful training work resumes: detection, restart, checkpoint load and warmup.
$\mathbf{MTTF_{GPU}}$	**GPU Mean Time to Failure**	hours	Mean time to failure of one GPU, its average operating time before it fails.
A_{all}	**Job Availability**	Dimensionless	Probability that every component a job needs is up at the same instant.
T_{restart}	**Job Restart Time**	seconds	Time for the scheduler to allocate resources and launch replacement processes after a failure.
T_{replay}	**Lost Work Replay Time**	seconds	Time to recompute the training steps lost since the last checkpoint after a restart.
k	**Redundant Replica Count**	Integer	Number of independent replicas of a service in a redundancy availability calculation, any one of which can serve the load.
A_{system}	**Redundant Service Availability**	Dimensionless	Probability that at least one of a service's independent replicas is up at a randomly chosen instant.
A_{single}	**Replica Availability**	Dimensionless	Probability that one serving replica is up at a randomly chosen instant.
n_{psu}	**Series Power Supply Count**	Integer	Number of power supply units in one node whose failure alone stops the node.
A	**Steady-State Availability**	Dimensionless	Probability that a component, replica or repairable system is up at a randomly chosen instant, its long-run fraction of up time.

Fleet capacity factors and goodput

Fleet capacity metrics compound single-device arithmetic efficiency, scaling efficiency, and operational losses. ML productivity goodput multiplies the scheduling, runtime, and program factors that chapter 9 defines.

Symbol	Definition	Unit	Notes
f_{compute}	**Useful Compute-Time Fraction**	Dimensionless	$(T_{\text{compute}}/N)/T_{\text{step}}(N)$. Measures how much step time is useful local arithmetic after distribution.
f_{overhead}	**Operational Overhead Fraction**	Dimensionless	Fraction of allocated wall time lost outside the productive steps measured by T_N, such as checkpoint pauses, failure recovery, scheduler preemption, or maintenance.
R_{eff}	**Effective Fleet Throughput**	FLOP/s	$R_{\text{eff}} = (NR_{\text{peak}}) \times \text{MFU} \times \eta_{\text{scaling}} \times \eta_{\text{runtime}}$, where MFU is the single-device baseline, η_{scaling} captures all in-step scaling loss, and η_{runtime} captures only out-of-step operational loss excluded from T_N.
O_{useful}	**Useful Model FLOPs**	FLOPs	Model FLOPs that advance training, excluding recomputation and padding; $\text{MFU} = O_{\text{useful}}/(NR_{\text{peak}}T_{\text{step}})$ measures fleet MFU and already includes in-step scaling loss. The throughput factorization uses single-device baseline MFU instead.
MPG, η_{program}, η_{runtime}, $\eta_{\text{scheduling}}$	**ML Productivity Goodput and Its Factors**	Dimensionless	Program, runtime, and scheduling goodput, with $\text{MPG} = \eta_{\text{scheduling}} \times \eta_{\text{runtime}} \times \eta_{\text{program}}$. For a job that holds its devices, R_{eff} equals peak capacity times $\eta_{\text{runtime}} \times \eta_{\text{program}}$, so η_{runtime} is also the operational factor of that product; MPG adds the scheduling factor.
ρ_{energy}	**Fleet Energy Productivity**	FLOP/J	Useful computation per unit energy, O_{useful} divided by the energy drawn inside the stated boundary.
C_{train}, C_{infer}	**Dollar Cost**	dollars	The subscript names the cost component. Carbon quantities use $\text{CO}_{2,\ldots}$, never C.
T_{wall}	**Allocated Wall Time**	seconds	Total wall-clock time for which a training job holds its allocated resources, productive or not.
T_{job}	**Job Duration**	seconds	Wall-clock time one job or run spends executing, from start to finish.
T_{useful}	**Useful Training Time**	seconds	Wall-clock time a training job spends on committed, productive steps that contribute to the final model.

Distributed Memory Hierarchy and Serving at Scale

Managing distributed memory requires partitioning weights, activations, optimizer states, and KV-cache tensors across nodes and tiers. At the same time, serving fleets must bound queueing delay and batching overhead under variable request arrivals.

Distributed memory and serving metrics

Reusable performance and serving quantities follow the same collision-avoidance rule as the iron law. Rates use R or descriptive Greek symbols; request counts use Q_{req} rather than overloading N; queue utilization uses a subscripted ρ so bare ρ remains available for other ratio models.

Symbol	Definition	Unit	Notes
$M_{\text{activations}}$	**Activation Memory**	bytes	Retained activations for the backward pass or serving intermediates.
λ_{arr}	**Arrival Rate**	requests/s	Request arrival rate. The subscript keeps bare λ free for fitted sensitivities.
R_{attain}	**Attainable Compute Rate**	FLOP/s	Roofline bound: $R_{\text{attain}} \leq \min(R_{\text{peak}}, I \times \text{BW})$. Uses R, not T, because this quantity is a rate.
$T_{\text{svc}}(B)$	**Batch Service Time**	seconds	Time to serve a batch of size B.
r_{comp}	**Compression Ratio**	Dimensionless	Uncompressed size divided by compressed size. A compressed payload has $1/r_{\text{comp}}$ of the uncompressed size; the subscript avoids bare C collisions.
$\mu_{\text{eff}}(B)$	**Effective Service Rate**	requests/s	Batched service rate, typically $\mu_{\text{eff}}(B) = B/T_{\text{svc}}(B)$. The unbatched service rate is $\mu = \mu_{\text{eff}}(1)$.
s_{elem}	**Element Storage Size**	bytes/element	Bytes per stored tensor element.
$M_{\text{gradients}}$	**Gradient Memory**	bytes	Memory occupied by stored gradients.
MFU	**Model FLOPs Utilization**	Dimensionless	Useful model FLOP/s divided by available peak FLOP/s. Text acronym avoids overloading η.
$M_{\text{optimizer}}$	**Optimizer-State Memory**	bytes	Momentum, variance, master weights, and related optimizer buffers.
R	**Replica Count**	Integer	Serving replicas among which a router chooses (for example, probing two of R and sending to the less loaded). Distinct from N, the devices in one job.
Q_{req}	**Request Concurrency**	requests	Average in-flight requests in a stable serving system ($Q_{\text{req}} = \lambda_{\text{arr}} \cdot T_{\text{lat}}$ via Little's Law). Avoids overloading N, which counts devices, elements, or samples elsewhere.
T_{lat}	**Request Time in System**	seconds	End-to-end queueing/serving latency for Little's Law. Distinct from L_{lat}, the fixed-latency term in the iron law.
I	**Arithmetic Intensity**	FLOP/byte	Workload FLOPs per byte moved. The Roofline Model uses I as the independent variable.
I_{ridge}	**Roofline Ridge Point**	FLOP/byte	$I_{\text{ridge}} = R_{\text{peak}}/\text{BW}$. Prefer this explicit form over starred shorthand so the meaning remains clear in prose.
ρ_{serv}	**Serving Utilization**	Dimensionless	Queue/server utilization. The subscript keeps bare ρ free for other ratio models.

Symbol	Definition	Unit	Notes
M_{total}	**Total Memory Footprint**	bytes	Sum of explicit memory components; avoids bare M ambiguity; the core's quantity.
M_{weights}	**Weight Memory**	bytes	Memory occupied by model weights ($P \times$ bytes-per-parameter); the core's quantity.
BW_{mem}	**Sustained Memory Bandwidth**	bytes/s	Empirically achievable memory bandwidth under target access patterns.
$R_{\text{consumption}}$	**Accelerator Data Consumption Rate**	bytes/s	Rate at which one accelerator consumes training input data while computing at full speed.
λ_{batch}	**Batch Arrival Rate**	batches/s	Rate at which batches arrive at a server when each batch is treated as one super-request, the request arrival rate divided by the batch size.
k	**Batch Fill Arrival Count**	Integer	Number of arrivals after a batch's triggering request needed to fill the batch, one less than the maximum batch size.
T_{fixed}	**Batch Fixed Overhead Time**	seconds	Part of a batch's service time paid once per batch whatever its size, such as weight loading and kernel launch.
$L_{\text{lat,form}}$	**Batch Formation Delay**	seconds	Time a request waits for its batch to fill before the batch is dispatched.
k	**Batch Index**	Integer	Position of one batch in the sequence of batches a data loader or runtime delivers.
T_{window}	**Batching Window**	seconds	Length of the batching window, the longest a dynamic batcher holds requests before dispatching a batch.
Q_{day}	**Daily Query Volume**	queries/day	Number of queries, requests or transactions a deployed model serves per day.
I_{decode}	**Decode Arithmetic Intensity**	FLOP/byte	Arithmetic intensity of the weight-dominated part of an LLM decode step, operations per byte of weights and activations moved, as a function of batch size.
M_{device}	**Device Memory Capacity**	bytes	Total memory a device provides for a model's weights and activations.
α_{acc}	**Draft Token Acceptance Probability**	Dimension-less	Probability that the target model accepts one drafted token in speculative decoding, taken as independent across draft positions.
$L_{\text{lat,total}}$	**End-to-End Request Latency**	seconds	Time from a request leaving the client to its response returning, summed over every stage on the request path.
B	**Error Budget Consumption**	Dimension-less	Share of one reliability target's error budget a service has used: the fraction of eligible observations that violate the target divided by the violating fraction the target allows.
$L_{\text{lat,infer}}$	**Inference Latency**	seconds	Time the model takes to compute a request's output.
$L_{\text{lat,SLO}}$	**Latency Service-Level Objective**	seconds	Latency target a serving system's service-level objective sets for a request.

Symbol	Definition	Unit	Notes
t_{req}	**Marginal Request Service Time**	seconds	Additional batch service time that one more request in the batch adds.
B_{max}	**Max Batch Size**	Integer	Largest batch a dynamic batcher forms, the size at which it dispatches without waiting for the window to close.
B_{min}	**Minimum Stable Batch Size**	Integer	Batch size at which a batched server's effective service rate equals the arrival rate, the boundary that stable batch sizes must exceed.
$L_{\text{lat,network}}$	**Network Latency**	seconds	Time a request and its response spend crossing the network, including propagation, routing and protocol handling.
N_{prefetch}	**Prefetch Buffer Count**	Integer	Number of buffers holding batches loaded ahead of use.
c	**Queue Server Count**	Integer	Number of identical servers in a multi-server queue with random arrivals and service.
K	**Queue System Capacity**	Integer	Largest number of requests a queueing system can hold at once, waiting plus in service, beyond which arrivals are rejected.
W_q	**Queue Wait Time**	seconds	Mean time a request waits in a queue before its service begins, excluding service time.
$L_{\text{lat,queue}}$	**Queueing Latency**	seconds	Time a request waits in queues before it is served.
n	**Realized Arrival Count**	Integer	One possible value of the number of requests that arrive after the trigger in a batching window, used as a summation variable.
i	**Reliability Target Index**	Integer	Position of one reliability target, such as availability, latency, freshness, or model quality, among the targets an evaluation contract budgets.
t	**Request Response Time**	seconds	Time one request spends in a serving system, the random variable whose distribution gives tail latency.
σ_t	**Response Time Standard Deviation**	seconds	Standard deviation of the time a request spends in a serving system.
μ	**Service Rate**	items/s	Rate at which one server, such as a worker, consumer, or model endpoint, completes items or calls.
K	**Speculative Draft Length**	Integer	Number of tokens a draft model proposes for the target model to verify in one speculative-decoding round.
τ	**Subsequent Arrival Time**	seconds	Time from the request that opened a batching window until a later arrival, indexed by arrival order.
$T_{\text{lat,p99}}$	**Tail Request Latency (99th Percentile)**	seconds	99th-percentile time a request spends in a serving system.

Symbol	Definition	Unit	Notes
ρ_{target}	**Target Serving Utilization**	Dimensionless	Serving utilization a system is sized not to exceed, chosen below one to keep latency headroom.
B_{util}	**Target Utilization Batch Size**	Integer	Smallest batch size whose serving utilization stays at or below the target utilization, under the linear batch service model.
Q_{arr}	**Triggered Window Arrival Count**	Integer	Number of requests that arrive after the request that opened a batching window and before the window closes.

Serving memory and data storage

At scale, serving is bounded by the memory its key-value cache occupies, and the data behind training is bounded by what it costs to keep. These symbols size both.

Symbol	Definition	Unit	Notes
M_{KV}	**KV-Cache Memory**	bytes	Total key-value cache footprint for autoregressive serving, $M_{\text{KV}} = B \cdot S \cdot m_{\text{token}}$.
m_{token}	**KV-Cache Bytes per Token**	bytes/token	$m_{\text{token}} = 2 N_L H_{\text{KV}} d_{\text{head}} s_{\text{elem}}$ (keys and values across all layers).
C_{store}	**Data Storage Cost**	dollars	Cost of keeping a training dataset in storage over its retention period.
N_{entities}	**Entity Count**	Integer	Number of entities, such as users or items, a recommendation table or feature store holds rows for.
T_{months}	**Storage Retention Time**	months	Length of time a dataset is kept in storage.
$D_{\text{vol,store}}$	**Stored Data Volume**	bytes	Bytes a retained dataset occupies in storage.
C_{total}	**Total Data Cost**	dollars	Total cost of a training dataset over its lifecycle: acquisition, labeling, storage and processing.

Deep Learning Foundations in Distributed Contexts

Distributed algorithms partition neural architectures defined by standard deep learning conventions (Goodfellow et al. 2016):

Symbol	Definition	Unit	Notes
d	**Hidden Dimension**	Integer	Size of the hidden state vector. *(Parallelism degrees carry subscripts, such as N_{DP}.)*

Symbol	Definition	Unit	Notes
d_{head}	**Attention Head Dimension**	Integer	Per-head hidden dimension in attention layers.
d_{in}	**Layer Input Width**	Integer	Number of input features in a layer.
d_{out}	**Layer Output Width**	Integer	Number of output features in a layer.
θ	**Model Parameters**	Vector	Trainable model weight and bias parameter vector θ.
π_θ	**Policy**	Function	Target neural network policy $\pi_\theta(a \mid s)$.
S	**Sequence Length**	Integer	Input context or sequence length S in tokens.
ℓ	**Layer Index**	Integer	Index for a layer. Use instead of bare L when indexing layers, since L collides with loss and latency. A numeric subscript marks a norm instead (ℓ_1, ℓ_2).
$\mathcal{L}$	**Loss Function**	Scalar	The objective function minimized during training.
$N_{\text{heads}}, H_{\text{KV}}$	**Number of Attention Heads**	Integer	Number of attention heads in a multi-head attention layer, and key-value heads H_{KV} (in GQA/MQA).
N_L	**Number of Layers**	Integer	Total number of layers in a network.
$p(x)$	**Distribution**	Probability mass/density	Use lowercase $p(\cdot)$ for generic distributions to avoid collision with P (parameter count).
$p(y \mid x)$	**Conditional Distribution**	Conditional probability/density	Use this form for generic label relationships.
$\Pr(\cdot)$	**Event Probability**	Probability	Probability of an event E, as in $\Pr(\text{batch} = 0)$; use $p(x)$ and $p(y \mid x)$ for distributions.
m	**Adam First Moment**	Varies	Per-parameter exponential moving average of gradients that Adam keeps, its first moment.
v	**Adam Second Moment**	Varies	Per-parameter exponential moving average of squared gradients that Adam keeps, its second moment.
$\mathbf{A}$	**Adapter Down Projection Matrix**	Matrix	First low-rank adapter matrix, which projects a layer's input down to the adapter rank, the LoRA down-projection.

Symbol	Definition	Unit	Notes
r	**Adapter Rank**	Integer	Rank of a low-rank adapter update, equivalently the bottleneck width of a residual adapter, which sets its trainable parameter count.
B	**Adapter Up Projection Matrix**	Matrix	Second low-rank adapter matrix, which projects the rank-sized intermediate up to the layer's output width, the LoRA up-projection.
K	**Attention Key Matrix**	Matrix	Matrix of key vectors, one row per token, in an attention layer.
Q	**Attention Query Matrix**	Matrix	Matrix of query vectors, one row per token, in an attention layer.
S_{ij}	**Attention Score Entry**	Dimensionless	Attention score of query i against key j, one entry of the score matrix.
S	**Attention Score Matrix**	Matrix	Matrix of attention scores, the scaled dot products of every query with every key before the softmax.
V	**Attention Values Matrix**	Matrix	Matrix of value vectors, one row per token, that attention weights combine into the output.
b	**Bias Vector**	Vector	Vector of learned biases one layer adds to its weighted sums, one per neuron or output channel.
K	**Class Count**	Integer	Number of classes a classifier distinguishes, or vocabulary entries it scores, the length of its softmax output.
j	**Class Index**	Integer	Index of an output class.
z	**Encoder Latent Representation**	Vector	Intermediate representation a shared encoder computes from an input, consumed by the heads that sit on top of it.
$\mathcal{N}$	**Gaussian Distribution**	Distribution	Gaussian (normal) distribution with the mean and covariance given as its arguments.
A	**GEMM Left Operand**	Matrix	Left input matrix of a general matrix multiply, whose rows match the output and whose columns match the right operand's rows.
C	**GEMM Output Matrix**	Matrix	Output matrix of a general matrix multiply, with the left operand's row count and the right operand's column count, which the operation updates in place.

Symbol	Definition	Unit	Notes
B	**GEMM Right Operand**	Matrix	Right input matrix of a general matrix multiply, whose rows match the left operand's columns.
M	**GEMM Row Dimension**	Integer	Number of rows of the left operand and of the output in a matrix multiply.
h	**Hidden Activation**	Vector	Activation vector a hidden layer outputs and passes to the next layer.
h	**Hidden Unit Output**	Dimensionless	Output of one hidden unit of a small network.
I	**Identity Matrix**	Matrix	Square matrix with ones on the diagonal and zeros elsewhere.
k	**Key Vector**	Vector	Key vector of one token, one row of the key matrix.
j	**Key-Value Tile Index**	Integer	Index of one key-value tile in tiled attention.
i	**Label Category Index**	Integer	Position of one label category among a classifier's output classes.
ℓ	**Layer Index**	Integer	Position of one layer within a network, counted from the input.
X	**Layer Input Matrix**	Matrix	Input to a layer in matrix form, one row per example or token, or a single-channel image.
x	**Layer Input Vector**	Vector	Vector of activations one layer receives as input.
Y	**Layer Output Matrix**	Matrix	Output matrix of a layer's matrix multiplication of the input matrix by the weight matrix, one row per example.
y	**Layer Output Vector**	Vector	Vector of activations one layer produces.
g	**Gradient**	Varies	Gradient of the training loss with respect to one model parameter, as an optimizer update uses it.
H	**Loss Hessian**	Matrix	Matrix of second derivatives of the loss with respect to every pair of model parameters.
D	**Multiply-Accumulate Destination**	Matrix	Destination matrix of a matrix multiply-accumulate instruction, which receives the product plus the accumulator input.
i	**Matrix Row Index**	Integer	Position of a row within a matrix.
f	**Model Predictor**	Function	Trained model viewed as a function that maps an input to its prediction.

Symbol	Definition	Unit	Notes
s	**Model Score**	Dimensionless	Score a classifier assigns to one individual, read as the predicted probability of the positive outcome.
w	**Model Weight**	Dimensionless	Value of one learnable weight of a model, such as the weight on one input of a neuron.
y	**Network Output**	Dimensionless	Scalar output of a neuron or of a small network.
θ^*	**Optimal Model Parameters**	Vector	Model parameters that minimize the training loss for a given architecture.
t	**Optimizer Step Index**	Integer	Position of one optimizer update in the sequence of training steps.
p	**Predicted Class Probability**	Dimensionless	Probability a classifier assigns to one label category for a given input.
$\hat{\mathbf{y}}$	**Predicted Output**	Vector	Model output for one example, such as its vector of class probabilities.
q_{im}	**Query Component**	Dimensionless	One component of one token's query vector.
$\mathbf{q}$	**Query Vector**	Vector	Query vector of one token, one row of the query matrix.
x	**Raw Pipeline Input**	Record	Raw input record before feature transformation, as received by the training or serving pipeline.
f_{serve}	**Serving Transform**	Function	Transformation the serving pipeline applies to a raw input to produce model features.
N	**Square GEMM Dimension**	Integer	Side length of the square matrices in a matrix multiply, the shared row, column and inner dimension.
Φ	**Standard Normal Cumulative Distribution**	Function	Cumulative distribution function of the standard normal distribution.
k	**Top Class Count**	Integer	Number of highest-scoring classes a top-k prediction returns or checks for the correct label.
f_{train}	**Training Transform**	Function	Transformation the training pipeline applies to a raw input to produce model features.
$\mathbf{W}$	**Weight Matrix**	Matrix	Matrix of learned weights one layer multiplies its input by, or the kernel tensor of a convolution layer.

Symbol	Definition	Unit	Notes
n	**Weight Matrix Column Count**	Integer	Number of columns of a layer's weight matrix.
m	**Weight Matrix Row Count**	Integer	Number of rows of a layer's weight matrix.
λ_{reg}	**Weight Penalty Strength**	Dimensionless	Coefficient that scales an absolute-value or squared penalty on weight magnitude added to the training loss, equivalent to weight decay under plain gradient descent.
$\mathbf{0}$	**Zero Vector**	Vector	Vector whose entries are all zero, such as the mean of zero-centered Gaussian noise.

Latin matrices and vectors are set in bold (**W**, **x**); scalars, dimensions, indices, and individual matrix entries stay italic (N, d, i, W_{ij}). The generic parameter symbol θ is the conventional exception and stays italic. Matrix operands in general matrix multiply (GEMM) are bold ($\mathbf{C} = \alpha\mathbf{AB} + \beta\mathbf{C}$), distinct from the scalar batch size B. GEMM dimensions are M, N, and K. Asymptotic complexity is written $\mathcal{O}(\cdot)$, distinct from total operations O.

Privacy, Robustness, Governance, and Distributed Constants

Federated systems, distributed coordination, and cluster operations add the statistical, privacy, and governance quantities collected below. These symbols standardize how the later chapters express differential privacy budgets, adversarial perturbation radii, drift statistics, and operational deadlines.

Privacy, robustness, and statistical testing

Part IV uses the standard symbols of differential privacy and adversarial robustness, and the operations and robustness chapters use those of hypothesis testing. The same Greek letters appear in several of these fields, so every use other than the one named below carries a subscript.

Symbol	Definition	Unit	Notes
(ϵ, δ)	**Differential Privacy Budget**	Dimensionless	ϵ bounds the privacy loss from adding or removing one protected record; δ is the allowed failure probability.
ϵ_{adv}	**Adversarial Perturbation Budget**	input units	Radius of the allowed input perturbation under a stated norm. *(Not the privacy budget ϵ.)*
K_{PGD}	**Attack Steps**	Integer	Inner iterations of a projected gradient descent (PGD) attack; adversarial training costs about $K_{\text{PGD}} + 1$ passes per batch.

Symbol	Definition	Unit	Notes
α_{sig}, β_{stat}	**Type I and Type II Error Rates**	Probability	Significance level and miss rate of a hypothesis test; statistical power is $1-\beta_{\text{stat}}$.
$\mathbb{E}[\cdot]$	**Expectation**	—	Expected value. Blackboard bold keeps it distinct from an event E and the energy terms such as E_{total}.
x_{adv}	**Adversarial Example**	Record	Adversarial example, an input an attacker forms by adding a bounded perturbation to a clean input so the model mispredicts.
δ_{adv}	**Adversarial Perturbation**	Vector	Perturbation an adversary adds to an input to change a model's prediction.
k_{anon}	**Anonymity Set Size**	Integer	Smallest number of records that share every quasi-identifier value in an anonymized release.
n_{feat}	**Attribution Feature Count**	Integer	Number of input features a feature-attribution method assigns contributions to.
γ_{cls}	**Classification Threshold**	Dimensionless	Score threshold above which a classifier outputs the positive class.
$z_{\alpha/2}$	**Confidence Critical Quantile**	Dimensionless	Positive standard normal critical value for a two-sided test at the chosen confidence level.
ϵ	**Conformal Miscoverage Rate**	Dimensionless	Allowed probability that the conformal prediction set misses the true referent.
$\mathcal{C}$	**Conformal Prediction Set**	Set	Calibrated set of referent candidates that cannot be excluded at the miscoverage rate.
A	**Current Bin Proportion**	Dimensionless	Proportion of current production observations falling in one bin of the population stability index.
P_t	**Current Distribution**	Distribution	Data distribution a deployed model sees in service at time t.
n	**Drift Test Sample Size**	Integer	Number of observations in one of the two samples a two-sample drift test compares.
g	**Environment Response Function**	Function	Response of the environment to a deployed model, mapping the current data distribution and the model's decisions to the next data distribution.
ϵ_{fair}	**Fairness Gap Tolerance**	Dimensionless	Largest allowed gap between protected groups in the fairness metric a release gate or monitor enforces.
t	**Feature Record Time**	seconds	Time at which a feature record became available, which a point-in-time join requires to be no later than the observation timestamp.

Symbol	Definition	Unit	Notes
a	**First Compared Group Label**	Record	First of two group labels compared in a group-fairness condition, one value of the protected group attribute.
$\mathcal{D}_{\mathbf{JS}}$	**Jensen-Shannon Divergence**	Function	Jensen-Shannon divergence between two probability distributions, a symmetric bounded measure of how far they differ.
$\bar{P}$	**Jensen-Shannon Mixture Distribution**	Distribution	Equal-weight average of the current and training distributions, the reference against which Jensen-Shannon divergence measures each.
$\mathcal{D}_{\mathbf{KL}}$	**KL Divergence**	Function	Kullback-Leibler divergence, the expected extra code length from encoding one distribution with a code built for another.
$\mathcal{D}_{\mathbf{KS}}$	**Kolmogorov Smirnov Statistic**	Dimensionless	Two-sample Kolmogorov-Smirnov statistic, the largest absolute difference between two empirical cumulative distribution functions.
χ^2	**McNemar Test Statistic**	Dimensionless	McNemar test statistic, the squared difference of the two discordant counts divided by their sum.
$\mathcal{S}$	**Mechanism Output Set**	Set	Set of possible outputs of a randomized mechanism over which a differential privacy bound must hold.
$\delta_{\mathbf{MDE}}$	**Minimum Detectable Effect**	Dimensionless	Smallest absolute difference in the outcome metric that an A/B test is designed to detect.
$x_{\mathbf{feat}}$	**Monitored Feature Level**	Varies	One value of a monitored feature, the argument at which its distribution or empirical cumulative distribution function is evaluated.
I	**Mutual Information**	Function	Mutual information between two random variables, how much observing one reduces uncertainty about the other.
X	**Neighboring Dataset**	Record	Dataset input to a randomized mechanism in the differential privacy definition, compared against a copy that differs in one record.
O	**Observable Model Output**	Record	Model output an adversary can observe, such as a prediction, score or generated text.
$p_{\mathbf{val}}$	**Observed Significance Level**	Dimensionless	P-value of a hypothesis test, the probability under the null hypothesis of a result at least as extreme as the one observed.
$\mathbf{s}$	**Pairwise Mask Secret**	Vector	Shared random mask vector two clients derive from a common secret, which one adds and the other subtracts so that it cancels in the secure-aggregation sum.

Symbol	Definition	Unit	Notes
$n_{\mathbf{bins}}$	**Population Stability Bin Count**	Integer	Number of fixed bins over which the population stability index sums.
z_β	**Power Critical Quantile**	Dimensionless	Positive standard normal critical value corresponding to the chosen statistical power of a test.
$\hat{Y}$	**Predicted Decision**	Dimensionless	Binary decision a classifier outputs for a randomly drawn individual, one for a positive prediction.
σ	**Privacy Noise Multiplier**	Dimensionless	Ratio of the Gaussian noise standard deviation to the gradient clipping norm in differentially private training.
z	**Proportion Test Statistic**	Dimensionless	Test statistic of a two-proportion z-test, the difference of two sample proportions divided by its pooled standard error.
G	**Protected Group Membership**	Record	Protected group a randomly drawn individual belongs to, as a random variable over group labels.
R	**Protected Training Record**	Record	Training record of one protected individual, the unit whose leakage a privacy claim bounds.
$\mathcal{M}$	**Randomized Mechanism**	Function	Randomized algorithm that maps a dataset to a released output, the object a differential privacy guarantee constrains.
b	**Reference Bin Index**	Integer	Position of one reference bin among the bins a continuous feature is discretized into for the population stability index.
E	**Reference Bin Proportion**	Dimensionless	Proportion of reference (training-time) observations falling in one bin of the population stability index.
$\alpha_{\mathbf{R}}$	**Rényi Order**	Dimensionless	Order of the Rényi divergence at which a Rényi differential privacy guarantee is stated, a number greater than one.
n	**Required Users Per Variant**	Integer	Number of users each variant of an A/B test needs to detect the minimum detectable effect at the chosen confidence and power.
b	**Second Compared Group Label**	Record	Second of two group labels compared in a group-fairness condition, one value of the protected group attribute.
H	**Statistical Hypothesis**	Record	A statistical hypothesis about a population, such as the null hypothesis or the alternative hypothesis.

Symbol	Definition	Unit	Notes
g	**Subgroup Index**	Integer	Label of one population subgroup whose outcomes are compared against a reference group.
P_0	**Training Distribution**	Distribution	Data distribution the model was trained on, the baseline that drift is measured against.
Y	**True Outcome**	Dimensionless	True binary outcome of a randomly drawn individual, such as whether an applicant repays, one for the positive class.
v	**True Outcome Level**	Integer	One value of a binary true outcome, zero or one, on which a fairness condition is evaluated.

Distributed governance, reliability, and safety constants

A few thresholds and limits recur across the governance and reliability chapters, from classifier decision thresholds to failure-detection timeouts and sequential test statistics. The table below collects these shared constants so their symbols stay distinct from model parameters and network latencies:

Symbol	Definition	Unit	Notes
$h(x)$	**Classifier**	Function	Binary classifier $h(x)$ whose positive-prediction rates the fairness criteria constrain.
C	**Gradient Clipping Norm**	Scalar	Per-example gradient clipping bound C in differentially private training; not a C^3 axis.
T_{deadline}	**Deadline**	seconds	Target latency deadline for batch or phase completion.
T_{timeout}	**Failure-Detection Timeout**	seconds	Interval without a heartbeat after which the coordinator declares a rank failed.
τ	**Response Threshold**	Scalar	Decision or classification threshold τ.

Units, Precision, and Disambiguation

A link rate quoted in gigabits per second looks eight times larger than the same rate in gigabytes per second, and an 80 GB memory label can mean either 80×10^9 or 80×2^{30} bytes depending on whether decimal or binary prefixes apply. The unit, precision, and disambiguation conventions below keep numerical comparisons consistent across every chapter.

Units and precision

- Physical units: This book uses SI (metric) units throughout, including meters, kilograms, seconds, watts, and °C, consistent with standard engineering and scientific practice. Where source data was originally reported in imperial

units, the book converts to SI and notes the original values parenthetically. A space always separates the number from the unit (for example, 100 ms, 2 TB/s).

- Data and memory: This book uses **decimal SI prefixes only**: KB = 10^3 bytes, MB = 10^6, GB = 10^9, TB = 10^{12}. Binary-prefixed units do not appear in prose; model sizes, activation footprints, throughputs, and transfer volumes are reported in decimal units (for example, 2 TB/s, 102 MB). Hardware memory capacities retain the vendor's nameplate figure and label. A modeled capacity of 80×2^{30} bytes follows the registered device assumption, not a guarantee implied by an 80 GB label. Where a worked example subtracts a computed footprint from a device capacity, the registered capacity in bytes and the footprint are both converted to decimal; Appendix G states this exception in full.
- Compute: The notation distinguishes operation counts from rates. Total work uses FLOPs (for example, GFLOPs, TFLOPs), while throughput uses FLOP/s with decimal prefixes (for example, GFLOP/s, TFLOP/s).
  - 1 TFLOP = 10^{12} FLOPs
  - 1 TFLOP/s = 10^{12} FLOPs per second
  - Arithmetic intensity conventionally uses FLOP/byte as a unit ratio (floating-point operations per byte moved).
- Network throughput: Reported in bytes/s (GB/s, TB/s) or bits/s (Gbps) depending on convention. InfiniBand and Ethernet specifications use Gbps; application-level throughput uses GB/s. The text states the convention on first use.
- Power: Power carries a subscript (P_{avg}, P_{device}, P_{cluster}, P_{IT}); bare P remains parameter count.
- Latency percentiles: Written p50, p95, and p99 in upright type, inside math as well as in prose.
- Currency: Dollar amounts use the dollar sign ($); unless otherwise noted, dollar-denominated costs are U.S. dollars (USD).
- Precision:
  - **FP64**: Double precision (8 bytes)
  - **FP32**: Single precision (4 bytes)
  - **TF32**: TensorFloat-32 (19-bit Tensor Core compute mode; inputs and storage remain FP32)
  - **FP16**: Half precision (2 bytes, standard range)
  - **BF16**: Brain float (2 bytes, wide dynamic range)
  - **FP8**: Quarter precision (1 byte, E4M3 or E5M2 format)
  - **FP4**: 4-bit floating-point format
  - **INT8**: 8-bit integer (1 byte)

- **INT4**: 4-bit integer; lower integer precisions follow the same uppercase `INTn` pattern (for example, INT3, INT2)

Quick reference: Resolving collisions

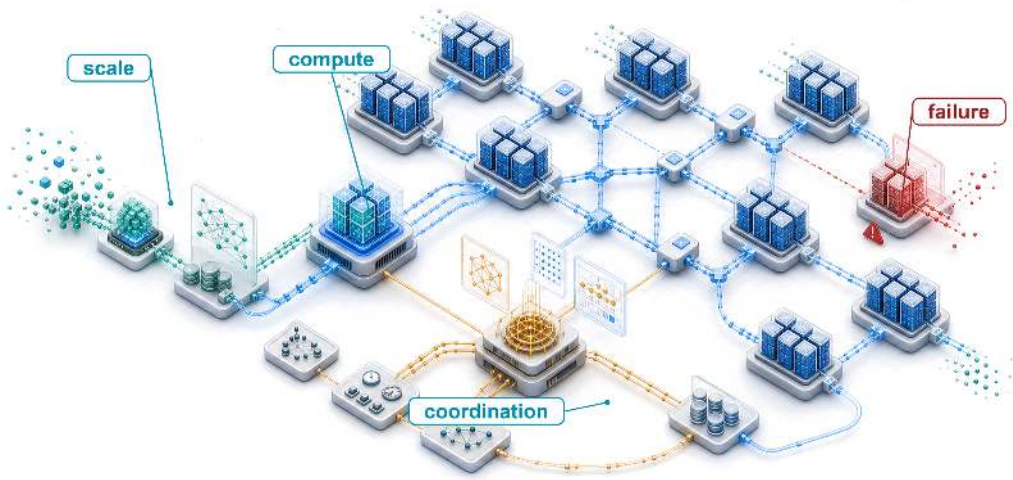
Several single-letter symbols carry conflicting default meanings in machine learning and systems papers. The table below resolves the four primary single-device collisions:

Symbol	ML meaning	Systems meaning	Book convention
B	**Batch Size**	Bandwidth	**Batch Size**. Use BW for bandwidth.
D	**Dataset Size**	Data Volume	**Dataset Size**. Use D_{vol} for bytes moved.
η	**Learning Rate**	Efficiency	**Learning Rate**. Use η_{hw} for efficiency.
P	**Parameters**	Peak FLOP/s	**Parameters**. Use R_{peak} for peak rate.

As a general principle, ML conventions take precedence for single letters, while systems concepts get subscripts or multi-letter symbols. This reflects the primary audience (ML practitioners learning systems) and preserves compatibility with the ML literature.

Additional collision points in distributed execution

Moving from a single accelerator to a multi-node cluster introduces symbol collisions across networking, queuing theory, and fault tolerance beyond those of single-device notation:



Symbol	ML meaning	Distributed meaning	Book convention
N	(none)	Number of Devices	**Device Count** in distributed context (accelerators, not host nodes); $N = N_{\text{GPU}}$.
M	GEMM dimension; memory root (M_{total})	Collective Payload	**Payload** when bare, outside GEMM shape statements. Memory footprints always carry a subscript.
λ	Regularization weight	Failure Rate	**Subscript every other use**. Bare λ is the per-component failure rate; arrival rate is λ_{arr}.
d, t, p	Hidden dimension; time; distribution $p(\cdot)$	Data-, tensor-, and pipeline-parallel degree	**Core meanings**. Parallelism degrees are N_{DP}, N_{TP}, and N_{PP}.

Symbol	ML meaning	Distributed meaning	Book convention
τ	Temperature or threshold	Checkpoint Interval or Delay	**Subscript every distributed use**. Checkpoint intervals are T_{ckpt} and T^*_{ckpt}; gradient staleness is τ_{stale}.
α	Significance Level	Network Latency	**Subscript every other use**. Bare α is α-β per-message latency; α_{scale} is the scaling exponent, α_{sig} the significance level, and α_{R} the Rényi order.
ρ	Correlation	Utilization or Ratio	**Subscript every other use**. Bare ρ is the communication-computation ratio; ρ_{serv} is serving or queue utilization.
ϵ	Small Constant	Privacy Budget	**Subscript every other use**. Bare ϵ is the privacy budget; ϵ_{adv} is the adversarial radius, and stabilizing constants carry their own subscripts.
g, G	Gradient $\mathbf{g}$	LogGP gaps; GPUs per node	**LogGP only** when bare. Gradients are bold $\mathbf{g}$; accelerators per node are G_{node}.
K	Top-K, key matrix $\mathbf{K}$	Attack Steps	**Local when bare**. PGD attack steps are K_{PGD}; other counts are defined at use or subscripted (K_{top}).

Purpose

Why are single-machine engineering principles insufficient for machine learning at fleet scale?

Machine learning at scale has a physics of its own. On one node, performance is often governed by the memory wall: data must reach the accelerator fast enough to keep the math busy. Scaling laws explain why one node stops being enough, because model quality improves predictably but sublinearly with compute, data, and parameters, so each further gain demands a larger fleet. In a distributed cluster, the memory problem stretches across machines. Data must move through network links between racks, and the slowest shared crossing can limit the entire job. Hardware failures also change character. A failure that stops one local training run can stall a whole distributed job when thousands of workers must advance together. This discontinuity explains why mastery of single-machine ML is no longer sufficient. A faster device may finish its local work sooner yet spend the saved time waiting for other machines. Adding devices can increase capacity while creating more shared work to coordinate and more components to recover. Serving introduces another consequence: spare capacity is useful only if requests can reach it within their deadlines. The engineering decision must therefore account for

Facility

the behavior of the whole fleet. That wider boundary also amplifies societal impact because these systems may serve billions of users. Bias in any model can cause harm, but bias in a widely reused foundation model can propagate across many downstream systems. In C^3 terms, compute, communication, and coordination turn algorithmic choices into questions of physical topology, fault tolerance, security, and governance.

Learning Objectives

- Explain why leaving one machine shifts the binding constraint from local memory to the network, energy, and routine failure
- Explain how empirical scaling laws drive fleet growth and where breakdown conditions bound compute-optimal allocation
- Diagnose fleet-scale distribution risks using reliability gaps, consistency-availability trade-offs, communication intensity, and routine failure rates
- Explain how Compute, Communication, and Coordination extend the Data-Algorithm-Machine lens for production fleets
- Apply the Fleet Law to separate a training budget's useful compute from its communication and coordination overhead
- Explain how the fleet stack connects infrastructure decisions to deployment and governance constraints

1.1 The Scale Moment

Machine learning on a single accelerator is governed by local memory hierarchy and arithmetic intensity, the physics of silicon. The boundary of single-machine systems appears when that local machine is no longer the system. As models move from research prototypes to global services, the binding constraints move outward into racks, networks, power delivery, and recovery machinery. That change is not a smooth extrapolation; it is the **scale moment**, the physical and operational transformation that occurs when models encounter three recurring walls: memory, network, and energy. On one accelerator the memory wall often binds; after distributing a communication-intensive workload across thousands of nodes, the network wall can replace local memory as the primary performance bottleneck. Its hard limits are speed-of-light latency and bisection bandwidth, the aggregate bandwidth across the narrowest cut that splits the fleet into two equal halves. Adding workers does not raise that bound, so a tightly coupled job whose traffic must cross the cut stops gaining speed once the cut saturates. Serving billions of users can then encounter the energy wall, making thermodynamic efficiency a first-order engineering requirement. Crossing those walls also opens a reliability gap, making hardware failure a routine event rather than a rare exception.

A synchronous distributed training step gives this change a concrete form. Each worker computes part of the update, exchanges model information with other workers, and waits until the required participants can advance together. These activities give the book its C^3 lens: Compute is local execution, Communication moves data between workers, and Coordination keeps their progress and state consistent, including after failures, across those resource limits. The Fleet Law expresses the corresponding time budget. Dividing a fixed workload across more devices can shorten local computation, but the step also pays for communication

and coordination, less whatever work can overlap. Faster accelerators help only when the remaining costs allow the saved compute time to shorten the whole step.

This book assumes familiarity with single-machine training, inference, and accelerator memory. Readers who want to refresh that foundation should begin with Appendix A, which restates it in reference form. The appendix covers the Data · Algorithm · Machine (D·A·M) lens that organizes single-machine diagnosis, the iron law, the Roofline Model and its arithmetic-intensity boundary, the accelerator memory hierarchy, the memory cost of training state per parameter, and the arithmetic of transformer layers. The book's aim is to develop engineering judgment across infrastructure, distributed execution, deployment, and governance, so that a local improvement can be evaluated against the behavior of the whole fleet. This chapter builds that judgment in the order a fleet engineer meets the problem. It first traces how far training compute and cluster size have grown and what changes when a job leaves one machine. It then turns to the empirical scaling laws that keep driving that growth, the physical, logical, and societal constraints that distribution imposes, and the C^3 taxonomy and Fleet Law that diagnose where a distributed step loses time. It closes with the fleet stack, an eight-row layered map of the fleet that locates each cost in the architecture, and three recurring workloads that test how the dominant cost changes. Parallelism, communication, and recovery techniques appear here only by name. The task in this chapter is to identify the constraint each one must address, and later chapters develop the mechanisms.

Between 2012 and the mid-2020s, public and third-party estimates place training compute growth from roughly 10^{18} FLOPs for AlexNet to approaching 10^{25} FLOPs for leading large models, seven to eight orders of magnitude. The difference is qualitative, not merely quantitative. A workload that once fit on two GPUs now spans tens of thousands of accelerators. Recent capability leaps have repeatedly come from applying computation at previously impractical scales, and the empirical scaling laws examined in section 1.3 explain why organizations keep paying for each further order of magnitude.

This growth unfolded across a sequence of landmark models. AlexNet trained on two GTX 580 GPUs for approximately 5–6 days (Krizhevsky et al. 2012). BERT required 64 Tensor Processing Unit (TPU)[1] chips for 4 days, roughly 6,144 chip hours (Devlin et al. 2019).

GPT-3 consumed an estimated 3.14×10^{23} FLOPs during training (Brown et al. 2020). A single A100, a generation newer than the V100 GPUs that trained it, would need about 32 years to perform that work even at its full 312 TFLOP/s peak, which is the plainest answer to why one node is no longer enough. A later carbon accounting instead pairs the budget with 10,000 V100 GPUs sustaining about 24.6 TFLOP/s each (roughly 20 percent of the V100's peak arithmetic rate) for roughly 15 days of training (Patterson et al. 2021). The gap between that delivered rate and the datasheet peak raises a question this book keeps returning to, namely how much of each accelerator a fleet actually puts to use. PaLM trained on 6,144 TPU v4 chips for 50 days and then on 3,072 for 14 days more, consuming approximately 10^{24} FLOPs (Chowdhery et al. 2022). OpenAI's GPT-4 report did

[1] **Tensor processing unit (TPU)**: Google's custom application-specific integrated circuit (ASIC) for machine learning, whose matrix units are systolic arrays, grids of multiply-accumulate cells that pass data between neighboring cells (Jouppi et al. 2017). At fleet scale, the inter-chip network matters as much as the array: TPU v4 joins its chips with an optically reconfigurable interconnect, so the topology of the network, not only the speed of each chip, determines how well many accelerators cooperate (Jouppi et al. 2023).

not disclose model size, training hardware, or training compute, so the GPT-4-class scenario in this section should be read as illustrative rather than a published configuration (OpenAI et al. 2023). These examples sit within the rapid training-compute growth trend documented by earlier compute-trend studies (Amodei and Hernandez 2018; Sevilla et al. 2022). Together, these landmarks show training budgets moving from single-machine experiments into distributed systems where hardware count, wall-clock time, and operational coordination are part of the model design (table 1.1).

Table 1.1: Training Compute Evolution: Growth in hardware scale and training duration across published landmarks and an illustrative GPT-4-class scenario, showing why distributed systems become central as training budgets move from 10^{18}-scale to the largest training runs.

Model	Year	GPUs/TPUs	Training time	Estimated FLOPs
AlexNet	2012	2 GPUs	5–6 days	~10^{18}
BERT-Large	2018	64 TPUs	4 days	~10^{20}
GPT-3	2020	10,000 V100 GPUs (run est.)	~15 days	3.14×10^{23} FLOPs
PaLM	2022	6,144 TPUs	~64 days	~10^{24}
GPT-4-class scenario	2023	~25,000 GPUs (illustrative)	~100 days (illustrative)	~10^{25} scenario

Epoch AI's database of notable models records, for each training run it can document, the compute the run consumed together with how many accelerators it used and for how long (Epoch AI 2026c). Plotted run by run, training compute climbs steadily on a logarithmic scale, and it separates early single-node vision models from multi-node transformer training (figure 1.1, panel a). Because training compute is the product of the accelerator count, the training duration, and the rate each accelerator delivers, the same records also show where the growth came from. Across the 146 runs from 2012 through 2024 that report all three, compute grew about 3.9× per year. The accelerator count grew 1.6× per year, the duration 1.3×, and the delivered rate per accelerator, which folds in both faster hardware and better utilization, 2× (figure 1.1, panel b). A higher delivered rate per accelerator supplied roughly half of the exponential. More accelerators running for longer supplied the other 51 percent, and that half is the fleet's to deliver.

The language-model points pull away from the vision points because compute demands escalated sharply as transformer architectures replaced convolutional pipelines. Landmark frontier runs grew their accelerator counts faster than the average run, roughly doubling every year (figure 1.2), a rate that quickly outpaced what any single node could host.

Across the four-order-of-magnitude climb charted in figure 1.2, accelerator counts rise from two GPUs for AlexNet to 16,384 H100 GPUs for Llama 3 along an annual doubling trajectory ($\sim 2\times$ per year). The one estimated point is GPT-3's,

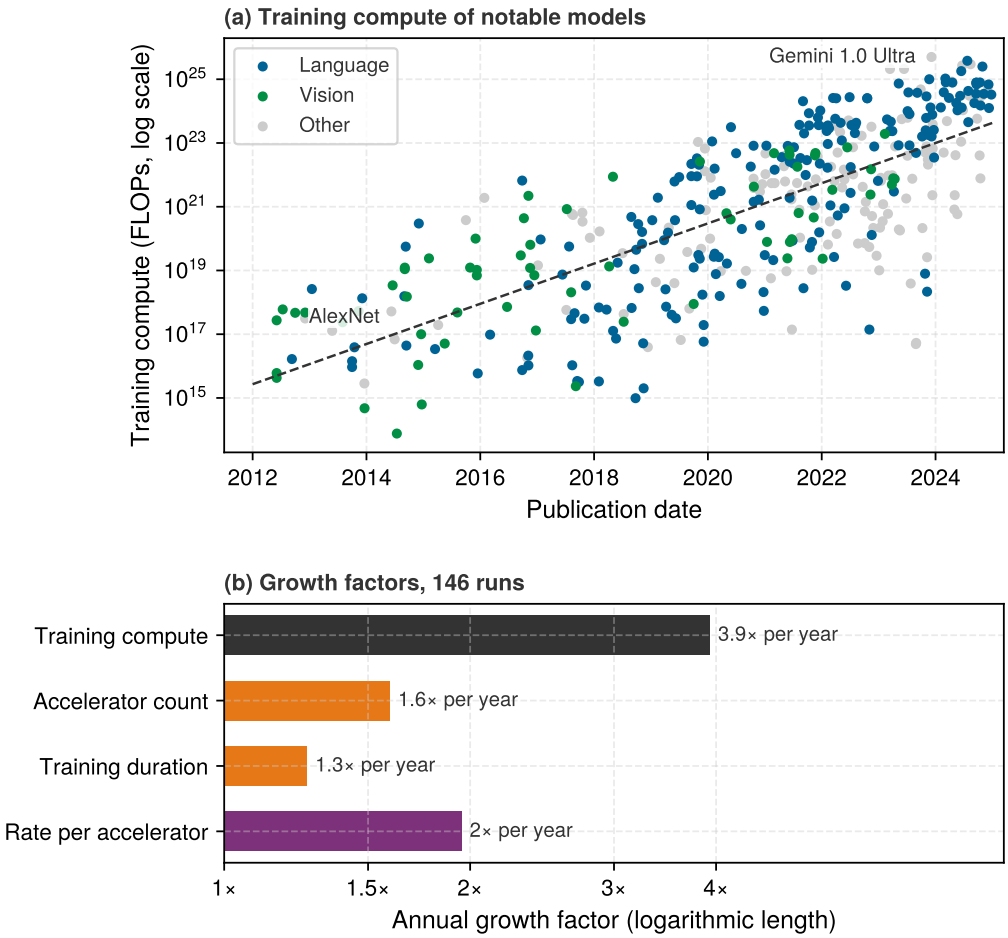

Figure 1.1: Where Training-Compute Growth Comes From: (a) Training compute of notable models published from 2012 through 2024 on a logarithmic axis, colored by domain, spanning about eight orders of magnitude from AlexNet to the largest runs; the dashed line is a least-squares fit. (b) Annual growth factors fitted to the runs that report accelerator count and training duration. Compute growth is the product of the other three bars, and the bar lengths are drawn on a logarithmic scale so each factor's share of the growth reads directly as its length. The delivered rate per accelerator includes both hardware speed and utilization. Data from Epoch AI (2026c); many values are Epoch AI estimates.

placed at the size of the Microsoft supercomputer built for OpenAI in 2020, more than 10,000 GPUs (Langston 2020). This empirical trajectory is the foundation of the scale moment, because leading models have required far larger accelerator fleets than earlier deep-learning landmarks. The curve alone, however, does not explain which constraint breaks first. Large language-model training, recommendation serving, and federated mobile learning all encounter fleet scale, but each stresses a different part of the system.

Lighthouse 1.1: Lighthouse archetypes at scale

Lighthouse archetypes are the canonical workloads that keep the scale moment concrete throughout this book. Their role at this point is to show that

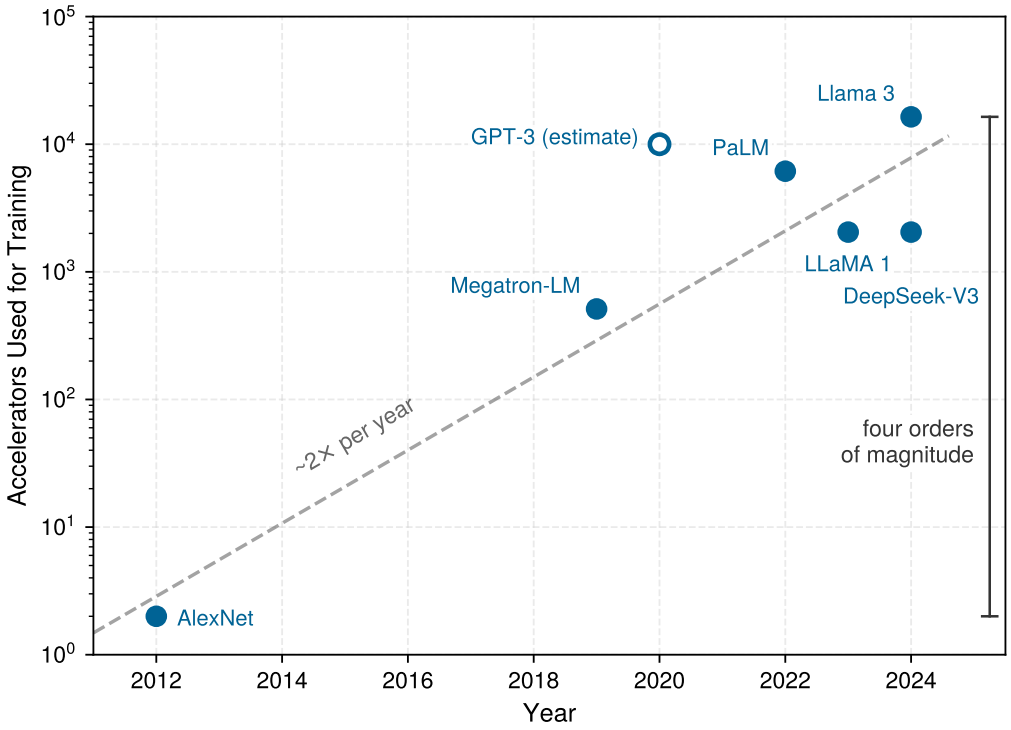

Figure 1.2: The Cluster Size Explosion: Number of accelerators used to train landmark models, 2012–2024. Verified counts from published papers are shown as filled circles; the GPT-3 estimate (hollow marker) reflects approximate cluster size from Microsoft infrastructure announcements rather than a precise published count. The dashed trend line indicates approximately 2× annual growth in cluster size, a rate that outpaces Moore's law and motivates the infrastructure challenges developed throughout the book.

"more machines" is not one engineering problem, because the dominant constraint depends on what must cross the fleet boundary. The full roster with the C^3 taxonomy mapping and binding-constraint analysis appears at section 1.6.1.

These archetypes turn the growth curve into an engineering question. The same increase in accelerator count can produce a network wall for a large language model split across devices, either within each layer (tensor parallelism) or by assigning consecutive groups of layers to different devices as pipeline stages (pipeline parallelism). It can produce a sparse-routing coordination bottleneck for a recommendation model whose embedding tables are spread across hundreds of nodes, or a per-device compute ceiling for federated learning across millions of phones, which carries that diversity of constraint regimes beyond the data center.

↪ Data, tensor, and pipeline parallelism, and the traffic each places on the fabric, are developed in chapter 6.

Moving from one machine to many changes the governing physics of the system, not merely its device count. A single node is bound locally by the memory wall between its accelerators and their high-bandwidth memory, and it has no peers to wait for. A fleet executes across a shared network fabric under a scheduler that

↪ Federated rounds across millions of devices, where dropouts, stragglers, and per-device budgets bind, are developed in section 11.7.

places and recovers the job, which exposes the workload to the network wall, to stragglers, and to routine node failures (figure 1.3).

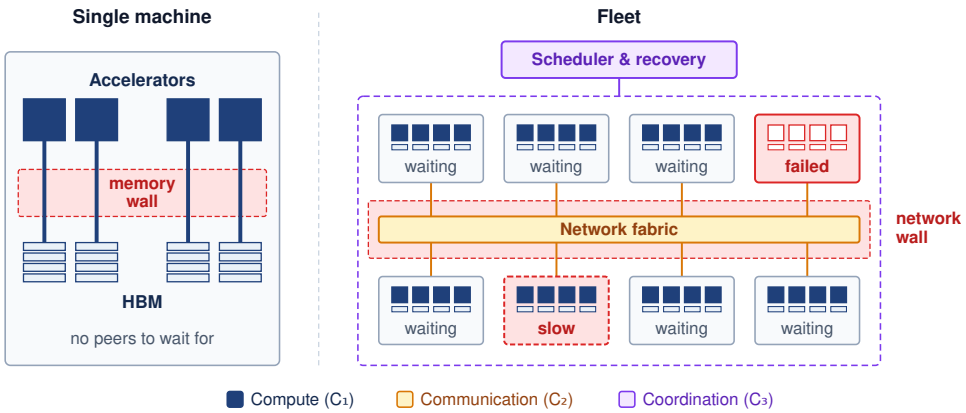

Figure 1.3: The Scale Discontinuity: On a single machine (left), the usual binding constraint is the memory wall between the accelerators and their high-bandwidth memory, and there are no peers to wait for. In a fleet (right), nodes exchange state over a shared network fabric under a scheduler that places the job and recovers it, so the three C^3 roles appear as separate components. The fabric can become the binding network wall, and failed and slow nodes become routine events that hold back the whole job.

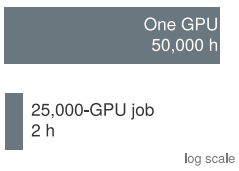
At fleet scale, the binding constraint may shift from local silicon to the network fabric, while resilience joins optimization as a primary concern. The unit of compute is no longer a single server but a **machine learning fleet**, an interconnected distributed system designed to act as a coherent engine.

Definition 1.1: Machine learning fleet

Machine learning fleet is a distributed collection of compute devices, storage, and networks managed together to train or serve machine learning models.

1. **Significance**: In tightly coupled synchronous training, the total time T can be governed by the slowest worker (straggler). Sustaining that workload requires balancing bisection bandwidth (BW_{bisect}) against aggregate compute capacity (R_{peak}). Serving fleets and heterogeneous edge fleets impose different communication and coordination requirements.
2. **Distinction**: The fleet is the unit of engineering, but its workers need not all advance together. Synchronous tight coupling makes a training job depend on a shared step barrier; serving replicas can process separate requests, and federated devices can participate intermittently. The workload determines the required coupling and recovery behavior.
3. **Common pitfall**: Treating an ML fleet as "just more servers" overlooks shared network, placement, and recovery constraints. A tightly coupled data-center fleet behaves as one machine, the warehouse-scale computer of section 1.2.2; an edge fleet extends the engineering boundary to devices outside that managed facility.

At the scale of thousands of GPUs, failure modes appear that a single GPU never encounters. A network partition can leave a synchronous job hung at a collective (an operation, such as a gradient exchange, that every worker must join) until a timeout aborts it, and in loosely synchronized designs it can let groups of workers drift apart. Stragglers (workers that process data slower than peers due to hardware variation or thermal throttling) can bottleneck entire training runs. Even infrequent component failures accumulate across a large fleet, so long training jobs must expect interruptions.[2] Systems must preserve recoverable state frequently enough to bound the work lost at each interruption.



The interruption cadence follows from simple arithmetic. Consider a hypothetical GPT-4-class training run on A100-class hardware, a cluster of 25,000 GPUs running for 100 days, values that follow a third-party estimate (Patel and Wong 2023) rather than an OpenAI disclosure (OpenAI et al. 2023). With an assumed per-GPU mean time to failure (MTTF) of 50,000 hours and independent failures, the system mean time between failures (MTBF) is the per-GPU MTTF divided by the GPU count, about 2 hours, or roughly 12 interruptions per day.

Production runs show a similar cadence. Meta's Llama 3 405B pretraining on 16,384 H100 GPUs recorded 419 unexpected interruptions over a 54-day snapshot, about one every 3 hours, from software, network, and host faults as well as GPU faults (Dubey et al. 2024). At that rate, a job that saved its state only every few hours would rarely reach its next save, and manual restart cannot keep pace, so recovery must be automated and designed into the system from the outset (section 7.2.2 follows how this run recovered).

Organizations answered these challenges with purpose-built fleets whose defining component is the network as much as the accelerator. Meta's Research SuperCluster, announced in 2022, was designed to reach 16,000 NVIDIA A100 GPUs connected by 200 Gb/s InfiniBand[3] links (AI 2022). Google's TPU v4 pods join 4,096 chips delivering 1.1 EFLOP/s of aggregate peak compute (Zu et al. 2024). Later Azure AI data center announcements describe training fabrics of tens of thousands of GPUs (Microsoft 2025). Each accelerator's share of that aggregate compute must exchange its results through links of a few hundred gigabits per second.

The scale moment establishes why exponential growth in compute demand forces some ML systems beyond any single machine, making the network fabric a potential bottleneck and component failure routine over long runs. The next question is how to organize the engineering response. Established distributed-systems techniques remain essential, but global barriers and large shared model state change their costs and determine which recovery and consistency mechanisms apply. Tracing how the layers of one machine map onto a fleet, starting with how sharply the links between servers fall below the bandwidth inside one, makes those dependencies explicit.

2 **Hardware failure rates at scale**: The arithmetic below uses an assumed per-GPU mean time to failure and independent failures to illustrate how interruption frequency grows with fleet size. Production job interruptions include software, networking, and maintenance as well as accelerator faults. Meta's Llama 3 report provides an observed example of this broader interruption category (Dubey et al. 2024); it does not establish a universal annual GPU failure rate.

A 25,000-GPU job fails 25,000 times as often as one GPU.

↪ The failure-rate arithmetic that turns a per-device MTTF into a job's interruption cadence, checked against production failure records, is developed in section 7.2.

1.2 From Single Node to Fleet

Inside one H100 server, NVLink moves tensors between accelerators at 450 GB/s in each direction per accelerator. Once a training job spans racks, the same tensors leave through an InfiniBand NDR port at 400 Gb/s (50 GB/s) in each direction, a bandwidth step down of roughly 9× for an accelerator served by one such port. That step illustrates a general pattern. The layered structure of an ML system persists across scale, while the physics at each layer changes. The **fleet stack** names the fleet's layers by grouping them into four bands, Infrastructure at the bottom, then Distribution, Serving, and Governance at the top, with two rows in each (figure 1.4). At the bottom, the hardware substrate of one node becomes the Infrastructure band, an RDMA fabric spanning racks. There the binding constraint can shift from the memory wall to the network wall as network congestion and message-passing latency consume a growing share of step time. One layer up, system software (a single CUDA runtime managing PCIe direct memory access (DMA)) becomes the Distribution band. This band holds the NVIDIA Collective Communications Library (NCCL) and RDMA libraries that coordinate thousands of processes across the fabric, together with the schedulers that place distributed jobs and the recovery machinery that restarts them. Efficient data movement inside each node remains a prerequisite, because a fleet of underutilized nodes only multiplies the waste.

[3] **InfiniBand**: A data-center interconnect whose defining feature for ML is remote direct memory access (RDMA), which bypasses the OS kernel to move data directly between application memory on different machines at microsecond-scale latency. HDR InfiniBand provides about 25 GB/s line-rate bandwidth per link and NDR about 50 GB/s; that per-link bandwidth, relative to the computation each worker performs between exchanges, decides whether large-model training is compute-bound or communication-bound. RDMA-capable Ethernet (RoCE) now offers comparable line rates.

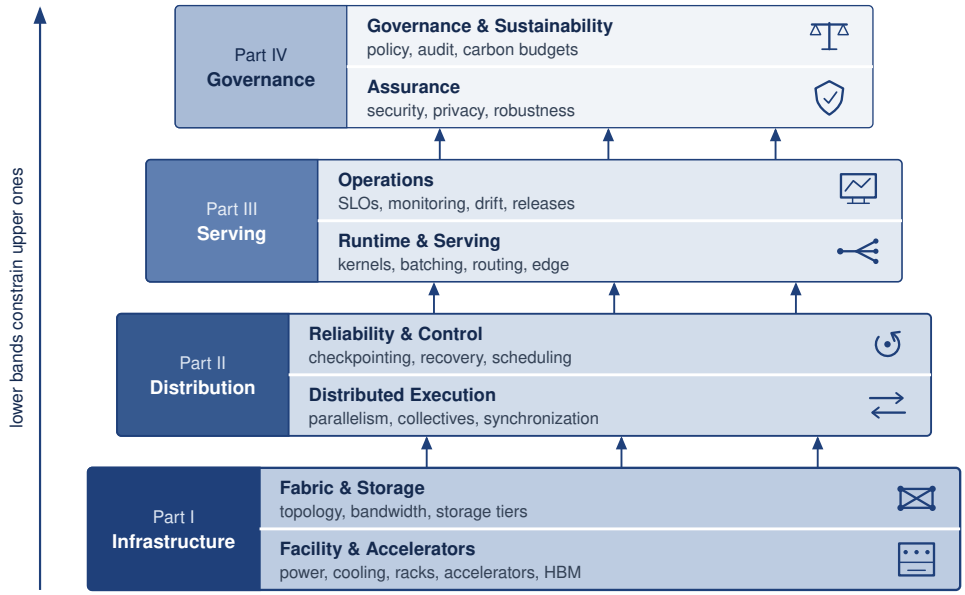


Figure 1.4: The Fleet Stack: The organizing framework for this book, eight rows grouped into four bands, one band per part. Each band is labeled with its part number and a short functional name for that part, and each row lists what it holds beside the icon that marks it in the chapter margin stacks; the Reliability & Control row, for example, is where orchestration, scheduling, and recovery live. Capabilities decided in a lower band constrain the choices available in the bands above it. The same stack, shaded to show each chapter's focus, appears beside the Purpose of every chapter.

The upper bands add responsibilities rather than replace the familiar software layers. The ML framework (PyTorch or JAX executing a training loop on one node) remains part of model execution. The Serving band adds request handling and deployment pipelines that manage rolling releases across the fleet. Applications also remain, while the Governance band sets security, robustness, sustainability, and responsible AI requirements for their operation. The full stack and its eight rows, the map that organizes the rest of this book, return in section 1.6. The stack identifies where a design decision belongs; C^3 identifies how that decision affects execution time.

A map of layers does not by itself explain why the same decision behaves differently once it spans a fleet. Three changes separate a fleet from a larger server: synchronous coupling turns independent tasks into a shared step, the facility itself becomes the computer, and communication can dominate the step. A fourth change, routine failure, was quantified at the scale moment; its availability model returns with the other constraints of scale in section 1.4.1. Archetype A (GPT-4/Llama-3), the large-language-model workload of the book's canonical roster (section 1.6.1), runs on a reference cluster of NVIDIA H100 accelerators and makes each change concrete where a chapter needs it.

1.2.1 Independent tasks vs. synchronous training steps

When one worker in a MapReduce job fails or slows down, the scheduler can retry that task alone while the rest of the cluster keeps making progress. When one worker in a synchronous training job slows by 10 percent on the critical path, every other accelerator waits at the step barrier and the whole job slows by nearly 10 percent. Many distributed systems isolate work into tasks or requests so that one failure need not stop unrelated work: **MapReduce** (Dean and Ghemawat 2004) partitions an input into retryable tasks, Apache Spark (Zaharia et al. 2016) processes data-parallel stages with explicit shuffle boundaries, and a web microservice handles requests whose failures can be isolated. Search engines and banking databases use other forms of replication, partitioning, and coordination; they are not uniformly independent or asynchronous. The useful contrast is therefore between failure domains and coupling patterns, not between "traditional" and ML systems.

Large synchronous training jobs operate under **synchronous tight coupling**. Parameter-server architectures (Li et al. 2014) and collective runtimes manage distributed state, but synchronous optimization updates a large shared model state across thousands of accelerators every few hundred milliseconds rather than completing independent one-shot tasks. At each synchronization point, progress can depend on the slowest participating worker, and communication-heavy partitions can also become bisection-bandwidth bound because large gradient or activation tensors cross the network every step. These properties do not invalidate established recovery techniques; they increase recovery cost and restrict which replication, re-execution, and consistency strategies preserve useful training progress.

↪ The barrier that makes every update wait for every required contribution, and the failure modes it creates, are developed in section 6.3.1.6.

The two execution pathways differ at the point of failure (figure 1.5). In MapReduce, a failed map task is retried on its own while its peers complete. In syn-

chronous data-parallel training, every worker holds a full copy of the model and processes a different slice of each batch. Before the shared parameter update can occur, every worker must contribute its gradient to an AllReduce, a collective operation that combines the gradients of all workers and returns the result to each of them. A slow map task can delay downstream reduction and job completion, but other map tasks finish without waiting; in synchronous training, by contrast, healthy workers sit idle whenever a straggler delays the collective.

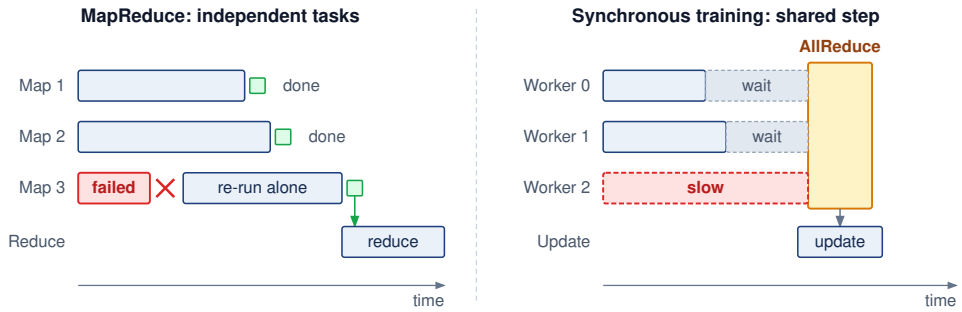

Figure 1.5: Retryable Tasks vs. Shared Training Steps: Map tasks (left) deliver their outputs independently, so a failed task is re-run on its own while the others finish; its missing output delays only the reducers that need it. In synchronous data-parallel training (right), the AllReduce needs every worker's gradient before the shared update can proceed, so a slow worker on the critical path holds the whole step and the healthy workers wait. How much the step stretches depends on overlap and the other costs of the step.

The collective barrier in figure 1.5 is why MapReduce-style localized task re-execution cannot be transferred directly to tightly coupled training. When all workers advance a single shared parameter step, recovery must restore mutually consistent model, optimizer, and input state across every participating node before coordinated execution can resume.

↪ Coordinated checkpointing, which captures that mutually consistent state so that recovery need not search for it, is developed in section 7.8.5.

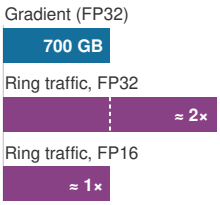
Checkpoint 1.1: The fleet mindset

These questions check whether the fleet mindset is clear:

- ☐ **Straggler impact**: compare how a slow map task can delay job completion with how a persistent straggler can delay repeated synchronous training steps.
- ☐ **Bisection bottleneck**: explain when frequent cross-rack tensor exchanges would make synchronous training more bandwidth-sensitive than a service handling mostly independent requests.
- ☐ **Tight coupling**: explain synchronous tight coupling and connect it to the need for all participating contributions before a shared training update completes.
- ☐ **Linear speedup myth**: using the barrier argument above, explain why doubling the GPUs in a synchronous training job need not halve its step time.

1.2.2 The shift to the warehouse-scale computer

Once a single training job spans thousands of accelerators across dozens of racks, a facility's cooling loops, power distribution, and optical spine can cap step throughput long before any individual chip reaches its arithmetic limit. A tightly coupled data-center fleet therefore demands the **warehouse-scale computer (WSC)**[4] perspective. Where a machine-centric view treats the data center as a building that houses many separate servers, the warehouse-scale view treats the data center itself as one computer. Single-node abstractions then map directly onto distributed infrastructure: the network fabric functions as the system bus, distributed storage serves as the local disk, and the fleet orchestrator acts as the operating system.



For this data-center regime, the engineering boundary extends from local execution to the shared power, network, and recovery systems that sustain the entire facility. The warehouse-scale computer is the standard design for large models. Wafer-scale engines, single processors built from an entire silicon wafer rather than one reticle-sized die, instead attempt to collapse this entire hierarchy into a single piece of silicon, trading the modularity of a distributed cluster for the extreme bandwidth of on-chip communication (section 2.2.1). Both designs answer the same constraint, the cost of moving data between chips, from opposite directions.

frame the data center itself as the computer. For ML fleets, power delivery, cooling topology, optical network layout, and bisection bandwidth become first-order constraints; a 100 MW facility can limit training throughput more than any single accelerator's TFLOP/s.

1.2.3 Communication dominance and the network wall

On a single GPU, a dense training step keeps its gradients in local memory, so matrix multiplications dominate step time and inter-node communication is zero. Once that workload spans racks in a warehouse-scale computer, every step must exchange gradients or activations across inter-server links before parameters can update, which can make communication the dominant cost and expose the network wall of the scale moment.

Distributed data-parallel training synchronizes gradients across workers after each batch. For a model with 175B parameters, FP32 gradients occupy about 700 GB before any collective algorithm is applied. Ring AllReduce arranges the AllReduce exchange among neighbors in a logical ring. With N workers, each worker sends roughly $2(N-1)/N$ times the gradient tensor size and receives the same amount across the reduction and distribution phases (section 5.6.3 derives this factor). For large N the factor approaches two, so each worker moves about twice the FP32 gradient per step, and half that when mixed-precision training exchanges 16-bit gradients. Network traffic therefore depends on precision, worker count, collective implementation, and partitioning. On slower interconnects or partitions with little computation per communicated byte, it can consume a large fraction of each iteration rather than a negligible one. Notebook 1.1 later converts the 16-bit volume into seconds of exposed transfer per step.

Ring AllReduce moves about twice the gradient per step; 16-bit gradients halve it.

That share grows as a fixed workload spreads across more devices, because each worker's local computation shrinks while its gradient exchange does not. Across illustrative tiers from 8 to 4,096 GPUs, compute can fall from 75 percent of the step to 20 percent as communication widens (figure 1.6). The fractions are assumed regimes rather than measurements. Gradient size, local batch size,

↪ The α-β communication model, with the per-interconnect latency and bandwidth parameters that turn a link's specifications into a predicted transfer cost, is developed in section D.1.

partition topology, and overlap determine where the critical path actually lies, so it must be measured at each scale.

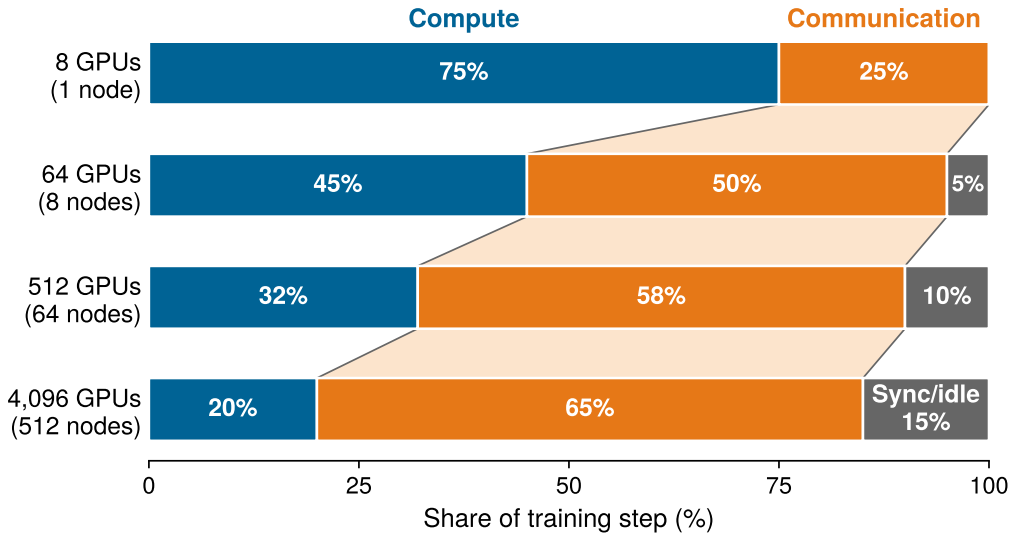


Figure 1.6: The Compute-Communication Timeline: Illustrative fractions show how exposed communication and synchronization can take a growing share of a training step as a fixed workload spreads across more devices. The fractions are assumed scenarios, not measurements or predictions for a particular model or cluster; they motivate measuring the critical path at each scale.

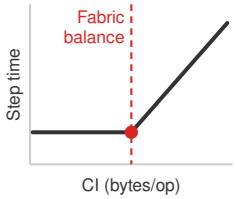
This exposed transfer cost explains why distributed training systems optimize communication so aggressively. Distributing work also distributes state that must move or be kept consistent. Horovod, for example, runs Ring AllReduce and fuses many small gradient tensors into fewer large transfers, so that the fixed cost of starting each exchange is paid fewer times (Sergeev and Balso 2018). Splitting each layer across devices, as Megatron-LM does with tensor parallelism (Shoeybi et al. 2019), and sharding optimizer state across workers, as ZeRO does (Rajbhandari et al. 2020), trade per-device memory for different traffic patterns. Gradient sparsification (sending fewer gradient bytes) and 3D parallelism (partitioning data, tensor, and pipeline dimensions across different fabric tiers) change how much data moves and where it moves. Chapter 6 develops these partitioning methods. Overlapping a transfer with independent computation instead reduces exposed waiting time without changing how many bytes move. The design decision at this stage is which cost prevents progress; selecting a particular mechanism requires the workload and fabric models developed later.

1.2.4 Communication intensity (the CI ratio)

If arithmetic intensity governs where a single accelerator stalls, **communication intensity (CI)** governs where a fleet stalls. On a single accelerator, the Roofline Model determines whether a kernel is compute-bound or memory-bound. At fleet scale, the same analysis extends to the network.



Equation 1.1 defines communication intensity as the ratio of data moved across the network to the operations performed locally. The numerator counts bytes and

the denominator counts operations for the same worker and interval, such as one training step; the ratio therefore has units of bytes per operation. A comparison must also state whether it counts sent bytes, received bytes, or both:

$$\mathrm{CI} = \frac{M}{O} \tag{1.1}$$

where M is the number of bytes the worker moves across the network and O is the number of operations it performs locally in the same interval.

Low communication intensity describes compute-heavy workloads whose accelerators spend most of their time doing math, so scaling is comparatively easy. High communication intensity describes workloads whose bytes per operation approach or exceed the hardware's fabric balance, the ratio of per-worker network bandwidth to peak arithmetic throughput. Past that balance point, network transfers take longer than the local computation they accompany. Splitting a fixed batch across still more accelerators shrinks the local operations O per worker while leaving gradient traffic M in place or adding collective overhead, which raises CI further and can make the step slower rather than faster. The boundary is configuration-specific because it depends on both local compute throughput and effective network bandwidth.

Past the fabric balance point, step time grows with communication intensity.

The 175B-parameter step gives the ratio a concrete value. Suppose each data-parallel worker processes 8,192 tokens per step, four full-length sequences. Its local work is about six FLOPs per parameter per token, or 8.6×10^{15} FLOPs, while its 16-bit ring AllReduce moves about 700 GB. The communication intensity is therefore about 8×10^{-5} bytes per FLOP, one byte for roughly every 12,000 FLOPs. An A100 on one 200 Gb/s InfiniBand link has a fabric balance of 8×10^{-5} bytes per FLOP, its link bandwidth divided by its peak arithmetic rate. The step sits near that balance point, so at line rate and peak throughput the exchange takes about as long as the computation, and without overlap it roughly doubles the step. The ratio describes workload demand; the fabric and execution schedule determine how much of that demand delays progress.

Communication costs, together with the recovery costs quantified at the scale moment, describe how a fleet executes work. Neither explains what drives the relentless growth in fleet size, or how much work a model should receive. Both answers lie in empirical relationships between model quality and resource investment, relationships that have made warehouse-scale infrastructure an economic necessity rather than an engineering luxury.

↪ The communication-computation ratio, and the threshold beyond which communication can no longer hide behind computation, are developed in section C.3.3.

1.3 AI Scaling Laws

The seven to eight orders of magnitude of training compute traced at the scale moment, from AlexNet to GPT-4-class estimates near 10^{25} FLOPs, were not an accident of ambition. Each order-of-magnitude increase in compute demanded a corresponding expansion of the machine learning fleet, and organizations paid for those expansions because the return on them had become predictable. Predictable is not the same as free. Measured learning curves estimate the quality a training

budget buys, while device throughput, execution efficiency, and the completion deadline determine how much fleet capacity that budget requires.

Rich Sutton's "bitter lesson" articulated the underlying principle: performance in machine learning is primarily driven by applying general methods at large scale rather than encoding human knowledge into algorithms (Sutton 2019). Scaling laws formalize this observation quantitatively. Model loss improves sublinearly as a power-law function of compute, dataset size, and parameters, $\mathcal{L}(X) \propto X^{-\alpha_{\text{scale}}}$ for a resource X (stated in full, with its irreducible floor, in theorem 1.1) (Kaplan et al. 2020; Hoffmann et al. 2022). Each equal-sized loss improvement therefore requires disproportionately more resources, a systems consequence this book later names as the empirical scaling law. Each scaling dimension (parameters, data, and compute) interacts with infrastructure constraints differently, making multi-dimensional efficiency optimization essential at production scale.

1.3.1 Empirical evidence for scaling laws

Over the longer history of AI, the growth rate of training compute broke sharply upward around 2010 (Sevilla et al. 2022). A fit to Epoch AI's records of notable models gives growth of about 1.5× per year before 2010, close to Moore's law, and of about 4.3× per year in the deep learning era (figure 1.7). The scale moment already decomposed that post-2012 climb into accelerator count, run duration, and delivered rate per accelerator (figure 1.1, panel b). When compute demand outpaces single-chip hardware gains by that margin, misallocating a training budget becomes prohibitively expensive, turning empirical scaling laws from a research curiosity into an engineering necessity.

Kaplan et al. (2020) demonstrated that transformer-based language-model loss follows predictable power-law relationships with model parameters, dataset size (measured in tokens), and total computational budget. The result was not a license to increase every dimension blindly; it showed that model quality depends on coordinated allocation across those resources, a point later sharpened by Chinchilla's compute-optimal scaling analysis (Hoffmann et al. 2022).

Across parameter scales from 10^3 to 10^9, larger models are also more sample-efficient, reaching any target loss with substantially fewer training tokens (figure 1.8, panel a). Compute-efficient training therefore stops far short of full convergence, because an early-stopped larger model attains the target loss with less total compute than a smaller model trained to its plateau (panel b).

Because each equal loss improvement costs disproportionately more, allocation grows more consequential as budgets grow. The question is how to divide a budget between the size of the model and the training data it consumes.

1.3.2 Compute-optimal resource allocation

A team that spends a fixed training-compute budget making a model twice as large while halving its training tokens[5] ends up with a higher-loss model that also costs twice as much memory and bandwidth to serve. Empirical studies of large language models (LLMs) show that, for a fixed computational budget and

[5] **Tokens**: Subword units produced by algorithms like byte-pair encoding, which iteratively merges the most frequent character pairs in a corpus. Token vocabulary size creates a direct systems trade-off: larger vocabularies can reduce sequence length for some languages and domains, but they expand the embedding table roughly in proportion to vocabulary size. GPT-3 used a 50,257-token vocabulary; moving to 100K+ tokens in newer models therefore trades tokenization efficiency against additional embedding memory.

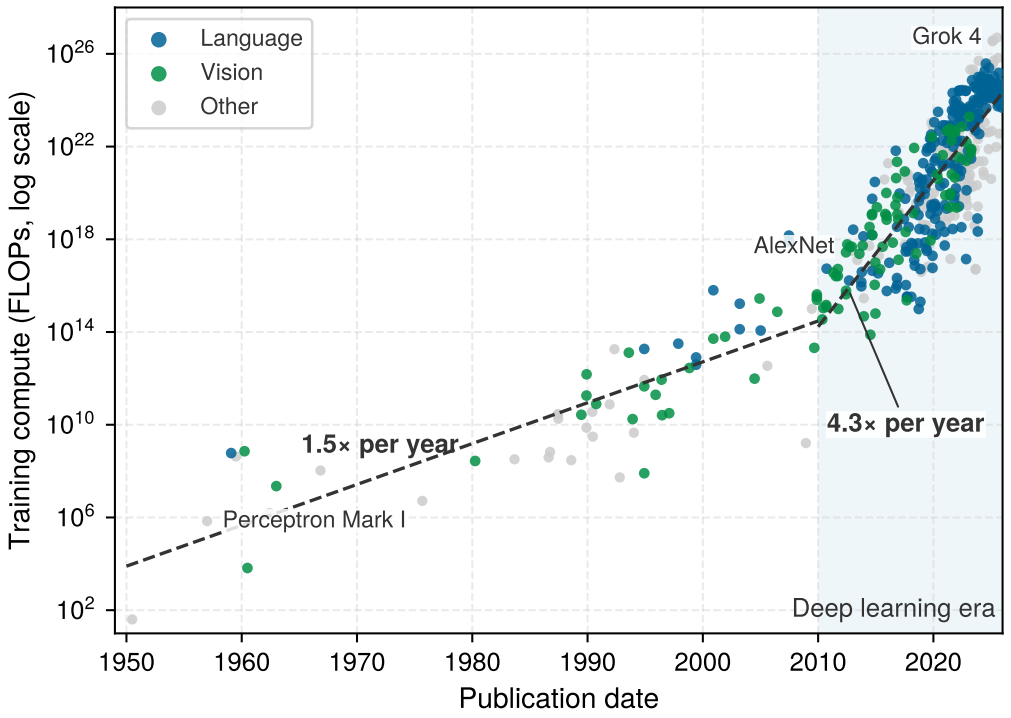


Figure 1.7: Model Training Compute Trends: Training compute of notable models published from 1950 through 2025, on a logarithmic axis, with one least-squares trend fitted to each era. Before 2010 the fitted rate is about 1.5× per year, close to Moore's law (a doubling about every 2 years); in the deep learning era it is about 4.3× per year, far steeper. The fastest stretch was steeper still. Within the 2012–2019 frontier subset measured by an earlier study (Amodei and Hernandez 2018), compute doubled approximately every 3.4 months. This trajectory explains why efficiency has become a strategic imperative rather than an optional optimization. Data from Epoch AI (2026c), licensed under CC BY 4.0; many values are Epoch AI estimates, and the era break at 2010 follows Sevilla et al. (2022).

within the studied scaling regime, balancing model size and dataset size minimizes training loss.

Holding the budget fixed and varying model size traces a U-shaped IsoFLOP curve of training loss against parameter count, whose valley marks the best model size for that FLOP budget (figure 1.9, panel a). As the budget grows, the valley moves toward larger models, and the optimal parameter count and the optimal number of training tokens rise along coordinated power laws (panel b), so compute-optimal training advances model size and token volume in tandem. Projected to a larger budget, the fits call for 63B parameters trained on 1.4T tokens, about 5.3×10^{23} FLOPs in total,[6] which is how compute-optimal frontiers guide resource allocation before cluster execution begins.

Within the studied regime, the Chinchilla result indicates that model size and training tokens should scale approximately proportionally for compute-optimal training, with a ratio on the order of 20 training tokens per parameter (Hoffmann et al. 2022). The allocation is a trade along a fixed product. Training a dense transformer costs about $O_{\text{train}} \approx 6PD$ FLOPs for P parameters and D training tokens, two per parameter per token in the forward pass and four in the backward pass (equation A.4). A fixed budget therefore fixes the product of model size

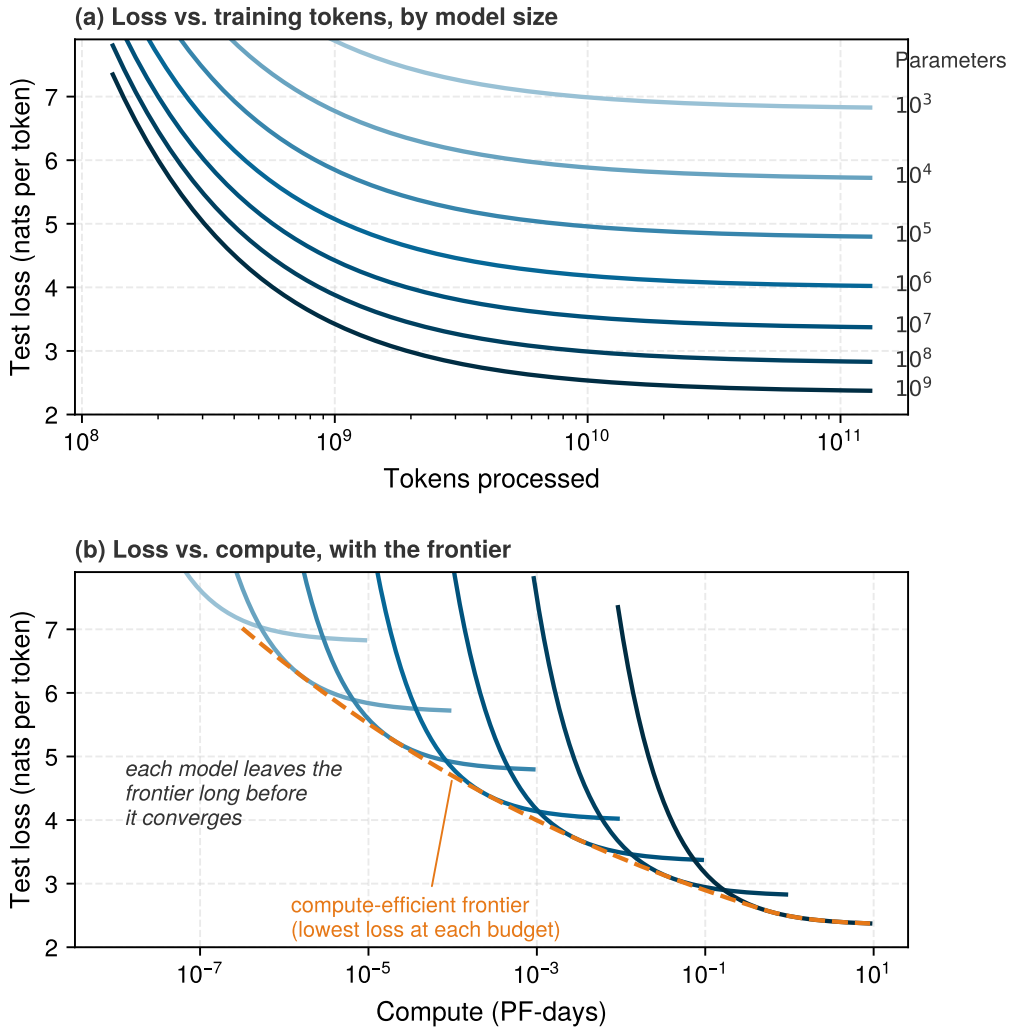

Figure 1.8: Scaling Laws and Compute Optimality: Test loss predicted by the fitted law of Kaplan et al. for models from 10^3 to 10^9 parameters. (a) Larger models reach any given loss with fewer training tokens and settle at a lower plateau. (b) The same curves against training compute; the dashed line is their lower envelope, the lowest loss any model size reaches at each budget. Each model leaves the envelope long before it converges, so compute-efficient training stops far short of convergence. The curves are drawn from the published fit of loss against parameter count and training steps at the paper's default batch size, not from training logs, and begin where the fit's early-training term falls to 5 nats. After Kaplan et al. (2020).

and tokens, and the ratio chooses the point along it. The projection in figure 1.9, 1.4T tokens for 63B parameters, or about 22 tokens per parameter, sits close to that ratio. This corrected earlier guidance that favored making models larger while training them on comparatively fewer tokens. The objective is loss at a fixed training-compute budget. A deployment that serves the model repeatedly must also account for inference cost; its preferred allocation need not minimize training compute alone.

When sizing GPT-3, the authors used scaling-law extrapolations to choose model size and training data (Brown et al. 2020; Kaplan et al. 2020). They trained an established transformer architecture with 175B parameters and approximately 300

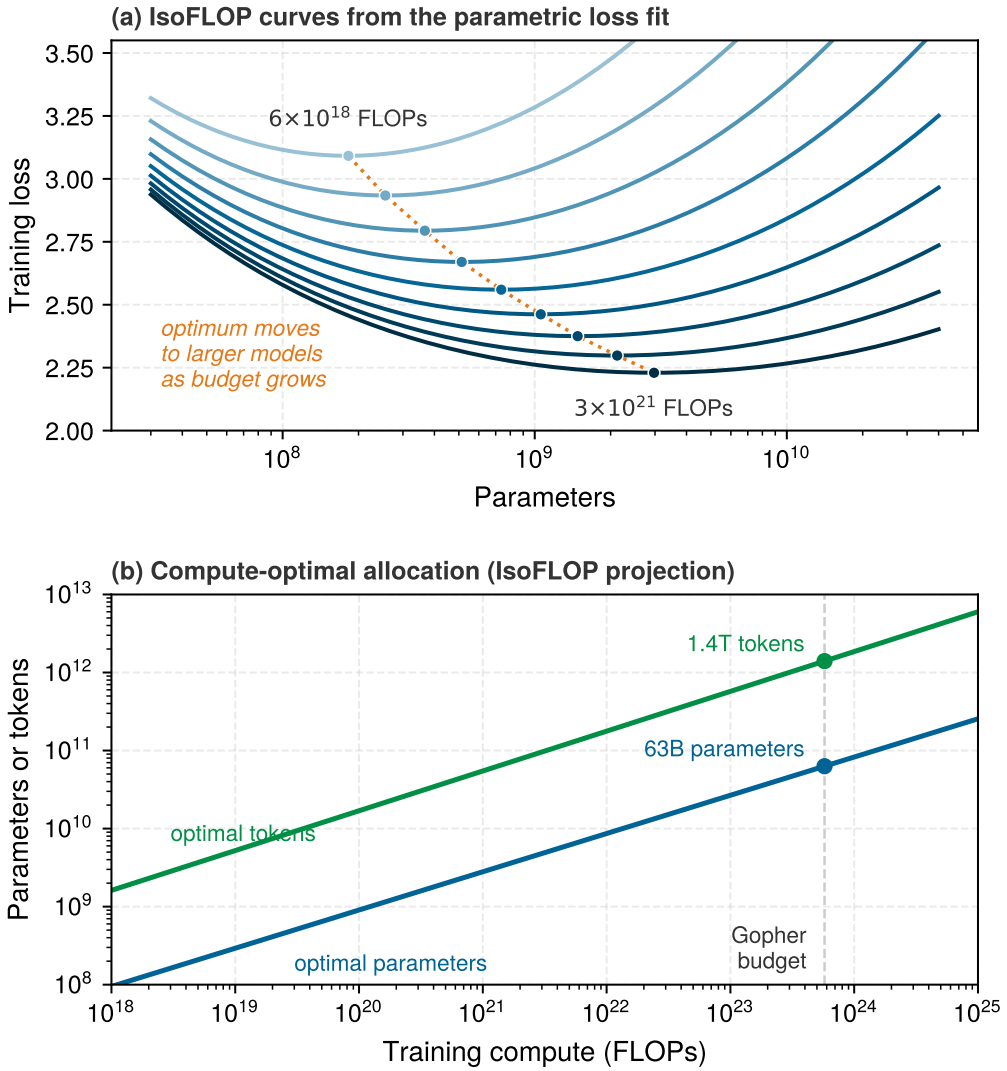

Figure 1.9: Optimal Compute Allocation: For a fixed computational budget, language-model loss depends on how the budget is divided between model size and training data. (a) IsoFLOP curves for nine budgets from 6×10^{18} to 3×10^{21} FLOPs, drawn from the paper's parametric loss fit; each valley marks the best model size for its budget, and the valleys move toward larger models as the budget grows. (b) Compute-optimal parameter and token counts from the paper's IsoFLOP analysis, projected to the Gopher budget, where they reach 63B parameters and 1.4T tokens. The two panels use different fitting methods from the same paper, so their optima do not coincide exactly. After Hoffmann et al. (2022).

billion tokens, about 1.7 tokens per parameter. Against the roughly 20 tokens per parameter of the later Chinchilla results, that point was undertrained relative to compute-optimal token allocation (Hoffmann et al. 2022).

The practical decision is how to divide a fixed budget among model size, data, and training duration, and a compute-optimal allocation answers it only in useful computational work. Converting that work into elapsed time requires a separate systems model. Communication can grow relative to per-worker computation as a fixed workload is split more finely, creating bandwidth bottlenecks that reduce

effective utilization. At multi-thousand-GPU scale, utilization depends on partitioning and interconnect. Narayanan et al. (2021) report Megatron-LM runs on 3,072 A100 GPUs at 52 percent of peak device throughput and note that slower interconnects or communication-heavy partitions hinder scaling.

1.3.3 Power-law scaling and operational regimes

Even when a cluster sustains high utilization on a compute-optimal run, scaling parameters and tokens in lockstep works only while both resources remain available and the loss curve stays well above its irreducible floor. Including that floor in the power-law proportionality stated with the bitter lesson explains why the same fleet can enter different operational regimes. The following analysis takes three cuts through these regimes, each with its own fleet consequence. The first cut is how compute and data are allocated, which decides the resource to buy next. The second is where diminishing returns set in with dataset size, which decides when storage and data pipelines matter more than accelerators. The last is when in the model's lifecycle computation is spent, which decides the part of the fleet, training or serving, that carries the load.

Theorem 1.1: Power-law scaling formulation

Scaling laws are expressed formally as power-law relationships. The general formulation is:

$$\mathcal{L}(X) = A_{\mathcal{L}} X^{-\alpha_{\text{scale}}} + C_{\mathcal{L}}$$

where loss $\mathcal{L}$ decreases as resource quantity X increases, following a power-law decay with rate α_{scale}, plus a baseline constant $C_{\mathcal{L}}$, the irreducible loss (a constant of the fit, not one of the C^3 labels). Here, $\mathcal{L}(X)$ represents the loss achieved with a resource quantity such as parameters, tokens, or compute; $A_{\mathcal{L}}$ and $C_{\mathcal{L}}$ are task-dependent constants; and α_{scale} is the scaling exponent that characterizes the rate of performance improvement. A larger value of α_{scale} signifies more efficient performance improvements with respect to scaling.

For a fleet, the exponent is the price list. Halving the reducible term $A_{\mathcal{L}} X^{-\alpha_{\text{scale}}}$ requires multiplying the resource X by $2^{1/\alpha_{\text{scale}}}$, so the smaller the exponent, the larger the multiple of accelerators, tokens, or training time that each further step in quality demands. These power-law predictions find empirical validation in the family of learning curves plotted in figure 1.10. Across six model scales spanning from 393.2K to 708M parameters, test loss descends predictably as dataset size grows from 10^7 toward 3×10^{10} tokens, with smaller architectures flattening into parameter-capacity plateaus while larger models sustain power-law error reduction.

1.3.3.1 Resource-constrained scaling regimes

Those plateaus show why buying more accelerators for a project whose dataset is already exhausted wastes hardware on overfitting, whereas collecting more tokens

6 **FLOPs vs. FLOP/s**: FLOPs denotes total computational work (operations performed), while FLOP/s denotes hardware throughput (operations per second); confusing the two leads to incorrect cost estimates. GPT-3 required 3.14×10^{23} FLOPs of work; an A100 delivers 312 TFLOP/s of throughput. Dividing work by peak throughput gives ideal wall-clock time, the roughly 32 years on one A100 computed at the scale moment. Actual time is approximately work$/(\eta_{\text{hw}} R_{\text{peak}})$, where the hardware utilization η_{hw} is the achieved fraction of peak throughput, so utilization below one multiplies ideal time by $1/\eta_{\text{hw}}$.

for a project whose cluster cannot train a larger model strands data in storage. Applying scaling laws in practice is therefore a scarcity diagnosis that asks which resource prevents balanced growth first. Compute budget, data availability, and model size create three regimes with different optimal responses.

In a compute-limited regime, compute scarcity restricts scaling potential despite abundant training data; measured learning curves guide the allocation between model size and training tokens within that budget. In a data-limited regime, computational resources exceed what the available dataset can support, meaning that increasing model size is useful only if validation measurements show that the available data can support additional capacity. Between these extremes lies the optimal regime, where compute and data grow in balance following compute-optimal scaling laws, as DeepMind demonstrated with Chinchilla by outperforming much larger models through proportional scaling of model size and training data (Hoffmann et al. 2022). Recognizing which regime governs a given project prevents common inefficiencies: over-parameterized models with insufficient training data, or under-parameterized models that waste available compute. For the fleet, the diagnosis decides where the next investment goes. A compute-limited project needs accelerator-hours, while a data-limited one gains more from the storage and data pipelines of chapter 4 than from additional accelerators.

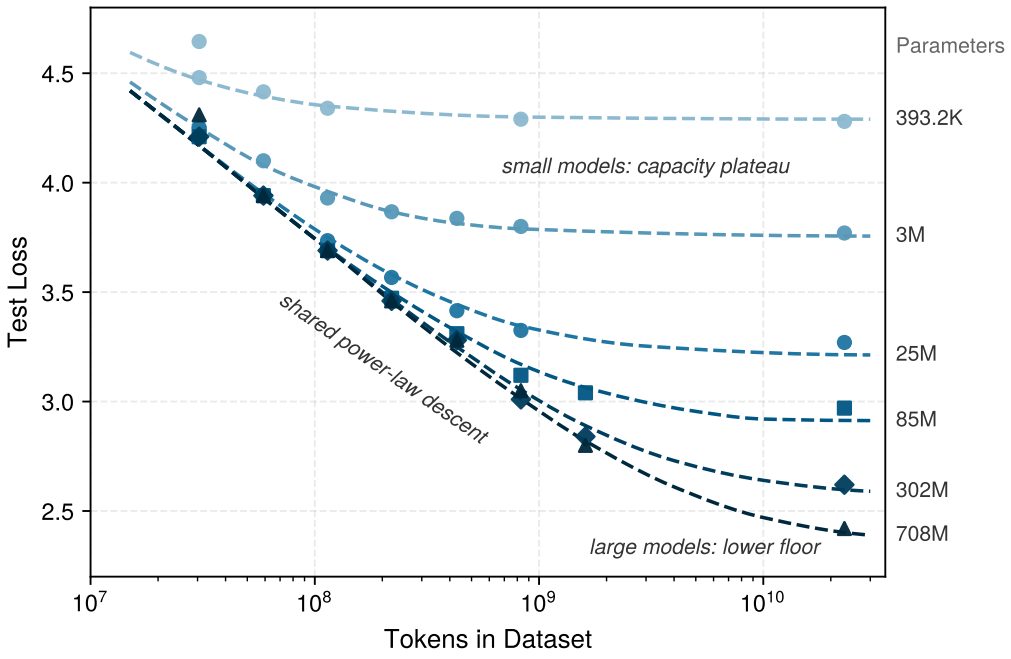

Figure 1.10: Loss vs. Dataset Size across Model Scales: Test loss curves show how models of different sizes (393.2K to 708M parameters) benefit from increased training data. Larger models achieve lower loss, but all curves exhibit diminishing returns at high token counts. Points and curves are digitized from Figure 4 (left) of Kaplan et al. (2020), so values carry the precision of a reading from the published plot.

The second cut through the operational regimes follows the return on additional data as a dataset grows, which decides when buying data stops paying. On log-log

coordinates, dataset scaling passes through three regimes (figure 1.11). In the initial Small Data Region, generalization error lingers near the upper Best Guess Error ceiling. As data volume expands into the central Power-Law Region, error drops sharply along a constant slope where data investment yields predictable returns. Finally, in the Irreducible Error Region, the curve flattens asymptotically against the Bayes noise floor, where further dataset expansion provides negligible gain. The systems consequence is that finite high-quality data, not compute, becomes the binding constraint once a model enters the saturation regime, which is why data efficiency complements brute-force scaling. An observed plateau does not by itself establish that the irreducible floor has been reached, however. Limited coverage, insufficient model capacity, and incomplete optimization can also flatten a learning curve, so the engineering task is to rule out these remediable limits before purchasing more data or compute.

↪ The data wall, and the storage traffic a fleet incurs when it generates, filters, and versions synthetic training data, are developed in section 4.7.2.

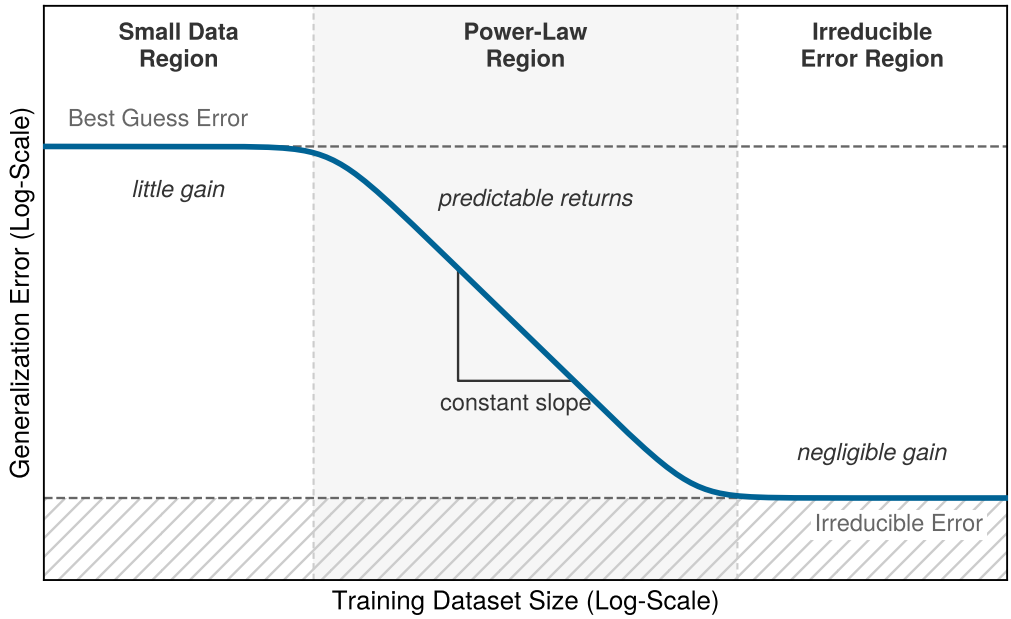

Figure 1.11: Data Scaling Regimes: Generalization error as a function of dataset size exhibits three distinct phases. In the small-data regime, error stays near the best-guess ceiling; the power-law regime demonstrates predictable error reduction; the irreducible-error regime represents the fundamental noise floor. Adapted from (Hestness et al. 2017); the axes carry no measured values.

The third cut follows lifecycle stage, because additional compute can be spent on the foundation run, on adapting the model afterward, or on each request in deployment (figure 1.12). Pretraining scaling (orange curve) increases the resource investment in the foundation run. Posttraining scaling (blue curve) adapts an existing model through fine-tuning or preference optimization. Test-time scaling (green curve, "long thinking") spends additional computation on a particular request through intermediate generation, search, or sampling, trading serving latency and throughput for a possible quality gain. Each phase stresses a different part of the fleet. Pretraining is one long, failure-sensitive foundation run whose

scaling-law gains must be realized in wall-clock time. Posttraining replaces that single large job with many smaller, coordination-heavy runs. Test-time scaling moves computation into the serving path, where it competes with latency targets. The schematic curves do not establish a universal efficiency ranking among these choices, so the full treatments belong with their workloads. Test-time compute at serving is treated in section 10.6.9. A resource plan must compare measured task improvements and costs before choosing where to spend the next increment of compute.

↪ The multi-model coordination that post-training alignment runs require is developed in section 6.7.1.

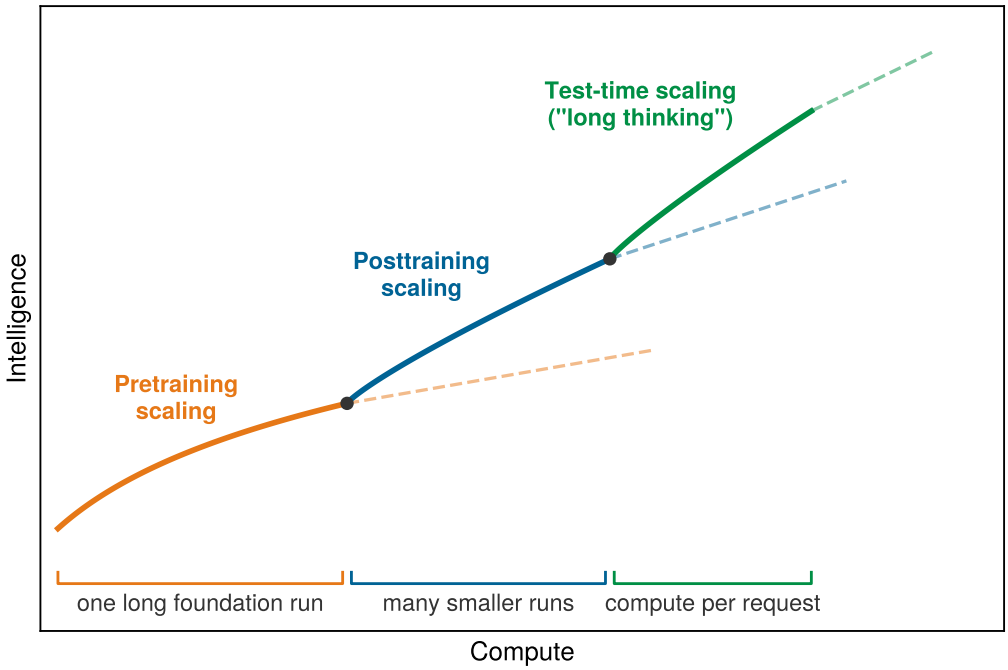

Figure 1.12: The Three Scaling Phases: A schematic of three points in the lifecycle where additional computation can raise capability. Pretraining scales with compute and data (Kaplan et al. 2020). Posttraining (reinforcement learning from human feedback, instruction tuning) refines behavior (Ouyang et al. 2022). Test-time scaling (chain-of-thought, search) spends additional computation on each request at inference (Snell et al. 2025). The curves are illustrative and carry no measured values.

1.3.4 Sustainability and cost implications

GPT-3's training run alone occupied about 148,000 GPU-days and drew an estimated 1,287 MWh of electricity (Patterson et al. 2021), and later frontier runs use more accelerators for longer. While scaling laws trace a path to lower loss, they also expose rapidly escalating resource demands whose training and deployment costs grow faster than the quality gains they buy.

Where that electricity is generated matters as much as how much is drawn. The same training run can differ by roughly 41× in CO_2 emissions depending on grid location, from about 20 g/kWh of CO_2 for Quebec hydropower to about 820 g/kWh for Poland coal. The siting of the cluster is therefore a first-order infrastructure decision. Financial cost scales with the same accelerator-days and megawatt-hours, which limits who can do large-scale research at all.

↪ How site selection and grid carbon intensity set the emissions of the same training run is developed in section 15.2.

Scaling laws do not guarantee unbounded improvement. Each incremental performance gain must be weighed against its resource cost. As systems approach practical scaling limits, the emphasis shifts from scaling alone to efficient scaling: balancing performance, cost, energy consumption, and environmental impact.[7]

[7] **Scaling law saturation**: Power-law relationships with a baseline loss term approach that floor rather than predict unbounded loss reduction. Downstream task utility may also stop improving even while the fitted loss decreases. That gap between loss and utility motivates testing data efficiency or model compression against task utility and resource cost; neither technique guarantees that a genuine information limit can be overcome.

1.3.5 When scaling laws break down

Doubling a model's parameter count without expanding its training dataset or interconnect capacity can stall loss improvements even as cluster cost doubles, because power-law fits hold only within the balanced regime in which they were measured. Most breakdowns at those boundaries share one root cause, growth in one dimension that outpaces the others. Hoffmann et al. (2022) show that many large language models were undertrained because model size grew faster than training-token budgets, and that compute-optimal training requires scaling parameters and tokens together. Hardware ceilings belong to the same family, because memory bandwidth, interconnect capacity, and I/O throughput cap how far a larger model can be distributed at all. Each imbalance requires different evidence. Training measurements can reveal an unsuitable optimization schedule. Held-out evaluation can distinguish improved generalization from memorization. Execution traces can reveal whether bandwidth or I/O prevents the fleet from completing the planned work. A lower benchmark loss also does not establish robustness to adversarial or out-of-distribution inputs. Each possible breakdown type pairs with a candidate cause and a representative scenario (table 1.2). The pairing guides investigation; it does not infer a cause from a plateau alone.

Table 1.2: Possible Scaling Breakdowns: The rows describe risks and representative scenarios, not inevitable consequences of increasing one resource. Training and validation measurements establish which failure mode, if any, applies to a particular allocation.

Dimension scaled	Type of breakdown	Underlying cause	Example scenario
Model Size	Overfitting	Model capacity exceeds available data	Billion-parameter model on limited dataset
Training Data Size	Diminishing Returns	Saturation of new or diverse information	Scaling web text beyond useful threshold
Compute Budget	Underutilized Resources	Insufficient training steps or inefficient use	Large model with truncated training duration
Imbalanced Scaling	Inefficiency	Uncoordinated increase in model/data/compute	Doubling model size without more data or time
All Dimensions	Saturation	Exhaustion of learnable patterns in the domain	No further gains despite scaling all inputs

Checkpoint 1.2: Applying scaling laws

These questions check whether scaling laws are being used as resource-allocation tools:

- ☐ **Compute vs. data regime**: identify the learning-curve evidence needed to choose between a larger model trained for fewer steps and a smaller model trained for more steps under fixed compute and limited data.
- ☐ **Scaling breakdown**: explain the risks of doubling model parameters at fixed dataset size, and what training and validation evidence would distinguish undertraining from overfitting.
- ☐ **Chinchilla optimality**: explain why Chinchilla optimality serves as a resource-allocation target and identify the minimized quantity.
- ☐ **Compute vs. capability**: classify the claim as true or false: scaling laws predict that doubling compute always yields a doubling of model capability.

1.3.6 Combining efficiency with scaling

Data saturation, infrastructure bottlenecks, and diminishing returns set hard limits on what brute-force scaling can achieve. The same constraints, however, point toward solutions along three interconnected dimensions. When compute is the scarce resource, algorithmic efficiency uses techniques such as sparsity and distillation to extract more capability per FLOP. When high-quality tokens run short, data efficiency uses curriculum learning and active selection to extract more information per training example. When the cluster itself stalls on transfers or barriers, systems efficiency uses communication hiding and pipeline overlap to extract more utilization per accelerator. Because each dimension addresses a different breakdown condition from table 1.2, identifying the limiting resource determines whether efficiency work should target the algorithm, the data, or the execution system. Systems efficiency is the subject of chapter 5 and chapter 6, which also develops algorithmic levers such as reduced precision and sparse mixture-of-experts execution. Data efficiency under device budgets returns in section 11.5.

Scaling laws and efficiency techniques determine how much computation large models require and how well the fleet uses it. They do not, however, address the physical and logical constraints that the fleet itself imposes. Hardware fails, bandwidth saturates, distributed systems face fundamental impossibility results, and societal impact at scale demands governance. These constraints cannot be optimized away; they must be engineered around.

1.4 Constraints of Scale

Scaling laws set how much work a frontier run must perform, but a cluster sized for that budget can still stall every few hours on a failed node, halt at a synchronization barrier during a network partition, or be blocked from release because its training pipeline lacks an audit trail. Those failure modes extend beyond the three walls of the scale moment into three broader categories of irreducible constraint: physical (the memory, network, and energy walls themselves, plus the reliability gap that opens as fleet size grows), logical (distributed systems face impossibility results like the CAP theorem), and societal (scale amplifies the impact of every technical

decision). For an initial C^3 diagnosis, the distinctions matter because a slow step may reflect a communication limit or coordination loss, while an otherwise fast design may exceed its energy or governance budget. The formal time decomposition follows after these examples establish what it must account for.

1.4.1 The reliability gap

A server node that is unavailable for less than an hour a year seems dependable in isolation, yet an unreplicated synchronous job spanning 25,000 GPUs can advance only while every required device is healthy at the same instant. This divergence opens the **reliability gap**: high component reliability in isolation does not ensure that every component required by an unreplicated job will be available simultaneously. The scale moment measured the gap as a rate, how often the job is interrupted; availability measures it as a probability, how likely it is that every required component is up at a given instant. Both views rest on the same independence assumption and degrade the same way as the job grows. For that 25,000-GPU job, equation 1.2 multiplies the component availabilities under an independence assumption to give the probability that all required components are available at the same instant (A_{all}):

$$A_{\text{all}} = (A_{\text{component}})^N \tag{1.2}$$

Here, N is the number of independent components that the job requires simultaneously, and $A_{\text{component}}$ is the availability of one component. The exponent carries the engineering implication. Every added required component lowers the probability that the full set is available, so reliability engineering becomes a scaling problem rather than a cleanup task.

For a single component, 99.99 percent availability corresponds to 52.56 minutes of unavailability per 365-day year. This is a time fraction, not a count of failures. If each node has an illustrative 99.9 percent availability and an unreplicated job requires every node, the probability that all 1,000 required nodes are available simultaneously is only 36.8 percent. Scale that job to 10,000 required nodes, and this probability drops to 0.0045 percent. Adding a nine to every node only postpones the collapse, because the exponent N eventually overwhelms any per-node availability below one (figure 1.13).

Because simultaneous all-node availability drops toward zero as job size expands into the thousands (the collapse zone of figure 1.13), an unreplicated synchronous workload cannot rely on unbroken component uptime. Section E.1 replaces this single per-node availability figure with the full failure-probability model, from component failure rates to the chance that a job fails before it finishes. The engineering lesson is that failure is the common case. At scale, resilience replaces prevention as the governing objective, and the system trades absolute uptime for recovery speed, checkpoint quality, and automated repair.

↪ The shift from keeping every component running to a fleet that recovers automatically when components fail is developed in chapter 7.

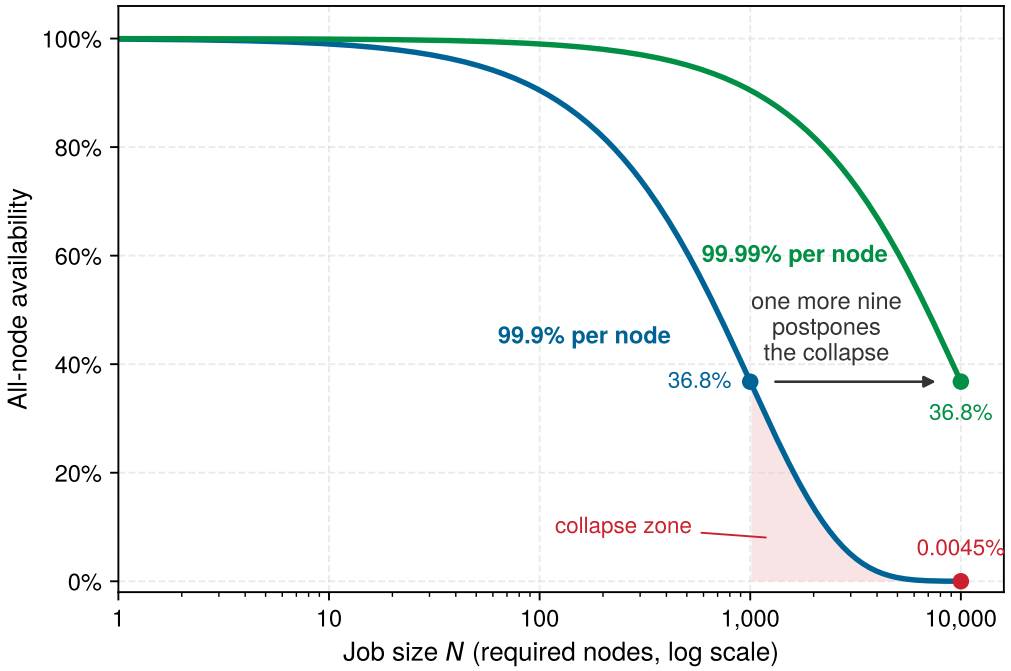

Figure 1.13: The Reliability Collapse: The simultaneous availability of every node required by an unreplicated job, shown as a function of job size for two per-node availability levels under an independence assumption. At 99.9 percent per-node availability (blue), all-node availability is only 36.8 percent for a 1,000-node job and approaches zero for a 10,000-node job. Even 99.99 percent per-node availability (green) yields 36.8 percent at 10,000-node scale.

Checkpoint 1.3: The scale mandate

These questions check whether the scale mindset has shifted from local execution to distributed constraints:

- ☐ **Communication intensity**: explain in CI-ratio terms why adding more nodes (N_{nodes}) to a high-CI workload can slow training rather than speed it up.
- ☐ **Reliability gap**: explain the reliability gap that prevents a 10,000-GPU cluster from remaining "perfectly healthy."
- ☐ **Arithmetic vs. communication**: distinguish arithmetic intensity (local memory) from communication intensity (global network).

1.4.2 Physical boundaries of distributed state

Scale forces distribution, because no single machine provides the compute required for the largest models and no centralized system can collect every data source that global user bases generate. Coordinating computation across physically separated machines connected by finite-bandwidth networks, however, creates constraints that no engineering can eliminate. The first stressor appears inside data centers, where synchronous training must choose how much consistency to

preserve under partitions and failures. The second appears at the edge, where the devices themselves are unreliable, power-limited, and policy-constrained.

1.4.2.1 The CAP theorem reality

When a worker becomes unreachable in the middle of a distributed training step, the runtime faces an immediate choice: pause the entire job until the worker returns or is replaced, or keep updating the model without its contribution. The **CAP theorem**[8] formalizes why that choice cannot be avoided, establishing that an asynchronous distributed system subject to a network partition cannot guarantee both atomic **consistency** and **availability**. **Partition tolerance** describes the network condition under which that trade-off applies, not a third interchangeable property that a system can choose to omit. Training is not a replicated database, and gradient freshness is not the theorem's atomic consistency, yet training faces the same forced choice under a fault. Synchronous training chooses a shared current model state, so the entire step halts when a required worker becomes unreachable. Asynchronous training makes the opposite trade, continuing through stragglers or unavailable workers at the cost of applying updates computed on stale model versions. Federated learning pushes that availability choice to the edge by letting intermittent devices train local models that diverge temporarily between rounds.

[8] **CAP (consistency, availability, partition tolerance) theorem** (Brewer's theorem): Brewer formulated the conjecture (Brewer 2000), and Gilbert and Lynch (2002) later proved it for asynchronous networks.

1.4.2.2 Edge distribution constraints

The coordination challenges discussed so far assume data-center distribution, where machines run in managed facilities. At the network edge, these challenges intensify along every dimension. Billions of smartphones and IoT devices operate in uncontrolled environments with unreliable connectivity and limited power. Privacy, consent, or policy constraints may prevent raw data from leaving the device, making federated learning a natural architecture (McMahan et al. 2017). Intermittent connectivity requires a participation policy, which may select currently available devices for a round or admit delayed updates under stated rules. Keeping raw data local does not by itself protect information exposed through model updates. Device budgets and the threat model determine whether additional compression, privacy mechanisms, or local execution are appropriate.

1.4.3 Governance and systemic risk at scale

Scale and distribution amplify impact beyond engineering. When a system serves billions of users, a technical bug becomes a societal risk. This amplification increases the reach of governance failures; smaller deployments still require controls appropriate to their uses and potential harms. Governance functions as the **control plane** of the machine learning fleet, not as a set of external rules.

That control plane first has to defend the fleet against security threats that grow more rewarding to attackers at production scale. Model extraction attacks steal proprietary intellectual property through normal API queries, whereas data poisoning corrupts the training pipeline from the inside to alter learned behavior; one objective is a backdoor that activates on a chosen input. At fleet scale, these threats become economically attractive targets for sophisticated attackers. Defending the fleet requires systematic approaches: access controls, differential privacy

(calibrated noise that bounds how much any single training record can influence what the model reveals), and continuous behavioral monitoring that go far beyond traditional perimeter security.

The same control plane must make the fleet auditable. Systems operating at scale attract regulatory attention. Regimes such as the EU AI Act and local privacy laws make **auditability**, the ability to reconstruct after the fact which data, code, and decisions produced a model's behavior, an architectural requirement for many deployments. Auditing whether a model trained on 10,000 GPUs ingested prohibited data requires end-to-end data lineage tracking, supported by controls that capture ingestion and subsequent transformations. A lineage record cannot establish the absence of inputs that were never recorded. Generating a human-interpretable explanation for a recommendation served within a tail-latency budget of tens of milliseconds demands techniques designed into the serving architecture. Meeting these requirements calls for technical capabilities (audit trails, bias testing, and consent management) built into the infrastructure from the outset.

↪ Defenses against data poisoning, model extraction, and gradient inversion across distributed fabrics are developed in chapter 13.

Beyond legal compliance, the machine learning fleet carries ethical obligations. Recommendation algorithms shape public discourse; hiring algorithms affect livelihoods. These systems rarely fail loudly; harm accumulates silently through bias and polarization, without a crash log. Responsible AI turns fairness, transparency, and accountability requirements into operational invariants with defined evidence, owners, and responses. A violation may require withholding a release, routing affected decisions to review, or suspending an unsafe operation; the response must contain the relevant harm. Together, these physical, logical, and societal constraints define the operating envelope of the fleet. Turning them into actionable systems decisions requires a diagnostic taxonomy that can isolate whether execution time is lost to local arithmetic, wire transit, or orchestration overhead.

1.5 The C^3 Taxonomy and Foundations of Scale

↪ The assurance lifecycle that turns responsible-AI requirements into evidence, accountable owners, and the authority to launch or stop a system is developed in section 16.2.

An idle accelerator does not identify its own bottleneck. It may be waiting for local operands, a gradient transfer, or a failed peer. The C^3 lens introduced at the scale moment separates these explanations and gives the preceding examples a common diagnostic language. On a single machine, diagnosing performance follows the **Data · Algorithm · Machine (D·A·M) taxonomy**. In that framework, Data governs what information the model learns from; the Algorithm defines the mathematical operations to execute; and the Machine supplies the silicon and memory hierarchy executing those operations.

When workloads stretch across thousands of interconnected nodes, the execution bottleneck shifts. Data-center hardware is procured and cabled around three physical pillars: Compute, Network, and Storage. At runtime, however, distributed execution spends wall-clock time in three distinct operational dimensions: Compute (C_1), Communication (C_2), and Coordination (C_3). Together, they form the C^3 taxonomy. Storage is not absent from this runtime model. It serves as the persistent physical substrate spanning all three dimensions: an extension of the node memory hierarchy in Compute (C_1), a high-throughput streaming pipeline

↪ The D·A·M taxonomy as a complete single-node framework, with its diagnostic summary, roofline bound, and scorecard, is developed in Appendix A.

across Communication (C_2), and the durable checkpointing engine required for fault-tolerant Coordination (C_3).

Each dimension leaves different evidence. Suppose a training job's step time grows by half after its cluster doubles. If time inside each node's kernels grew while their model FLOPs utilization (MFU), the fraction of peak arithmetic throughput spent on the model's own operations, fell and memory-bandwidth counters saturated, local execution is responsible. If link utilization and collective timing rose, transfers are; if barrier waiting and recovery records grew, coordination is. The three diagnoses call for different interventions, and optimizing the wrong mechanism leaves the end-to-end bottleneck in place. As in single-machine systems, the governing limit is the *binding constraint*: the bottleneck whose relaxation yields an end-to-end reduction in training time or serving latency. The C^3 taxonomy is therefore an operational diagnostic loop: identify the binding axis, apply the appropriate systems intervention, and remeasure, because relaxing one limit frequently shifts the bottleneck to another.

Definition 1.2: The C^3 taxonomy

C^3 taxonomy is a diagnostic framework that classifies distributed machine learning execution time and system bottlenecks along three operational dimensions: Compute (C_1, the math), Communication (C_2, the wire), and Coordination (C_3, the logic). The goal is to identify which dimension binds fleet-scale performance.

1. **Significance**: The diagnostic power is concrete even before inspecting complex distributed traces. If accelerators are computing at low MFU because tensor cores starve for local operands or un-fused kernels, the binding axis is Compute (C_1). If accelerators sit idle waiting for AllReduce gradient transfers or activation tensors across the network fabric, the binding axis is Communication (C_2). If progress halts due to straggler-induced barrier waiting, node recovery rollbacks, or preemptions under gang scheduling (which allocates all of a job's workers at once or none of them), the binding axis is Coordination (C_3).
2. **Distinction**: Unlike data center procurement categories (Compute, Network, Storage), which classify physical hardware assets, the C^3 taxonomy classifies runtime execution cost. Storage does not execute model arithmetic; rather, it serves as the persistent physical substrate across all three dimensions (local NVMe in C_1, remote dataset streaming in C_2, and durable checkpointing in C_3).
3. **Common pitfall**: Treating the three dimensions as independent variables. Upgrading to faster accelerators (C_1) often converts a compute-bound job into a communication-bound job (C_2). Sharding model states to eliminate memory redundancy (C_1) increases collective communica-

> tion volume (C_2) and state coordination complexity (C_3). The dimensions move together.

1.5.1 The three dimensions of the fleet

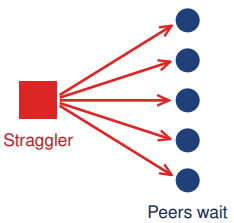
Each dimension of the C^3 taxonomy governs a distinct physical layer of the fleet and exposes a different operational bottleneck, separating local node execution from inter-device transfers and cluster-wide orchestration.

1.5.1.1 Node compute substrate

When operands cannot reach a node's arithmetic units fast enough to keep tensor cores busy, the memory wall binds Compute (C_1, the math). This axis covers execution within the server node across arithmetic units, high-bandwidth memory, and local Non-Volatile Memory Express (NVMe) storage. Improving MFU on this axis requires reducing local data movement, for example through operator fusion, rather than merely increasing peak arithmetic throughput.

↪ The memory wall, from high-bandwidth memory (HBM) bandwidth to the Roofline Model that locates it for one accelerator, is developed in section 2.3.

1.5.1.2 Network communication backbone



When gradient, activation, or dataset-shard transfers saturate a cluster's finite bisection bandwidth, they expose communication time (T_{comm}) during which accelerators wait for remote data. Communication (C_2, the wire) captures this data movement between worker devices across both scale-up fabrics inside a server and scale-out networks between servers; reducing bytes transferred or overlapping transfers with useful work can shorten that exposed time.

1.5.1.3 Orchestration coordination layer

Because a synchronous job waits for its slowest required participant, a single straggler or node fault can stall thousands of healthy peers even when both local kernels and network links have spare capacity. Coordination (C_3, the logic) captures the schedulers, synchronization barriers, and checkpointing protocols that manage reliability collapse (equation 1.2) and bind separate, failing machines into one distributed computer. Its objective is goodput, the rate of useful training progress after wasted and repeated work are accounted for. It is one of several measures that share the name, and section 9.2.4 tells them apart. Overlap where dependencies permit and bounded recovery rollback improve that rate.

1.5.2 Projection from D·A·M to C^3

When a model or dataset that fit on one server is split across a cluster, the single-machine D·A·M components do not disappear; each one generates a distinct pattern of fleet-level compute, communication, and coordination work. The single-machine D·A·M taxonomy and the fleet-scale C^3 taxonomy therefore operate in tandem. D·A·M describes the workload: the *nouns* of the system (the training data, the executed algorithm, the hardware substrate). The C^3 taxonomy describes the execution cost: the *verbs* of the fleet (computing the math, communicating the

One straggler holds every synchronous peer.

results, coordinating the state). The C^3 taxonomy projects that workload onto a distributed fleet.

Stretching an algorithm across nodes creates communication (C_2), such as the activation and gradient exchanges that tensor and pipeline parallelism add between partitions of one model. Stretching data across nodes also moves shards and gradients over the fabric (C_2), as when AllReduce synchronizes data-parallel replicas, and it requires coordination (C_3) through distributed samplers, gradient-aggregation barriers, and non-blocking checkpointing. Finally, managing hardware faults across a warehouse-scale machine requires orchestration and dynamic node recovery (C_3). Fleet-scale ML systems engineering requires solving the cross-products of D·A·M and C^3 rather than addressing each dimension in isolation.

1.5.3 The C^3 intersection landscape

The dimensions interact at their pairwise intersections, where an intervention along one axis alters costs across another. At the intersection of compute and communication ($C_1 \cap C_2$), overlapping transfers with arithmetic can hide network latency, but only while independent computation remains available. Between compute and coordination ($C_1 \cap C_3$), checkpointing preserves training progress against failure, yet it consumes execution resources; its frequency and placement trade present overhead against future recovery loss. Across communication and coordination ($C_2 \cap C_3$), collective synchronization depends jointly on transfer completion and participant readiness, so faster physical links alone cannot eliminate straggler waiting.

At the center ($C_1 \cap C_2 \cap C_3$), all three constraints converge simultaneously. Partitioning a model determines both which device computes each operation and what information must cross the network; recovering a failed partition requires restoring the corresponding shared state. These dependencies explain why parallelism, state sharding, and serving policies must be designed together. Each dimension contributes one term to the distributed step time, and each pairwise overlap names an interface where the dimensions trade costs by hiding latency, preserving progress against failure, and synchronizing collectives (figure 1.14).

The diagram organizes competing explanations for the same observed delay. A diagnosis may begin with one dimension or with a coupled mechanism, such as checkpoint traffic delaying a collective. The evidence determines which interaction to investigate; the diagram does not prescribe an order in which the dimensions must be optimized. Surrounding these three operational dimensions are the non-negotiable operating invariants developed across Part IV. They are the thermodynamic energy and cooling limits that constrain data centers, the adversarial security and differential privacy guarantees required of distributed pipelines, the robustness against silent corruption and distribution shift, and the systemic governance, auditing, and safety invariants needed when operating at societal scale. Every chapter ahead uses the C^3 figure the same way, diagnosing which intersection binds before intervening.

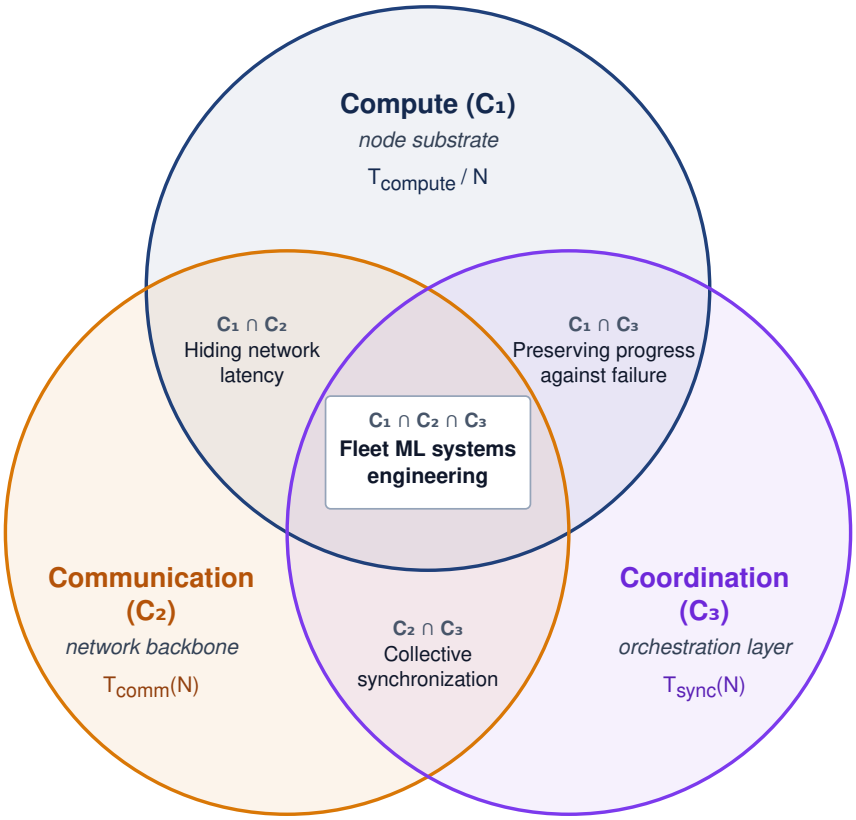


Figure 1.14: The C³ Intersection Landscape: Each circle is one operational dimension (Compute, C_1, the node substrate; Communication, C_2, the network backbone; Coordination, C_3, the orchestration layer), labeled with the Fleet Law term it contributes to step time. Each pairwise lens names the interaction between two dimensions: hiding network latency behind computation, preserving training progress against failure, and synchronizing collectives. At the center, where all three meet, is fleet ML systems engineering. The techniques and chapters for each region are collected in table B.3.

1.5.4 The Fleet Law

The C³ intersection landscape defines *where* distributed execution spends time and where trade-offs bite. The Fleet Law turns that diagnostic map into a first estimate of distributed step time. Its terms are a simplified accounting model, so a prediction must state how work is divided and which costs overlap. On a single machine, execution time is governed by the iron law of performance, $T = D_{\text{vol}}/\text{BW} + O/(R_{\text{peak}} \cdot \eta_{\text{hw}}) + L_{\text{lat}}$, decomposing into data movement, computation, and overhead. At fleet scale, that single-machine view no longer suffices. Equation 1.3 establishes the **Fleet Law**, which decomposes the idealized distributed training step into the terms of the C³ engine:

$$T_{\text{step}}(N) = \frac{T_{\text{compute}}}{N} + T_{\text{comm}}(N) + T_{\text{sync}}(N) - T_{\text{overlap}} \tag{1.3}$$

The arithmetic idealization used below assumes that local memory can supply operands fast enough to sustain the modeled compute rate. A measured local-execution reference can instead include local memory stalls and dispatch costs in the Compute term, provided those costs divide with the work as assumed. The interpretation of the compute-time fraction follows that convention, measuring local execution time for the measured reference and useful math for the arithmetic idealization. Each term in the Fleet Law maps directly onto a region of the C^3 landscape in figure 1.14:

- $\frac{T_{\text{compute}}}{N}$ is the Compute (C_1) term, assuming ideally divisible local arithmetic for a fixed workload distributed across N devices.
- $T_{\text{comm}}(N)$ is the Communication (C_2) term, capturing the wire transit time moving gradients, activations, and parameter shards across the network fabric.
- $T_{\text{sync}}(N)$ is the Coordination (C_3) term, capturing time consumed by barrier semantics, straggler waiting, cluster scheduling decisions, and failure recovery.
- T_{overlap} is the Co-Design ($C_1 \cap C_2$, $C_1 \cap C_3$, $C_2 \cap C_3$) term, representing communication or coordination hidden behind useful compute via techniques such as interleaving forward and backward work across pipeline stages, running transfers on separate execution streams, and writing checkpoints asynchronously.

Doubling the device count shows why the subtraction matters. The local compute term falls to $T_{\text{compute}}/(2N)$, but communication and barrier synchronization persist, and the shorter compute window leaves less room to hide transfers, so T_{overlap} shrinks as well. The step on $2N$ devices therefore takes well over half as long as the step on N (figure 1.15).

Weak scaling, load imbalance, memory-capacity changes, and algorithmic changes require modifying these terms rather than treating T_{compute}/N as invariant. Measurements must also separate transfer from coordination time: a barrier interval that includes an unfinished transfer cannot be charged in full to both terms. Subtract only overlap supported by the execution timeline. Equation 1.4 rewrites this decomposition as the compute-time fraction. It measures useful arithmetic under the arithmetic idealization and local execution under the measured-reference convention:

$$f_{\text{compute}} = \frac{T_{\text{compute}}/N}{T_{\text{step}}(N)} \tag{1.4}$$

This decomposition is a diagnostic instrument. When f_{compute} drops below 0.5, more than half the step lies outside the modeled Compute term; under the arithmetic idealization, that means outside useful local arithmetic. The C^3 taxonomy identifies where the time goes. If $T_{\text{comm}}(N)$ dominates, upgrade interconnects or overlap communication with computation. If $T_{\text{sync}}(N)$ dominates, consider asynchronous methods or reduce barrier frequency. If T_{compute}/N dominates, the

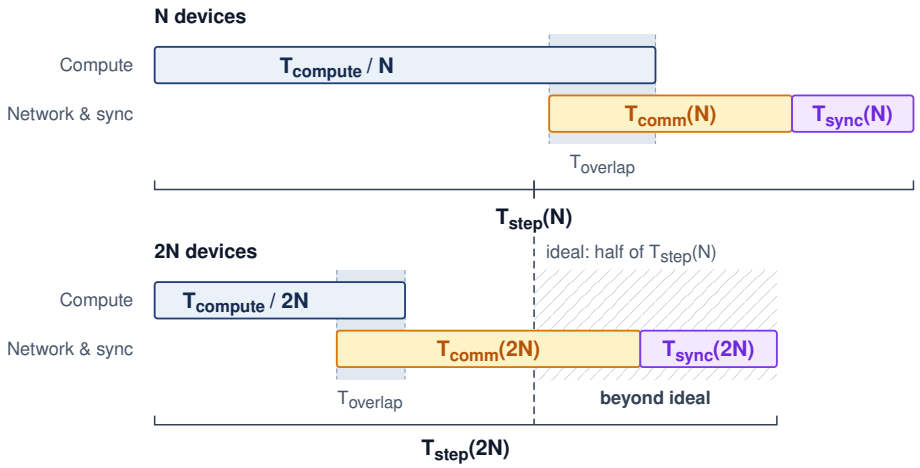

Figure 1.15: Anatomy of a Fleet Law Step: Each row is one training step for the same workload, with local computation on the upper lane and communication and synchronization on the lower lane. Read the step length from the bracket, not from any single bar: overlap (gray band) removes only the transfer time that runs beneath compute, so doubling the devices halves T_{compute}/N yet leaves $T_{\text{step}}(2N)$ well past the ideal half-length step (dashed line), by the hatched span. Bar lengths are illustrative, not measured.

modeled local execution sets the step time. The **displacement of overhead** is a diagnostic heuristic: reducing one overhead can relocate cost among the three dimensions. Asynchronous training removes some coordination barriers but introduces gradient staleness, in which workers apply updates computed from an older copy of the model. Pipeline parallelism can reduce some communication exposure but adds bubble time, the intervals in which pipeline stages sit idle waiting for work.

The compute-time fraction describes how a single N-device configuration divides its own step time. A production team also needs a scalar that compares that distributed step against a single-device baseline to show whether adding devices actually speeds up the job. The scaling efficiency (η_{scaling}) of the fleet is the ratio of ideal parallel step time to actual step time:

$$\eta_{\text{scaling}} = \frac{T_1}{N \times T_N}$$

where T_1 is the single-device time for the same work and $T_N = T_{\text{step}}(N)$ is the step time on N devices. When local execution divides cleanly by N, T_1/N matches T_{compute}/N and the two ratios agree. In practice, partitioning a workload across more devices can also shrink per-device batch slices enough to lower local kernel utilization or add recomputation work, which reduces η_{scaling} even before communication and synchronization time are counted. Section 6.4.1 develops the measure in full.

↪ The component decomposition that maps each term of $T_{\text{step}}(N)$ to measurable activities is developed in section B.3.1.

> **Systems Perspective 1.1: Amdahl's distributed pitfall**
>
> The Fleet Law applies Amdahl's reasoning (Amdahl 1967) to a strong-scaling experiment: a fixed amount of useful work is divided across more devices while communication and coordination terms are measured for that configuration. A common shortcut reads a measured 20 percent network share as a 5× speedup ceiling, but Amdahl's bound applies only if that 20 percent of the original workload remains irreducibly serial as compute is accelerated. A network share measured at one device count is not automatically invariant; changing the partition, topology, collective algorithm, or overlap can change both its absolute time and its fraction of the step. The Fleet Law therefore diagnoses the scaling limit of a stated workload and configuration rather than asserting a universal network fraction.

Several efficiency measures have now appeared, and each answers a different question. Percent of peak compares achieved arithmetic throughput with peak throughput over a stated measurement interval, and the result depends on what it counts as arithmetic. MFU counts only the model's own forward and backward work, and GPT-3's roughly 20 percent is a measure of this kind. Megatron-LM's 52 percent counts every executed operation, including activations recomputed during the backward pass, so it runs higher than the MFU of comparable runs, which the PaLM report puts at 30.2 percent for Megatron-Turing NLG and 46.2 percent for PaLM (Chowdhery et al. 2022). GPT-3's estimate averages over the training run, so it includes idle time within that interval; a measurement restricted to active kernels uses a different denominator. The compute-time fraction asks how much of one step belongs to the modeled local-execution term, and scaling efficiency asks how close N devices come to an N-fold speedup over one. Goodput widens the window from one step to the whole run by discounting work lost to failures and repeated after restarts; Meta's report of more than 90 percent effective training time for Llama 3 is a measure of this last kind. Google's ML productivity goodput shares the name but answers a fleet-wide question, the fraction of capacity that becomes useful work, as the product of scheduling, runtime, and program goodput (Wongpanich et al. 2025). Section 9.2 defines the three factors and the boundary at which each one counts a loss. A fleet can score well on one measure and poorly on another, so a claim about fleet efficiency must name the measure and measurement interval it uses.

The Fleet Law, the compute-time fraction, and scaling efficiency together describe the time side of fleet efficiency. They separate modeled local execution from exposed communication and synchronization costs and compare the resulting step time with the single-device baseline. Fleet efficiency also has an energy side, because every exposed transfer and every idle accelerator still draws power.

1.5.5 The energy accounting boundary

While the Fleet Law accounts for time, comparing fleet designs on energy requires a fixed **energy accounting boundary**, the set of energy consumers that every

design in the comparison is charged for. The boundary is what stays fixed, not any particular efficiency value. Equation 1.5 defines **fleet energy productivity** (ρ_{energy}), measured in FLOP/J, within a simplified operational boundary:

$$\rho_{\text{energy}} = \frac{O_{\text{useful}}}{E_{\text{device}} + E_{\text{cooling}} + E_{\text{network}}} \tag{1.5}$$

where O_{useful} is useful work in FLOPs. The three energy terms cover compute devices, attributable cooling, and the network fabric, without counting the same consumption twice. Host, storage, and other facility loads must be added explicitly for a complete operational estimate; embodied impacts lie outside this boundary. Comparisons must use the same boundary and useful-work definition. The resulting Pareto frontier balances minimizing T_{step} with maximizing ρ_{energy}.

An illustrative, communication-heavy GPT-3-class synchronization scenario connects the time and energy accounts, because exposed Ring AllReduce traffic both delays computation and consumes network energy. Notebook 1.1 prices both taxes for a 175B-parameter gradient exchange across InfiniBand and Ethernet fabrics.

↪ Power usage effectiveness, the ratio of total facility energy (including cooling and power conversion) to IT energy, and what it leaves out are developed in section 15.4.1.3.

Over InfiniBand, exposed communication fills 96 percent of this illustrative step.

Napkin Math 1.1: The time and energy cost of communication

Problem: What compute-time fraction and endpoint network-energy cost result in an illustrative GPT-3 synchronization scenario using 100 Gb/s Ethernet versus 200 Gb/s InfiniBand? Assume 1.2 seconds of local computation per worker per iteration, with no communication overlap. This chosen input defines the scenario; it is not a measured GPT-3 training-step time.

Physics: To synchronize 175B parameters (FP16), a Ring AllReduce with many workers transmits approximately 700 GB of data per participating accelerator endpoint per iteration. This payload is the 16-bit case of the ring traffic computed in section 1.2.3, numerically equal to the FP32 gradient size quoted there.

Analysis: The Fleet Law exposes the communication cost of each interconnect choice. Over 200 Gb/s InfiniBand, an optimistic line-rate transfer of that volume takes about 28 seconds, against 1.2 seconds of computation, which yields a compute-time fraction of only 4.1 percent. Accelerators compute for 4.1 seconds out of every 100 seconds, and the remainder is exposed communication time. Across 100 Gb/s Ethernet, the transfer stretches to about 56 seconds and the compute-time fraction falls further to 2.1 percent, leaving the devices productive for roughly 2.1 seconds out of every 100 seconds.

Energy: The energy wall is the thermodynamic cost of the same synchronization. Charging each transmitted bit once at the InfiniBand fabric energy cost, each endpoint's gradient synchronization consumes approximately 196 J across the network fabric (at 35 pJ/bit). In a training run of 1,000,000 steps, the endpoint network movement alone accounts for about 196 MJ of energy before multiplying by the number of participating accelerators.

Systems insight: Advertised line rate gives an optimistic transfer estimate that excludes latency, software overhead, and contention. Conversely, omitting overlap exposes all communication, so the summed step time is not a lower bound for an implementation that hides transfers. The compute-time fraction changes with local workload, partitioning, and overlap; the small fraction here diagnoses the chosen scenario, not every large fleet.

↪ The energy that exposed collectives and idle, synchronization-stalled accelerators add to a distributed training run is measured in section 15.7.2.1.

1.6 The Fleet Stack and the Lighthouse Archetypes

When a distributed step stalls on exposed communication or synchronization, the Fleet Law and the C^3 dimensions tell us which cost dominates, but not which layer of the system caused it or which workloads will trigger it next. Three architectural maps work together to close that gap: the fleet stack locates system responsibility, C^3 and the Fleet Law diagnose execution cost, and the lighthouse archetypes test those costs across representative production workloads. The fleet stack, traced upward from the hardware of one node in section 1.2, arranges the fleet into eight rows grouped into four ascending bands (figure 1.4). Capabilities fixed in the lower rows, from facility cooling and RDMA fabrics up through distributed execution, constrain the serving runtimes and governance mechanisms above them. Those four bands correspond to the book's four parts: the physical fleet, distributed ML, the fleet in production, and the responsible fleet. The chapter map at section 1.7 follows that dependency order.

Six **engineering practices** guide decisions at every band of the stack: instrument first, reserve headroom for recovery and tail latency, expect bottlenecks to migrate, treat failure as steady state, compound small efficiency gains across the fleet, and co-design hardware with algorithms. For example, faster accelerators can expose a network bottleneck; instrumentation identifies that migration, and hardware co-design aligns the fabric with the workload. The practices describe how a fleet engineer works. The principles of distributed ML systems describe what the physics of the fleet makes true, whatever the practice. Each part of this book establishes its share of those principles. Section 17.2 gathers them into six, one or two for each part, and pairs each with the practice it demands.

1.6.1 Three systems archetypes

A single benchmark workload cannot test every band of the fleet stack, because a dense language model, a sparse recommendation service, and an on-device federated learner fail in completely different places. Three lighthouse archetypes at scale recur across the book where they illuminate a chapter's central constraint; no chapter must force all three into its argument. Together they sample distinct C^3 regimes by stressing communication, coordination, or compute in different ways.

1.6.1.1 Archetype A (GPT-4/Llama-3)

A dense language model with hundreds of billions of parameters cannot fit in the memory of a single server. Splitting it across thousands of accelerators using

3D parallelism (data, tensor, and pipeline) risks exposing enough gradient and activation traffic to make the network the binding bottleneck. GPT-4 and Llama-3, the autoregressive transformer architectures behind this archetype, generate text one token at a time. At single-accelerator scale, autoregressive language models are memory-bandwidth probes. At the scale of hundreds of billions of parameters, and in some proprietary systems potentially more, training demands ExaFLOP/s of sustained compute distributed across thousands to tens of thousands of accelerators. Serving requires memory bandwidth sufficient to load billions of weights for every generated token. Archetype A therefore probes the communication dimension of C^3, although its actual dominant term depends on the model, partition, topology, and degree of overlap.

Where a chapter needs a concrete instance, Archetype A is a 175B-parameter dense transformer of the GPT-3 class, chosen because its configuration is published while GPT-4's is not, trained with mixed precision and the Adaptive Moment Estimation (Adam) optimizer. Its training state occupies 16 bytes per parameter (BF16 weights and gradients, FP32 master weights, and two FP32 Adam moments), or 2.8 TB. A resumable checkpoint omits the gradients and needs 14 bytes per parameter, or 2.45 TB. The reference cluster is 1,024 H100 GPUs, arranged as 128 nodes of 8 accelerators each. A chapter that studies a larger cluster or a different model says explicitly how it varies this reference.

1.6.1.2 Archetype B (DLRM at Scale)

Where a dense language model spends most of its memory on weights that every token uses, a production recommender spends its memory on sparse embedding tables that reach 10 TB or more across hundreds of nodes. It serves roughly 10 million queries per second (QPS) within a <100 ms tail-latency budget. DLRM, the deep learning recommendation model that Meta published as a reference architecture for personalized content ranking, derives its capacity from dense matrix multiplications, as LLMs do, and also from large embedding tables that map billions of user and item features into dense vectors. Those tables far exceed any single accelerator's memory, so they are sharded across devices while each worker processes its own slice of the request batch for the dense layers. Because a worker's requests reference embedding rows stored on many other devices, serving and training must coordinate AllToAll exchanges, collective operations in which every worker sends a distinct subset of looked-up vectors to every other worker across $\mathcal{O}(N^2)$ potential communicating pairs. The resulting byte volume and contention depend on the request batch, partitioning, and network topology. In the C^3 taxonomy, Archetype B stresses coordination: sparse feature routing, shard placement, request scheduling, and embedding-update consistency determine whether the AllToAll traffic can be served within tail-latency limits.

1.6.1.3 Archetype C (Federated MobileNet)

Both of those workloads run inside managed data centers. Federated learning instead trains a model across millions of varied smartphone-class devices whose power budgets span roughly 2 W to 10 W (a few watts sustained, with brief bursts

toward 10 W), without ever moving raw user data off the device. MobileNet, a family of efficient convolutional neural networks designed for on-device execution under tight memory and power budgets, serves as the reference workload for this federated learning setting. Microcontroller-class sensors that run on hundreds of kilobytes of memory and milliwatts of power lie at an extreme below this archetype. In the C^3 taxonomy, Archetype C probes the per-device compute envelope: local execution must fit within the device's power, memory, and thermal limits. That local constraint does not by itself determine the bottleneck of a federated round. Uploading updates can expose communication limits, while selecting available participants and waiting for their results can expose coordination limits. The fleet challenge is coordinating model updates across millions of such compute-constrained, unreliable devices using federated averaging, which periodically averages device updates at a coordinator. Data distributions that are not independent and identically distributed (i.i.d.) and intermittent participation affect the resulting learning process; convergence claims must state the assumptions under which they hold.

The three archetypes are constraint probes, not a catalog of model families. The LLM case asks whether dense synchronization can keep thousands of accelerators useful, the DLRM case asks whether sparse feature routing can meet tail-latency budgets, and the federated MobileNet case asks whether local device constraints can be coordinated into a statistically coherent update. Each of the three canonical workloads pairs a C^3 diagnostic regime with the fleet challenge it raises (table 1.3), and section 1.7 traces how the chapters climb the fleet stack to meet them.

Table 1.3: Lighthouse Archetypes at Scale: The three canonical workloads in representative diagnostic regimes, with the fleet-scale challenge each raises. These are constraint probes, not invariant bottleneck assignments; workload, partitioning, topology, and overlap determine the binding cost. The MobileNet row describes the local device envelope, not the bottleneck of a complete federated round.

Archetype	C^3 diagnostic regime	Fleet challenge
Archetype A (GPT-4/Llama-3)	Communication (fleet-wide)	Partition hundreds of billions of parameters, and potentially larger proprietary models, across thousands to tens of thousands of GPUs using 3D parallelism without the network becoming the bottleneck.
Archetype B (DLRM at Scale)	Coordination (routing and placement)	Shard 10 TB+ embedding tables across hundreds of nodes; process millions of QPS with <100 ms tail latency while managing sparse feature routing, shard placement, and exchanges among $\mathcal{O}(N^2)$ potential pairs.

Archetype	C^3 diagnostic regime	Fleet challenge
Archetype C (Federated MobileNet)	Compute (per-device envelope)	Coordinate learning across millions of compute-constrained, unreliable edge devices using federated updates; raw data cannot leave the device.

1.7 The Structure of This Textbook

Meeting those three fleet challenges requires climbing the fleet stack in dependency order, because choices fixed in the physical substrate constrain every algorithm, runtime, and governance control built above it. The chapter sequence is therefore a dependency map rather than a topic inventory. Silicon, cooling, and network limits constrain training partitioning; partitioned algorithms create fault-tolerance and orchestration obligations; and those mechanisms support production operation. Requirements also flow in the other direction: security, governance, and service targets constrain which lower-layer designs are acceptable. Part I builds the physical cluster substrate, Part II coordinates distributed execution and fault recovery, Part III runs the fleet in production, from efficiency and serving through edge deployment and operations, and Part IV enforces governance, security, and sustainability invariants (figure 1.16).

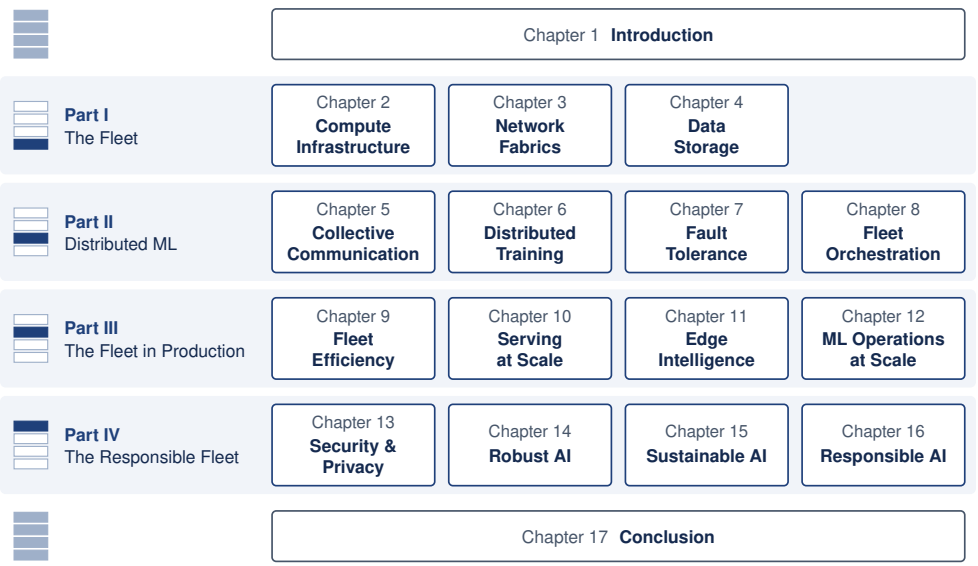

Figure 1.16: The Chapter Roadmap: The chapters in reading order, top to bottom. The introduction frames the book; the four parts then climb the fleet stack of figure 1.4 from physical infrastructure through distribution and production to governance, as the small stack beside each part shows by lighting that part's band; the conclusion gathers the principles of all four parts.

The infrastructure arc begins with a limit no algorithm can ignore, because no single server has enough memory, power, cooling, or I/O to train the largest models. Chapter 2 therefore starts with high-density silicon and facility physics, chapter 3 turns isolated machines into a cluster-scale gradient bus, and chapter 4 completes the substrate by keeping accelerators fed without letting storage become the hidden bottleneck.

The distribution arc begins once the physical fleet exists and coordination costs become unavoidable. Splitting math across machines creates two new problems: replicas must exchange state fast enough to behave like one optimizer, and failures become routine rather than exceptional. Chapter 5 develops the communication primitives that bind independent nodes into a coherent computer and prices each exchange. Chapter 6 uses them to build partitioning strategies for models with hundreds of billions to trillions of parameters. Chapter 7 treats recovery speed as more important than individual-node uptime. Chapter 8 manages the multi-tenant cluster where those jobs must be placed, isolated, and rescheduled.

The production arc puts the built fleet to work on real jobs and live traffic. Once a fleet runs in production, the binding question is no longer only time-to-train; it is whether utilization, latency, and lifetime serving cost stay inside the operating envelope. Chapter 9 measures how much of the fleet's capacity becomes useful work, in a training step and a serving replica alike, and charges each loss to scheduling, runtime, or the program. Chapter 10 turns each replica's measured capacity into admission, batching, and routing policy for millions of users. Chapter 11 moves learning onto phone-class devices whose memory, battery, and thermal budgets decide what adaptation they can afford. Chapter 12 develops the shared controls (registries, release gates, monitoring, and cost accounting) that govern hundreds of models as one fleet.

The governance arc treats responsibility as an engineering layer rather than an afterword. At global scale, technical bugs become societal hazards: adversaries can poison data or extract weights, open-world inputs can break brittle models, energy use becomes a fleet constraint, and governance failures can turn technical capability into social harm. Chapter 13, chapter 14, chapter 15, and chapter 16 develop those obligations as system properties that must be designed, measured, and operated.

1.8 Fallacies and Pitfalls

The following fallacies and pitfalls capture architectural mistakes that waste development resources, miss performance targets, or deploy systems critically mismatched to their operating constraints. Each represents a pattern observed repeatedly in the transition from single-machine ML to the machine learning fleet.

Fallacy: *Faster accelerators always shorten the training step.*

An accelerator upgrade that changes only arithmetic throughput shrinks the T_{compute}/N term of the Fleet Law while leaving the other costs unchanged. In the no-overlap scenario of notebook 1.1, local computation takes 1.2 seconds per iteration while the exposed Ring AllReduce over 200 Gb/s InfiniBand takes about

28 seconds. Accelerators 2× faster shorten that step by only 2.1 percent. The scenario is deliberately communication-heavy, but the direction of the effect is general: relieving the Compute axis tends to expose Communication or Coordination as the binding cost, the displacement of overhead described with the Fleet Law. A real upgrade may also change memory capacity, transfer rates, or available overlap. An accelerator purchase must therefore be judged against the fleet's measured step decomposition, not against the datasheet ratio.

Pitfall: *Assuming that reliable components make a reliable job.*

A per-GPU MTTF of 50,000 hours describes a part that rarely fails. A synchronous job, however, needs all of its parts at once. As section 1.1 showed, a job spanning 25,000 GPUs has an MTBF of about 2 hours, or roughly 12 interruptions per day. Component reliability characterizes one part; the reliability gap (section 1.4.1) characterizes the job, whose availability decays exponentially with the number of parts it requires simultaneously. Recovery practices that suit a single machine, such as manual restart and infrequent checkpoints, fail at fleet scale even though no individual part has become less reliable.

Fallacy: *Edge deployment efficiency requirements are simply scaled-down versions of cloud requirements.*

The fallacy treats edge systems as resource-constrained cloud systems. Edge devices face qualitatively different constraints. For example, an autonomous vehicle traveling at 120 km/h covers 3.33 m during every 100 ms of processing delay, adding that distance to its reaction distance. While cloud deployments scale to kilowatts, a phone-class device of the kind Archetype C models sustains only a few watts. A cloud-optimized model with 95 percent accuracy and 50 ms latency might be unusable on an edge device where thermal throttling increases latency to 200 ms and drains the battery in under an hour.

Pitfall: *Treating a compute budget as a wall-clock performance prediction.*

This pitfall, sometimes called the linear scaling fallacy, confuses useful computational work with the time required to execute it. The empirical loss relation $\mathcal{L}(X) = A_{\mathcal{L}} X^{-\alpha_{\text{scale}}} + C_{\mathcal{L}}$ estimates model quality within a validated regime; the Fleet Law separately estimates the time needed to perform that work. A team distributing a fixed training workload might predict a 3× improvement but achieve only 1.8× if coordination and communication overhead consumes 40 percent of the scaled step time. This shortfall does not by itself invalidate a loss scaling law. It shows why a resource plan needs both a model-quality estimate and a measured execution-cost estimate.

1.9 Summary

Fleet planning now separates two questions that single-machine practice could merge. Scaling laws answer how much model size, data, and useful computation a quality target requires; the Fleet Law answers how long a fleet takes to execute that work. Single-machine diagnostic skills remain necessary at that scale, but the engineering boundary expands, because a fleet can lose useful progress to network

transfers, inconsistent shared state, or failed participants even when its local kernels are efficient. C^3 distinguishes compute, communication, and coordination costs, while the fleet stack locates the decisions that shape them. With these tools, a resource plan can be traced through to execution behavior, subject to the reliability, energy, and governance constraints of the mission.

Key Takeaways: Scale makes a new machine

- **More devices change the engineering boundary**: Distributing work introduces shared network and failure dependencies. Synchronous training couples every worker to one shared step, so a single slow or failed participant holds back the whole job. Local performance remains necessary, but fleet decisions must also account for synchronization, recovery, power delivery, and governance across that wider boundary.
- **Communication can consume the speedup**: Dividing fixed work across accelerators shortens ideal local compute time while exposing communication and coordination costs. A 175B-parameter model can move hundreds of gigabytes of gradients per step. Comparing communication intensity, the bytes moved per local operation, with the fabric's balance point shows whether local computation or the network sets the step time.
- **Failure becomes steady state**: In the modeled 25,000-GPU job, independent component failures interrupt tightly coupled training every few hours despite long per-GPU lifetimes. Checkpointing, recovery, and observability must therefore be designed into normal operation.
- **Scaling laws set the demand; the Fleet Law sets the price**: Within a validated regime, loss falls as a power law in compute, data, and parameters, so each equal quality gain needs disproportionately more resources, and compute-optimal plans grow parameters and tokens together. Those laws say how much work is worth buying; the Fleet Law says how long the fleet takes to deliver it. Task-level evaluation, not loss alone, establishes whether the predicted gain justifies the resources, and training-compute optimality alone does not establish the lowest lifetime serving cost.
- **C^3 extends local intuition**: The Data, Algorithm, Machine lens describes the workload and substrate; Compute, Communication, and Coordination expose the costs of fleet execution. The Fleet Law connects useful local work to transfer, synchronization, and overlap costs as device count changes, and the fleet stack locates the layer where each decision belongs.
- **Impact needs a control plane**: Foundation-scale systems amplify security, privacy, fairness, and policy failures across large user populations.

> Governance is not an appendix to infrastructure; it is the mechanism that decides what the fleet is permitted to optimize and deploy.

The premise of this book is that scale can move the binding constraint outside the node. A local speedup is therefore evidence about one component, not yet evidence that the fleet makes more useful progress. Engineering judgment requires tracing that change through communication, coordination, and the mission's operating constraints before accepting it as an improvement.

What's Next: From requirements to silicon

The scaling laws set how much work a frontier model demands, the walls of the scale moment mark where that demand meets physical limits, and the Fleet Law prices each distributed step. Those requirements say what the fleet must sustain, not what hardware can sustain it. Chapter 2 turns to that hardware. It begins where the scaling laws leave a growing model, too large for one accelerator's memory, and climbs from the accelerator through the node and rack to the pod. At each scale it asks which physical resource runs out first: memory bandwidth, power and cooling, communication bandwidth, or failure exposure. Those limits form the Facility and Accelerators row at the base of the fleet stack, the substrate on which every later chapter builds.

I

THE FLEET

Part I

1

Fleet Principles

The scaling laws of section 1.3 reward more parameters, more training tokens, and more compute together, so each further gain in model quality asks the fleet for more memory, more arithmetic, more bytes moved between machines, and more data stored and read. With that demand set, Part I builds the physics of supply: the silicon, the wires, the cooling systems, and the storage hierarchies of the warehouse-scale machine learning fleet, where the network is the bus, power density limits deployment, and component failures are routine at scale. The broader fleet also includes geographically distributed serving systems and heterogeneous edge devices, whose constraints appear in Part III. Across this physical foundation, the focus shifts from the single accelerator to the data-center-scale machine, and the engineering question is no longer how to compute on one device but how to move energy and information at a scale that challenges the limits of the physical infrastructure.

At this scale the individual accelerator becomes one component of a larger, tightly coupled system. The principles of the fleet are therefore not best practices for cluster management. They are constraints, most of them physical, that dictate what kind of models can be trained and how they can be served. These constraints range from the efficiency of specialized silicon and the heat a rack can shed to the bisection bandwidth of the network fabric. They define the boundaries of the Infrastructure band of the fleet stack, the two rows (Facility and Accelerators, Fabric and Storage) on which every other part of the book rests. The C^3 taxonomy tracks costs across Compute, Communication, and Coordination. An optimization can reduce total execution time while shifting which cost dominates; reducing local compute, for example, can expose communication that was previously hidden. The engineering obligation is to measure the complete path rather than assume that a local saving yields the same fleet-wide gain.

The principles below preview the constraints that Part I makes concrete through compute infrastructure, network fabrics, and storage, in the order those chapters develop them. Their implications name some mechanisms developed later in the book; those names are signposts, not prerequisites for reading this part. The first constraint applies before any machine is assembled, because the choice of accelerator decides how much of its silicon and power go to useful arithmetic.

Principle 1: The generality tax

Invariant: For workloads with stable computation patterns, specialization can improve performance per watt by reducing general-purpose overhead, while also reducing programmability and workload flexibility.

$$\rho_{\text{energy,specific}} \gg \rho_{\text{energy,general}} \quad \text{for a fixed power budget}$$

Here, ρ_{energy} denotes useful computation per unit energy; the comparison illustrates the potential advantage for a workload suited to the specialized design.

Implication: The trajectory from CPU to GPU to Tensor Processing Unit (TPU) to fixed-function ASIC is a workload-dependent architecture trade-off, not a universal physical law. Each step can trade programmability for efficiency, and the fleet architect must choose the right point on this curve for each workload.

A specialized accelerator still holds only as much model state as its memory allows, and that capacity gives the first reason to divide a model. When parameters, gradients, and optimizer states outgrow a single package, the computation can proceed only by splitting that state across multiple devices.

Principle 2: The memory capacity gap

Invariant: Frontier model memory requirements have grown faster and more irregularly than single-accelerator HBM capacity.

Implication: When a model and its training state exceed one device's memory, the system must divide that state across devices. Part II develops the parallelism strategies for doing so: tensor parallelism divides individual operations, and pipeline parallelism assigns groups of layers to different devices. Complementary data parallelism distributes training examples across model replicas. Because per-device bandwidth falls roughly tenfold at each physical boundary, from device memory to the node interconnect to the cluster fabric, the division that exchanges the most data, tensor parallelism, stays inside the fastest domain. Part I establishes the capacity and communication constraints those strategies must respect.

Dividing a model across more accelerators packs more of them into each rack, and the rack's power budget is the first limit on that density. Keeping latency-sensitive peers close enough for high-bandwidth copper links concentrates electrical draw into a narrow physical footprint.

Principle 3: The power density wall

Invariant: Cluster scaling is constrained by thermal dissipation limits (watts per rack) and cooling capacity, not just silicon area or floor space.

Implication: Watts per rack, together with power-delivery losses and the cooling class the facility installs, bound how many accelerators can share a rack, and therefore how large a fast interconnect domain can be. Accelerator power has risen faster than rack power budgets, so installable compute is set by the rack envelope rather than by peak FLOP/s.

Every watt the rack draws becomes heat that the facility must remove. Sustaining that electrical load therefore turns a power-delivery specification into a continuous heat-rejection requirement.

Principle 4: The thermodynamic limit

Invariant: Irreversible computation and data movement dissipate electrical energy as heat; at data-center scale, the practical limit is the rate at which that heat can be removed.

$$\dot{Q}_{\text{IT}} \leq \dot{Q}_{\text{remove,max}}(\text{facility}, \text{cooling configuration})$$

where $\dot{Q}_{\text{IT}}$ is the heat produced by IT equipment and $\dot{Q}_{\text{remove,max}}$ is the maximum heat-removal rate of the installed facility and cooling configuration.

Implication: A rack can operate only while its heat output remains within the installed cooling system's capacity. The cooling class is chosen to match that heat load. Engineered air cooling remains viable for configurations designed for its airflow, while denser configurations need cold-plate or immersion liquid loops, which carry the same heat with far less flow at a cost in serviceability and leak and loss-of-flow risk.

Once a model is divided across devices, the network becomes part of the execution path. The time to move a single message has a structure of its own, which determines whether a transfer is limited by fixed startup cost or by bandwidth.

Principle 5: The bandwidth-latency trade-off (α-β model)

Invariant: In the latency-bandwidth model, communication time combines fixed startup latency (α) with the transfer time for a message of size n at effective bandwidth β.

$$T(n) = \alpha + \frac{n}{\beta}$$

Implication: Small messages (for example, routing metadata or control signals) are latency-bound; large messages (for example, gradients) are

bandwidth-bound. Optimization strategies must match the regime: fuse small messages to amortize α, compress large messages to reduce n.

The α-β model prices one message on one path. When every worker communicates at once, those messages compete for the links that join one half of the cluster to the other, and the capacity of that cut bounds their aggregate rate.

Principle 6: The bisection bandwidth theorem

Invariant: Communication that crosses a network cut is limited by the aggregate bandwidth of that cut. For traffic that must cross between two halves of a cluster, the minimum bisection bandwidth bounds the achievable transfer rate.

Implication: Synchronized training requires bisection bandwidth commensurate with the traffic crossing the fabric. A collective operation coordinates communication among a group of workers; AllReduce, for example, combines their contributions and returns the result to every worker. Part I explains how network topology limits this traffic; Part II develops the collective algorithms that generate it.

A fabric that carries every exchange on time still helps only if the training pipeline can keep the accelerators fed. Every training step begins by pulling fresh batches from storage, so an underprovisioned input path stalls the cluster before arithmetic or gradient exchange even starts.

Principle 7: The I/O wall

Invariant: When storage throughput cannot deliver training data as fast as accelerators consume it, accelerators idle regardless of their computational power.

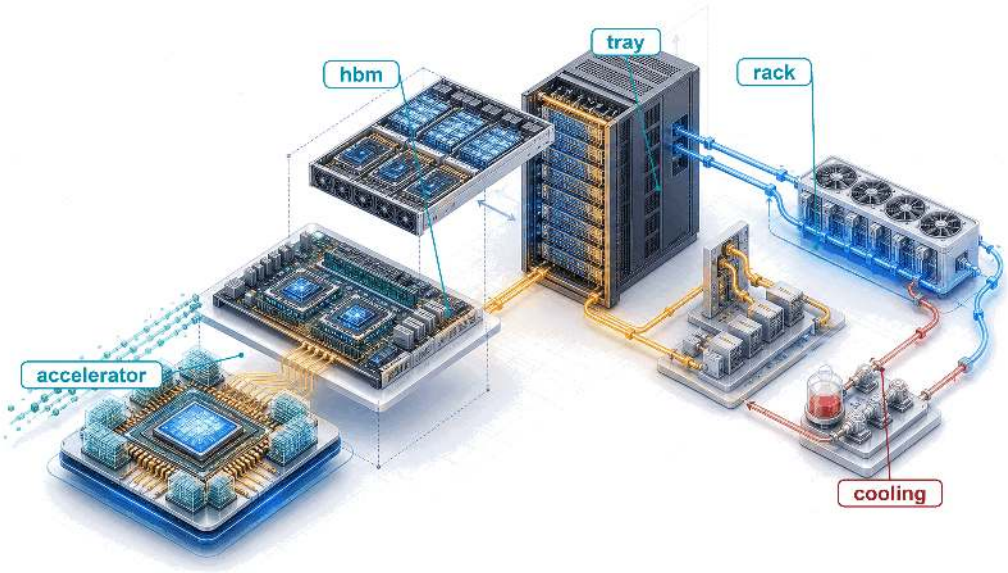
$$\text{Utilization} = \min\left(1,\ \frac{\text{BW}_{\text{storage}}}{N_{\text{GPU}} \times R_{\text{consumption}}}\right)$$

where $\text{BW}_{\text{storage}}$ is aggregate storage bandwidth, N_{GPU} is the number of accelerators, and $R_{\text{consumption}}$ is each accelerator's data-consumption rate.

Implication: A storage system that was adequate for 8 accelerators can become the bottleneck at 64 if its provisioned throughput cannot meet the higher aggregate demand. The I/O wall scales with the number of accelerators: at a fixed per-device consumption rate, every accelerator added raises the throughput floor that storage must sustain. Without matching capacity, the data pipeline can become the limiting factor.

Meeting that demand requires a hierarchy rather than a single undifferentiated storage pool. No single storage medium offers both the petabyte capacity of a training corpus and the terabyte-per-second bandwidth of an accelerator pod.

🏛 Principle 8: The storage hierarchy principle



Invariant: Storage hierarchies are designed so that tiers farther from the accelerator typically trade higher access latency and lower per-stream bandwidth for greater capacity and lower cost per byte; aggregate throughput still depends on provisioning and parallelism.

Implication: The systems engineer's task is to ensure that the right data is on the right tier at the right time. Data format choices, caching strategies, prefetch buffer sizing, and tiering policies all exist to manage movement upward through the hierarchy so that accelerators do not starve.

These constraints make the fleet a first-class engineering object. Following the introduction's account of why single machines no longer suffice, Part I builds the physical machine from the ground up, starting with the silicon, power, and cooling systems of the AI data center and the network fabrics that connect the fleet. It then turns to the storage hierarchy that feeds the training pipeline, preserves its checkpoints, versions the artifacts a run depends on, and serves retrieval at inference time. Each chapter sets one or more terms of the Fleet Law (equation 1.3). Compute infrastructure sets the per-device rate behind T_{compute}/N and the failure exposure that later surfaces in $T_{\text{sync}}(N)$. Network fabrics set $T_{\text{comm}}(N)$ and the barrier tail. Storage adds the input stalls and checkpoint pauses that the step pays whenever prefetching and asynchronous writes cannot hide them. Together, these chapters fix the physical rates within which the communication, partitioning, and recovery mechanisms of Part II must work, for each of the lighthouse archetypes (section 1.6.1) traced across this book.

Purpose

Why does infrastructure, not algorithms alone, determine who can participate in advancing machine learning at scale?

Machine learning systems have a physical reality beyond their code. Public algorithms do not make large-scale training equally accessible: executing them requires power, cooling, memory, and communication capacity that organizations must build and sustain. A model that outgrows one machine turns a local resource problem into a shared infrastructure commitment. Buying more accelerators adds arithmetic capacity, but it also adds data transfers, heat, and components whose failures can interrupt collective work. The useful capacity of the fleet depends on whether those demands can be met together. Hardware that appears attractive in isolation may spend much of its deployment waiting for data or operating below its advertised speed. A facility that can house equipment may lack the electrical or cooling capacity to run it at the intended density. These mismatches consume both capital and operating budgets while reducing the experiments that can finish on schedule. Infrastructure decisions also outlast individual models, so an organization must weigh the efficiency of specialization against the flexibility needed for future workloads. Single-machine performance remains part of that

judgment, but multiplying it by the number of machines cannot establish what the complete installation will deliver. Participation at scale therefore depends on turning purchased hardware into sustained, usable capacity within physical and financial limits. In C^3 terms, the physical substrate sets the compute and communication bounds within which the fleet must coordinate useful work.

Learning Objectives

- Explain how the memory, communication, power, and reliability walls bind at successive physical scales and cascade upward
- Compare GPU, TPU, and ASIC specialization as a bet on workload stability against refresh cycles and facility lifetime
- Distinguish memory capacity from memory bandwidth as separate procurement tests, using roofline placement to find bandwidth-bound phases
- Calculate token-latency floors, memory budgets, and pod training time from accelerator specifications and sustained utilization
- Match tensor, pipeline, and data parallelism to the available interconnect bandwidth hierarchy
- Evaluate rack and pod designs using power density, cooling limits, topology, and facility reliability constraints
- Select accelerator infrastructure using sustained throughput, power constraints, workload fit, and deployment cost

2.1 The Infrastructure Walls

The scaling laws of section 1.3 are why demand outruns any single device. Loss falls predictably as parameters, training tokens, and compute grow together, so each step up in capability multiplies both the memory a model occupies and the arithmetic its training consumes; a GPT-3-class model already needs several accelerators merely to store its FP16 weights. A model that exceeds one accelerator's memory capacity forces a hardware decision before training begins. Adding accelerators supplies capacity, but also creates transfers between devices, increases power demand, and couples progress to more components that can fail. The familiar single-node compute and memory limits therefore become inputs to fleet design. Four recurring physical constraints appear at escalating physical scales, from an eight-GPU node to a 25K-accelerator fleet (figure 2.1). Memory bandwidth, rack power, pod communication, and fleet failure exposure provide the examples; the workload and configuration determine which constraint binds at each scale. These are the memory, energy, and network walls of the scale moment and the fleet's reliability gap, seen from the hardware that imposes them. Because this chapter studies the hardware, it names each constraint by the physical resource that runs out. It uses these four names from here on: the memory wall, the power wall (the energy wall as power delivery and heat removal), the communication wall (the network wall as link bandwidth), and the reliability wall (the reliability gap as a failure interval).

The 175B model anchors this progression. It is the chapter's running instance of Archetype A (GPT-4/Llama-3), a GPT-3-class dense transformer trained with mixed precision and the Adaptive Moment Estimation (Adam) optimizer, whose reference training cluster is 1,024 H100 GPUs in 128 eight-GPU nodes. Accelerator

↩ The memory, network, and energy walls of the scale moment are established in section 1.1.

selection establishes the compute rate, memory capacity, and power envelope that a fleet can buy. The node must connect enough of those accelerators to hold and execute the workload; the rack must power and cool them; the pod must sustain communication and survive component failures. This is the hardware contribution to C^3: useful fleet compute depends on the communication and coordination costs created at each physical boundary.

↩ The three fleet workload archetypes are established in section 1.6.1.

One naming refinement accompanies the fourth wall: the reliability calculation starts from a per-GPU failure figure that section 1.1 calls an MTBF. A failed GPU is replaced rather than repaired, so this chapter calls the per-device figure a mean time to failure (MTTF) and reserves mean time between failures (MTBF) for nodes and fleets, which keep running through repeated failures and replacements. The number is the same; only the label records what is being counted.

↪ The running model's parameters and reference cluster are developed in section G.1.

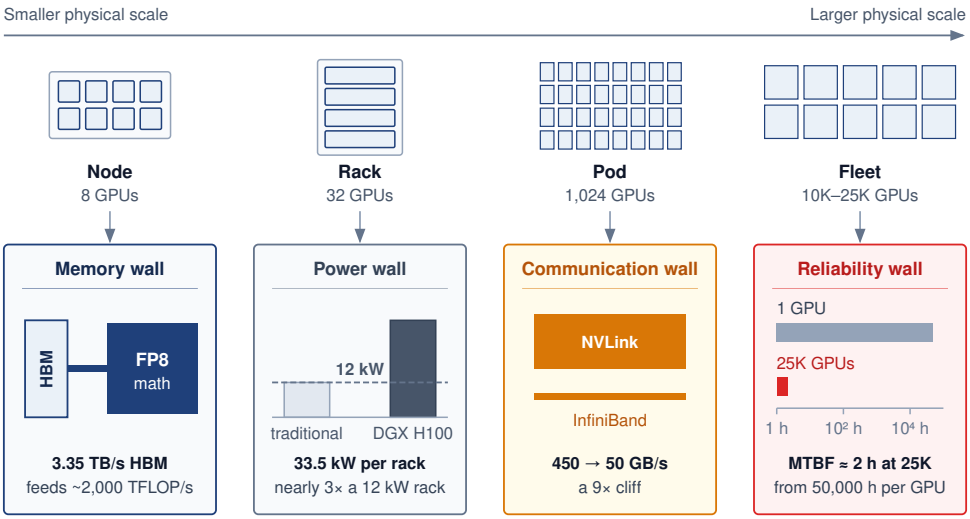

Figure 2.1: The Four Infrastructure Walls: Read left to right, the examples illustrate four constraints at increasing physical scales; the workload and configuration determine which one binds. The node compares 3.35 TB/s of HBM3 with about 2,000 TFLOP/s of FP8 arithmetic; the four-node DGX H100 rack draws 33.5 kW; the pod compares per-direction NVLink bandwidth with one InfiniBand port, a ninefold budget gap; and the fleet assumes independent GPU failures, reducing a 50,000-hour per-GPU mean time to failure (MTTF) to about 2 hours between failures at 25K GPUs.

The chapter climbs the same scale ladder, so the four walls arrive in the order the figure reads, though not one wall per section. The memory wall begins at the accelerator and is developed in section 2.3. The communication wall first appears inside the node, where section 2.5.1 measures the cliff between local and inter-node links, and returns at pod scale in section 2.7. The power wall binds at the rack (section 2.6.1), and the reliability wall accumulates from node health (section 2.5.5) through facility controls to the fleet-scale failure interval of section 2.7.1.

2.2 The Accelerator

The progression begins with the accelerator, because every wall above it is measured against the rates one device can compute, store, and draw. An accelerator

purchase commits the fleet to a workload and software stack for longer than one experiment. A research group changing model operations frequently needs programmability; a service executing a stable computation at sustained volume can justify more specialization. The familiar trade-off between control flexibility and arithmetic efficiency matters here because an architectural mismatch is replicated across the fleet. Comparing programmable and specialized accelerators therefore starts with how much of the workload and compiler stack can remain stable over the deployment's lifetime.

Systems Perspective 2.1: The generality tax

General-purpose CPUs allocate silicon to caches and control logic as well as arithmetic. Branch predictors, reorder buffers, and instruction decoders support code with irregular control flow and data access. Matrix multiplication has a more regular schedule, so some of that flexibility contributes little to its dominant computation. The generality tax (principle 1) is the area and energy devoted to capabilities outside the dominant workload.

Specialized accelerators reduce this tax by replacing general-purpose control with a dataflow matched to the workload. In the approximate shares of figure 2.2, the arithmetic fraction of the die rises from roughly 5–10 percent on a CPU to 50–60 percent on a GPU, 70–80 percent on a Tensor Processing Unit (TPU), and over 90 percent on a custom application-specific integrated circuit (ASIC). The shares mark a direction rather than measured proportions for any product. The selection question is how much of the complete workload can use the specialized hardware.

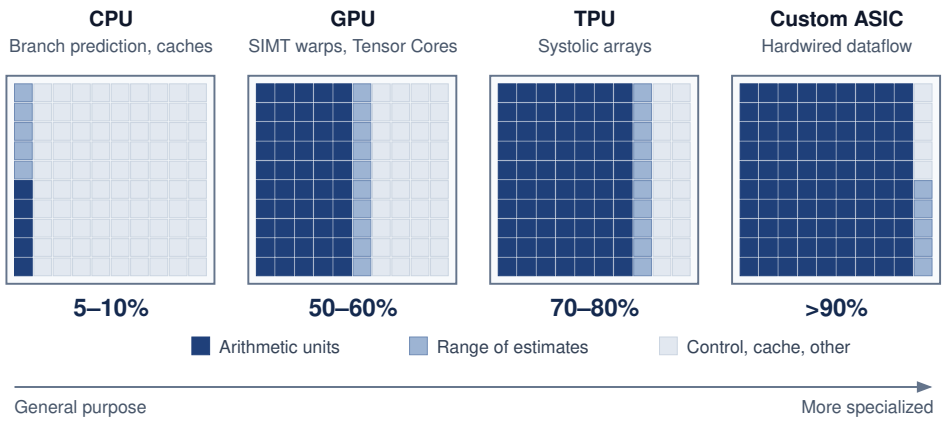

Figure 2.2: The Accelerator Spectrum: Each die is drawn as a grid of 100 cells divided between arithmetic units (dark) and control, cache, and other logic (light), with the medium cells marking the spread of each approximate, illustrative share. Read left to right, the arithmetic share grows from 5 to 10 percent on a CPU to over 90 percent on a custom ASIC, because hardwired dataflow replaces instruction fetch, decode, and scheduling; each step buys throughput per watt by narrowing the range of model architectures the silicon runs well.

Along the spectrum of figure 2.2, GPUs retain substantial programmability and provide 10–100× the matrix throughput of CPUs, while custom ASICs at the far end hardwire a specific dataflow for maximum efficiency at the cost of flexibility. The spectrum is not a ranking from "bad" (general-purpose CPU) to "good" (custom ASIC). It is a continuum of trade-offs in which each position is the best match for a different combination of workload characteristics and deployment constraints.

GPUs represent the first major step away from general-purpose computing toward large-scale parallelism while retaining programmability. An NVIDIA H100, for example, contains 16,896 CUDA cores organized into 132 streaming multiprocessors (SMs). The SMs keep thousands of threads in flight under the single instruction, multiple threads (SIMT) model, so a programmer-written kernel can express any mathematical operation, from convolutions to attention to custom loss functions. Neural network operations have uniform enough control flow that this programmability costs the GPU little on ML workloads.

TPUs specialize the matrix dataflow while retaining other units for operations that do not map onto it. Google's Tensor Processing Units use a **systolic array**[1] architecture, a fixed grid of multiply-accumulate (MAC) units that pass operands and partial results between neighboring cells on a regular schedule, so local reuse replaces per-operation instruction fetch and memory traffic. The complete accelerator still needs control, data movement, and execution of nonmatrix operations.

The cost of this efficiency is reduced programmability. Models must be compiled through Accelerated Linear Algebra (XLA), which maps high-level operations onto the fixed dataflow. Workloads with irregular control flow or dynamic shapes may not map well to this architecture, and the compilation process itself can be time-consuming (minutes to hours for complex models), which slows the iteration cycle during model development.

The programming model distinction between GPUs and TPUs has practical implications for organizational decisions. A research team that frequently adds custom operations, such as new attention patterns or activation functions, needs a path to implement them as kernels without waiting for compiler support, and must check how each platform expresses and optimizes those operations. A team running a stable computation at scale can place more weight on sustained utilization and compilation cost amortized over many runs. CUDA kernel support and XLA graph compilation offer different development paths, but neither establishes a utilization advantage without evaluating the workload and implementation. Software fit belongs in the hardware comparison because unsupported or poorly mapped work can leave specialized arithmetic idle.

1 **Systolic array**: From Greek *systole* (contraction), the name describes data pulsing through a grid of processing elements in a heart-like rhythm. Kung and Leiserson (1979) proposed the design for VLSI chips whose limiting resource was memory access rather than logic (Kung 1982): each operand fetched once is reused by every cell it passes. That ratio of computation to memory traffic is exactly what matrix multiplication at ML scale rewards.

Example 2.1: The TPU origin story

Scenario: In 2013, Google projected that if users spoke to Android phones for 3 minutes per day using voice search, handling the inference load on

general-purpose CPUs would require doubling data center compute capacity at prohibitive cost (Jouppi et al. 2017).

Diagnosis: Standard CPU architectures paid a heavy generality tax, spending significant silicon area and power on out-of-order execution, branch prediction, and complex caches rather than matrix multiplication throughput.

Systems lesson: Hardware specialization is economically justified when a workload is large, stable, and dominated by a single mathematical kernel (MatMul). The TPU v1 hardwired a 256×256 systolic array to deliver 92 TOPS (INT8) within a 75 W footprint, establishing custom ASIC accelerators in production serving infrastructure.

Custom ASICs occupy the specialized end of the spectrum, where the economics of silicon can justify giving up much of the general-purpose programmability. When an organization runs a stable workload at enormous scale, designing a chip specifically for that workload may become economically rational. A custom ASIC can improve energy per operation and sustained utilization on its target workload by removing features that computation does not require.

Tesla's Dojo D1 chip, for example, is optimized for the spatial and temporal structure of video-based vision models. Its hundreds of tightly coupled processing nodes are designed around the dataflow needs of Tesla's vision pipeline, with on-chip SRAM sized to keep spatial tiles close to the compute units. This reduces the repeated round-trips to off-chip memory that a general-purpose GPU would require for the same computation. AWS Trainium takes a different approach, targeting the broad category of Transformer training rather than a single model. Trainium systems combine compiler-managed memory scheduling with hardware-assisted collective communication, so common training patterns such as tensor-parallel synchronization and data-parallel reductions can be optimized in the accelerator fabric rather than handled entirely by host software.

The risk of custom silicon follows from the same specialization. A change in the dominant model architecture can reduce the value of a fixed dataflow if the new operators, tensor shapes, or memory demands map poorly onto it. Sharing matrix operations across model families can preserve some of that investment, so a change from convolutional neural networks (CNNs) to Transformers does not by itself make an accelerator unusable. The forecasting window is long. Even Google's first TPU, a high-priority project, took 15 months to design, verify, build, and deploy (Jouppi et al. 2017), and a chip then serves for several years more. The design decision must therefore anticipate which operations will remain useful years after the workload was profiled, and how much flexibility is needed for the rest. In 2015, few would have predicted that attention-based Transformers would replace CNNs as the dominant architecture within five years, a span of only a few ASIC design cycles.

Custom silicon is therefore a bet on workload stability, and the organizations that make this bet are typically those with enough scale to justify a large up-front design investment and enough workload volume to amortize that NRE (nonrecurring

engineering) cost across many chips. Google can justify the TPU's development cost because high-volume services such as Search, YouTube recommendations, and Gmail spam filtering can amortize a shared accelerator platform. A research lab running a few hundred GPUs cannot justify the same investment.

The bet can pay off when workloads are stable. The first-generation TPU reported 30–80× the performance per watt of contemporary GPUs and CPUs on its inference workloads (Jouppi et al. 2017), and TPU v4 reported 1.3–1.9× lower power than the A100 for similar-sized training systems (Jouppi et al. 2023). A workload shift can strand that advantage because the chip's fixed dataflow may not accommodate a substantially different computational pattern. Pushing the locality argument further raises a question of physical scale: whether the compute fabric can expand to the size of an entire wafer.

2.2.1 Wafer-scale engines

Slicing a silicon wafer into discrete chips forces every exchange between accelerators to leave the die and cross slower, higher-energy package, board, or rack links. Wafer-scale engines (WSE) avoid those crossings by keeping most of a silicon wafer intact as one continuous compute fabric the size of a dinner plate, as in the Cerebras WSE-3, rather than dicing the wafer and reconnecting the pieces across packages and boards.

For its 2024 WSE-3 configuration, Cerebras reported 900,000 AI-optimized cores, 44 GB of distributed on-chip SRAM, and 21 PB/s of aggregate memory bandwidth in its registration filing (Cerebras Systems 2024). These specifications are not directly comparable to GPU-cluster peak FLOP/s or high-bandwidth memory (HBM) bandwidth because the architectures expose different dataflows, memory organizations, precisions, and workload mappings. The durable comparison is topological: on-wafer links avoid package-, board-, and rack-level transfers for work that maps onto the fabric.

A multi-GPU chassis and a wafer-scale engine draw their package and board boundaries in different places (figure 2.3). The eight GPUs of a chassis exchange state through NVSwitch, and transfers to other nodes cross the external network. A wafer-scale engine instead routes between 900,000 on-wafer cores on the 300 mm wafer. Defect-aware routing lets the fabric use working regions despite local manufacturing flaws. In the documented CS-2 configuration, twelve power supplies in a 9+3 redundant arrangement could deliver up to 23 kW to the WSE-2 (Systems 2021). That configuration-specific design illustrates why wafer-scale power delivery and cooling require system-level liquid-cooling hardware rather than a conventional accelerator heatsink.

Wafer-scale engines specialize the *physical* architecture while retaining flexibility in the *computational* model through programmable cores. That trade-off exchanges manufacturing complexity and defect-aware routing for an on-wafer fabric that replaces package- and board-level communication between its cores, though SRAM capacity and data injection still constrain which parts of a workload can benefit from that locality. Where the wafer-scale engine removes the package boundary

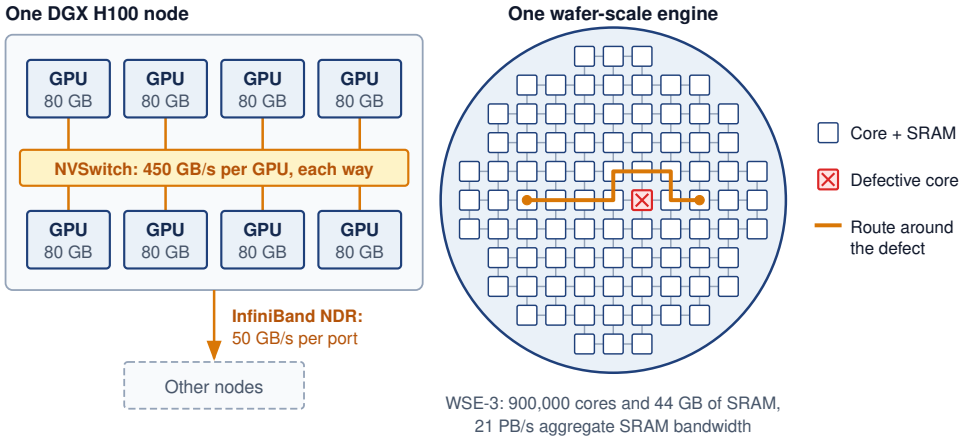

Figure 2.3: Wafer-Scale Engine (WSE) Architecture: A DGX H100 node (left) joins eight separately packaged GPUs through an NVSwitch fabric and must leave the chassis over InfiniBand to reach other nodes, so every exchange crosses a package, board, or network boundary. A WSE (right) instead uses most of a 300 mm wafer as one routed mesh of cores, each with local SRAM; defect-aware routing steers traffic around unusable cores, and the on-wafer mesh replaces off-package transfers for mapped operations. The WSE-3 figures are the vendor's reported totals and are not directly comparable to GPU HBM bandwidth.

by never dicing the wafer, chiplet designs keep the package and change what goes inside it.

2.2.2 Chiplet-based accelerators

Once a monolithic processor die grows to the optical exposure limit of a lithography scanner, adding more arithmetic units or HBM controllers on a single piece of silicon becomes impossible without stitching exposures at lower yield and sharply higher cost. Chiplet architectures, exemplified by NVIDIA's Blackwell and AMD's Instinct MI300 series, break through that ceiling by partitioning the processor into smaller dies connected by a high-bandwidth die-to-die interconnect on a common package substrate. This approach addresses two physical limits that constrain monolithic designs.

First, the maximum die size is capped by the photolithographic reticle limit, the largest area that a lithography scanner can pattern in a single exposure. The limit comes from the optics of photolithography, because the lens system of an extreme-ultraviolet (EUV) scanner projects a pattern onto a field of only about 26×33 mm (858 mm^2). A larger die would need multiple exposures stitched together, which is technically possible but sharply raises cost and lowers yield. The limit caps the number of Tensor Cores, SMs, and HBM stacks a monolithic GPU can integrate. Chiplet designs bypass this limit by placing multiple dies on a single package, with the B200's two reticle-limited dies effectively creating a processor of about 1,700 mm^2.

Second, manufacturing yield depends on die area and defect density. Under the standard Poisson defect model, the fraction of defect-free dies falls exponentially with die area at a fixed defect density, because a single killer defect anywhere on the die can render it unusable. Smaller dies expose less area to each defect, and

testing can select known-good chiplets before package assembly, so one defect discards a small die rather than a reticle-sized one. The resulting yield advantage must be weighed against the cost and yield of the package, its interconnects, and the additional testing. Chiplets change the manufacturing trade-off; they do not guarantee a lower cost per unit of compute.

The trade-off is the die-to-die interconnect. Communication between chiplets within a package is faster than communication between packages (NVLink) but slower than communication within a single monolithic die (the on-die mesh network). Workloads that generate frequent, fine-grained communication between processing elements (such as operations that share data between nonadjacent SMs) may experience a latency penalty when those SMs reside on different chiplets. GPU vendors mitigate this by making the die-to-die link transparent to the programmer, so the software sees a single logical GPU regardless of the underlying chiplet topology. Seeing why modern accelerators reached that multi-die boundary requires tracing how successive GPU and TPU generations spent their single-die transistor budgets first.

2.2.3 Evolution of GPU architectures

NVIDIA's data center GPUs show the specialization bet placed one generation at a time. Each generation added hardware aimed at a bottleneck that production ML workloads had exposed, rather than more transistors of the same kind. The Volta architecture (2017) introduced the first-generation Tensor Core, dedicated matrix-multiply-accumulate hardware placed beside the existing CUDA cores, because neural network training spends most of its time in matrix multiplications. Volta accelerated that dominant pattern without giving up the general-purpose programmability that made GPUs attractive for research.

The Ampere architecture (2020) expanded Tensor Core support to TF32 and BF16 and introduced Multi-Instance GPU (MIG), which partitions one GPU into up to seven isolated instances so that several inference workloads can share it. The change that mattered most for infrastructure was Ampere's third-generation NVLink, which doubled per-GPU bandwidth to 600 GB/s from Volta's 300 GB/s, the bandwidth that tensor parallelism needs because it splits each layer's matrices across GPUs.

The Hopper architecture (2022) added the Transformer Engine, whose FP8 recipes and autocast integration run supported Transformer operations in FP8 with managed scaling while retaining higher precision where the configured recipe or implementation requires it. Hopper also introduced NVLink 4.0 at 900 GB/s per GPU and the NVLink Switch, enabling NVLink connectivity beyond the 8-GPU boundary.

The Blackwell architecture (2024) takes the chiplet route of section 2.2.2 past the 858 mm^2 reticle limit. The B200 pairs two GPU dies in one package over a 10 TB/s die-to-die link, fast enough that the two dies appear to software as a single logical GPU for many operations, and its fifth-generation NVLink doubles intra-node bandwidth again to 1800 GB/s per GPU. Its FP8 rating in table 2.1 is not

an FP16/BF16 figure; those comparisons should use the lower precision-specific vendor rate.

Each generation thus targeted the bottleneck its predecessor exposed. Volta added dedicated matrix hardware, Ampere widened mixed-precision support, Hopper added FP8 for Transformer workloads, and Blackwell worked around the die-size limit with two dies in one package. Because architects choose those targets by profiling the workloads of their era, accelerator design follows model architecture, which is why Transformer workloads have shaped accelerator design since 2017.

Because accelerator generations turn over faster than the facility that houses them, a data center must anticipate refresh cycles before the first rack arrives. Those generations also changed interconnect capacity and power (table 2.1). From V100 to B200, dense FP16 throughput rose 18×, memory bandwidth 8.9×, and thermal design power (TDP) 3.3× (figure 2.4). These are growth multiples over the whole span, not annual rates, and their ratios carry the planning lesson. Each byte delivered from memory must now feed about twice as many operations, and each watt of the power allowance supplies more than five times as many peak operations. That first ratio raises the data reuse a workload needs to approach peak throughput. Even with the fivefold gain in peak operations per watt, reaching the 18× compute multiple still required raising per-device TDP by 3.3×, and that higher per-device wattage multiplied by device count sets the proposed rack load. A facility refreshed one-for-one for compute density therefore outruns both its memory delivery and its cooling envelope.

Table 2.1: NVIDIA GPU Architecture Evolution: Each generation introduces architectural features targeted at the dominant ML workload pattern of its era. Efficiency rises substantially but unevenly across generations, while NVLink bandwidth increases from 300 GB/s on V100 to 1,800 GB/s on B200, with a smaller 1.5× A100-to-H100 step between the larger doubling jumps.

Architecture	Year	Key innovation	Peak tensor	TDP	NVLink BW
Volta (V100)	2017	First Tensor Core	125 TFLOP/s FP16	300 W	300 GB/s
Ampere (A100)	2020	Multi-precision, MIG	312 TFLOP/s FP16	400 W	600 GB/s
Hopper (H100)	2022	Transformer Engine, FP8	1,979 TFLOP/s FP8	700 W	900 GB/s
Blackwell (B200)	2024	Dual-die, NVLink 5	4,500 TFLOP/s FP8	1000 W	1,800 GB/s

Because table 2.1 mixes FP16 and FP8 peaks, its per-watt efficiency must be read at fixed precision. At dense FP16, dividing each generation's peak throughput by

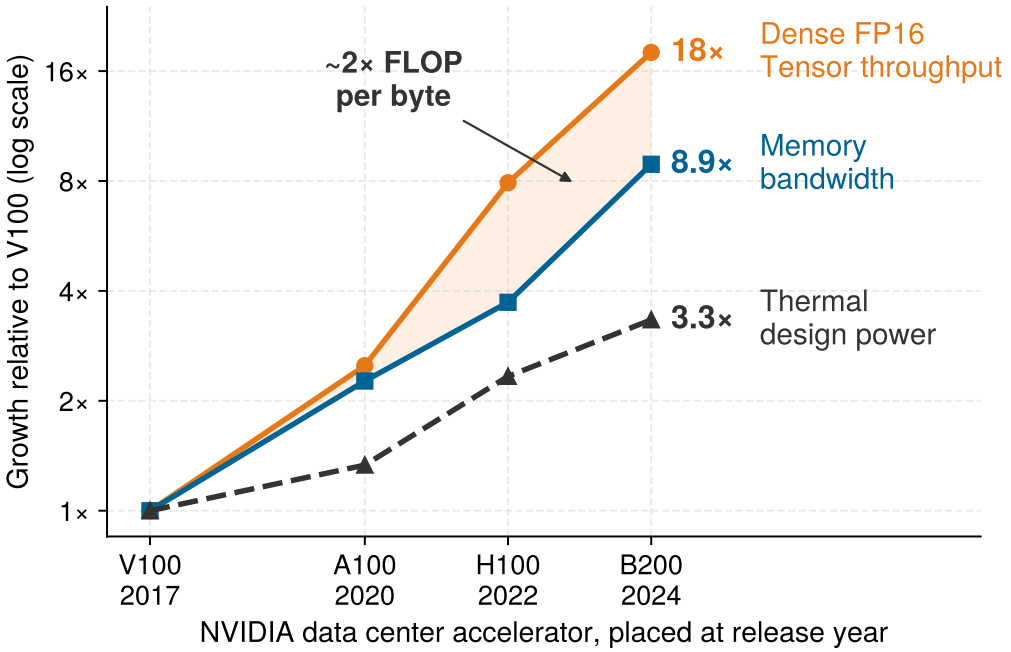

Figure 2.4: Compute, Bandwidth, and Power Scale at Three Different Rates: Dense FP16 Tensor throughput, memory bandwidth, and thermal design power for NVIDIA data center accelerators, normalized to the V100 on a log scale, where the shaded gap between the compute and bandwidth lines is the growth in arithmetic intensity a kernel needs to stay compute-bound. Compute rises 18×, bandwidth 8.9×, and TDP 3.3×, so the endpoint gains in arithmetic exceed the gains in memory bandwidth and power allowance. These are peak specifications, not measured application throughput. Specifications come from the MLSysIM hardware registry.

its TDP (table 2.2) gives a V100-to-B200 gain of 5.4× in peak throughput per watt, the more-than-fivefold figure above, against 18× in raw throughput. The rest of the raw gain came from a power allowance that itself rose 3.3×. The same caution applies between adjacent generations. The H100's FP8 peak per watt of TDP is 6.8× the V100's FP16 figure, but a factor of two of that comes from the change of precision, and at equal FP16 precision the gain is 3.4×. Facilities must therefore accommodate higher device power as well as greater arithmetic capacity, which connects this trend to the power wall in section 2.6.1.

Table 2.2: Power Efficiency across GPU Generations: Dense FP16 tensor arithmetic peak divided by accelerator TDP, with no sparsity multiplier. These ratios compare arithmetic ceilings, not measured training throughput or facility energy. Matched workload measurements must also include achieved utilization, memory and communication stalls, and non-accelerator power.

Generation	Dense FP16 peak TFLOP/s	TDP (W)	TFLOP/s per watt	Relative efficiency
V100 (2017)	125 TFLOP/s (FP16)	300 W	0.42 TFLOP/s/W	1×
A100 (2020)	312 TFLOP/s (FP16)	400 W	0.78 TFLOP/s/W	1.9×
H100 (2022)	989 TFLOP/s (FP16)	700 W	1.41 TFLOP/s/W	3.4×

Generation	Dense FP16 peak TFLOP/s	TDP (W)	TFLOP/s per watt	Relative efficiency
B200 (2024)	2250 TFLOP/s (FP16)	1000 W	2.25 TFLOP/s/W	5.4×

The four generations in table 2.2 sit on a broader and slower trend. Across the 64 accelerator models released since 2017 for which Epoch AI records both a dense FP16 tensor rate and a TDP, from every major vendor, peak arithmetic per watt improved about 1.2× per year, doubling roughly every 4 years (figure 2.5) (Epoch AI 2026b). The leading NVIDIA parts improved faster, 5.4× from the V100 to the B200 in seven years (the fixed-precision gain noted earlier), because frontier devices adopt new process nodes and tensor formats first. A fleet on a 4-year refresh cycle therefore gains about 2× in peak arithmetic per watt each cycle on the broad trend. Peak ratios bound what a refresh can deliver, and only measurements at the workload level decide how much of it a given fleet realizes.

↪ How these peak ratios screen a fleet refresh decision is developed in section 12.9.3.1.

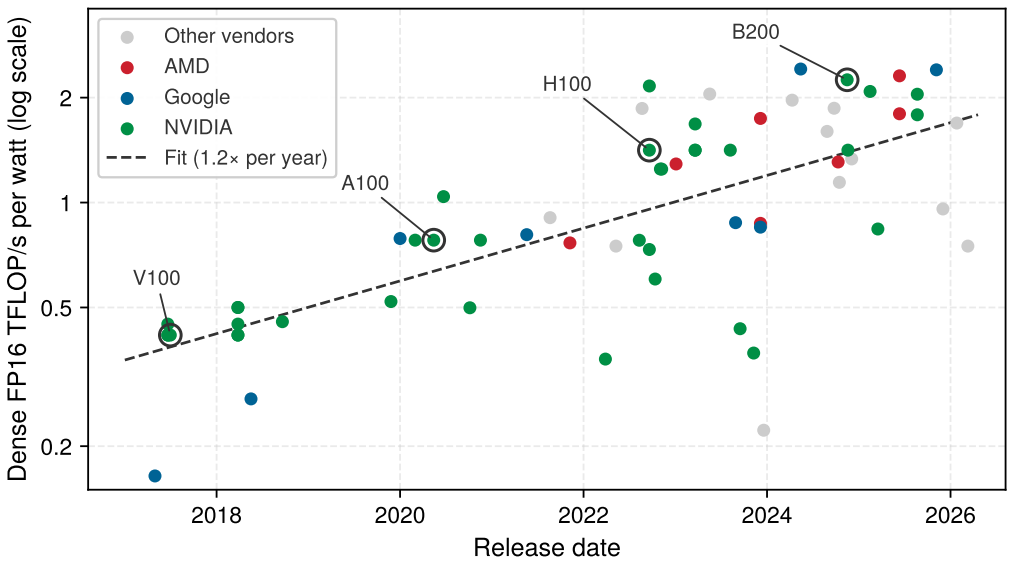

Figure 2.5: Peak Arithmetic per Watt over Time: Dense FP16 tensor throughput divided by TDP for ML accelerators released since 2017, on a logarithmic axis, colored by vendor. The dashed line is a least-squares fit across all devices; the four GPUs of table 2.2 are circled and labeled. The ratio compares arithmetic ceilings, not measured energy per workload. Data from Epoch AI (2026b).

2.2.4 Evolution of TPU architectures

Faster per-chip arithmetic leaves a cluster stalled if inter-chip collectives still have to traverse host CPUs and general-purpose PCIe switches. Google's TPU trajectory attacked that bottleneck directly by treating the multi-rack pod, rather than the individual chip, as its unit of design from its second generation onward. While GPUs emphasize peak per-chip throughput and software flexibility (CUDA), every

TPU chip since TPU v2 integrates dedicated inter-chip interconnect (ICI) links that route traffic directly between accelerators without touching the host CPU.

The generation sequence shows how that pod-first design moved from inference to training. After the inference-only TPU v1 of the origin story, TPU v2 (2017) and TPU v3 (2018) shifted the architecture toward training. They added bfloat16 (BF16), which avoids the dynamic range problems of standard FP16, and they scaled the pod concept until a TPU v3 pod joined 1,024 chips with about 126 PFLOP/s of aggregate BF16 peak. TPU v4 (2021) extended the same logic into the network itself. It added an optical circuit switch so the physical topology could be reconfigured for different workloads, introduced SparseCore units that accelerate embedding lookups, and raised per-chip BF16 throughput to 275 TFLOP/s.

The TPU v5p (2023) continued this pod-scale design for high-end training. It features 459 TFLOP/s of BF16 compute, 95 GB of HBM2e with 2,760 GB/s memory bandwidth, and 1,200 GB/s bidirectional ICI bandwidth per chip. The ICI figure matters for hardware selection because collectives such as AllReduce run over those links. AllReduce combines values such as gradient sums across a group of accelerators and returns the result to every participant. Section D.2.1 develops the complexity model and algorithm choices that determine when those exchanges limit training throughput. The pod-first design took shape over successive TPU generations (table 2.3).

Table 2.3: Google TPU Architecture Evolution: The TPU's development highlights a "pod-first" design philosophy where inter-chip interconnect bandwidth and compiler-level optimization (XLA) are as important as peak per-chip arithmetic. Note: TPU v1 was INT8 only.

Generation	Year	Key innovation	Peak BF16	HBM	ICI BW (aggregate, one direction)
TPU v1	2015	Systolic array (inference)	92 TOPS*	—	—
TPU v2	2017	High-bandwidth memory	46 TFLOP/s	16 GB	248 GB/s
TPU v3	2018	Liquid cooling, pod scale	123 TFLOP/s	32 GB	280 GB/s
TPU v4	2021	Optical switch, SparseCore	275 TFLOP/s	32 GB	300 GB/s
TPU v5p	2023	Larger pods, HBM2e	459 TFLOP/s	95 GB	600 GB/s

The GPU and TPU lines follow two design philosophies (table 2.1, table 2.3). GPU evolution packs more arithmetic, in ever lower-precision Tensor Core formats, onto one package, and turns to chiplets once a single die reaches its size limit. TPU evolution treats the pod as the product. Per-chip arithmetic matters, but inter-chip

bandwidth and reconfigurability decide how much of it a large training job can use. Both lines combine local computation with memory and interconnect improvements; they place those resources differently. The warehouse-scale perspective of section 1.2.2 treats chip throughput, collective bandwidth, and reconfigurability as parts of one system (Barroso et al. 2019), so the useful comparison is how each candidate sustains the intended workload across that complete system.

2.2.5 Matrix units

Both lines concentrate their peak arithmetic in specialized matrix units, called Tensor Cores on NVIDIA GPUs and Matrix Multiply Units (MXUs) on Google TPUs. A Tensor Core executes matrix-multiply-accumulate instructions of the form $\mathbf{D} = \mathbf{A} \times \mathbf{B} + \mathbf{C}$ on small tile matrices, concentrating the dominant neural-network operation in dedicated hardware that supplies most of the chip's peak arithmetic.

With 528 Tensor Cores across the chip (4 per SM, 132 SMs), the H100 reaches its 989 TFLOP/s dense FP16/BF16 peak. The important systems point is the architectural specialization rather than the exact per-cycle instruction accounting. The die dedicates a large fraction of its arithmetic area to dense tiled matrix operations rather than general-purpose scalar execution.

Google's MXUs organize multiply-accumulate units into the systolic array introduced with the TPU above. In the MXU's weight-stationary dataflow, a weight tile stays resident in the array while activations stream through it. Every operand fetched from memory is therefore reused by an entire row or column of cells, which is the reuse that a Tensor Core kernel obtains by staging tiles in shared memory and registers. Each TPU v5p chip contains two TPU cores (which Google calls TensorCores, a name unrelated to NVIDIA's Tensor Cores) with four 128×128 MXUs each, together providing 459 TFLOP/s of BF16 throughput. Approaching that peak requires compatible tile shapes and a sustained operand supply; pipeline fill, partial tiles, and dependencies can leave cells idle. Vector and scalar units handle other operations, so complete-workload efficiency depends on how computation maps across the accelerator.

For our 175B model, compiler and kernel support determine how much work reaches the specialized arithmetic units. CUDA kernels can combine matrix operations with thread-level work, while XLA maps the computation graph onto the TPU dataflow. In either stack, fusion keeps intermediate results in registers or shared memory instead of repeatedly writing them to HBM. Sustained throughput therefore depends on operation coverage and data reuse as well as the matrix units themselves.

> **Definition 2.1: Tensor core**
>
> ***Tensor Core*** is a specialized ML accelerator hardware unit that performs a fused matrix-multiply-accumulate operation $\mathbf{D} = \mathbf{A} \times \mathbf{B} + \mathbf{C}$ on small tiles (for example, $16 \times 8 \times 16$ in BF16) as a single hardware instruction, delivering dramatically higher throughput than general-purpose CUDA cores by trading programmability for fixed-function matrix arithmetic.

1. **Significance**: Tensor Cores provide the bulk of the H100's 989 TFLOP/s FP16/BF16 peak (and ~1,979 TFLOP/s at FP8), roughly 14.8× the ~67 TFLOP/s delivered by CUDA (vector) cores alone. This comparison changes both the execution unit and precision. Reductions and element-wise operations in layer normalization or softmax require a different performance model; their throughput is not a fixed fraction of the matrix peak.
2. **Distinction**: A Tensor Core is a fixed-function matrix-multiply-accumulate unit, not a faster general-purpose core. CUDA cores execute arbitrary scalar and vector work; Tensor Cores execute only the tiled $\mathbf{D} = \mathbf{A} \times \mathbf{B} + \mathbf{C}$ primitive, which is why peak throughput and delivered throughput diverge so sharply by workload.
3. **Common pitfall**: A frequent misconception is that all GPU operations benefit from Tensor Cores. Operations must map to the $\mathbf{D} = \mathbf{A} \times \mathbf{B} + \mathbf{C}$ tile computation to use those units. Element-wise activations, normalization, and embedding lookups have different execution and data-access demands. A fixed 10–30× penalty per FLOP is not a workload-independent model for their runtime.

Table 2.4: The Accelerator Spectrum: The architectures place arithmetic, control, and memory differently. Specialization can improve throughput per watt when the workload and software stack use its dataflow; the table does not rank measured efficiency. Wafer-scale engines replace package and board boundaries with an on-wafer fabric of programmable cores.

Feature	CPU	GPU (H100)	TPU (v5p)	Wafer-scale	Custom ASIC
Arithmetic core	Scalar/vector	Tensor Core	Systolic array	RISC-style core	Fixed dataflow
Execution	Instruction	SIMT	Data-driven	Dataflow	Hardwired
Memory control	Cache	L1/L2 + HBM	Scratchpad	On-chip SRAM	Compiler-managed
Flexibility	Extreme	High	Moderate	High	Low

Across the whole spectrum, from CPU to custom ASIC, the architectures differ in arithmetic core, execution model, and memory control (table 2.4). For the 175B running model, the choice among these columns is not purely about peak FLOP/s. A research lab experimenting with novel architectures weekly can justify the GPU's generality tax by its flexibility. An organization deploying a fixed Transformer at scale for years may find that the TPU's dataflow efficiency or a custom ASIC's power advantage dominates total cost. The accelerator spectrum is ultimately an economic question of *how much flexibility can be surrendered, given the stability of the workload*. Even when the H100's arithmetic engine reaches 1,979 TFLOP/s in its advertised low-precision mode, eligible operations approach that throughput only when data reaches the compute units fast enough. Accelerator selection

therefore requires a second comparison, between the workload's data demand and the memory system that feeds the arithmetic.

2.3 The Memory Wall

That comparison between arithmetic supply and data delivery exposes a structural divergence: because transistor scaling has multiplied logic throughput far faster than off-chip interconnects can supply operands, specialized matrix units routinely spend more time waiting for bytes than executing math. This divergence is the memory wall (Wulf and McKee 1995), and the weight and activation streams of large neural networks make memory bandwidth rather than peak compute the governing constraint across major inference and training regimes.

↪ The diagnostic table that maps memory-bound, compute-bound, and latency-bound symptoms to the optimizations that help is developed in section A.3.2.

Single-request inference on our 175B running model turns that divergence into a user-visible delay. Its weights occupy 350 GB in FP16. In dense autoregressive decode at batch size 1, each generated token uses all of those weights, whose footprint far exceeds on-chip storage, so every token must stream them in from memory. Suppose, hypothetically, that one H100 could hold them. Streaming the whole 350 GB through that device's HBM at about 3.35 TB/s takes over 100 ms per token, long enough to be a perceptible pause between generated words. No real H100 holds the model, so the figure is a floor on bandwidth demand rather than a prediction of deployed latency, but it shows that the memory wall is a delay a user can notice, not an abstract architectural ratio.

Three levers lower that floor. Sharding spreads the weights across more memory paths, so each path streams fewer bytes. Quantization shrinks the bytes themselves. Reuse lets each fetched byte feed more arithmetic, which HBM's bandwidth and on-chip tiling make possible. The Roofline Model, recapped for one machine in section A.3.1, tests whether the resulting data supply can feed the arithmetic units. Its ridge point, peak arithmetic divided by memory bandwidth, is the number of operations a kernel must perform per byte fetched before arithmetic rather than memory becomes the limit. The ridge point recurs throughout the analysis below, and section 2.3.2 evaluates it for the H100. Where each architecture places its bytes sets how much bandwidth those levers can draw on (figure 2.6), because moving the active working set closer to arithmetic increases available bandwidth while reducing the capacity that can reside there.

Accelerators do not line up along a single performance axis; they fall into structural clusters according to where each architecture places its bytes (figure 2.6). Edge devices in the lower band keep memory cheap and compact, but their bandwidth remains constrained, and the devices of Archetype C (Federated MobileNet) sit in that corner. On each device, the binding limit is the power envelope that bounds compute. A phone-class device sustains only 2 W to 3 W, while one H100's thermal envelope is about 233× larger. A federated fleet therefore grows by adding devices rather than by moving up the memory tiers, and at fleet scale, as section 1.6.1 noted, communication and which devices participate in each round limit progress as well.

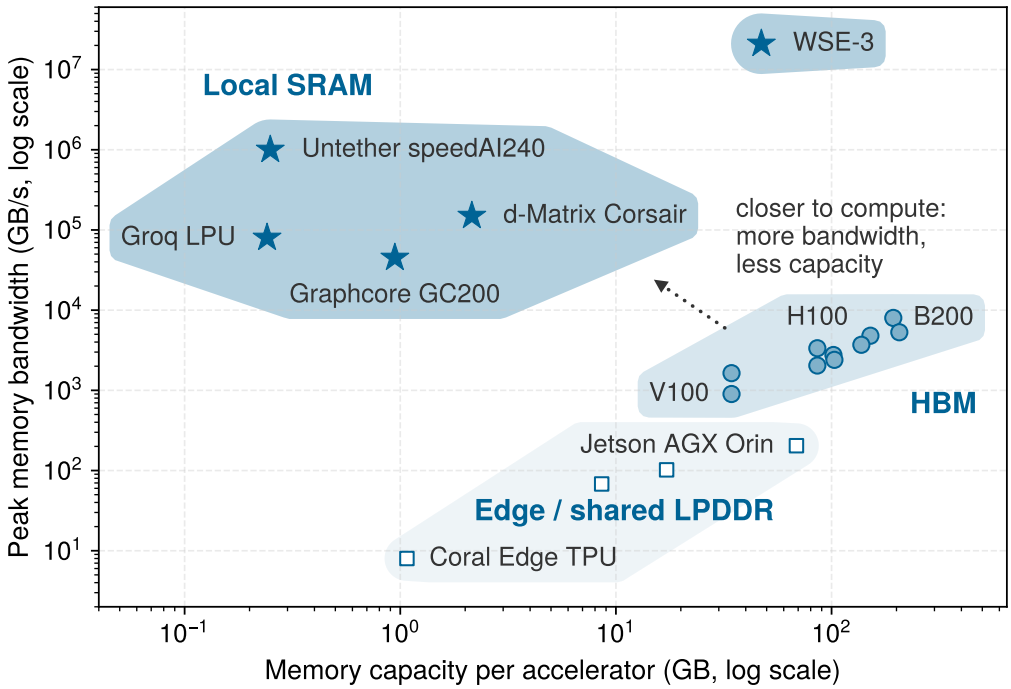

Figure 2.6: Accelerator Memory Tiers: Peak memory bandwidth and capacity separate local-SRAM designs (solid stars), HBM accelerators (half-tone filled circles), and edge and shared-LPDDR devices (hollow squares); all three are memory, so they share one hue and differ by marker. The dotted arrow marks the design trade-off: moving data closer to compute raises bandwidth but reduces capacity.

Within the data center tiers, HBM moves memory onto the accelerator package, buying enough capacity and enough bandwidth for active model state. Local-SRAM designs push the working set still closer to arithmetic, buying extraordinary bandwidth at the cost of much smaller resident capacity. That tier map explains why HBM is the next engineering response. HBM is not the fastest memory in the system, but it is the highest-bandwidth tier that can hold tens to hundreds of gigabytes next to the compute die.

↪ The power, thermal, and memory limits of phone-class edge devices are developed in section 11.3.

2.3.1 HBM and the memory wall

An H100 can execute 1,979 TFLOP/s of low-precision matrix arithmetic, but the batch-1 weight-streaming example for our 175B model supplies too little reuse to approach that peak. In a bandwidth-floor model its arithmetic units would use well under 1 percent of the matrix peak while the weights stream in. The limiting resource is the speed of *delivery* relative to *multiplication*. Once weights fit through sharding or compression, the serving path must still deliver the active shards at the required rate. Additional arithmetic capacity alone does not raise a binding bandwidth ceiling. HBM increases that data supply within the package.[2]

HBM is the bottom on-package tier of the accelerator memory hierarchy, beneath the register file, the L1 and shared memory (SRAM),[3] and the L2 cache. Aggregate bandwidth falls from hundreds of TB/s at the registers to the 3.35 TB/s of the H100's 80 GB of HBM3, while capacity grows in the opposite direction.

The bandwidth gap between registers and HBM is approximately 100×, but that ratio alone does not specify stalled time. Utilization depends on **arithmetic intensity**, the floating-point operations performed per byte moved from memory (FLOP/byte), which tiling raises by staging matrix blocks on chip so that each fetched operand feeds many multiply-accumulate operations. Section A.5 collects tiling with the other kernel-level levers for reference.

Definition 2.2: HBM

HBM is a 3D-stacked DRAM architecture used by ML accelerators, with through-silicon vias (TSVs) connecting memory dies vertically within each stack and a wide interface across the package interposer connecting the stack to the processor.

1. **Significance**: HBM3 in the H100 delivers approximately 3.35 TB/s of memory bandwidth (roughly 17× DDR5's ~200 GB/s) at roughly 4 pJ/bit for an HBM2-class stack (O'Connor et al. 2017) vs. roughly 20 pJ/bit for off-package DRAM (Horowitz 2014). This bandwidth sets the BW term of the single-machine iron law given in section A.2. The H100's FP16 ridge point is approximately $989\,\text{TFLOP/s}/3.35\,\text{TB/s} \approx 295$ FLOP/byte, so any operator with arithmetic intensity below 295 FLOP/byte (for example, single-request decode, which performs two FLOPs for every two-byte FP16 weight it reads) remains memory-bound even with HBM.
2. **Distinction**: Unlike socketed DDR memory, which communicates across centimeters of printed circuit board (PCB) trace, an HBM stack sits beside the processor on the package. Its micrometer-scale vertical connections can be 1,000× shorter than board traces, but the complete processor-to-memory path also crosses the interposer. The wide, short on-package interface raises bandwidth without relying on a proportionate increase in per-pin signaling rate.
3. **Common pitfall**: A frequent misconception is that HBM solves the memory wall. HBM moves the wall rather than eliminating it. From the V100 (900 GB/s with 125 TFLOP/s FP16) to the H100 (3.35 TB/s with 989 TFLOP/s FP16), peak arithmetic (R_{peak}) grew faster than HBM bandwidth.

Traditional DDR memory connects to the processor through pins on the edge of a printed circuit board. Each DIMM communicates over a 64-bit bus, and even with multiple channels (8 channels is typical for a high-end server CPU), a modern server tops out at roughly 200 GB/s of aggregate memory bandwidth.

The physical distance from the DIMM slot to the processor die is measured in centimeters, and every centimeter of copper trace introduces capacitance, signal attenuation, and energy loss. At DDR5 data rates (4,800–6,400 MT/s per pin), the signal conditioning circuits must compensate for significant channel impairment, consuming substantial power per bit transferred. Increasing the data rate on these

[2] **HBM origin**: Standardized by JEDEC in 2013 as a joint development between AMD and SK Hynix, originally for graphics cards. ML accelerators adopted HBM because neural networks share the same bandwidth-hungry, capacity-moderate access pattern as high-end rendering. Each HBM generation has roughly doubled bandwidth (128 GB/s in HBM1 to 1.2 TB/s per stack in HBM3e), yet the gap between memory bandwidth and arithmetic throughput continues to widen, which makes HBM a necessary but never sufficient response to the memory wall.

[3] **SRAM energy (pJ/bit)**: Reading a bit from an 8–32 KB on-chip SRAM array costs roughly 0.15–0.3 pJ at the 45 nm node (Horowitz 2014), while fetching a bit from HBM2 costs about 4 pJ (O'Connor et al. 2017). This order-of-magnitude energy difference is the physical driver behind kernel fusion: every intermediate result kept in SRAM instead of written to HBM saves both time and significant power and thermal headroom.

long traces requires progressively more power for signal conditioning, creating a diminishing-returns curve that DDR5 is already approaching.

HBM sidesteps that board-level degradation through 2.5D integration (figure 2.7). Instead of driving signals horizontally across centimeters of motherboard trace over a narrow 64-bit bus, it stacks DRAM dies vertically and places the stack beside the processor on a silicon interposer.

↪ The single-accelerator memory hierarchy, from registers and shared memory through HBM to host memory, is collected for reference in section A.4.

↪ Arithmetic intensity and the boundary it draws between memory-bound and compute-bound work are collected for reference in section A.3.

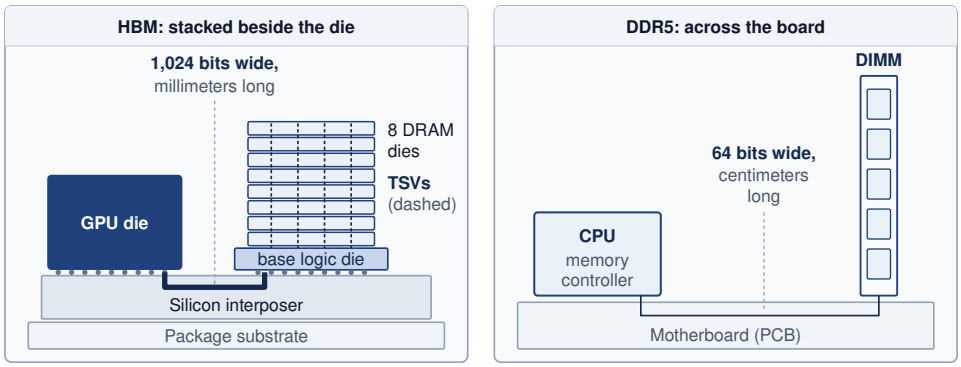

Figure 2.7: HBM 3D-Stacked Architecture: Left: high-bandwidth memory stacks DRAM dies on a base logic die, links them vertically with through-silicon vias (TSVs), and places the stack on a silicon interposer beside the GPU die, so each stack reaches the GPU over a 1,024-bit interface only millimeters long. Right: DDR5 instead sits on a DIMM across the motherboard, reached over a 64-bit channel through centimeters of board trace. The wider, shorter path raises bandwidth and lowers energy per bit, but HBM bandwidth and capacity remain finite, so the memory wall moves rather than disappears.

The vertical stacking changes how bandwidth scales. Rather than pushing signals faster through long copper traces (the DDR approach, which has diminishing returns), HBM multiplies the number of parallel signal paths. A single HBM stack bonds 8–12 DRAM dies, threading thousands of through-silicon vias (TSVs),[4] copper pillars etched through each die, to form a 1024-bit-wide interface per stack, compared to 64 bits for a DDR5 channel. This 16× wider interface is the main source of HBM's bandwidth advantage; HBM need not exceed DDR's per-pin signaling rate. The processor and HBM stacks share a package and communicate across the silicon interposer, shortening the electrical path relative to socketed DIMMs. This packaging primarily improves bandwidth and energy per transferred bit; it does not by itself imply that complete HBM load latency is only a few nanoseconds.

The shorter path also lowers transfer energy per bit by roughly 5×, from approximately 20 pJ/bit for off-package DRAM (Horowitz 2014) to about 4 pJ/bit for HBM2 (O'Connor et al. 2017), because the short interconnects present less capacitance and need less driving current. The same reduced loading lets the 1024-bit interface run at moderate per-pin rates instead of the high-power signaling that long board traces require. Propagation delay shrinks by only a fraction of a nanosecond, small next to the DRAM array and controller delays that dominate access latency, so HBM's advantage lies in bandwidth and energy per bit rather than in latency. Modern accelerators therefore widen the memory interface across an interposer rather than driving off-package pins faster; set side by side in table 2.5,

[4] **TSV (through-silicon via)**: A vertical copper pillar, 5–10 micrometers in diameter, etched through a silicon die to connect stacked layers. Originally developed for CMOS image sensors in smartphone cameras, TSVs enabled HBM by replacing centimeters of PCB trace with tens of micrometers of vertical silicon, roughly a 1,000× shorter signal path, which is what lets a stack expose a 1024-bit interface within an accelerator's power budget.

the bandwidth, interface-width, and energy differences all trace to placement and width rather than to faster signaling.

Checkpoint 2.1: HBM and the memory wall

These questions check whether the physical benefits of 3D-stacked memory are clear:

- ☐ **HBM vs. DDR5**: explain why HBM achieves higher bandwidth than DDR5 despite having a lower clock frequency.
- ☐ **Off-package signaling cost**: explain why off-package DDR memory has higher energy per bit and how vertical stacking (TSVs) reduces that cost.
- ☐ **Capacity overflow**: locate where the remaining 60 GB must reside when an H100 has 80 GB of HBM and a 70B parameter model requires 140 GB for FP16 weights.
- ☐ **Bandwidth not capacity**: classify the claim as true or false: HBM's primary benefit is increasing the total memory capacity available to the GPU.

Table 2.5: HBM vs. Standard DRAM Comparison: HBM achieves its bandwidth advantage through three simultaneous innovations: 3D die stacking (more bits per package), TSV interconnects (shorter signal paths), and on-package placement (proximity to the processor). The bandwidth figures describe each memory's local requester path: CPU to host DDR5 and H100 GPU to its own HBM3. A GPU request to host DRAM must also traverse the node interconnect and is not represented by the DDR5 channel figure. The energy row uses published per-bit access estimates for off-package DRAM at the 45 nm node (Horowitz 2014) and for HBM2 (O'Connor et al. 2017) rather than measurements of the DDR5 and HBM3 parts named in the column heads.

Metric	CPU-local host DRAM (DDR5)	GPU-local accelerator **HBM** (H100 HBM3)	Scaling factor
Mechanism	2D PCB traces	3D die stacking	-
Placement	Socketed DIMMs	On-package (substrate)	Physical proximity
Bandwidth	~200 GB/s	~3.35 TB/s	~17× faster
Interface width	64-bit	1024-bit per stack	16× wider
Energy	~20 pJ/bit	~4 pJ/bit	~5× efficiency

This bandwidth advantage comes at a price. HBM costs approximately $10–$15 per GB, compared to roughly $3 per GB for DDR5 server memory. For an H100 with 80 GB of HBM3, the memory alone represents approximately $800–$1,200 of the accelerator's manufacturing cost. For a B200 with 180 GB of HBM3e, the memory cost rises to $1,800–$2,700 per accelerator, making HBM one of the most expensive components in the system.

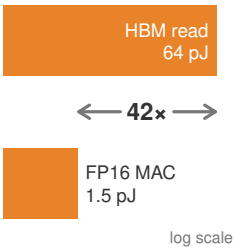
Packaging adds manufacturing stages beyond fabricating the memory dies. The stacking process includes thinning, alignment, bonding, and vertical interconnection, so usable stack yield depends on both the dies and their assembly. Those yields compound, because a 12-high HBM3e stack is usable only if every die and every bonding step succeeds, so even small per-step losses multiply into a complete-stack yield below that of a single DRAM die. The silicon interposer must also accommodate the processor and multiple HBM stacks. With each stack occupying roughly 100 mm^2, an illustrative large package that pairs a reticle-sized processor with several stacks needs an interposer exceeding 1,000 mm^2. Testing, repair provisions, and assembly yield all affect cost; die count alone does not determine how many complete stacks remain usable. Supply is a constraint as well as cost: HBM production is concentrated among a few manufacturers whose stacking steps need specialized equipment, so memory availability can pace accelerator delivery, a lead-time risk that section 12.9.5.1 plans for.

For our 175B model, this cost-capacity trade-off explains why accelerators typically offer 80 GB to 192 GB of HBM while the host server provides 512 GB to 2 TB of DDR. The *fast* memory holds state touched every step (weight shards, activations, gradients, and usually the sharded optimizer state), while the *cheap* memory holds staging buffers, data loading queues, and colder state that capacity pressure forces out, such as offloaded optimizer shards.

The boundary between what resides in HBM and what resides in DDR is a critical design parameter for training frameworks, and managing this boundary efficiently is one of the key challenges addressed by ZeRO (Zero Redundancy Optimizer) sharding and offloading strategies. Sharding divides optimizer, gradient, and parameter state across workers; offloading places colder state in host DRAM or Non-Volatile Memory Express (NVMe) when HBM capacity is the binding limit. Getting this boundary wrong in either direction is costly. Placing too much data in HBM wastes expensive capacity, while placing too much in DDR creates bandwidth stalls that idle the arithmetic units.

↪ Memory-efficient sharding of optimizer, gradient, and parameter state is developed in section 6.3.3.

Lighthouse 2.1: Archetype B (DLRM at Scale): The capacity wall



Archetype A (GPT-4/Llama-3) has so far exposed the bandwidth side of the memory wall. Archetype B (DLRM at Scale) exposes the capacity side, the boundary between fast and cheap memory just examined. An embedding table of 10 TB or more cannot fit into the 80 GB HBM of a single H100, nor can it fit into the aggregate HBM of a single 8-GPU node (640 GB nameplate, about 687 GB in decimal bytes). Capacity alone requires at least 15 such nodes before accounting for replication, hot-table headroom, and bandwidth balance. Sharding makes lookup routing and result exchange part of the request path. An AllToAll exchange sends distinct portions to different participants; its traffic depends on the batch and placement. Clearing the capacity limit therefore creates a second question about bandwidth and latency.

2.3.1.1 Energy cost of data movement

Data movement also dominates energy. At 3.97 pJ per bit, the HBM2 access energy that O'Connor et al. estimate (2017), reading one 16-bit operand costs about 64 pJ. One FP16 multiply-accumulate costs roughly 1.5 pJ at the 45 nm node (Horowitz 2014). The raw fetch therefore costs about 42× the arithmetic it feeds, until tiling and reuse spread it across many operations. From off-package DRAM at about 20 pJ per bit, the same fetch costs roughly 5× more again. That ratio is why accelerators devote so much silicon to reuse, and why the levers that cut bytes, such as quantization and fusion, improve power efficiency as well as speed. Section 5.2 extends the per-boundary accounting to collective communication, and section 15.4.2.3 turns these per-byte costs into an energy roofline.

2.3.1.2 HBM generations and the scaling boundary

HBM has grown alongside model sizes, but far more slowly than parameter counts, which is why capacity pressure keeps pushing models across devices. Each generation increases the number of stacked dies, the signaling rate per pin, and the total capacity per stack. The projected HBM4 generation in table 2.6 marks the scaling boundary, doubling the interface width from 1024 to 2048 bits for the first time since HBM's introduction, because pin-rate increases alone no longer sustain the required bandwidth growth. The wider bus also needs more interposer area for routing, one reason accelerator packages have grown as bandwidth targets rise.

Data movement dwarfs arithmetic in energy cost.

Table 2.6: Evolution of High-Bandwidth Memory: Each generation increases aggregate accelerator memory bandwidth, tracking the growth of large model sizes. The jump to HBM4 doubles the interface width for the first time since HBM's introduction, signaling that pin-rate increases alone can no longer sustain the required bandwidth growth.

Metric	HBM2e (A100)	HBM3 (H100)	HBM3e (B200)	HBM4 (future)
Peak bandwidth	~2.04 TB/s	~3.35 TB/s	~8 TB/s	12–16 TB/s (projected)
Typical capacity	40–80 GB	80–96 GB	180 GB	288 GB+
Interface width	1024-bit	1024-bit	1024-bit	2048-bit
Stack height	8 dies	8–12 dies	12 dies	16 dies

The generations in table 2.6 move both capacity and bandwidth for our running example, and the step to HBM3e matters most. Using decimal bytes consistently, an A100 with 85.9 GB of HBM2e holds 24.5 percent of our 175B model's FP16 weights. An H100 with 85.9 GB of HBM3 holds the same fraction while delivering the data 64 percent faster. A B200 with 193.3 GB of HBM3e raises the resident share to 55.2 percent at about 8 TB/s. Because even HBM3e leaves nearly half the

model outside a single package, multiple accelerators are still needed in a node (section 2.5).

Quantization changes the capacity story for inference. Storing weights in INT8 or INT4 halves or quarters the footprint, and section 2.8.1 works through how many accelerators the running model then needs. The capacity constraints that drive multi-accelerator nodes for training, where FP16 or BF16 precision is typically required, are substantially relaxed for inference, where INT8 or INT4 quantization is often acceptable, which is one reason training and inference infrastructure have different optimal configurations.

Aggregate package bandwidth scales with the number of HBM stacks that can sit beside the processor die on the silicon interposer. The H100 has 5 HBM3 stacks, each providing approximately 670 GB/s, for a total of 3.35 TB/s aggregate bandwidth. A B200-class Blackwell GPU package uses 8 HBM3e stacks for an aggregate of about 8 TB/s. The number of stacks is constrained by the interposer area available for HBM placement. Each HBM stack occupies approximately 100 mm^2 of interposer area, and the total interposer must accommodate both the processor die(s) and all HBM stacks. Larger interposers allow more HBM stacks (and therefore higher bandwidth and capacity) but are more expensive and harder to manufacture.

The interposer area constraint creates a concrete design tension. Making the processor die larger (more Tensor Cores, more SMs) leaves less interposer area for HBM stacks, potentially reducing bandwidth. Making the processor die smaller (fewer Tensor Cores) frees interposer area for more HBM but reduces peak compute throughput. The optimal balance depends on the target workload's position relative to the ridge point. Compute-bound workloads, whose arithmetic intensity sits above it, benefit from a larger processor die (more Tensor Cores). Bandwidth-bound workloads below it benefit from more HBM stacks, so a workload's arithmetic intensity predicts which side of the balance it falls on before any silicon is committed.

2.3.1.3 Memory bandwidth and token latency

Adding or upgrading HBM stacks raises both memory *capacity* (how many gigabytes the package can store) and memory *bandwidth* (how many terabytes per second it can deliver), which answer two separate procurement questions. Capacity determines whether a model's weights *fit*, with headroom for the remaining live state; bandwidth limits how fast the model can *run* when data movement sets the critical path. Dense autoregressive decode at batch size 1 isolates the second question because each weight serves only one token before the next weight load. The next three calculations step down from the running model to Llama-3 70B. Its FP16 weights span two H100s rather than the running model's five, and the H200 comparison that follows needs a model whose serving behavior a real memory upgrade can change; the arithmetic carries over to the 175B model by scaling the bytes.

Napkin Math 2.1: The physics of token latency

Problem: A weight-only model of batch-1 decode for Llama-3 70B uses 141.2 GB of FP16 weights. To isolate the two resource demands, assume hypothetical capacity sufficient to hold them while retaining one H100-equivalent compute rate and HBM path. Which term gives the larger time estimate: arithmetic or weight transfer?

1. **Compute time**: Each token requires $2 \times 70.6 \times 10^9 = 1.41 \times 10^{11}$ floating-point operations. At 989 TFLOP/s of FP16/BF16 Tensor Core peak throughput, the arithmetic takes $T_{\text{compute}} \approx$ **0.14** ms.
2. **Memory time**: Loading 141.2 GB of weights from HBM at 3.35 TB/s takes $T_{\text{memory}} \approx$ **42.1** ms.

Systems insight: The memory term accounts for 99.7 percent of the sum of these two idealized times. That ratio identifies a bandwidth-dominated estimate; it is not a measurement of cycles spent idle. Raising compute throughput alone barely changes this estimate. A faster memory path reduces the weight-transfer floor, while actual token latency also includes the other memory traffic, communication, and execution costs omitted here.

Holding that weight load fixed and changing only the memory system shows how directly each HBM generation moves the floor. For the same 70.6B FP16 model, with 141 GB of weights, the single-path streaming floor is roughly 141 GB/2.04 TB/s = 69.2 ms at A100-class bandwidth. At H100-class bandwidth (the notebook's memory term) it is 141 GB/3.35 TB/s = 42.1 ms, and at B200-class bandwidth it is 141 GB/8 TB/s = 17.7 ms. The floor falls nearly in proportion to each bandwidth gain. As in the notebook, each case isolates one accelerator-equivalent HBM path even though the full FP16 model does not fit on one A100 or H100. These bounds screen memory bandwidth against a latency target; whether token latency improves by the same ratio depends on the other work on the request's critical path.

The same floor at trillion-parameter scale shows the limit of bandwidth gains alone, even at the projected 12–16 TB/s of an HBM4-class package. A dense 1T-parameter model requires roughly 2 TB of FP16 weight storage. Streaming those weights through one B200-class path at about 8 TB/s gives 2000 GB/8 TB/s = 250 ms for one batch-1 weight load. At the assumed 16 TB/s, that floor becomes roughly 125 ms. Neither path has been shown to hold the full model, and even the faster floor limits a single path to about eight tokens per second for one request. A responsive trillion-parameter service must therefore split its weights across many memory paths, shrink them with reduced precision, or both; which combination depends on the latency target and the quality the reduced precision preserves. The cleanest test of how far a memory upgrade moves real latency compares two accelerators that differ only in their memory system.

Napkin Math 2.2: The memory wall: H100 vs. H200

Comparing the NVIDIA H100 against the H200 isolates a memory-system upgrade for large language models (LLMs). While both chips share the same compute cores (same peak TFLOP/s), the H200 provides 1.4× higher memory bandwidth and 1.8× more HBM capacity.

This comparison uses a Llama 3 model with 70.6B parameters, sequence length 2,048, and batch size 1. Both cases retain FP16 weights and the hypothetical capacity convention of notebook 2.1: each streams the complete payload through one accelerator-equivalent HBM path, even though it cannot fit on one H100. The comparison isolates path latency rather than establishing two feasible single-device deployments.

The reported speedup comes from a serving-latency model whose inter-token latency adds two terms to the weight-streaming time, the key-value cache reads for the request's context and a fixed per-layer kernel-launch overhead, so it is not a raw bandwidth ratio alone. The weight-only estimate provides a comparison. Its memory term accounts for 99.7 percent of the summed compute and transfer times, so reducing that term suggests a gain near the HBM bandwidth ratio, 4.8 TB/s ÷ 3.35 TB/s ≈ 1.4×.

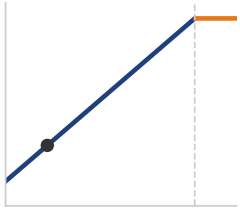
Systems insight: For the modeled configuration, the latency model predicts an H200 speedup of 1.4× over the H100 despite equal peak arithmetic throughput. Its agreement with the bandwidth ratio supports the memory-bound diagnosis for this case. Changing batch size, context length, or partitioning requires evaluating the new configuration; the estimate does not establish one bottleneck for all autoregressive models.

The modeled memory-time share, 99.7 percent in this example, indicates the memory-boundedness of this workload under the stated assumptions. A workload this memory-bound gains almost nothing from more TFLOP/s and nearly proportionally from more TB/s, which is what the H200 comparison shows, so bandwidth per dollar rather than peak arithmetic is the useful procurement metric for this regime. A measured execution timeline is still needed to determine how much transfer overlaps computation and which delays remain exposed, which keeps a hardware-screening calculation separate from a performance forecast. For training workloads, reusing weights across more tokens can instead shift the constraint toward arithmetic throughput; the Roofline Model tests the compute and bandwidth ceilings for the actual operation and batch shape before either specification becomes a procurement metric.

2.3.2 Roofline model

The token latency calculation in notebook 2.1 makes memory bandwidth the relevant procurement metric for the batch-1 workload. The Roofline Model of Williams, Waterman, and Patterson (Williams et al. 2009) tests whether that diagnosis survives a change in batch shape, precision, or accelerator by relating

the workload's arithmetic intensity to the candidate accelerator's compute and bandwidth ceilings.



For an H100 (989 TFLOP/s FP16, 3.35 TB/s HBM), the ridge point is about 295 FLOP/byte. Most LLM inference operators fall well below this threshold, which is why the roofline remains the first diagnostic tool for identifying whether more compute or more bandwidth will improve performance. The quantity that places a workload on the plot is the arithmetic intensity introduced with tiling above, written I in FLOP/byte.

As the single-machine recap in section A.3.1 derives, the Roofline Model expresses the maximum achievable performance of a workload as the lesser of two ceilings:

$$\text{Achievable FLOP/s} = \min\left(R_{\text{peak}},\ \text{BW} \times I\right) \tag{2.1}$$

In equation 2.1, below the ridge point the sloped bandwidth ceiling, which grows with I, is the lower one; above it the flat compute roof binds, and a measured kernel can sit below either.

↪ Placing measured kernels on the roofline by arithmetic intensity is developed in section 9.6.3.

Decode sits deep in the memory-bound regime, far below the ridge.

Definition 2.3: Ridge point

Ridge point is the ML accelerator arithmetic intensity where the memory bandwidth ceiling meets the compute ceiling ($I_{\text{ridge}} = \frac{R_{\text{peak}}}{\text{BW}}$).

1. **Significance**: It is the accelerator's efficiency threshold. Below the ridge point, bandwidth supplies the lower modeled ceiling (BW); above it, arithmetic supplies the lower ceiling (R_{peak}).
2. **Distinction**: Unlike peak FLOP/s, which describes only the horizontal ceiling, the ridge point describes the balance between arithmetic and memory delivery in the architecture. A rising ridge point over hardware generations indicates that compute is growing faster than bandwidth, making utilization harder.
3. **Common pitfall**: A frequent misconception is that an accelerator has a single ridge point. In reality, it varies by precision: because R_{peak} is higher for INT8 than FP32 while BW is constant, the ridge point for INT8 is much higher, requiring more data reuse to saturate the hardware.

Machine learning workloads land in different regions of the roofline plot depending on the operation and the batch configuration, not on the model family. Single-request autoregressive decode streams the full weight tensor (two bytes per parameter in FP16) from HBM to perform two floating-point operations per parameter, an arithmetic intensity of about 1 FLOP/byte, far below the H100's ridge point of 295 FLOP/byte. The token-latency calculation in notebook 2.1 showed that the arithmetic finishes in microseconds while the weight movement takes milliseconds. Every other regime in table 2.7 comes from reusing each byte fetched from HBM across more operations. Decode also reads the key-value (KV) cache,

the stored attention keys and values of earlier tokens, and because each request has its own cache, batching does not amortize that traffic.

Table 2.7: Roofline Placement by Workload Phase: Language-model intensities count only weight traffic at the HBM level, the same idealization used for figure 2.8, against an H100 FP16 ridge point of 295 FLOP/byte; the convolution value is a representative scenario figure rather than a derived count. Attention is not plotted in the figure because its placement depends on shape. Measured placement must also count activation, key-value cache, and optimizer traffic.

Workload phase	Source of reuse	Idealized intensity	What moves it
Decode, batch 1	None; each weight serves one token	1 FLOP/byte	Batching requests, lower-precision weights
Decode, batch 32	Each weight read serves every request in the batch	32 FLOP/byte	Batch size, until key-value cache traffic dominates
Prefill, 512-token prompt	Each weight read serves every prompt token	512 FLOP/byte	Prompt length and batch size
Convolution training (ResNet-50)	Filters reused across spatial positions and the batch	200 FLOP/byte	Channel depth, tensor layout, operator fusion
LLM training, 2048 local tokens	Each weight read serves every token on the device	2,048 FLOP/byte	Local microbatch size and sequence length
Attention	Keys and values reused across queries	Shape-dependent, on either side of the ridge	Sequence length, head dimension, SRAM tiling

The table's intensities are idealized reuse counts that classify an execution phase and batch shape, not a model family, and tensor layout, fusion, precision, and cache residency move the measured point. Which kernel-level change then helps, more reuse and fewer bytes below the ridge or a cheaper operation above it, is a diagnosis that section 9.6.3 develops.

A measured workload point below its roofline ceiling needs further diagnosis. Dependencies, insufficient parallel work, irregular accesses, synchronization, and power limits can all prevent a kernel from approaching that ceiling. The gap identifies a question for profiling; it does not establish that software optimization can recover the entire difference.

Whole phases spread even wider than individual operators. The idealized intensities of decode and training differ by 2,048×, which is why the same hardware shows widely different utilization across them. Batch-1 decode sits near 1 FLOP/byte, far left of the ridge and deeply bound by memory bandwidth, while large-batch training near 2,048 FLOP/byte crosses the ridge and reaches the compute roof (figure 2.8). The training point assumes that 2048 tokens on

one accelerator share each weight read, the local reuse that a large global batch alone does not guarantee, so it counts tokens rather than sequences and local rather than global batch. It is a contrast case, not a universal intensity for training. Actual placement requires counting bytes at the memory level being modeled and accounting for tensor shapes, fusion, and reuse.

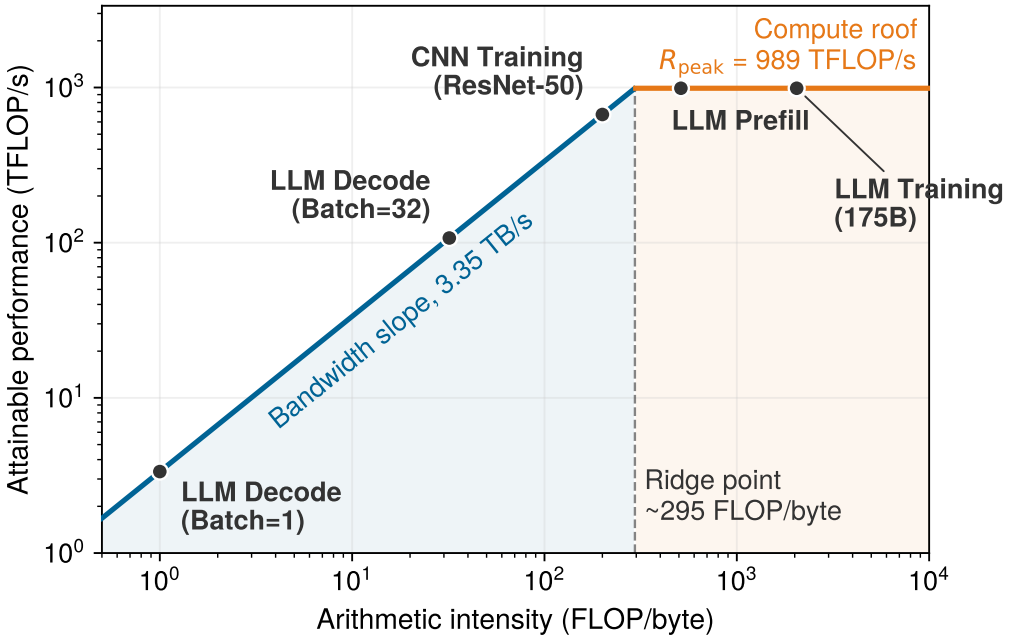


Figure 2.8: The H100 Roofline Landscape: Attainable FP16 throughput is the lower of two ceilings, the memory-bandwidth slope (blue) and the compute roof (orange), which meet at the dashed ridge point. Each dot places a representative workload by its arithmetic intensity; workloads left of the ridge stay capped by bandwidth however much compute the chip offers, and only those to its right can approach peak throughput.

The table's batching rows can be turned into a utilization bound. For inference serving, batching multiple requests together moves the workload point rightward on the plot, because each weight read is multiplied against more activations. Under the weight-traffic-only bound, batch-1 decode on an H100 can use at most 0.34 percent of the FP16 peak. At batch size 64, each weight read from HBM serves every request in the batch, the intensity rises to 64 FLOP/byte, and the bound climbs to about 22 percent of peak, a 64× gain that still leaves the workload below the ridge. The linear growth holds only in this approximation; key-value cache traffic, which batching does not amortize, activation traffic, and capacity limits lower both figures in practice. The gain has a cost. Waiting to assemble a batch can introduce queuing latency, although a serving policy can instead dispatch a smaller batch when a latency deadline approaches. Serving systems must carefully balance this trade-off between throughput (larger batches, higher utilization) and latency (smaller batches, faster response per request).

For fleet procurement, the roofline is a screening test rather than a throughput forecast. It rules out upgrades that raise a nonbinding ceiling, while the gap below the relevant ceiling identifies work still needed in software or communication. Col-

lected into a single procurement comparison for the running model, the two ends of the landscape give opposite hardware answers, and that diagnostic becomes most valuable when a proposed upgrade changes the wrong ceiling. Memory capacity and bandwidth therefore screen out infeasible accelerator choices, while for the candidates that remain, fleet sizing also needs a sustained compute rate at a precision the workload can use, within the node's memory budget, the interconnect, and the facility power envelope.

Example 2.2: Roofline analysis: Training vs. inference

Scenario: An engineering team evaluates hardware choices for serving (decode batch size 1) vs. training (batch size 2048) a 175B parameter model on an H100 GPU (ridge point 295.2 FLOP/byte).

Diagnosis: The weight-traffic model gives single-token decode arithmetic intensity $I = 1$ FLOP/byte $\ll$ 295.2 FLOP/byte, bounding throughput to 0.34 percent of the selected peak FLOP/s. The assumed training reuse raises intensity to $I = 2{,}048$ FLOP/byte $\gg$ 295.2 FLOP/byte, making arithmetic the lower roofline ceiling. This placement identifies the relevant bound without establishing achieved throughput.

Systems lesson: Hardware selection starts with the phase's arithmetic intensity and memory footprint. The modeled training phase benefits from arithmetic capacity, while batch-1 decode benefits from bandwidth. Sustained throughput at the required quality and latency determines whether either advantage justifies its cost.

Checkpoint 2.2: Roofline diagnosis

A team is serving a 13B-parameter model at batch size 1 on an H100 and observing 25 ms per token. The profile shows low tensor-core utilization during decode.

- ☐ **Arithmetic intensity**: estimate the arithmetic intensity of the workload.
- ☐ **Peak-throughput upgrade**: explain what the roofline estimate can establish about a higher peak-TFLOP/s accelerator and what requires measured execution.
- ☐ **Binding constraint**: identify the profile measurements needed to distinguish exposed HBM transfers from communication, launch overhead, or insufficient parallel work before selecting an improvement.

2.4 Sustained Compute and Precision

A fleet sized from advertised matrix throughput can miss its training deadline when operations cannot use the advertised precision or keep the matrix units of

section 2.2.5 busy. The relevant hardware contract includes both the eligible matrix operations and their sustained contribution to the complete workload.

Tensor Core precision support widened with each generation traced in section 2.2.3, from FP16 on Volta to FP8 on Hopper, because neural network training and inference tolerate lower numerical precision than was once assumed. Transformer Engine recipes and FP8 autocast decide which supported operations run in FP8, recording tensor ranges and applying scale factors so values fit the format, but they do not establish that a layer is numerically safe at that precision. Precision policy therefore remains a software configuration and validation decision, which section 6.4.8 develops for training.

The relationship between numerical precision and hardware throughput matters for infrastructure planning because it directly affects how much useful work each accelerator can perform per second. Lower precision representations use fewer bits per number, which has two compounding benefits: more numbers fit in the same HBM capacity (reducing memory pressure), and the arithmetic units can process more operations per cycle (increasing throughput). Each format an H100-class accelerator supports unlocks a different dense peak rate and plays a usual role in training or inference (table 2.8).

Table 2.8: Precision Formats and Hardware Throughput on H100: The table uses dense peak throughput where Tensor Core support exists; structured sparsity can roughly double several of these advertised peaks. The choice of precision affects both the training dynamics (convergence, numerical stability) and the infrastructure requirements (memory capacity, bandwidth utilization). TF32 preserves the FP32 exponent width but reduces mantissa precision so Tensor Cores can accelerate common FP32 training workloads.

Format	Bits	Exponent	Mantissa	H100 dense peak	Typical use
FP32	32	8	23	~67 TFLOP/s	Master weights, loss computation
TF32	19	8	10	494.5 TFLOP/s	Training (NVIDIA default)
BF16	16	8	7	989 TFLOP/s	Training, fine-tuning
FP16	16	5	10	989 TFLOP/s	Training with loss scaling
FP8 (E4M3)	8	4	3	1,979 TFLOP/s	Forward pass, weights
FP8 (E5M2)	8	5	2	1,979 TFLOP/s	Backward pass, gradients
INT8	8	N/A	N/A	1,979 TOPS	Post-training quantization

For training, many workloads use the standard mixed-precision recipe, which decouples storage from arithmetic precision by keeping FP32 master weights while the forward and backward passes run in BF16 or FP16 at full Tensor Core

throughput. The node memory examples in section 2.5.3 assume retained FP16 gradients; implementations that retain a full FP32 accumulation buffer must add that buffer to their peak budget. The FP8 recipes described earlier extend the same decoupling one step further, running eligible matrix operations in eight bits while the master weights stay in FP32.

↪ The byte widths of each format and the per-parameter memory of mixed-precision training are collected for reference in section A.6.

The practical implication for fleet design is that peak TFLOP/s specifications are precision-dependent. The H100 delivers 989 TFLOP/s in FP16 but twice that (1,979 TFLOP/s) in FP8. FP8 therefore doubles the advertised arithmetic ceiling for supported operations on the same hardware. The complete training run gains less when communication, memory traffic, or higher-precision operations remain on the critical path. Precision engineering is therefore a primary optimization lever for infrastructure planners, alongside its effect on model accuracy.

Approaching peak throughput requires pipeline balance. Operand staging and reuse must supply the arithmetic units at the rate the operation requires. Kernel fusion and tiled attention such as FlashAttention improve that balance by keeping intermediate values on chip instead of making separate HBM round-trips, mechanisms that section A.5 collects for reference. For our 175B model, the fleet-level gain depends on how much step time the affected kernels consume. A faster attention kernel shortens the step only in proportion to attention's share of it, the same Amdahl accounting that bounds every partial speedup.

2.4.1 Peak vs. sustained throughput

A training run budgeted for 1,000 GPU-hours from datasheet TFLOP/s will consume 2,500 GPU-hours in practice when the workload sustains only 40 percent of peak throughput. Infrastructure planning therefore separates *peak* throughput (the maximum rate for the vendor-specified operation and precision) from *sustained* throughput (what the complete workload delivers). Peak TFLOP/s assumes that eligible arithmetic units remain fed under the stated sparsity, precision, and clock conditions; it does not include memory stalls, ineligible operations, communication, or software overhead. Sustained fractions therefore vary with model shape, batch size, precision, implementation, and scale. The gap arises from several sources, each representing a different physical or software limitation.

Memory stalls occur when the Tensor Cores complete their current tile multiplication before the next tile has been loaded from HBM. Even with the H100's 3.35 TB/s HBM bandwidth, the Tensor Cores can consume data faster than HBM can deliver it for certain matrix dimensions, creating idle cycles while the arithmetic units wait for data.

Dependency stalls arise when one operation must complete before the next can begin, leaving some processing elements idle. In a Transformer layer, the attention computation must complete before the feed-forward network can begin, and the feed-forward computation must complete before the next layer's attention can start. These sequential dependencies create brief periods where some hardware resources are unused, even within one accelerator. When the model is split into sequential stages on different accelerators (pipeline parallelism), the same dependencies become pipeline bubbles, idle slots in which a whole stage waits for its

predecessor. Splitting each batch into microbatches reduces the waste by feeding later microbatches into stages that would otherwise wait. The term pipeline bubble refers only to this cross-device case, whose scheduling chapter 6 develops. At the infrastructure level, the lesson is that peak throughput assumes every unit stays busy, while real training includes dependency gaps that lower sustained utilization.

AllReduce operations used in tensor parallelism and gradient synchronization used in data parallelism can likewise delay computations that depend on their results; even when communication overlaps computation on separate streams, operations that depend on the collective output cannot proceed until the transfer completes. Kernel submission, memory allocation, and framework control also consume time, and when each kernel completes in microseconds, launch overhead of a similar size becomes a comparable share of the step that only a host-and-device execution trace can separate from slow arithmetic or memory access. Achieving high sustained utilization is therefore largely a matter of minimizing the time Tensor Cores spend idle between operations, which is why kernel fusion and specialized kernel libraries such as FlashAttention and the Transformer Engine exist.

The last source of the gap is the device itself, and no kernel change removes it. Device variation, sometimes called the silicon lottery, means that nominally identical accelerators sustain different clocks. Clock behavior also depends on the configured power limit, temperature, and workload, so a slow participant should not be diagnosed from its product label or frequency alone. In synchronous training, a participant that finishes dependent work late delays its whole process group. One device sustaining a clock about 2.5 percent below its peers can slow every synchronous step it joins by up to that fraction, because the other participants wait for it at each collective. Fleet management systems therefore track per-device sustained throughput and can move persistent underperformers to pools, such as inference serving, where they do not gate a synchronized group. Profiling must determine whether local arithmetic, memory, communication, or a power limit caused that delay before changing placement or replacing hardware.

Capacity planning must use a measured or conservatively modeled sustained rate, not the peak specification. A run estimated at 1,000 GPU-hours from peak FLOP/s requires $1/\eta_{\text{hw}}$ times that estimate when its measured utilization fraction is η_{hw}. Infrastructure teams track model FLOPs utilization (MFU), the useful model computation per second divided by the selected hardware peak, as the standard measure of η_{hw}, but comparisons remain meaningful only when model-FLOP conventions, precision, hardware peak, and system scale match.

The accelerator's physics establish a concrete problem. Our 175B model requires 350 GB of memory for its weights alone in FP16, and Adam-style training state raises the requirement to multiple terabytes once optimizer moments, gradients, and activations are included. A single H100 provides 80 GB of HBM. No single accelerator can hold this model, an instance of the memory capacity gap (principle

↪ MFU as the measure of program goodput, one factor of fleet-level ML goodput, is developed in section 9.2.2.

2), in which frontier memory requirements outgrow single-accelerator HBM. The system must expand to the next physical level: the node.

2.5 The Node

The running model needs more memory than one accelerator provides. A node supplies several accelerators in one chassis, but each retains its own memory; dividing the work creates communication that the local fabric must sustain. Tensor parallelism divides an operation across accelerators, pipeline parallelism assigns successive model stages to different groups, and data parallelism assigns different training examples to model replicas whose updates must be combined. These strategies impose different traffic patterns, and the node's internal fabric decides which of them it can carry at the speed the partition needs.

Aggregating accelerators solves the capacity problem only if the interconnect between them is fast enough that the group behaves as one machine rather than as several machines passing messages. The 175B model's weights span at least five accelerators, and the full training state spans an entire 8-H100 node and more, so some model state must live on different chips. Depending on the partition, execution exchanges partial results, activations, gradients, or parameter shards. Whether those exchanges are cheap or ruinous depends on the local fabric, which is why the node is the first scale level where the accelerator's specifications matter less than the wires between accelerators. The training system can combine tensor parallelism, optimizer sharding, and memory offload as needed to meet its capacity budget, and each strategy places a different demand on the interconnect.

Definition 2.4: Node

Node is the ML training cluster's physical server chassis that aggregates multiple accelerators (typically 8) through a high-speed intra-node interconnect (NVLink or ICI), providing a physical packaging and failure boundary. The fast communication domain can coincide with one chassis or extend across several, depending on the fabric.

1. **Significance**: The NVLink bandwidth within a DGX H100 node reaches 900 GB/s bidirectional, or 450 GB/s per direction, while inter-node InfiniBand NDR provides 50 GB/s, a 9× per-direction gap that constrains where each parallelism strategy can run. For this DGX H100 topology, frequent tensor-parallel collectives favor the intra-node NVLink domain; pipeline parallelism can span nodes when the network sustains stage-boundary activation traffic. The node is also the primary failure domain: a single node failure in a bulk synchronous parallel training job, where workers advance in lockstep at step barriers, idles the entire cluster until recovery.
2. **Distinction**: Unlike a single accelerator (which provides fast HBM bandwidth but limited capacity), a node aggregates 8× the HBM capacity and 8× the compute of a single chip. That is enough to place large FP16

weight shards (8 × 80 GB = 640 GB on DGX H100), but not enough to keep the full Adam training state in HBM.

3. **Common pitfall**: A frequent misconception is that nodes in a distributed training job operate independently. In bulk synchronous parallel training, all nodes are synchronously coupled at every step barrier: a performance degradation on one node (from thermal throttling, a faulty NIC, or a slow storage read) stalls the entire cluster and drops overall MFU for the duration of that step.

Why not hold the overflow in host DRAM instead of wiring eight accelerators together? A server's DDR5 channels supply ample capacity (512 GB to 2 TB per node) at a fraction of HBM's cost, but their bandwidth is orders of magnitude too slow to feed Tensor Cores on the active forward and backward path. Pooling the HBM of eight accelerators inside one chassis keeps the active working set in high-bandwidth memory, with the crucial caveat that each accelerator's HBM remains private to its own package. Software must shard or replicate tensors explicitly and invoke collectives or peer-to-peer transfers whenever an operation crosses device boundaries, so an eight-GPU node delivers 8× aggregate capacity and 8× aggregate compute without ever behaving like a single shared-memory processor.

The capacity arithmetic also explains the appeal of multiple packages. Holding a 175B model's 350 GB of FP16 weights on one accelerator, at the example 17–24 GB per HBM stack, would require 350 GB spread across roughly 15–21 stacks. That exceeds the 5-stack H100 and 8-stack B200-class configurations used here. Such a package would need its own area, yield, power, and cooling analysis. Distributing capacity across 8 accelerators instead uses available packages and pays for communication between their private memories.

2.5.1 Bandwidth hierarchy

Placing a layer-by-layer tensor-parallel collective across a 50 GB/s inter-node link instead of a 450 GB/s intra-node link multiplies its transfer floor ninefold and stalls every accelerator in the group. Multi-accelerator systems are governed less by the *number of chips* than by the *speed at which they can exchange data* across physical boundaries. Data movement speed drops by orders of magnitude as it crosses package, board, and rack boundaries, each with a different physical medium, connector technology, and signaling constraint. This physical ordering of data transfer rates, from on-chip SRAM at the fast end to the wide-area network at the slow end, is the bandwidth hierarchy; this ordering dictates where in the hierarchy each type of parallelism can operate efficiently.

The hierarchy reflects the physical cost of distance. Shorter signal paths over denser wiring achieve higher throughput at lower energy per bit, so at each boundary the effective bandwidth (BW) drops by roughly an order of magnitude while latency (L_{lat}) rises. The exact size of each gap depends on link count, signaling, and the measurement boundary, but the gradient itself sets a scaling ceiling for

distributed training. The common mistake is to treat all cluster communication as equal. Parallelism placement must be hierarchy-aware, because putting high-frequency synchronization such as tensor parallelism on a slow tier leaves the arithmetic units (R_{peak}) waiting and collapses scaling efficiency (η_{scaling}).

The bandwidth hierarchy can be read as concentric zones around each accelerator (figure 2.9), losing 7.4× to 9× of bandwidth at each physical boundary on the way out through NVLink, InfiniBand, and remote storage. The innermost zone is the HBM on the same package, with terabytes per second of bandwidth and sub-microsecond access latency. The next zone holds the other accelerators in the node's NVLink domain, reachable at hundreds of gigabytes per second per GPU with microsecond-scale transfer latency. The outermost zone spans the other nodes in the cluster, reached through InfiniBand ports that each supply tens of gigabytes per second per direction, with point-to-point latency measured in single-digit microseconds. Latency figures are comparable only when they measure the same thing (a memory access, a link transfer, or a complete collective), and bandwidth ratios only when they compare matching endpoints and directions, as the representative paths of table 2.9 do.

Table 2.9: The Bandwidth Hierarchy: These representative paths have different bandwidth budgets. Link bandwidths are per direction; link count, signaling, and system configuration determine the gap between tiers. These example bandwidth gaps favor placing frequent tensor-parallel collectives within the fast communication domain, which need not coincide with a server boundary.

Domain	Inter-connect	Bandwidth	Latency	Scaling limit
Intra-package	Silicon inter-poser	~3.35 TB/s	$<$ 100 ns	Single chip
Intra-node	NVLink/ICI	~450 GB/s	~0.5 µs	Node (8–16 chips)
Intra-node (I/O)	PCIe Gen5 x16	~64 GB/s	~1 µs	CPU-GPU, NIC-GPU
Inter-node	Infini-Band NDR	~50 GB/s	~5 µs	Pod (thou-sands)

Napkin Math 2.3: The physics of the staircase

Problem: A 10 GB buffer must move one hop at each tier of the hierarchy, with a local HBM read as the reference point. How much does the tier it crosses change the transfer time?

Math: Transfer time is $T_{\text{transfer}} = D_{\text{vol}}/\text{BW}$.

1. **HBM (local read, the reference point)**: 10 GB / 3,350 GB/s ≈ 3.0 ms.

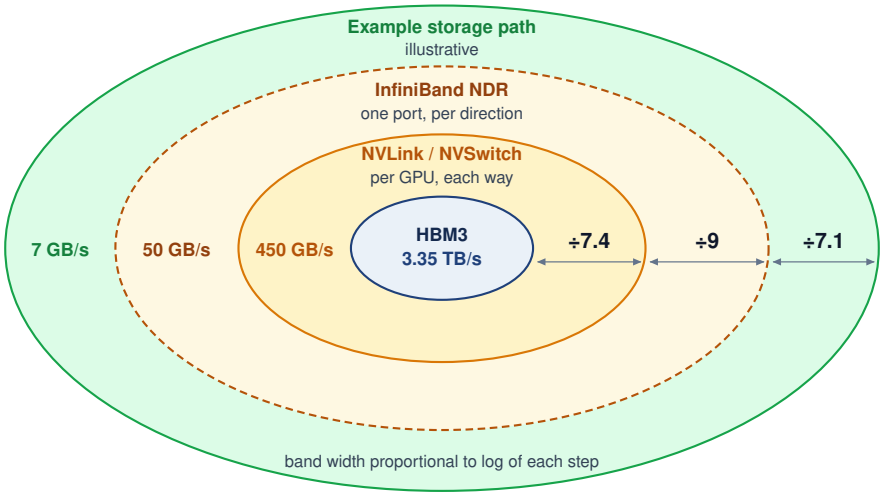

Figure 2.9: The Infrastructure Bandwidth Hierarchy: Concentric zones place each tier an ML workload crosses farther from the accelerator's own memory. HBM (3.35 TB/s) sits at the center; the outward tiers are NVLink/NVSwitch (450 GB/s per direction per GPU), one InfiniBand NDR port (50 GB/s per direction), and an illustrative 7 GB/s storage path. Each step outward cuts bandwidth by roughly 7.4, 9, and 7.1 times, not by a universal tenfold law. Exploiting this hierarchy through tiered algorithms is the primary task of distributed systems engineering.

2. **NVLink (intra-node)**: 10 GB / 450 GB/s $\approx$ 22.2 ms.
3. **InfiniBand (inter-node)**: 10 GB / 50 GB/s $\approx$ 200 ms.

Systems insight: For the same payload, the example inter-node path has a transfer-time lower bound 9× larger than the example intra-node path. Size alone does not decide which traffic may cross that cliff; frequency and overlap do. Tensor parallelism exchanges activations inside every layer, on the critical path, so it favors the fast local NVLink domain in this configuration. Data parallelism moves the largest buffer, the full gradient, but only once per step and overlapped with the backward pass, so it can cross the scarce InfiniBand tier. A partition that fits in memory can still spend much of a step waiting if its exposed exchanges exceed the communication budget.

Each cliff in the bandwidth staircase has a physical cause at its distance scale. Millimeter-long traces on a silicon interposer can carry a wide, slow-clocked parallel interface without serializer/deserializer (SerDes) transceivers. NVLink crosses tens of centimeters of board copper, which requires SerDes transceivers with equalization to recover the signal at high per-lane rates. PCIe pays for universal compatibility with protocol overhead (packet headers, flow-control credits, and error checking). InfiniBand crosses meters of cable between racks, adding optical conversion on longer runs, forward error correction, and switch hops. Section 3.3.3 develops the signaling physics behind these cliffs. For node design, link count and sustained bandwidth must be evaluated together with the power and cooling load of the components that provide them.

The practical consequence for model partitioning is that tensor parallelism (TP), which splits individual matrix multiplications across accelerators and requires collective exchanges within layers, generates communication volume proportional to the model's hidden dimension hundreds of times per second. Over NVLink, each of these exchanges takes under a millisecond for the running model (section 2.5.2 computes the idealized lower bound). At the reference InfiniBand port rate, the bandwidth-only lower bound for the same exchange is 9× as large; the step-time effect also depends on startup, routing, and overlap. For this topology TP therefore stays within a node, although a system whose fast scale-up fabric spans several chassis can place a tensor-parallel group across them; communication cost, rather than the server enclosure, determines the useful partition.

The hierarchy also explains why pipeline parallelism occupies an intermediate position in the bandwidth requirements. In pipeline parallelism, the model is divided into sequential stages, with each stage assigned to a different group of accelerators. The communication between stages consists of activations flowing forward during the forward pass and gradients flowing backward during the backward pass, with a volume proportional to the batch size times the hidden dimension.

For our 175B model with hidden dimension 12,288 and a microbatch of 4 sequences at 2,048, the activation tensor at each stage boundary is approximately $4 \times 2,048 \times 12,288 \times 2B$ bytes (FP16) $\approx$ 201 MB. This is far smaller than the 350 GB gradient AllReduce required by data parallelism, which is why pipeline parallelism places less demanding requirements on the inter-node network.

Activation transfers occur once per microbatch per stage boundary. That is far less often than tensor parallelism's AllReduce inside every layer, yet more often than data parallelism's gradient exchange, which happens once per step. Small messages at an intermediate frequency let pipeline parallelism tolerate the lower bandwidth of inter-node links, which makes it the natural way to split a model whose layers do not fit in one node.

Both pipeline and data parallelism therefore cross node boundaries, for different reasons (table 2.10). Pipeline traffic is small per message and sits between the other two in frequency. The data-parallel gradient exchange is the largest transfer, but it occurs once per step and can overlap the backward pass. That overlap makes it the most latency-tolerant of the three, although any unfinished exchange still delays the update. For the example topology, the resulting mapping places tensor parallelism within the node, pipeline stages across nodes, and data-parallel groups across the cluster. This *de facto* pattern is a starting point for the capacity and timing calculation; a different scale-up domain, message size, or overlap opportunity can justify a different placement.

Table 2.10: Traffic Shape by Parallelism Strategy: The placement rule follows from size and frequency together. Frequent exchanges on the critical path need the fastest tier, while the largest exchange can cross the slowest tier because it happens once per step and overlaps the backward pass.

Strategy	Size per exchange	Frequency	Overlap with computation	Placement on this topology
Tensor parallelism	Activation-sized partial results	Inside every layer, forward and backward	Little; later operations depend on the result	Within the NVLink domain
Pipeline parallelism	One microbatch's activations at a stage boundary	Once per microbatch per boundary	Partial, through microbatch scheduling	Across nodes, adjacent stages close together
Data parallelism	The full gradient	Once per step	Substantial, during the backward pass	Across the cluster

The mapping constrains how the scheduler assigns devices and nodes. Members of a tensor-parallel group belong inside one fast domain (on this topology, one chassis joined by NVLink), because their dependent exchanges recur inside every layer. Adjacent pipeline stages belong in the same rack or neighboring racks, where their activation and gradient traffic crosses the fewest InfiniBand switch hops. Data-parallel groups can span the whole cluster. Physical adjacency helps only when it corresponds to better connectivity. The node's PCIe hierarchy adds another placement constraint by connecting accelerators to host CPUs, network interface cards (NICs), and storage, including the path used to reach host DRAM.

2.5.1.1 The PCIe hierarchy within a node

While NVLink carries GPU-to-GPU traffic, PCIe Gen5 connects accelerators, host CPUs, network adapters, and storage through the node's peripheral hierarchy. Host DRAM attaches to the CPU's memory controllers; a GPU transfer to that memory also traverses its host-facing PCIe path. PCIe bandwidth, approximately 64 GB/s per direction (128 GB/s bidirectional) per x16 link, can therefore constrain data loading, checkpointing, or GPU-to-network transfers. Which traffic competes depends on the actual links and switches those paths share.

A standard DGX H100 node features two host CPUs, each managing a PCIe root complex, and PCIe switches fan those lanes out. Each of the 8 GPUs and each of the 8 InfiniBand host channel adapters (HCAs, the network interface cards of an InfiniBand fabric) has its own x16 link (figure 2.10). This configuration provides an aggregate theoretical bandwidth of about 2 TB/s within the chassis. However, this bandwidth is shared among competing traffic streams. During a single training step, the PCIe bus simultaneously carries host-to-GPU data batches, GPU-to-HCA gradient shards for inter-node AllReduce (via GPUDirect remote direct memory access (RDMA)), and periodic CPU-to-NVMe checkpoint writes. Contention between these streams can cause unexpected pipeline stalls, particularly when gradient synchronization saturates the links typically used for data loading.

The dual-CPU architecture introduces significant non-uniform memory access (NUMA) effects. The 8 GPUs are physically partitioned, with 4 connected to CPU

0's root complex and 4 to CPU 1's. A GPU connected to CPU 0 can reach CPU 0's DRAM through its local PCIe root complex, whereas access to CPU 1's DRAM also traverses the inter-socket link. The latency and bandwidth penalty depends on the processor, socket interconnect, PCIe topology, transfer size, and concurrent traffic, so no fixed percentage applies across nodes. Data-loading pipelines should measure this topology and place worker processes, pinned buffers, NICs, and target GPUs within the same NUMA domain when the local path improves sustained ingestion. Placement is therefore part of the parallelism strategy, because a scheduler that ignores PCIe roots, NIC locality, and NUMA domains can turn an otherwise valid tensor- or pipeline-parallel plan into a host-bound bottleneck.

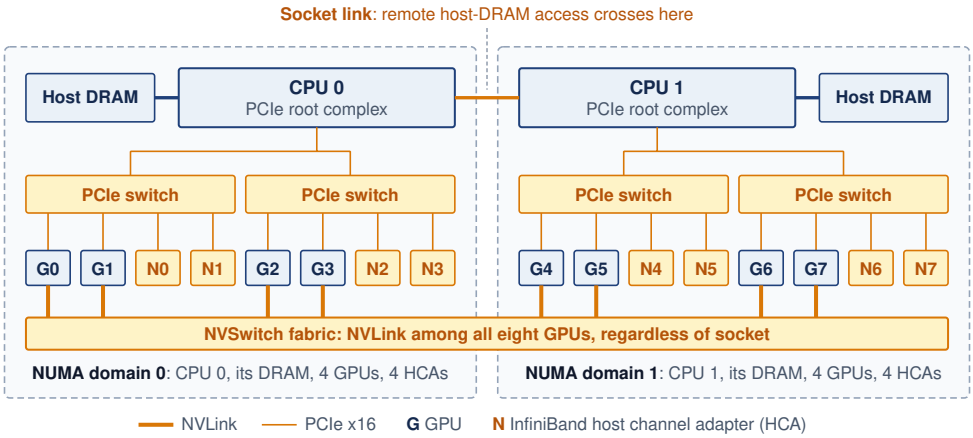

Figure 2.10: Two Fabrics inside One Eight-GPU Node: NVSwitch joins all eight GPUs for GPU-to-GPU traffic, but every path to host memory, storage, or the network runs through a PCIe tree rooted at one of two CPU sockets. A GPU, its InfiniBand host channel adapter (HCA), and the host DRAM it reaches most cheaply therefore sit in one non-uniform memory access (NUMA) domain, and a transfer to the other socket's DRAM also crosses the socket link. The two PCIe switches per socket are schematic; switch count and lane routing vary by server design.

↪ Mapping data, tensor, and pipeline parallelism onto intra-node and inter-node bandwidth tiers is developed in section 6.6.

2.5.2 Dense node designs

Given the bandwidth hierarchy, the node must connect 8 accelerators with enough bandwidth for tensor-parallel operations across their private memories. A switched fabric can provide full bisection bandwidth, enough capacity across any equal division of the endpoints to carry their full injection rate. Comparing a ring, a mesh, and a switched design shows what connectivity costs and which communication patterns it supports.

Eight GPUs in one chassis can be wired as a ring, a full mesh, or a switched fabric (figure 2.11). A ring is inexpensive, needing only G_{node} links for G_{node} GPUs, and suits ring-AllReduce, in which each GPU sends to one neighbor while receiving from the other so that every link stays busy. Tensor parallelism, however, issues frequent collectives after sharded matrix operations. These include ReduceScatter, which leaves each participant with one shard of a combined result, and AllGather, which assembles shards at every participant. A ring's fixed multi-hop paths (up to four hops between distant GPUs) constrain those patterns. A full mesh reaches

every peer in one hop but needs $G_{\text{node}}(G_{\text{node}}-1)/2 = 28$ links for 8 GPUs, a count that grows quadratically and soon becomes impractical to route. The NVSwitch crossbar puts every pair one switch hop apart and provides full-bisection switched connectivity with a manageable number of switch chips.

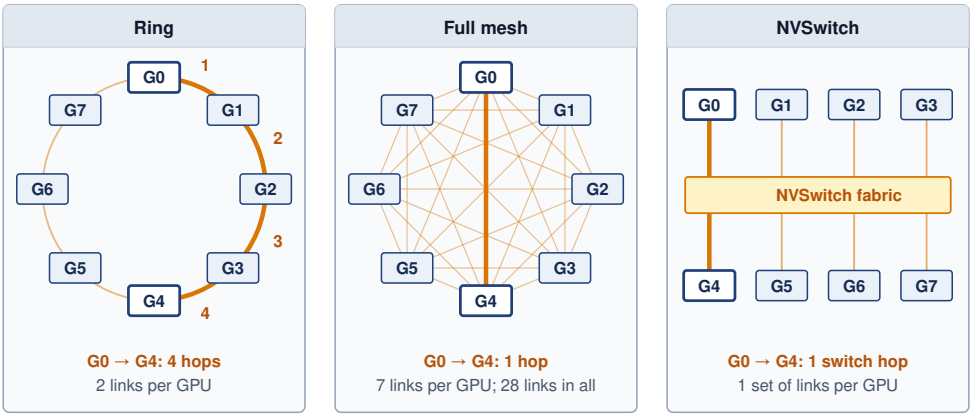

Figure 2.11: Intra-node GPU Topology Comparison: Three ways to wire eight GPUs inside one node. Left: a ring gives each GPU only two links, so traffic between distant GPUs passes through up to four hops. Center: a full mesh reaches every peer in one hop but needs $G_{\text{node}}-1$ links per GPU and $G_{\text{node}}(G_{\text{node}}-1)/2$ links in total, which becomes impractical to route beyond about eight GPUs. Right: an NVSwitch fabric gives each GPU one set of links to the switch and puts every pair one switch hop apart, with up to 450 GB/s per direction per H100 SXM GPU (900 GB/s bidirectional); that per-GPU injection bandwidth is not the aggregate bisection bandwidth of the switch fabric.

Consider the NVIDIA DGX H100 architecture. Eight H100 GPUs sit on a single baseboard, each connected to four NVSwitch chips via 18 NVLink 4.0 lanes. The NVSwitch chips form a non-blocking crossbar[5] through which any GPU can reach any other GPU. Each GPU's port budget is 900 GB/s bidirectional, or 450 GB/s in one direction, shared across that GPU's simultaneous transfers; it is not a separate full-bandwidth link for every GPU pair.

The result is a node with 640 GB of aggregate HBM capacity and a combined peak compute throughput of 8 × 1,979 TFLOP/s, while each GPU retains private HBM. Training frameworks partition tensors explicitly across those devices, and NVSwitch reduces the communication cost between shards without making placement or collective synchronization transparent. The NVSwitch chips themselves consume approximately 200 W each (800 W total for the NVSwitch fabric), a nontrivial power overhead justified by the bisection bandwidth it provides. In physical terms, the NVSwitch fabric alone consumes more power than an entire previous-generation GPU (the V100 drew 300 W).

Tracing one tensor-parallel step of the running model shows what that NVSwitch power budget buys. Assume a schedule with one activation-sized AllReduce per layer in each forward and backward pass; the partition and collective schedule are scenario inputs, not a universal Transformer schedule. During the modeled tensor-parallel forward pass, each GPU holds one shard of each weight matrix and computes its portion of the matrix multiplication. For a Transformer layer with hidden dimension 12,288 (typical for a 175B model), each of the 8 GPUs holds a

[5] **Crossbar switch**: A topology providing a dedicated path between every input-output pair simultaneously. An $k \times k$ crossbar needs k^2 crosspoints, so its cost grows quadratically with port count; that growth is why a full crossbar stays inside a node and larger systems switch to multi-stage fabrics. Within that bound, the crossbar buys the all-to-all bandwidth that tensor parallelism demands.

$12{,}288 \times 1{,}536$ slice of the weight matrix at the projection that reduces the split inner dimension back to the full hidden width. Because that slice keeps the full output width while covering only one eighth of the inner sum, each GPU produces a full-width vector of partial sums for every token, and an AllReduce operation sums those partial results across all 8 GPUs over NVLink.

The logical output tensor for one AllReduce contains $4 \times 2{,}048 \times 12{,}288 \times 2$ bytes (FP16). For a microbatch of 4 sequences at 2,048 tokens, that payload is roughly 201 MB. An ideal ring AllReduce with 8 participants moves $2(N-1)/N = 1.75$ times the payload per GPU (chapter 5 derives this factor), or about 352 MB. At 450 GB/s of one-direction bandwidth, the transfer-time lower bound is approximately 0.783 ms.

Across 96 forward layers and 96 backward layers, the 192 transfers sum to about 150.3 ms per step before overlap. NVSwitch provides the paths needed for the collective, but this value remains an ideal bandwidth-only lower bound that excludes startup latency, software overhead, and competing traffic.

↪ The α-β model, which adds the fixed per-message startup latency this bound omits to the bytes-over-bandwidth transfer time, is developed in section D.1.

Judging that bound needs a compute time to compare it with. This scenario assumes 200 ms of computation per step for the tensor-parallel group, a stated input rather than a derived value; the fractions below scale with it, so a longer compute time makes the same communication matter less. Against that assumption, the unoverlapped NVLink lower bound leaves computation at 57.1 percent of combined compute-plus-communication time. Actual tensor-parallel efficiency can be higher when collectives overlap useful computation or lower when latency, contention, load imbalance, and nonparallel work add delay, so it must be measured rather than inferred from peak link bandwidth alone.

Example 2.3: The NVLink bandwidth surprise

Scenario: A team evaluates tensor parallelism over a hypothetical PCIe Gen5 path with 64 GB/s bandwidth, using the payload and the assumed 200 ms per-step compute time stated with the NVLink estimate above.

Diagnosis: The modeled tensor-parallel schedule executes 192 AllReduce events per step across 96 layers. Its PCIe bandwidth-only transfer times sum to 1057 ms per step. Without overlap, communication accounts for 84.1 percent of the combined compute and transfer estimate; this is not a measured stall fraction.

Systems lesson: Under the same assumptions, NVLink lowers the transfer bound to 0.783 ms per AllReduce and raises computation to 57.1 percent of the combined time. The comparison explains why this partition favors a fast local fabric. Real collective performance must also include startup, topology, contention, and overlap.

The DGX H100 pairs each GPU with its own InfiniBand ConnectX-7 HCA, which reads and writes GPU memory directly over PCIe through GPUDirect RDMA, so inter-node gradient exchange avoids staging copies in host DRAM while still consuming PCIe and network bandwidth. The host CPU prepares and loads

batches, submits kernels, and coordinates the training framework. Sufficient CPU capacity and I/O bandwidth let that work overlap the accelerator fabric's computation and communication; otherwise, slow preprocessing or submission can starve the GPUs even when their local memory and interconnect are fast enough.

Host CPUs also pay a "data center tax" of shared infrastructure work. A profile of Google's fleet found that such common building blocks consumed nearly 30 percent of cycles across jobs (Kanev et al. 2015), and network protocol processing, storage virtualization, and security functions add to that load on cloud hosts. ML nodes can therefore incorporate data processing units (DPUs) or SmartNICs. Devices like the NVIDIA BlueField DPU offload these infrastructure tasks to dedicated ARM cores and hardware accelerators integrated into the network adapter itself. Moving the control plane for RDMA, firewall rules, and storage protocols to the DPU recovers cycles for the ML pipeline: data loading, tokenization, and kernel orchestration on the host CPU. The DPU also acts as an isolated security domain, allowing cloud providers to maintain control over the network and storage layer via the DPU while granting customers full access to the host CPU and GPUs. For our 175B model training, DPU offload can keep RDMA protocol processing outside the host CPU critical path for gradient synchronization, which flows from GPU HBM toward the network fabric without host CPU involvement.

↪ The RDMA and GPUDirect data path that bypasses host memory is developed in section 3.4.1.

2.5.2.1 Alternative node architectures

Spending board area, power, and cost on four NVSwitch chips makes sense when tensor-parallel collectives sit inside every layer, but workloads dominated by embedding capacity, data parallelism, or cost-sensitive serving hit different limits first. Alternative node designs reallocate that budget. An AMD MI300X server emphasizes large HBM capacity on each package, Google TPU pods wire chips directly into a mesh without a central baseboard switch, and Intel/Habana Gaudi nodes integrate Ethernet RDMA ports directly onto the accelerator die. Comparing them against a DGX H100 node reveals where each architecture spends its scarce budget.

In a switch-rich node like the DGX H100, universal any-to-any local exchange is the priority because each Transformer layer places intra-node collectives inside the model's inner loop. The 900 GB/s H100 NVLink fabric therefore buys a software abstraction, in which the training framework can treat eight accelerators as one tightly coupled tensor-parallel group for the layers that must be split across chips.

Other systems move that boundary. TPU pods use the inter-chip interconnect and a mesh-oriented topology instead of making a central switch the defining component of the node; a TPU v5p chip's vendor-specified ICI bandwidth is 1,200 GB/s. The mesh can reduce switch cost and expose a regular structure to the compiler, but it also makes placement more visible, because the runtime must respect neighbor relationships rather than assuming that every chip pair has the same communication path. That is a reasonable trade when the workload is regular enough for the compiler and collective libraries to map communication onto the topology.

The MI300X shifts the pressure point from local switching toward memory capacity. Its package exposes 192 GB of HBM at 5.3 TB/s, compared with 80 GB on an H100-class accelerator. An eight-accelerator MI300X node would therefore provide 1,536 GB of aggregate HBM, enough to hold the 350 GB FP16 weight tensor for our 175B running model. That does not eliminate the optimizer, gradient, activation, and fragmentation problem that section 2.5.3 quantifies, but it changes how often the system must spill state into slower memory tiers and how much microbatch headroom remains before offload becomes mandatory.

Gaudi takes a different route by integrating RDMA-capable Ethernet into the accelerator and using a more network-centric design for communication. A Gaudi 2 accelerator's 24 integrated 100 GbE ports supply 300 GB/s of aggregate RDMA over Converged Ethernet (RoCE) bandwidth, against the 900 GB/s of local exchange per GPU in an H100-class NVLink node. The newer Gaudi 3 keeps that Ethernet-centric design while carrying 128 GB of HBM per accelerator, so capacity is not the trade being made. The question is whether simplifying the fabric and using Ethernet consistently across node and pod is worth giving up the high local exchange bandwidth of a switch-rich NVLink design. That trade can be attractive when data parallelism, inference serving, or cluster cost dominates, and less attractive when tensor-parallel collectives sit inside every layer.

These alternatives are not a ranking of vendors. They are different placements of scarce resources: switching bandwidth in the node, regular topology in the pod, HBM capacity in the package, or network attachment on the accelerator. For the 175B model used throughout this chapter, the tensor-parallel portion of training makes local accelerator communication unusually important, so the DGX-style answer is natural. In other regimes, especially memory-heavy recommenders, topology-regular training, or cost-sensitive serving fleets, a different boundary can become the one that matters most. Software ecosystem maturity, supply availability, and total cost of ownership then decide whether the theoretical architectural fit becomes a deployable system.

2.5.3 Node memory partitioning

The node's aggregate HBM must hold far more than the weights, and how that state divides across the node's memory tiers decides which parallelism strategies are possible. Consider the memory budget for training our 175B model. The model weights in FP16 require 350 GB. The Adam optimizer maintains two additional values for every parameter (first and second moments) in FP32 precision, adding $175 \times 10^9 \times 2 \times 4$ bytes = 1,400 GB. Gradients require another 350 GB. This subtotal is approximately 2.1 TB, far exceeding both a single accelerator's 80 GB HBM and an 8-H100 node's 640 GB aggregate HBM, and it still omits two terms. Activations are the intermediate results the backward pass needs. The FP32 master weights are a full-precision copy of the parameters that the optimizer updates, kept because an update far smaller than a weight would be lost to FP16 rounding; this is the mixed-precision copy introduced with the precision formats in section 2.4.

A common misconception is that a model's memory footprint equals its weight storage. With those two terms included, the FP32 master weights, optimizer mo-

ments, gradients, and activations collectively consume about 7–8× more memory than the FP16 parameters alone. These components reside in different tiers of the node's memory hierarchy. For our 175B model, training memory partitions across six distinct components (table 2.11).

Table 2.11: Training Memory Breakdown for a 175B-Parameter Frontier Model: The optimizer state alone (first and second moments in FP32) consumes 4× the memory of the model weights, making optimizer memory the dominant component of training memory. This is why memory optimization techniques focus heavily on optimizer state sharding and offloading.

Component	Precision	Memory per parameter	Total for 175B model
Model weights	FP16	2 bytes	350 GB
Gradients	FP16	2 bytes	350 GB
Master weights	FP32	4 bytes	700 GB
Optimizer (Adam m)	FP32	4 bytes	700 GB
Optimizer (Adam v)	FP32	4 bytes	700 GB
Activations	Mixed	Variable	100–400 GB
Total			**2.9–3.2 TB**

The 2.9–3.2 TB budget of table 2.11 extends the earlier subtotal with the master weights and activations. Its five persistent rows sum to 16 bytes per parameter, or 2.8 TB, the training state given for Archetype A in section 1.6.1.1, and activations add the rest. The Adam optimizer state in FP32, not the FP16 weights, is the dominant term, and the activation peak, which scales with batch size and sequence length, is the most variable. The lesson for parallelism selection is that the FP16 weights are among the smaller pieces of what the node must hold, so a strategy that only shards weights leaves the largest consumers, the FP32 optimizer moments and master weights, untouched.

A DGX H100 node provides 640 GB of aggregate HBM across its 8 GPUs, plus 2 TB of host DDR5 DRAM. The HBM capacity alone is insufficient for the full training state, as the memory arithmetic for each parallelism strategy shows. With pure data parallelism, each GPU must hold replicated state, and even the 2,100 GB subtotal of weights, gradients, and optimizer moments, before master weights and activations, is physically impossible on an 80 GB device. Even ZeRO stage 3, when confined to a single node that shards all three components across only 8 GPUs, yields 2,100 GB / 8 ≈ 262.5 GB per GPU, still more than triple the available HBM.

Fitting the state into HBM therefore requires expanding across multiple nodes so that a larger pool of accelerators shares the memory footprint. The standard approach combines intra-node tensor parallelism (which splits tensors and operations within layers across GPUs, reducing per-GPU weights to 350 GB / 8 = 43.75 GB) with ZeRO-style optimizer sharding across the data-parallel replicas on other nodes. In a cluster configuration with TP-8 within each node and 128-way data

parallelism across nodes, each node acts as one model replica whose GPUs keep their 43.75 GB weight shards resident for every forward and backward layer. Because the optimizer moments are needed only once per step during the parameter update, they do not need to stay replicated on every node and are partitioned twice, first by the 8-way tensor split and then across the 128 data-parallel replicas. Each GPU therefore holds approximately 1,400 GB / (1024) ≈ 1.4 GB of optimizer state, or 10.9 GB per 8-GPU tensor-parallel group, before gradients, activations, buffers, and fragmentation. The weight-plus-optimizer subtotal of roughly 45.1 GB is only the starting point. The memory-budget exercise in section 2.5.3.1 examines a single node without this cross-node sharding and shows why optimizer offload alone is insufficient there. This arithmetic is why tensor parallelism, optimizer sharding, activation checkpointing, and memory tiering are used together for large-model training. The node is therefore a high-bandwidth compute and communication unit, not a standalone container for the entire training state.

Because even full ZeRO-3 sharding within one node leaves each GPU above its HBM capacity, sharding must be combined with other techniques. Activation checkpointing stores only a subset of intermediate activations for the backward pass and recomputes the rest from the nearest checkpoint, trading extra forward computation for activation memory, a trade that section 6.3.1.2 develops.

CPU offloading stores state in host DDR5 DRAM and may also move optimizer computation to the CPU. The implementation determines which gradients, weights, or optimizer buffers traverse the PCIe Gen5 path at 64 GB/s. Its cost depends on those bytes, host computation, and the time available to overlap transfers; a short GPU update does not establish cheap offload. NVMe offloading extends storage to SSDs, with the illustrative 5–7 GB/s sequential read rate introducing a further bandwidth constraint that prefetching can hide only when consumption leaves enough time.

An offloaded configuration uses the node's memory hierarchy as a tiered system sorted by how often each piece of state is touched. HBM holds the weight shards, activations, and accumulating gradients needed on every layer of the forward and backward passes. Host DDR5 absorbs the optimizer moments and master weights, which are read and written only once per step during the parameter update. NVMe extends capacity for the largest models by holding seldom-accessed shards that can be prefetched within the step budget. A configuration with sufficient distributed HBM can instead retain optimizer shards on accelerators. The placement follows the capacity and transfer-time calculation, rather than a fixed assignment of every state type to one tier.

The training framework's memory manager moves state between these tiers much as a cache controller does, prefetching the next layer's offloaded weights into HBM during the current layer's computation and evicting state that will not be needed soon. Prefetch depth sets the balance, because too shallow a prefetch stalls computation on PCIe transfers and too deep a prefetch crowds out the current step's activations and gradients. Table 2.12 quantifies the gaps the manager must bridge, more than two orders of magnitude in bandwidth between HBM and an

NVMe drive. For our 175B model, a capacity plan must therefore choose among additional sharding, offload, and reductions in live state, and the next budget tests whether a proposed combination actually fits within one node.

Table 2.12: Node Memory Hierarchy: Each tier trades capacity for bandwidth. Latencies are seen from the GPU, so host DRAM includes the PCIe crossing, and a GPU's own share of host bandwidth is limited by its PCIe link rather than by the aggregate DDR5 figure. The training framework's memory manager must orchestrate data flow across these tiers to fit models whose total state exceeds the aggregate HBM capacity.

Memory tier	Capacity	Bandwidth	Latency	Role
GPU HBM3	80 GB × 8 = 640 GB	3.35 TB/s per GPU	< 1 µs	Active computation
Host DDR5	2 TB	hundreds of GB/s aggregate	~1 µs over PCIe	Optimizer state
NVMe SSD	8–30 TB	up to 7 GB/s per drive	~100 µs	Overflow, checkpoints

2.5.3.1 Node-level memory budget

Combining all five memory components for our 175B model on a single DGX H100 node in example 2.4 shows why closing the budget requires coordinating sharding, checkpointing, and offload together rather than tuning any one component in isolation.

Example 2.4: Memory budget for 175B training on DGX H100

Scenario: An engineering team calculates the memory budget for training a 175B parameter model using 8-way tensor parallelism on an 8-GPU DGX H100 node (80 GB HBM per GPU).

Diagnosis: Without ZeRO sharding, each GPU's TP-8 slice of the optimizer state alone requires 175 GB per GPU, which is more than the weights and gradients combined (88 GB). A separate FP32 master-weight shard adds 87.5 GB. Together with retained FP16 gradients, the assumed activations, and workspace, these components bring the per-GPU budget to 375 GB, well past the 80 GB HBM limit. That budget already assumes activation checkpointing; its activation peak is a scenario input that must be replaced by measurements for the chosen microbatch and sequence length.

Systems lesson: Sizing training memory requires managing weights, gradients, optimizer states, activations, and buffers holistically, because relieving one component does not necessarily clear the envelope. Offloading the optimizer moments and master weights to host DDR5 removes those FP32 components and still leaves 113 GB per GPU, because 8-way tensor parallelism keeps a full weight and gradient shard resident on every GPU. Further reductions require offloading or shrinking another live component. Alternatively, adding devices creates an additional data-parallel group across which ZeRO can shard state. The same eight GPUs already assigned to TP-8 do not provide an

independent eight-way data-parallel sharding axis; parallel degrees multiply to the allocated device count.

2.5.4 Data loading and I/O pipeline

Even after the node's memory budget closes, its accelerators still need a continuous stream of training data from outside the chassis. If the data loading pipeline cannot keep pace with the accelerators' consumption rate, the most expensive component in the node sits idle; this is the I/O bottleneck. For pre-tokenized language-model training, the raw demand is small: at 500,000 tokens/s stored as 4-byte token IDs, ingestion is only 2 MB/s. The pressure falls instead on the host CPU cores that read, decode, shuffle, and batch examples, on the PCIe paths that data shares with gradient and checkpoint traffic (section 2.5.1.1), and on shared storage that every node reads at once. GPUDirect Storage can remove the host-memory bounce copy for data that needs no host-side preprocessing, and staging data on local NVMe can absorb synchronized bursts that would otherwise hit a shared filesystem. For node design, the hardware contract is end-to-end sustained bandwidth at the intended concurrency: storage servers, network paths, host preprocessing, host memory, and accelerator transfer must all keep pace, because a local benchmark that satisfies one node says little about a shared path serving the fleet. Keeping that node productive over a multi-week run then turns on how often a component fault inside the chassis interrupts execution.

↪ Sizing the input pipeline end to end, with every stage from storage read to host-to-device transfer held at or above the required bandwidth, is developed in section 4.4.

2.5.5 Node health and reliability

When a single GPU suffers an uncorrectable HBM error or a rack power shelf trips, it does not fail in isolation; it takes its entire eight-GPU tensor-parallel group or multi-node rack out of the synchronous training step. A **failure domain** is the set of resources that a single fault takes out of service together, and the physical hierarchy nests these domains inside one another. A failed GPU breaks its tensor-parallel group, which usually spans its node. The node sits in a rack whose shared power shelf, top-of-rack switch, and cooling loop can take every node in it down at once. Racks share row-level power and coolant distribution, and halls share a building's utility feed, cooling plant, and fire compartment. For a synchronous training job the node is the smallest domain that matters. An eight-way tensor-parallel group within a node becomes unusable when any one GPU fails, because its collectives require all eight participants. The node's effective MTBF depends on the combined failure exposure of every component whose loss stops the job, as well as shared power and cooling failures. The node's figure is therefore an MTBF, the expected interval between successive failures of a unit that keeps running through replacements, while each GPU contributes an MTTF, the distinction drawn with the reliability wall in section 2.1.

Failure exposure spans memory, interconnects, and the electrical and mechanical systems that support them. An uncorrectable error-correcting code (ECC) fault in an HBM stack forces the accelerator out of service and aborts the active training step. High-speed links degrade as repeated thermal cycles stress connectors and

cables, which shows up as link retraining or a fatal communication drop. Power-supply components and the pumps and fans of the cooling path wear out under sustained load, and a loss of power or cooling can take several accelerators down together. The accelerator itself usually dominates the count. In Meta's report on the Llama 3 405B pretraining run, faulty GPUs and HBM3 memory errors together caused nearly half of the unexpected interruptions, ahead of software bugs and network switches and cables (Dubey et al. 2024). The ordering in a given fleet still depends on its equipment and operating conditions, so local incident data should confirm it before it guides spare capacity or preventive maintenance.

Health monitoring can flag a node for investigation before another long job lands on it. A rising rate of corrected ECC errors, rising junction temperature at constant load, and intermittent link retraining are the most useful early signals, although no single signal establishes a cause or a time to failure. The fleet telemetry that collects them is developed in section 12.6.1. For our 175B model training across 128 nodes, a composite node-level MTBF assumption of 1,000 hours, which includes GPUs, host components, power, cooling, and network links, predicts about 43 node failures over a run of 336 hours, roughly 3.1 failures/day. A GPU-only bound from the per-GPU MTTF of 50,000 hours would predict only 6.9. The node, not the GPU, is therefore the unit that spare capacity and recovery tooling must be sized for. The same accounting, applied to every component of a facility and then to every GPU of a fleet, reappears at larger scope in the facility reliability controls of the rack and the hours-scale fleet failure interval of section 2.7.1.

For our 175B model, a single DGX H100 node provides 640 GB of aggregate HBM, enough to hold the FP16 model weights but not the full Adam training state without sharding and offload. Training also requires processing hundreds of billions of tokens, and a single node would need more than a year of compute to do so (section 2.7 works through the numbers), so completing training in weeks requires tens to hundreds of nodes. Stacking those nodes into a physical enclosure defines the next level of infrastructure, where the constraints shift from bandwidth and capacity to raw power and heat.

↪ Layered fault detection, from ECC and error-rate monitoring to known-answer stress tests on nodes pulled from production, is developed in section 7.4.3.

2.6 The Rack

A standard 42U server rack in a traditional data center draws about 12 kW and can be cooled by room-temperature air pushed through perforated floor tiles. The chapter's four-node DGX H100 rack scenario draws 33.5 kW, a figure that includes the rack's allocated cooling overhead. At this density, the engineering constraints shift from silicon and signal integrity to power delivery and thermodynamics. The rack is where the power wall and heat transfer become dominant design forces.

For our 175B model, training across 1,024 GPUs requires 32 racks (4 nodes of 8 GPUs each per rack). Across the cluster, the modeled rack power, which includes each rack's allocated cooling overhead, sums to approximately 1.1 MW. Delivering this power reliably and removing the resulting heat without allowing any component to exceed its thermal limit is a multidisciplinary engineering challenge spanning electrical, mechanical, and civil engineering. A failure at any

point in the power delivery chain, from the utility substation to the individual GPU voltage regulator, can halt the entire training run, wasting hours of computation and potentially corrupting the training state.

Definition 2.5: Rack

Rack is the physical infrastructure unit, a standardized 42U enclosure, that houses multiple compute nodes, a top-of-rack (ToR) switch (the first network aggregation point connecting all nodes in the rack to the broader cluster fabric), power distribution units, and cooling distribution manifolds, defining the granularity at which power and cooling capacity must be provisioned.

1. **Significance**: AI rack power density has grown dramatically. The chapter's four-node DGX H100 scenario contains 32 GPUs at 700 W each and draws 33.5 kW once host, network, conversion, and allocated cooling overhead are included. This exceeds the roughly 12 kW typical of general-purpose data center racks and requires purpose-designed electrical distribution and cooling capacity. Whether that cooling is engineered air or liquid depends on the system configuration and facility design.
2. **Distinction**: A node packages compute; a rack integrates shared power, cooling, and network distribution. Components and nodes remain individually serviceable, but their maintenance and replacement must respect the capacity and failure boundaries of those shared systems.
3. **Common pitfall**: A frequent misconception is that rack placement is a logistical afterthought. Nodes within the same rack share a ToR switch and have single-hop connectivity; nodes in different racks cross at least two switch hops. Placing pipeline stages within a rack can reduce inter-rack traffic when the actual paths and available capacity support the stage-boundary exchanges.

2.6.1 Power and thermal envelopes

Sustaining the compute rate that HBM and Tensor Cores make possible requires a power-delivery and cooling system sized for the workload. Delivery itself adds heat before any computation does, because each of the five voltage-conversion stages between the medium-voltage utility grid and the sub-volt GPU die loses part of the power it passes on (figure 2.12).

The illustrative conversion losses in figure 2.12 require roughly 1.3 MW upstream to deliver 1 MW to the dies, before heat removal is counted. Facilities summarize that overhead with power usage effectiveness (PUE), total facility power divided by IT-equipment power, and because the IT boundary already contains some of these conversion losses they must not be counted twice. Section 15.4.1.3 defines the ratio and draws its boundary.

Every floating-point operation dissipates energy as heat. Dense Tensor Core activity during large matrix multiplications drives heat proportional to the switch-

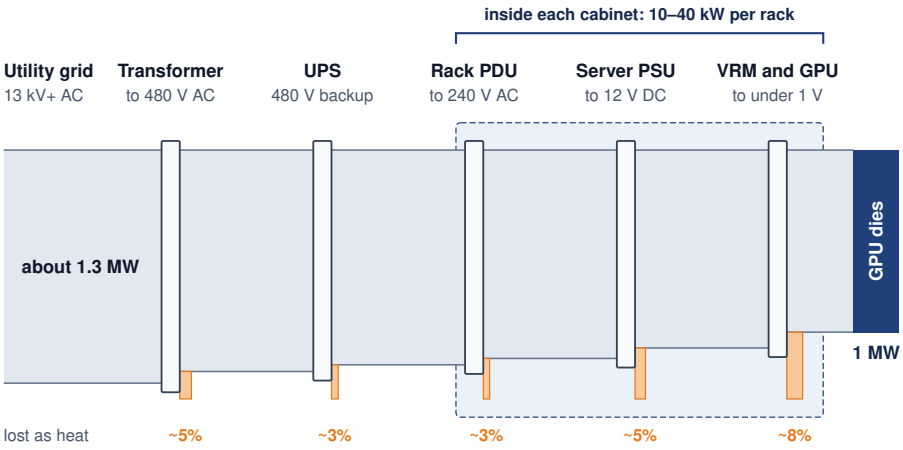

Figure 2.12: The Power Delivery Path: Energy passes through five conversion stages between the medium-voltage grid and the sub-volt supply at the GPU die, and each stage loses a few percent as heat; the band's height is drawn proportional to the power it carries. The per-stage losses shown are illustrative round values, not measurements of a particular facility; compounded, they lose about a fifth of the power, so delivering 1 MW to the dies draws about 1.3 MW before cooling. PUE uses an IT-equipment boundary and includes facility conversion losses as well as cooling; these losses must not be counted twice. The critical engineering challenge is the rack power distribution unit (PDU) to voltage regulator module (VRM) transition, where 10–40 kW of power must be delivered within a single cabinet.

ing activity of billions of transistors. Fleet design must pair each accelerator's sustained power envelope with any documented transient excursion requirement. At dense fleet scale, this produces the power wall, the point at which facility power delivery and heat removal, rather than available arithmetic units, determine how much compute can be installed and sustained.

The thermodynamic limit (principle 4), which holds that every joule a computation draws ends as heat and that a facility can run only as fast as it removes that heat, makes heat removal part of usable compute capacity. A facility can reach its power or cooling envelope while arithmetic capacity is still available to purchase, so the scarce quantity becomes watts per unit of floor area rather than FLOP/s. The power density wall (principle 3) adds that spatial constraint, bounding cluster scaling by the watts each rack can dissipate rather than only by silicon area or floor space. If a proposed rack exceeds the engineered airflow's heat-removal capability, the design must lower its density or move to liquid, which at the 100 kW class of high-density training racks is part of the rack design rather than an option.

Definition 2.6: Thermal design power (TDP)

Thermal design power (TDP) is a vendor-defined sustained thermal design target in watts for a specified product configuration and operating condition.

1. **Significance**: The H100 SXM5 configuration used in this chapter carries a 700 W design target. Sustaining the intended operating point requires a thermal path and facility loop qualified for that target under the vendor's inlet and coolant conditions.

2. **Distinction**: TDP does not denote one universal instantaneous-power maximum. TGP, board power, configurable limits, and transient specifications describe related electrical constraints under conventions that differ by vendor and product.
3. **Common pitfall**: A frequent misconception is that the advertised wattage alone specifies rack power and cooling. Fleet design must combine the sustained thermal target, configured power limit, workload behavior, component overhead, and transient-power requirement.

The trajectory of TDP records a scaling regime reaching its limits. For three decades, Dennard scaling[6] allowed chip designers to shrink transistors while maintaining approximately constant power density: smaller transistors required lower voltage, so packing more transistors into the same area did not increase heat output per unit area. As voltage scaling and leakage limits ended that regime, architects had to treat energy, cooling, and parallelism as first-order constraints rather than free byproducts of process shrinks (Dennard et al. 1974; Hennessy and Patterson 2019). Since then, each generation of accelerator has had to trade performance against power and heat. The era of "free" performance improvements through process shrinks is over; every gain in throughput now has to be paid for in watts, cooling capacity, or specialization.

The V100 (2017) operated at 300 W TDP, the A100 (2020) increased to 400 W, the H100 (2022) reached 700 W, and the B200 (2024) draws 1000 W. In seven years, TDP has more than tripled, growing at approximately 19 percent per year.

If this growth rate continued as a planning scenario on a two-year product cadence, a generation after Blackwell would approach 1,400 W per accelerator, and the generation after that would reach about 2,000 W. At that level, a single 8-GPU node would consume 16 kW of GPU power alone, requiring liquid cooling infrastructure (section 2.6.2) that can remove heat at rates approaching those of industrial process cooling equipment. The applicable sustained power envelope is not merely a specification on a data sheet; it propagates through every level of the infrastructure stack. The power-delivery chain, cooling system, rack design, and facility electrical infrastructure must accommodate deployed accelerators, their documented transients, and the plausible envelope of future refresh cycles.

The propagation is visible at both ends of the stack in published data. Vendors publish a power rating for each accelerator package, and figure 2.13 (a) collects those ratings across 14 NVIDIA, Google, AMD, and Intel parts. The ratings follow each vendor's own convention (TDP, maximum board power, or maximum TGP), so they bound design envelopes rather than measure consumption, but they climb steadily from one generation to the next. Panel (b) plots the facility power of supercomputers that Epoch AI tracks for AI work, together with the largest one operating at each date (Epoch AI 2026a; Pilz et al. 2025). From 2013 through 2021 that record stayed between 20 MW and 30 MW, a level set by national high-performance computing systems. The Frontier supercomputer raised it to 40 MW in 2022, and AI training clusters then lifted it to about 350 MW by 2025, a 9×

[6] **Dennard scaling**: Named after Dennard et al. (1974) at IBM, who showed how MOSFET dimensions, voltage, and current could scale so that power density stayed roughly constant. Later voltage-scaling limits and leakage effects ended that constant-power-density regime; Hennessy and Patterson (2019) describe the resulting post-Dennard power wall as one reason modern architecture turned toward parallelism and specialization. For ML infrastructure, the V100-to-B200 TDP trajectory (300 W to 1,000 W) is an illustration of the post-Dennard planning problem: cooling and power delivery are now co-equal design constraints with the silicon itself.

increase in three years. Over the same three years the rating of one package rose from the H100's 700 W TDP to the B300's 1,400 W maximum TGP, roughly a 2× increase across the two rating conventions. Hotter packages explain only a small part of the jump. The rest comes from the number of accelerators a single system joins together and the facility built to feed them, which is why the power wall at fleet scale is a provisioning problem for the building as much as a thermal problem for the chip.

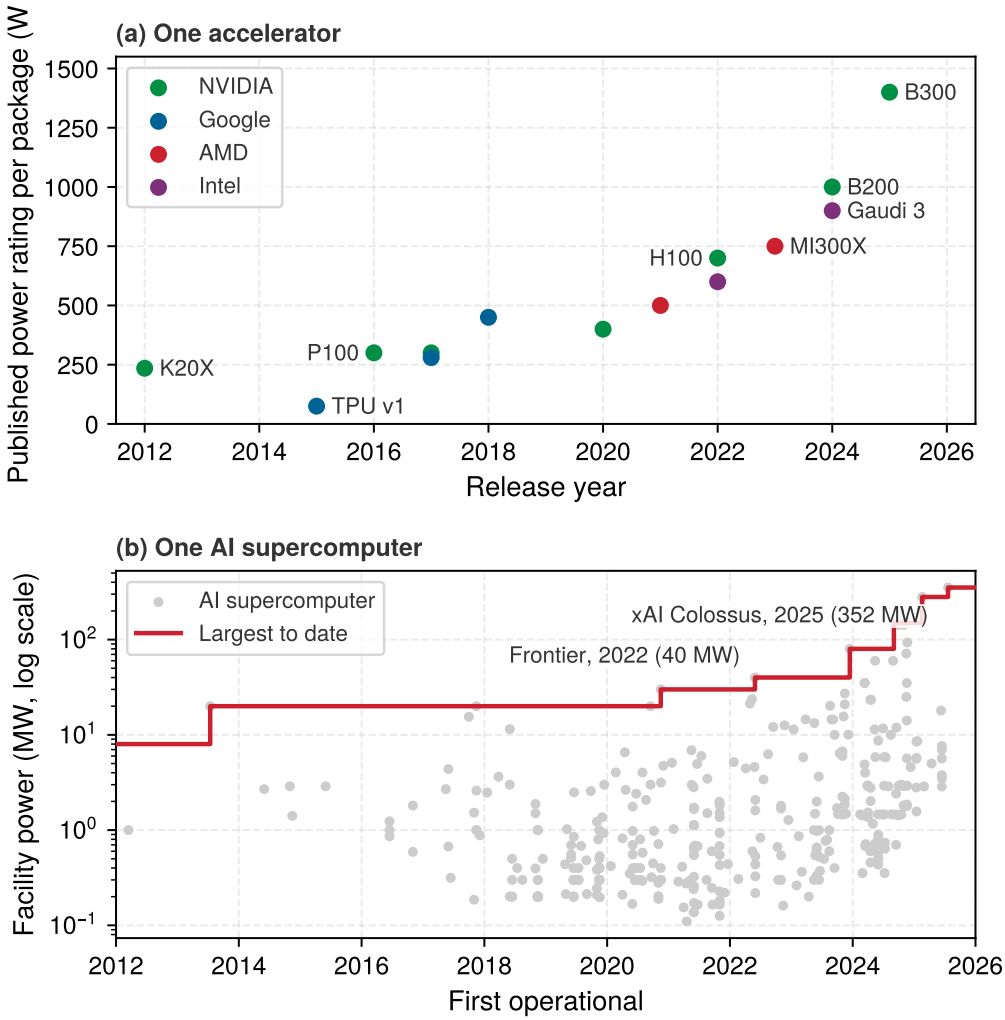

Figure 2.13: Package Power versus System Power: (a) Published power rating of one accelerator package by release year. Ratings follow each vendor's convention (TDP, maximum board power, or maximum TGP) and describe design envelopes, not measured workload power. (b) Facility power of AI supercomputers by first operational date on a logarithmic axis; the red line tracks the largest system operating at each date. The record held near 20 to 30 MW for most of a decade before AI training clusters raised it roughly ninefold between 2022 and 2025. Sources: (a) NVIDIA (2013), Foley and Danskin (2017), Choquette et al. (2018), Choquette et al. (2021), Choquette (2023), NVIDIA (2024), NVIDIA (2025), Jouppi et al. (2021), Advanced Micro Devices (2021), AMD (2023), Intel Habana Labs (2023), Intel (2024); (b) Epoch AI (2026a).

Accelerators implement sophisticated power management to operate within their TDP envelope. When the workload does not fully use all SMs (for example, during the communication phase of a training step when the GPUs are waiting

for AllReduce to complete), the GPU firmware can disable the clock signal to idle circuitry through **clock gating**. Clock gating eliminates dynamic switching power and frees thermal headroom for the active SMs. A separate mechanism, dynamic voltage and frequency scaling (DVFS), adjusts the chip's clock frequency and supply voltage to stay within power and thermal limits. During a large matrix multiplication that activates all SMs simultaneously, DVFS reduces the clock frequency to keep total power within TDP. When some SMs are idle, the active SMs can boost frequency because total chip power is below TDP, so the actual clock, and therefore the actual throughput, varies throughout a training step.

Dynamic power management means that the actual power draw of a GPU varies continuously during training. A typical training step might see power swing from 400 W (during communication phases when most SMs are idle) to 700 W (during the forward and backward pass when all Tensor Cores are active) and back, with each transition occurring in microseconds. The voltage regulator modules (VRMs) on the baseboard, which convert the board supply to the sub-volt core voltage, must respond to these transitions fast enough to maintain a stable supply voltage despite the rapidly changing current draw.

DVFS also couples software optimization to the power envelope. A kernel that achieves high SM occupancy (many active warps per SM) draws more power, potentially triggering a frequency reduction that partially offsets the occupancy benefit. Conversely, a kernel with moderate occupancy may run at a higher clock frequency, achieving comparable throughput at lower power. Power-normalized throughput (TFLOP/s per watt) is therefore a more robust comparison metric than raw TFLOP/s, and it explains why the same GPU can show different sustained clock frequencies depending on the workload and the cooling solution.

At fleet scale, DVFS also affects power planning. Average workload draw can fall below the configured limit because communication phases and incomplete occupancy leave circuitry idle, but averages do not replace sustained and transient design cases. Some operators deliberately lower accelerator power caps to fit more devices within a fixed facility budget, accepting workload-dependent throughput loss in exchange for lower per-device draw. Power capping is a form of the compute-efficiency trade-off at the operational level.

To appreciate the physical challenge, consider what 700 W means in terms of heat flux. An H100 die measures approximately 814 mm^2 (roughly 29×28 mm). Dissipating 700 W from this area produces a heat flux of approximately 86 W/cm^2. For comparison, the surface of an electric stovetop burner at high heat produces approximately 10 W/cm^2. An H100 die generates 8.6× the heat flux of a stove burner, concentrated on an area the size of a large postage stamp.

The B200's 1,000 W envelope spans a dual-die package. In this comparison, the average heat flux remains comparable while the package heat-removal rate increases by 43 percent. Cooling must keep junction temperature and memory temperature within the applicable product limits under the specified inlet and

load conditions. A single temperature threshold cannot stand in for those separate requirements.

The thermal interface material (TIM) between the package and its cooling assembly is one part of that heat-transfer path, and it is the part that ages. Training alternates compute-dense phases with communication phases, so the die heats and cools many times per minute; under that cycling, a phase-change or paste TIM can pump out (migrate away from the contact surface) or crack. Increased thermal resistance can raise temperature at the same load, but the performance effect depends on the remaining thermal margin and the device's control policy. A temperature trend alone does not identify the cause; inlet conditions, flow, contact, and workload also require inspection. When thermal limits reduce clocks without stopping execution, the result is a gray failure, a performance degradation that monitoring must distinguish from an application or network bottleneck.

Arithmetic per watt offsets only part of rising TDP, and a larger capability target can increase total work despite improved efficiency, so facility planning must compare the proposed device count, power envelope, and completion time together. Packing accelerators close together shortens communication paths but concentrates heat. A four-node DGX H100 rack already draws 33.5 kW including its allocated cooling overhead, several times the load of a conventional server rack. The accelerators of a 10,000-GPU cluster, the round fleet size this chapter uses for warehouse-scale examples, alone draw 7 MW before hosts, network, and cooling are counted. Rack and pod designs must reconcile that proximity with enough space and infrastructure to deliver power and remove heat across all participating nodes.

Power-envelope implications recur throughout the infrastructure hierarchy. At the node level, configured limits constrain how many accelerators can share a chassis (section 2.5). At the rack level, aggregate sustained load and heat flux help determine whether engineered air or liquid cooling can meet the design point (section 2.6.2). At the pod level, coincident demand and transient behavior shape megawatt-scale power delivery (section 2.7). Every level above the die must therefore manage both sustained heat and electrical variation. Accelerator selection must compare useful workload throughput within that facility envelope, rather than treating power as a cost added after the compute decision.

2.6.1.1 Power delivery networks and transient dynamics

Fitting redundant AC power supply units inside every eight-GPU chassis consumes enclosure volume needed for cooling manifolds and high-speed interconnects, especially as rack loads climb toward 100 kW in liquid-cooled clusters. Many dense-rack designs therefore replace per-chassis AC supplies with rack-level DC power distribution. In this architecture, a centralized power shelf converts mains AC to a 48V DC busbar that runs the height of the rack. Power reaches the server backplane through the 48V bus, and local DC-to-DC converters supply the lower voltages required by the components. Consolidation can recover chassis volume for cooling loops and high-bandwidth interconnects, but it does not by itself establish fewer conversion stages or a fixed efficiency gain. The comparison must account

for each design's actual stages and conversion efficiency across the intended load range. Shared power shelves and busbars also create a rack-level failure boundary whose redundancy and serviceability must be qualified.

A training step makes each accelerator's current draw jump. When a collective barrier releases a node's GPUs from a communication phase into dense arithmetic, each one steps from a few hundred watts toward its full power envelope within microseconds, and the barrier correlates those steps across the node. The power delivery network (PDN) must hold the supply voltage steady through that step, and the difficulty grows as the voltage falls from the 48V busbar to the sub-1V rail at the die.

At a fixed power, current scales inversely with voltage, so the core rail carries far more current than the busbar; the voltage regulators transform voltage and current between those boundaries. What disturbs the supply is the rate of change of that current, its slew rate di/dt. Every conductor loop has inductance, a property that resists changes in current, so a fast current step produces a momentary voltage dip, or droop, even when average power remains within the facility budget.

Definition 2.7: Power delivery network (PDN) and transient dynamics

Power delivery network (PDN) is the electrical distribution hierarchy that supplies the processor through regulators, interconnects, and decoupling capacitors. Parasitic loop inductance contributes to voltage fluctuations during changes in current.

1. **Significance**: Synchronized workload transitions can correlate accelerator demand. Supply excursions outside the device's specified limits can cause timing errors, protective throttling, or resets.
2. **Distinction**: Local electrical transients require a faster response than facility power-control loops can provide. Regulators and nearby charge storage address different timescales within the same hierarchy.
3. **Common pitfall**: A frequent misconception is that the full core-current slew acts on a single inductance summed from rack to die. Regulation and decoupling change the current waveform at each stage; the relevant inductance and current must belong to the same path.

For a particular inductive path, the voltage excursion contributed by its inductance follows equation 2.2:

$$\Delta V = L_{\text{parasitic}} \frac{di}{dt} \tag{2.2}$$

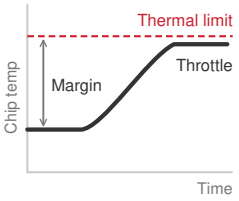
Here $L_{\text{parasitic}}$ is the loop inductance of that path, and di/dt is the current slew through it. Local capacitors initially supply part of a load-current increase, so the current slew seen upstream need not equal the slew at the core. A complete rail model also accounts for resistance, capacitance, and regulator response.

A worked estimate for one accelerator shows why the hierarchy matters. When an H100 moves from its communication-phase draw of about 400 W to its 700 W envelope on a 0.8 V core rail, its core current rises by about 375 A. Suppose the board loop between the voltage regulator and the package has 50 pH of inductance. If package capacitors supply the fast edge so that this loop sees the step over 1 µs, equation 2.2 gives a droop of about 19 mV, or 2.3 percent of the rail. If the same step reached that loop in 100 ns, the droop would be about 190 mV, roughly 23 percent of the rail and far outside a 5 percent operating band. The inputs are scenario assumptions, but the tenfold sensitivity to rise time is physical. The same current step stays inside tolerance or corrupts timing depending on which charge store answers it first.

The collective barrier that aligns transitions from communication to arithmetic raises the correlation of demand across a rack, but it does not imply that every accelerator switches on the same nanosecond or that their core currents flow through one shared low-voltage loop. Engineers must evaluate both each device's local voltage excursion and the aggregate demand seen by upstream supplies. A rising load can produce voltage droop, where droop below the specified operating minimum can invalidate timing margins, while an abrupt load reduction can produce overshoot that must remain within the device's specified limits as well. Neither the magnitude nor the resulting failure mode follows from workload synchronization alone. The mitigation is a hierarchy of charge storage and control, in which each tier answers the transients too fast for the tier above it (table 2.13), with placement and parasitic impedance determining which frequencies each tier can address.

Table 2.13: Decoupling Tiers in the Power Delivery Network: Each tier supplies charge on a timescale the slower tier above it cannot reach, so a fast edge that bypasses a tier lands on a larger inductance.

Tier	Charge store or control	Response timescale	Transients it absorbs
On-die	On-die capacitance	Sub-nanosecond	Switching activity within a kernel
Package	Package and interposer capacitors	Nanoseconds	Kernel launches and streaming-multiprocessor activation edges
Board	Bulk capacitors, regulator control loop	Microseconds	Communication-to-compute phase changes of one accelerator
Facility	Uninterruptible power supply (UPS), utility	Milliseconds to seconds	Synchronized power swings across racks and the cluster



The facility row of table 2.13 is where the barrier's correlation appears in aggregate. For an illustrative calculation, assume 1,024 GPUs change together from 400 W to 700 W each over 100 µs. The assumed aggregate step is 307 kW, giving a ramp rate of 3.07 GW/s. This is a load-side scenario, not a measured utility input. No single regulator carries this step, because each accelerator draws its share through its own board, yet the shared upstream supplies see the sum.

↪ How energy buffering presents this ramp to the grid as a smoother, more easily connected load is developed in section 15.6.2.

Workload-level controls complement these hardware tiers. Power ramping can reduce abrupt demand changes where the hardware and firmware support it, but a design must verify those controls rather than assume that every kernel launch receives automatic smoothing. The fleet-level lesson is that average power capacity and transient voltage integrity require separate checks.

2.6.2 Cooling class and heat removal

The power path ends in heat. Under the thermodynamic limit (principle 4), nearly every joule an accelerator draws leaves as heat through switching, leakage, and resistive losses. During a transient some of that energy warms the chip and its surroundings, but in steady operation the stored thermal energy stops rising, so cooling must remove heat at about the rate the rack consumes electricity. When removal falls behind generation, temperature climbs through the available thermal margin until throttling lowers clocks and throughput, and sustained overheating can damage the hardware. The rack's cooling class, air or liquid, is the choice of fluid that carries this heat away, and it bounds how dense the rack can be.

When cooling falls behind, temperature climbs through the thermal margin until throttling caps it.

Heat transfer explains why density reshapes the rack. Air carries far less heat per unit volume than liquid, so an air-cooled rack needs enough airflow, pressure, and temperature rise to carry away its heat. How much a hall can supply depends on the server and facility design rather than on one rack-power threshold.

Air cooling, the dominant technology for decades, works by blowing room-temperature air across heat sinks attached to the chips. The air absorbs heat at a rate determined by its specific heat capacity, roughly 1.0 kJ/kg/K. The heated air is exhausted from the rear of the rack, typically 15–20 degrees Celsius warmer than the inlet, and directed to a computer room air conditioning (CRAC) unit that cools it before recirculating.

Air is a poor thermal conductor. Its thermal conductivity is only 0.026 W/m/K, compared to 0.6 W/m/K for water and 400 W/m/K for copper. Removing a large heat load with air requires substantial volumetric flow. Fan power depends on that flow, pressure drop, and fan efficiency; rack power alone does not specify a fixed cooling fraction.

The heat that a coolant stream removes depends on how much fluid flows, how much heat each kilogram absorbs per degree of warming, and how far the fluid warms (equation 2.3):

$$P_{\text{thermal}} = \dot{m} \times c_p \times \Delta T \tag{2.3}$$

where P_{thermal} is the heat removed (watts), $\dot{m}$ is the mass flow rate (kg/s), c_p is the specific heat capacity (J/kg/K), and ΔT is the temperature difference between outlet and inlet. For air with c_p of 1,005 J/kg/K and a typical ΔT of 15 K (inlet at 20 degrees C, outlet at 35 degrees C), removing 100 kW requires a mass flow rate of 100,000 ÷ (1,005 × 15) ≈ 6.6 kg/s. At sea-level air density of 1.2 kg/m^3, this corresponds to a volumetric flow rate of 5.5 m^3/s, or approximately 11,713 CFM (cubic feet per minute). Moving this much air through the confined space of a server rack requires powerful fans that themselves consume substantial power.

At higher power densities, the airflow and pressure required to cool a rack raise fan energy and can make air cooling impractical before the IT load itself reaches a power limit. The exact crossover depends on rack geometry, inlet temperature, pressure drop, and fan-control policy rather than on one universal rack-power threshold.

Water has a specific heat capacity of 4.18 kJ/kg/K, over four times that of air, and a thermal conductivity roughly 23× higher. Its much greater density also lets a small fluid volume carry substantial heat. To appreciate the magnitude of the difference, consider how much fluid must flow to remove 700 W from a single GPU. Air at a 15-degree temperature rise requires tens of liters per second of airflow (a small wind tunnel). Water at the same temperature rise requires only about 0.01 liters per second (a thin stream). This thousands-fold difference in volumetric flow permits compact liquid paths, but it does not determine pumping energy. Pressure drop through cold plates, pipes, and fittings, together with pump efficiency, determines the power needed to sustain that flow.

At rack scale the same equation sizes the liquid loop. Removing the modeled 120 kW load of a GB200 NVL72 rack through water that warms by 10 °C takes about 170 liters per minute, and a smaller temperature rise needs proportionally more flow. A real design must use the heat fraction the liquid loop actually captures and account for residual air cooling; flow capacity, pressure, leak containment, and loss-of-flow response are separate requirements, which the facility controls of section 2.6.4 treat as failure domains.

Direct-to-chip liquid cooling routes coolant through cold plates mounted on GPU packages. The cold plate contacts the heat spreader through thermal interface material; the resulting thermal resistance depends on the package, interface, plate design, and flow. The coolant carries heat through manifolds and pipes to a coolant distribution unit (CDU) at the rack or row level. The permissible supply temperature depends on the equipment, so liquid cooling need not require chilled water.

In a two-loop design, the CDU transfers heat from the chip-level coolant to the facility water loop, which carries it toward cooling towers or dry coolers. Isolation lets each loop maintain its required fluid chemistry and pressure. The chip-level coolant must satisfy the equipment's compatibility and cleanliness requirements to control deposits, corrosion, and blockage; purity alone does not establish suitability. Liquid cooling can reduce server airflow requirements, although memory modules (DIMMs), voltage regulator modules (VRMs), and other components without cold plates may still need fans, and lower fan demand can also reduce noise.

A more aggressive approach, immersion cooling, submerges entire server boards in a tank of nonconductive dielectric fluid. The fluid absorbs heat from wetted surfaces, replacing server airflow; high-heat-flux components may still need heat sinks or directed flow, and flow, local heat flux, material compatibility, and heat-exchanger capacity still determine component temperatures. Single-phase immersion cooling uses a fluid that remains liquid throughout the process, with heat carried away by convection currents in the tank. The heated fluid rises to the

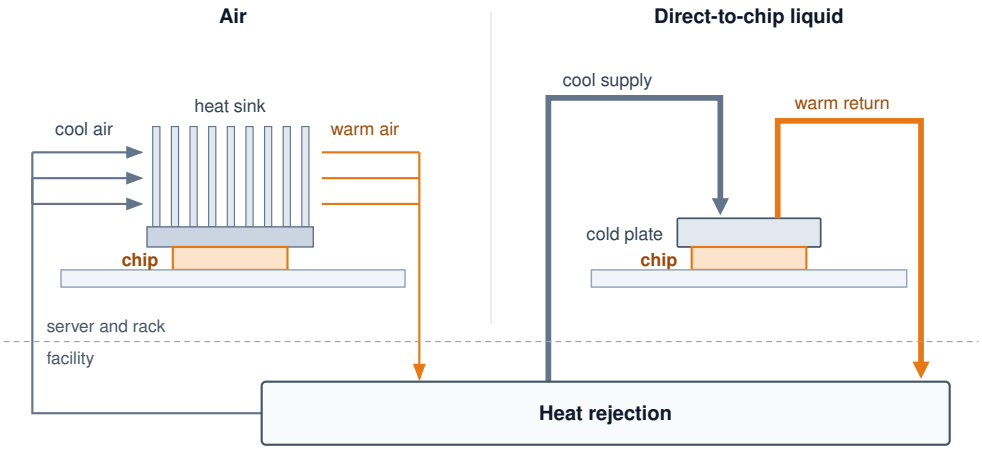
surface, is pumped through a heat exchanger to reject the heat to the building's chilled water loop, and returns to the bottom of the tank. Two-phase immersion cooling takes this further: fluid boils at heated surfaces, carries latent heat to a condenser, and returns as liquid, with heat removal depending on the fluid, pressure, condenser capacity, and operating conditions. The complete facility still spends energy on heat rejection and electrical distribution, so the cooling mechanism alone does not settle facility energy.

The trade-off is serviceability. Accessing a failed component requires handling fluid-wetted hardware, and the dielectric fluids themselves are expensive ($20–$50 per liter). A single immersion tank holding four server boards may contain 500–1,000 liters of fluid, representing $10,000–$50,000 in coolant cost alone. The operational procedures for immersion-cooled facilities differ sharply from air-cooled ones, requiring specialized training for technicians and different approaches to cable management, since all wetted materials must be compatible with prolonged fluid exposure. Depending on the fluid and its additives, metals can corrode, while polymer insulation and seals can swell or degrade. Qualifying compatible materials adds engineering work and can constrain component choices. These serviceability costs enter the design decision alongside the heat paths, binding limits, and parasitic loads of the air and liquid regimes (table 2.14).

Table 2.14: Cooling Architecture Trade-Offs: Feasible rack density follows from the particular equipment and facility design. The example design points differ by 10× in rack power, yet there is no universal rack-power threshold or PUE that separates air and liquid cooling. Compare qualified operating envelopes and total facility energy.

Design question	Air cooling	Direct-to-chip liquid cooling
Heat path	Chip to heat sink to moving air	Chip to cold plate to coolant loop
Binding limits	Airflow, pressure drop, inlet temperature, and allowable component temperature	Cold-plate resistance, flow, coolant temperature, and heat-rejection capacity
Parasitic loads	Server and facility fans; conditioning where required	Pumps, CDU, heat rejection, and any residual air cooling
Service constraints	Air containment, filters, and access paths	Fluid compatibility, leak management, and maintainable connections
Facility metric	Measure complete IT and non-IT energy	Measure the same boundary; liquid cooling does not determine PUE by itself
Example design point	Enterprise rack near 12 kW; best air-cooled facility profile PUE 1.12	GB200 NVL72 rack at 120 kW; liquid-cooled facility profile PUE 1.06

Direct-to-chip liquid cooling supports higher heat flux than forced air because cold plates route chip heat directly into circulating fluid with high volumetric heat capacity before reaching facility heat rejection, whereas air systems rely on convective dissipation across finned heat sinks (figure 2.14). Ambient wet-bulb temperature (the lowest temperature that evaporation can bring outdoor air to, which bounds evaporative heat rejection) and rack power density determine whether an air, liquid, or hybrid loop satisfies the chip junction temperature envelope.



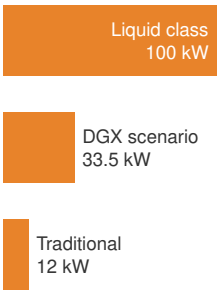


Figure 2.14: Air and Liquid Heat Paths: Air transfers chip heat through a heat sink and moving air; direct-to-chip liquid cooling transfers it through a cold plate and coolant. Both require heat rejection. Capacity, parasitic energy, and water use depend on the engineered system rather than the cooling medium alone.

Two anchors bound the choice for this chapter's racks. The four-node DGX H100 scenario at 33.5 kW can use engineered air cooling in a suitable facility, while racks in the 100 kW class of high-density training racks need liquid, which raises heat-removal capacity and can reduce fan energy. Between the two anchors, the facility's airflow capacity decides. Cooling class is therefore a configuration constraint. Rack layout and heat-removal capacity, not accelerator count alone, determine whether the intended configuration can sustain its workload or must reduce density or power.

Engineered air can still cool the DGX rack; the 100 kW class needs liquid.

↪ What heat removal adds to facility energy (PUE), and the water that heat rejection consumes, are developed in section 15.6.3.

2.6.3 Rack design considerations

Packing 33.5 kW of compute and thermal hardware into a standard 42U frame leaves almost no room for conventional server layouts. In an enterprise 42U rack, servers are installed as independent 1U or 2U pizza-box units, each with its own fans, power supplies, and cable connections. A single DGX H100 instead occupies 8U and contains 8 GPUs, the NVSwitch fabric, multiple power supplies, and (in liquid-cooled configurations) coolant manifolds with quick-connect fittings. Four DGX units fill 32U of a 42U rack, leaving only 10U for networking switches, cable management, and PDUs.

The transition from traditional server form factors to ML-optimized designs is driven by the same power density challenge that motivates engineered airflow or liquid cooling. A traditional 1U server dissipates 300–500 W and requires only modest airflow for cooling. A DGX H100 node dissipates approximately 8.4 kW across its 8 GPUs, NVSwitches, and supporting components, requiring either high-volume forced airflow (in air-cooled configurations) or liquid cooling plumbing (in liquid-cooled configurations). The form factor must accommodate both the compute hardware and the thermal management infrastructure, which is why ML nodes are substantially taller (8U vs. 1U) than traditional servers.

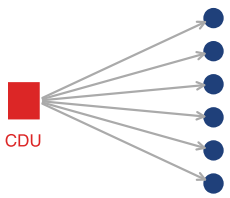
Cable management is a nontrivial engineering challenge. Each DGX H100 node has eight InfiniBand cables (one per GPU), two Ethernet management cables, power cables, and, for liquid-cooled units, coolant hoses. A fully populated rack contains over 40 high-speed cables whose layout is governed by three strict physical constraints: airflow clearance, minimum bend radius, and electromagnetic interference. In air-cooled designs, cables must not obstruct intake or exhaust airflow, because even a localized blockage creates hot spots that trigger thermal throttling. High-speed cables simultaneously enforce a minimum bend radius (for installed fiber optic cable, typically 10–15$\times$ the outer diameter, per the manufacturer's specification (The Fiber Optic Association 2020)), below which optical fibers suffer attenuation and induce bit errors or complete link drops. Densely bundling high-speed copper cables can also induce electromagnetic crosstalk that degrades signal quality. In large installations, the cable plant alone can take weeks to install and test, and cable routing errors are one of the most common causes of post-installation debugging delays.

The rack's network attachment needs the same density-driven rethinking, starting with the top-of-rack (ToR) switch. In traditional data centers, a ToR switch provides 1–10 Gb/s Ethernet connectivity to each server, aggregated into uplinks to higher-level switches. In an ML rack, the ToR switch is an InfiniBand or high-speed Ethernet switch providing 400 Gb/s per port, and it must handle the bursty, synchronized traffic patterns of distributed training. In a conventional design all eight GPUs of a node share one ToR switch, so a data-parallel AllReduce converges on that switch and its uplinks. A rail-optimized design instead gives each GPU index its own leaf switch (GPU 0 of every node on leaf 0, GPU 1 on leaf 1, and so on), so same-index collectives stay on one switch. The price is extra switches and cabling, and the benefit depends on how the job's process groups map onto the rails.

↪ How rail-optimized topologies align cabling with collective traffic is developed in section 3.5.3.

2.6.4 Facility reliability and environmental controls

A coolant leak or electrical fault in a single DGX H100 rack threatens $1.4 million in hardware and can halt a multi-rack training job across the upper levels of the failure-domain hierarchy introduced in section 2.5.5. Data centers housing ML infrastructure therefore pair physical security with continuous environmental monitoring that becomes part of the compute design rather than a facilities afterthought. Beneath raised floor tiles and along liquid cooling piping, water sensors identify leaks within seconds and close automatic coolant isolation valves,



while humidity controls keep the air within a moderate band, dry enough to prevent condensation and humid enough to limit static discharge. Inside the cabinets, aspirating smoke detectors sample rack air continuously to catch combustion byproducts at concentrations far below what sprinkler-activating detectors can sense. Vibration sensors on the building structure and rack frames flag seismic events or construction shocks before they can damage disk drives or loosen cable connections.

Cooling failures threaten both hardware and useful fleet work. When coolant flow stops, a dense rack loses heat-removal capacity and must throttle or shut down before thermal runaway. N+1 redundancy in CDUs, temperature monitoring, and automatic load shedding limit the affected capacity. An emergency air path can support reduced-power operation where the facility design provides one.

Serviceability also changes the failure budget. Leaks can damage equipment and drain cooling capacity, which is why the leak sensors above drive isolation valves, while quick-disconnect fittings allow node replacement without draining the entire loop. Their seals and coolant compatibility therefore belong in the maintenance plan. The fleet-level consequence depends on how much synchronized work shares the failed cooling domain.

The economics of cooling reliability shift when moving from independent inference servers to tightly coupled training clusters. In a distributed training run using synchronous parallelism, a cooling-loop failure that idles one slice of the cluster can halt the entire job. Consider a cooling failure that triggers a thermal shutdown of the 256 GPUs served by one coolant distribution unit within a 10,000-GPU cluster, about ten times the 1,024-GPU reference cluster. The example counts lost compute capacity, excluding repair and replacement costs. If the repair time for a CDU pump is 4 hours, the immediate loss of 256 GPUs at the fleet's reference in-service rate of $2 per GPU-hour is $2,048. Assuming the job cannot continue elastically and the remaining 9,744 GPUs remain unavailable for other work, the synchronous blast radius inflates the cost to $80,000 in lost compute time. Adding checkpoint retrieval and rollback of 30 to 60 minutes of lost computation brings the illustrative lost-compute total to $90,000–$100,000 before any additional recovery delay. Whether N+1 cooling redundancy is worth its price follows from comparing these expected outage losses and recovery behavior with that price, rather than from treating redundancy as an unconditional requirement. The energy the rollback repeats belongs to the facility energy account of section 15.6.3.

Coolant condition is another reliability input. **Deionized water** and compatible inhibitors control **galvanic corrosion**, the damage caused by electrochemical differences between metals in the loop. **Biofilm** on heat-transfer surfaces impedes cooling and increases pumping demand. Maintenance must preserve coolant chemistry and heat-transfer performance, because a fouled or corroding loop loses capacity before it fails outright.

One cooling failure can idle the whole training job.

These controls bear directly on reliability and uptime. A fire in a single rack can shut down an entire data center hall for days while the fire suppression system is recharged and the affected area is decontaminated. The 2021 OVHcloud fire in

Strasbourg shows how a single-building incident, absent the right compartmentalization, escalates into a site-wide failure domain.

War Story 2.1: The data center that became the failure domain (2021)

Context: OVHcloud operated four data centers at its Strasbourg site, serving customers whose systems depended on the site's physical power, fire, and recovery design (OVHcloud 2021).

Mechanism: On March 10, 2021, a fire broke out in building SBG2. Uncontained fire spread and shared power pathways destroyed building SBG2, damaged adjacent SBG1, and forced emergency shutdown of SBG3 and SBG4.

Impact: Thousands of servers were physically destroyed, taking over 3.6 million websites offline worldwide and destroying unbacked-up customer data.

Fix: OVHcloud rebuilt the site with independent physical fire barriers, isolated power distribution per building, and mandatory free off-site backup storage.

Systems lesson: Compute infrastructure extends beyond GPUs and network topology. Fire compartments, power isolation, backup geography, and disaster-recovery assumptions determine whether a rack-scale incident becomes a site-scale outage. Multi-node ML training clusters inherit this physical dependency: a single data-center power or cooling domain failure halts active training runs and destroys un-replicated checkpoint states unless recovery paths cross physical facility boundaries.

Once rack-level controls are in place, the reliability question moves up to facility redundancy, where the same failure-domain logic that isolates a leaking rack also decides how much duplicate power, cooling, and recovery capacity the site should buy. Data center reliability is commonly classified using the Uptime Institute Tier system, with Tier III and Tier IV representing common options for mission-critical compute (Uptime Institute 2026). A Tier III facility is concurrently maintainable: redundant capacity components and distribution paths let operators maintain or replace equipment without shutting down IT operations. Tier IV adds fault tolerance through independent, physically isolated systems, so a single equipment failure or distribution-path interruption should not affect IT operations. The practical difference is not a magic availability number; it is how much failure prevention the building buys in electrical and mechanical infrastructure before software-level resilience takes over.

For ML training, the calculus differs from traditional enterprise computing. A training run is a long-running batch process, not a real-time transaction system. A facility outage during a two-week run therefore usually costs a restart from the last checkpoint rather than permanent data loss, provided a valid checkpoint survives in an accessible failure domain and usable compute becomes available. The restart still incurs lost work, recovery time, and potentially a missed deadline. Many training deployments therefore pair concurrently maintainable (Tier III)

facilities with aggressive application-level fault tolerance. Rather than buying every layer of building-level redundancy, they invest in checkpointing, job restart, and storage that can absorb rare facility interruptions, and redirect the avoided resiliency spend toward accelerators, networking, or storage. Facility redundancy and application-level recovery address different parts of the same risk. A design can trade some preventive infrastructure for checkpointing and recovery capacity only after checking which failures the recovery path survives and whether the resulting completion-time risk is acceptable.

Checkpoint 2.3: Infrastructure physics

A team is planning to deploy 256 H100 GPUs (32 nodes, each drawing about 8.4 kW as computed in section 2.6.3) in an existing air-cooled data center with 250 kW of available facility power, a PUE of 1.5, and a cooling plant that can reject 200 kW of IT heat.

- ☐ **Facility power**: calculate the total power draw, including cooling overhead.
- ☐ **Binding capacity**: identify whether power capacity or cooling capacity is the binding constraint.
- ☐ **Required modifications**: specify what modifications would be needed to support the full deployment.

The rack concentrates power and heat into a physical volume where thermodynamics, not software, sets the limits. A single rack of 32 GPUs, however, is far from sufficient for our 175B model, which needs tens to hundreds of nodes, many racks' worth, to train on a practical schedule. The next level of infrastructure aggregates tens to hundreds of racks into a unified computing system: the pod, whose physical interconnect fabric must be engineered around the communication patterns and failure domains the workload creates.

2.7 The Pod

Training our 175B model on a single DGX H100 node (8 GPUs, 15,832 TFLOP/s of aggregate FP8 peak) would take about 1.4 years at the efficiency assumed below, even if the model state could fit. Roughly 37 nodes bring the compute-only time down to two weeks, and about 512 nodes bring it to a single day, before any communication or recovery overhead. A pod is the cluster-scale unit that makes this possible: many racks under one high-speed fabric, power envelope, and cooling design. The engineering challenge is wiring those nodes together into a network fast enough to keep gradient synchronization from becoming the bottleneck, so that the fabric serves the role a system bus serves within a single machine. Pod design is the first point where topology, power, and failure domains become shared infrastructure rather than per-rack concerns. Two fabric families dominate: a switched fat tree supplies full bisection bandwidth across node uplinks, while a direct-connect torus wires each node to its neighbors, using

fewer switches but giving bisection bandwidth that grows more slowly than node count. Section 3.5.2 and section 3.5.4 develop both.

The pod-scale examples that follow deliberately step up to eight times the 1,024-GPU reference cluster. A 1,024-node DGX H100 cluster contains 8,192 GPUs, 4,096 NVSwitch chips, 8,192 InfiniBand HCAs, several hundred InfiniBand switches, tens of thousands of cables, and draws approximately 8.6 MW of rack power, including each rack's allocated cooling overhead. It occupies 256 four-node racks across one or more data center halls.

The physical weight of such a cluster is also substantial. Each DGX H100 node weighs approximately 130 kg (288 lb), so 1,024 nodes weigh over 133 metric tons. Racks, switches, cables, and cooling infrastructure add substantially to that total. The data center floor must be structurally engineered to support this concentrated load, which is far denser than the loading that traditional server rooms were designed for. This structural requirement is often overlooked during facility planning and can be a blocking constraint for retrofitting existing buildings.

The physical layout of the data center hall reflects these density constraints. The high power density of ML training racks requires strict hot aisle/cold aisle containment in air-cooled sections, where cold air is forced into the enclosed front of the rack and waste heat is captured immediately at the rear exhaust. The "spine" of the hall, the central cable corridor connecting all racks to the aggregation switches, must accommodate thousands of fiber optic cables and power feeds. Overhead cable trays are preferred over under-floor routing to improve airflow and accessibility, carrying the heavy copper power feeds and fragile fiber interconnects that form the nervous system of the cluster. The layout must also accommodate the liquid cooling infrastructure: coolant distribution unit placement, coolant piping runs, and isolation valves that allow individual racks to be serviced without draining the entire cooling loop. These physical layout decisions, made during facility design, constrain the network topology options available to the training team years later.

Training a 175B model on this cluster costs about $6 \times P \times D$ floating-point operations for P parameters and D training tokens, the training-compute estimate of section 1.3.2. The token count is where the scaling laws of section 1.3 enter the hardware plan, because a compute-optimal allocation would give a model of this size many times more tokens than GPT-3 saw, multiplying this budget, and the pod-hours it consumes, by the same factor. Notebook 2.4 turns the budget into a compute-only baseline under an assumed local compute efficiency. That efficiency is not measured distributed MFU, because MFU over a distributed step already includes its communication and pipeline losses. On the 1,024-GPU reference cluster itself the same baseline would take about 4 days. In the terms of the Fleet Law (equation 1.3), that baseline is the T_{compute}/N term alone.

In practice, communication overhead, pipeline bubbles, checkpoint I/O, hardware failures, and maintenance windows compound to extend the actual wall-clock time beyond that baseline. The first two are the Fleet Law's exposed $T_{\text{comm}}(N)$ and $T_{\text{sync}}(N)$ terms, and the rest are operational losses around the step. The note-

book chains these factors into a scenario estimate of wall-clock time; production schedules can stretch further once queueing, data readiness, debugging, reruns, and site-specific operational margins enter the plan. At pod scale, the schedule therefore depends on fleet overhead as well as on local execution, and recovering the lost time draws on better networks, overlapped communication, and proactive maintenance.

Napkin Math 2.4: Training time for 175B

The training time for our 175B model derives from first principles.

1. **Total FLOPs**: Using the same $6 \times P \times D$ approximation, where $P = 175 \times 10^9$ and $D = 300 \times 10^9$ tokens: 3.15×10^{23} FLOPs
2. **Cluster throughput**: 8,192 H100 GPUs at 1,979 TFLOP/s peak, assuming 45 percent local compute efficiency before distributed overhead: $8,192 \times 1979 \times 10^{12} \times 0.45$ FLOP/s before distributed overhead $\approx$ 7.30 EFLOP/s
3. **Compute-only training baseline**: $(3.15 \times 10^{23}$ FLOPs$)/(8,192 \times 1979 \times 10^{12} \times 0.45$ FLOP/s$) \div 3600 \approx$ 12.0 hours
4. **Illustrative overhead chain**: The scaling factor already includes pipeline fill and drain, so no separate bubble step follows. Each subsequent percentage adds time relative to the preceding subtotal, not to final wall time; the factors are scenario assumptions, not independent measured losses:
    - Distributed-step losses (scaling efficiency 0.56, the modeled tier for 8,192 GPUs, covering communication and pipeline bubbles): $\div 0.56 \rightarrow$ 21.4 hours
    - Checkpoint overhead ($\approx 3\%$): $\times 1.03 \rightarrow$ 22.1 hours
    - Hardware failures and restarts ($\approx 10\%$ of the checkpoint-adjusted subtotal): $\times 1.10 \rightarrow$ 24.3 hours
    - Maintenance windows ($\approx 5\%$): $\times 1.05 \rightarrow$ 25.5 hours

The total training time is 25.5 hours in this simplified scenario chain, or about 1.1 days. Real production calendars may still stretch to weeks after queueing, debugging, reruns, and site-specific operational margins are included. Recovering this lost time is the domain of distributed systems engineering.

2.7.1 The pod as a warehouse-scale computer

When a single training job spans 10,000 H100 GPUs across an entire data center hall, about ten times the reference cluster, a slow network tier or a single device failure stalls the whole building's computation. At this scale, the pod operates as a warehouse-scale computer (WSC) (Barroso et al. 2019) and requires a matched budget for arithmetic, communication, and recovery. Rounding the pod up to 10,000 GPUs keeps the warehouse-scale arithmetic easy to follow, and the chapter's other fleet-scale power, cost, and failure examples use the same round figure. Such

a WSC supplies approximately 9.89 EFLOP/s of FP16 peak and 19.8 EFLOP/s at FP8. Non-blocking InfiniBand at 50 GB/s per GPU, the injection bandwidth each endpoint can push into the fabric, provides 500 TB/s of aggregate injection bandwidth and 250 TB/s across the bisection, the cut that splits the cluster into two equal halves. With 4:1 oversubscription at that boundary, meaning the switch tier above it has one quarter as much uplink as downlink capacity, the modeled crossing capacity falls to 62.5 TB/s. The effect on a collective depends on how much traffic crosses the constrained paths, its schedule, and competing transfers. The bandwidth ratio alone is not a collective-time multiplier.

↩ The warehouse-scale computer as the unit of fleet design is established in section 1.2.2.

Treating the building as one computer means that a server assigned to a distributed training job contributes to a shared completion time, and the network fabric, distributed storage, and fleet orchestrator make the building's resources available as one training system. Rack placement, the power delivery chain, and the network topology must therefore be co-designed, because a mistake at any layer propagates through the others. The first physical consequence concerns communication: the network can set the scaling ceiling. Within a single node NVLink supplies enough bandwidth for tensor parallelism, but across nodes the fabric must carry gradient tensors, activation checkpoints, and pipeline stage outputs, so a building-scale machine is only as fast as the wires that bind its cores. The WSC reframing makes the interconnect a first-class architectural component rather than a peripheral.

The second consequence is that *failure is a physical certainty, not an exceptional event*. Under the scenario assumption of independent failures and a per-GPU MTTF of approximately 50,000 hours, a cluster of 10,000 GPUs has a mean interval of roughly five hours between GPU failures, and the 25K-GPU fleet of figure 2.1 about two. That is an expectation, not a periodic schedule, and shared power or cooling faults add correlated exposure. The node failure estimate of section 2.5.5 and the facility controls of section 2.6.4 are the same exposure at smaller scope. Redundant infrastructure, such as dual-path power feeds and redundant switch fabrics, can prevent some interruptions; checkpoint storage and recovery capacity limit lost progress when a running job must stop. Both belong in the physical design. Redundancy keeps many component failures from halting the job, and checkpoints bound the work lost when one does.

The third consequence is that the building blocks combine differently depending on the workload they must carry. A pod is not assembled from a single canonical part list; the interconnect, the switching, and the memory placement are each chosen against the communication and capacity pattern the dominant workload imposes. Three pod designs show the range (table 2.15). An NVIDIA SuperPOD wires GPUs through an InfiniBand fat-tree for any-to-any flexibility, a Google TPU pod hard-wires chips into a torus for dataflow throughput, and a recommendation pod built for Archetype B arranges the same class of accelerators around embedding memory rather than raw compute.

Table 2.15: Pod Architecture by Workload: Each pod's interconnect, switching, and memory emphasis reflects the communication and capacity pattern of its dominant workload, not a single best design.

System	NVIDIA SuperPOD	Google TPU Pod	Recommendation pod
Interconnect	InfiniBand Fat-Tree	3D Torus ICI	RoCE (RDMA over Ethernet)
Switching	External Switches	Direct Chip-to-Chip	Leaf/Spine Ethernet
Topology	Any-to-any	Nearest-Neighbor Mesh	Rail-optimized
Optimization	Flexibility	Dataflow Throughput	Embedding Memory
Dominant workload	Diverse Research	LLM Training	Recommendation

The recommendation pod is the clearest case of memory placement, not compute, driving the layout, and it is the physical form of Archetype B (DLRM at Scale). Its embedding tables reach 10 TB or more, which lighthouse 2.1 showed would need at least 15 DGX H100 nodes of HBM merely to hold, while the dense neural-network layers that operate on those embeddings are comparatively small. A recommendation-first design splits the two across the memory hierarchy. The terabyte-scale embedding tables reside in host CPU DRAM (roughly \$3–\$5/GB), and the dense layers execute on GPUs, where the compute density justifies the \$10–\$15/GB cost of HBM. Embedding tables create a capacity requirement, but small random lookups can also saturate aggregate memory bandwidth or expose access latency at high concurrency. Host placement trades capacity cost against lookup throughput and host-to-accelerator transfer, so the workload must validate both budgets. The systems lesson is that optimal infrastructure is workload-specific, not specification-maximizing. Deploying compute-optimized nodes for a memory-capacity-bound workload would strand most of the accelerator's throughput on a problem its silicon was never the bottleneck for.

The physical design supplies constraints, not an operating policy; later chapters turn its power, capacity, topology, reliability, and sustained-throughput measurements into placement, recovery, monitoring, and ownership decisions. One hardware decision remains for this chapter. With every level from the accelerator to the warehouse-scale computer in view, the choice of accelerator can now be judged against the whole hierarchy rather than against its data sheet.

2.8 Accelerator Selection for Fleet Workloads

The same H100 that sustains 30–50 percent of peak throughput during well-tuned large-batch training may achieve less than 5 percent utilization during single-request inference, because the binding constraint shifts from arithmetic to memory bandwidth. An accelerator's compute throughput, memory bandwidth, memory capacity, and power consumption are meaningful only in relation to the workload running on it. Selecting the right accelerator therefore requires mapping each

↪ The ownership decision, in which sustained fleet utilization sets the build-versus-buy threshold, is developed in section 12.9.2.

workload archetype to its position on the roofline plot and identifying which physical resource dominates its performance.

For the 175B running example, large local matrix operations can place substantial training work above the roofline ridge point. Arithmetic throughput then matters alongside the capacity needed for sharded state and the interconnect needed by the partition. H100, B200, and TPU v5p configurations are candidates to evaluate under the same workload and quality target. The selected software stack must express the required operations efficiently enough for the hardware advantage to appear in sustained execution.

Serving the same language model changes the answer, for the reason the token-latency notebook 2.1 established. At batch size 1, the H100's 3.35 TB/s bandwidth determines decode throughput while much of the arithmetic silicon waits, so the key metric becomes memory bandwidth per dollar rather than peak TFLOP/s. Batching helps for the reason section 2.3.2 quantified, reusing each weight read across more requests, which is why serving systems work so hard to batch without violating tail-latency service-level objectives (SLOs). The workload did not change names, but the binding term of the single-machine iron law moved from arithmetic to data movement, and the accelerator choice changes with it.

Where recommendation models split the decision across sparse lookup and dense computation, the memory-placement case that the recommendation pod of section 2.7.1 already resolved, vision and diffusion workloads move back toward arithmetic throughput because convolutions, attention blocks, and denoising networks reuse data heavily. Diffusion inference makes this especially clear. A standard Stable Diffusion v1.5 configuration runs 50 denoising steps, so the service pays for a sequence of full model evaluations rather than one decode step per token. For these workloads, TFLOP/s per dollar often dominates bandwidth per dollar once model state fits in memory.

Mixture of experts (MoE) activates only part of a much larger parameter set for each token (Shazeer et al. 2017); Mixtral-8x7B (A. Q. Jiang et al. 2024) has 46.7B total parameters but only 12.9B active per token because its router chooses 2 experts of 8 experts experts. That saving routes tokens among devices through the AllToAll collective, so the selection consequence is a fabric with enough bisection bandwidth, together with load balancing, for the theoretical saving to appear in the training trace (Fedus et al. 2022; Lepikhin et al. 2021). Multi-modal models similarly combine phases with different arithmetic intensity and batching behavior, such as vision encoding and text decode. Their relative cost and placement determine whether flexible scheduling, additional memory, or communication capacity changes the critical path; modality count alone does not select an accelerator architecture, so the planner must follow the data exchanged between the actual phases.

↪ MoE AllToAll routing and expert load imbalance are developed in section 5.8.1.

> Systems Perspective 2.2: Matching hardware to workload
>
> Workload diversity can justify a heterogeneous fleet, with each pool provisioned for its binding resource. The gain comes from matching hardware to the work assigned to it, while keeping each tightly synchronized training group balanced. The fleet-wide decision must account for that matching benefit together with the cost of supporting multiple platforms.

2.8.1 Precision and throughput trade-offs

Booking a twofold training speedup from FP8 on a capacity spreadsheet, or sizing a serving pool for FP16 weights when INT4 would pass quality validation, can misstate fleet device counts by a factor of two or more. The number formats and peak rates of section 2.4 become fleet decisions as soon as they set how many accelerators a job requires. FP8 doubles the H100's advertised arithmetic ceiling for supported operations, from 989 TFLOP/s to 1,979 TFLOP/s per GPU, but that doubling is a peak-capacity comparison, not a training speedup that can be booked before workload validation. Infrastructure sizing must use the sustained rate of a validated precision policy.

For inference, quantization changes both weight storage and the possible hardware topology. Our 175B model at FP16 requires 350 GB, so the parameters alone span at least five 80 GB H100 GPUs. Quantizing to INT8 halves the weight payload to 175 GB, which fits on three GPUs, and INT4 shrinks it further to 87.5 GB, which fits on two GPUs. These are weight-only capacity bounds; quantization metadata, attention state, and workspace also need memory. Reading 4-bit rather than 16-bit weights quarters the raw payload, but it does not change physical bandwidth or guarantee a fourfold token-latency reduction. Kernel support, conversion work, other traffic, and any change in device count determine the realized gain, subject to validation of model quality.

2.8.2 Benchmarking accelerator performance

A procurement team comparing accelerators needs a published number that predicts the performance the organization will actually achieve. Peak TFLOP/s, memory bandwidth, and TDP describe *potential*, not *achieved* performance, so the decision turns on whose measured results to trust and under what rules they were produced. The industry-standard reference is MLPerf, maintained by MLCommons: MLPerf Training reports the time to train reference models to a target accuracy, and MLPerf Inference reports serving throughput and latency under realistic batching and streaming conditions. Both capture complete system performance, including software stack efficiency, communication overhead, and memory management, rather than raw silicon speed alone.

Closed-division results fix the workload and quality target so implementations can be compared, and open-division results allow broader changes, rules that section 9.3.1 reads as one instance of a measurement contract. Neither division predicts a deployment automatically. Compare the submission's workload, software,

precision, hardware count, and quality target with the intended system before using its result for procurement.

For our 175B model, training, fine-tuning, and serving need separate measurements. Batch shape, trainable state, sequence length, and partitioning can change both capacity demand and the critical path. Fine-tuning does not occupy a fixed point between training and decode merely because it updates an existing model. Evaluate the intended phases on candidate hardware with the actual model and data pipeline, using published MLPerf results as comparative evidence rather than deployment forecasts. MFU reports the share of the chosen peak that useful model computation averages over a measurement window. Time to train a reference model to a target metric also captures the I/O stalls, checkpointing, and restart delays that a steady-state MFU window can omit, although neither establishes the model quality reached.

2.8.3 Inference-specific infrastructure considerations

Training and serving place opposite demands on the same cluster because they optimize over different timescales. A large training run is one long job that occupies its allocation for days or weeks and is judged by sustained *throughput* and time to a target quality. Its steps repeat the same exchanges, so communication demand is easier to characterize than an arrival stream, and an individual operation can take milliseconds to seconds without harm, although failures, I/O, and changes in execution shape still affect the schedule. Serving trained models must instead turn the same hardware into responses for many independent, short-lived requests arriving at irregular intervals, each under a latency target that for interactive use is measured in tens of milliseconds.

Serving infrastructure must meet *latency* targets at an acceptable *cost per query* under a variable request load. Independent requests can be assigned to separate replicas, but a replica that shards a model across devices still communicates within each request. Prompt processing, successive decode steps, and complete responses also have different latency budgets. Capacity planning must therefore specify the request mix, model placement, and service targets before concluding that serving needs less network capacity than training; training and serving part ways on utilization, model placement, network traffic, and the cost metric that judges them (table 2.16).

Table 2.16: Training vs. Serving Infrastructure: Training and serving optimize different hardware behaviors, so capacity planning must compare utilization, model placement, network traffic, and cost in the mode the fleet will actually run.

Dimension	Training infrastructure	Serving infrastructure
GPU utilization	Large local batches push dense layers into the compute-bound regime; well-tuned runs commonly sustain 30–50% MFU.	Batch-1 decode is deeply memory bound and can fall below 5% MFU; batching raises utilization at the cost of latency, within memory capacity.

Dimension	Training infrastructure	Serving infrastructure
Model placement	Tensor and pipeline parallelism distribute a single model across many GPUs.	Replicas of the model, or large shards of it, handle independent requests, so memory demand scales with concurrent serving capacity.
Network traffic	The partition determines gradient, activation, and parameter exchanges between workers.	Independent replicas can serve separate requests, but sharded replicas still require inter-device exchanges within each request.
Cost metric	Cost per completed run at a target quality includes the measured schedule and recovery overhead.	Cost per request or per 1,000 tokens depends on request shape, latency targets, utilization, and provisioned capacity.

Serving therefore cannot be planned as training with smaller batches, because the optimization target changes from synchronized throughput to latency-bounded, continuously billed requests. The implication is that effective serving infrastructure often uses different hardware, different software, and different facility designs than the training infrastructure. Some organizations use previous-generation GPUs (A100s) for serving because the memory bandwidth per dollar can be competitive with newer GPUs, and the lower TDP (400 W vs. 700 W) allows higher rack density and lower cooling costs.

The inference workload itself splits into two distinct phases with opposing bottlenecks. The prefill phase processes prompt tokens in parallel, increasing weight reuse and potentially approaching the compute ceiling when the prompt and batch shapes supply enough work. The decode phase generates tokens sequentially for each request and is deeply memory-bandwidth-bound at small batch sizes. Serving systems raise utilization by admitting and retiring requests at iteration boundaries, called continuous batching, and by limiting how much prompt work delays the next decode iteration, mechanisms that chapter 10 develops.

A napkin estimate shows how quickly serving capacity reaches training scale. One tensor-parallel replica of the running model on an eight-GPU node streams its FP16 weights once per decode step, which takes at least 13.1 ms at H100 HBM bandwidth. Batching 32 concurrent requests yields about 2,450 tokens/s per replica. A service handling 1,000 requests/s at 250 output tokens each must generate 250,000 tokens/s, which requires at least 103 replicas, or 824 GPUs, most of the 1,024-GPU training reference cluster. The estimate is a lower bound because it ignores key-value cache traffic, prefill work, and headroom for bursts and failures; section 10.6 replaces it with batching models that account for key-value cache capacity, variable request lengths, and latency targets. Reliability objectives differ as well: a training job can absorb an occasional failure because checkpointing recovers the lost progress, whereas a stalled serving replica delays every request routed to it until traffic fails over.

2.8.4 The accelerator decision matrix

Combining workload regime, precision policy, and serving latency targets yields the procurement screen in table 2.17. Its candidate configurations rest on representative assumptions rather than fixed assignments of model families to bottlenecks or vendors: the rule is to diagnose the binding constraint first, then compare sustained useful work within the capacity, quality, latency, and facility budgets. The table's constraint column is the per-device one, what a single accelerator must supply. The archetype roster of section 1.6.1 answers a different question, which constraint binds the fleet as a whole, so a workload can be compute-bound on each device and still communication-bound across the cluster, as Archetype A is.

Table 2.17: The Accelerator Decision Matrix: The optimal accelerator depends not on peak specifications but on which physical resource (compute, bandwidth, or capacity) is the binding constraint for the target workload. The Roofline Model screens the compute and bandwidth ceilings at the intended precision and shape. Among candidates that clear capacity and facility constraints, measured sustained useful work at the required quality and latency determines value.

Workload	Binding constraint	Key metric	Recommended class
LLM training (>100B)	Compute (high batch size)	Sustained useful throughput at validated precision, interconnect BW	H100/B200, TPU v5p
LLM inference (batch=1)	Memory bandwidth	GB/s per dollar	A100, H100 (bandwidth/$)
LLM inference (batched)	Compute + bandwidth	Sustained token throughput within latency and capacity limits	H100, B200
Vision model training	Compute (large spatial dims)	Sustained useful throughput at validated precision	H100/B200 configurations to evaluate
Recommendation (embeddings)	Memory capacity	GB per dollar	CPU DRAM + GPU hybrid
Fine-tuning (<13B)	Memory capacity (state near HBM limit)	HBM capacity	A100-class capacity candidate
Research/prototyping	Flexibility	Software ecosystem	GPU or accelerator with required operator support

For our 175B running example, table 2.17 separates the training purchase from the serving purchase. The workload constraint comes first; software support, deployment lifetime, and measured sustained throughput are compared only among candidates that clear it. A cheaper accelerator-hour is useful only if it supplies the required throughput within the capacity, latency, and facility budgets.

Checkpoint 2.4: Accelerator selection

An engineering team needs to deploy a 70B-parameter model for both training and inference. Training will use batch size 2048 across 256 GPUs for 3 months. Inference will serve 10,000 requests per second at batch size 1 for 2 years.

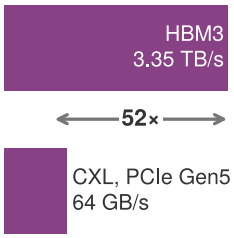
- ☐ **Training intensity**: identify the local microbatch, sequence length, and partitioning information needed to estimate training intensity; compare it with batch-1 decode under the chapter's weight-traffic approximation.
- ☐ **Hardware split**: identify which measurements are needed to determine whether training and inference should use the same hardware or different hardware.
- ☐ **Two-year cost**: formulate the 2-year inference-cost comparison between H100s rented at a cloud rate of $4/GPU-hour and A100s already in the fleet, charged at its reference in-service rate of $2/GPU-hour, and identify the prompt and output lengths, replica placement, sustained throughput, and capacity assumptions required to evaluate it.

Each of these selections assumes the memory, communication, and power boundaries stay fixed at today's package and rack limits. Hardware technologies now entering deployment do not remove those walls, but they relocate where each constraint binds across a facility's lifetime.

2.9 Infrastructure Technologies That Move the Walls

A new data center will host several generations of accelerators over its facility life, which operators typically depreciate across 15–20 years (Barroso et al. 2019), so future-facing technologies matter only when they change a durable planning constraint. The useful test is not whether a technology is novel, but which wall it moves, what new wall appears after the move, and which fleet-design decision changes as a result. Compute Express Link (CXL) moves the memory-capacity boundary, wafer-scale integration the chip-to-chip communication boundary, and optical circuit switching the fabric topology and power boundary, while advanced packaging moves the die boundary inside the accelerator package. None of them repeals the physics of data movement; each relocates the place where infrastructure teams must spend power, cooling, cost, and software complexity.

2.9.1 Compute express link (CXL)



Holding 1,400 GB of Adam optimizer state or terabyte-scale embedding tables inside accelerator HBM consumes the most expensive memory tier in the cluster for data touched only once per parameter update or sparse lookup. **CXL** addresses this capacity bottleneck by building protocols for I/O, caching, and coherent memory access on top of the PCIe physical layer. Supported device types and platform configurations determine which of those capabilities are available. Memory expanders and pooled memory can make host capacity less rigid, but accelerator

access also requires a supported data path and software placement. Fleet planning must establish those capabilities before treating a pool as available training memory.

For ML training, the natural target is cold or phase-local state rather than the active matrix-multiply working set. The 1,400 GB Adam optimizer state of our 175B model is touched during parameter updates rather than streamed through every Tensor Core operation. A shared CXL pool could therefore reduce per-node memory pressure by holding optimizer shards, embedding-table spillover, or local data-cache buffers outside the accelerator HBM tier. The training framework still has to schedule this state carefully, but the placement problem becomes less binary than "fits in this node" or "spills to storage."

The new wall is bandwidth. A representative CXL memory path over PCIe Gen5 x16 provides 64 GB/s, while H100 HBM provides 3.35 TB/s. That 52× gap means weights and activations for the forward and backward passes still belong in HBM. CXL is a capacity tier, not an HBM replacement. For fleet design, planners should ask whether server platforms, rack layouts, and orchestration software can absorb CXL memory pooling, not whether CXL removes the need for high-bandwidth accelerator memory.

2.9.2 Wafer-scale planning constraint

HBM remains 52× faster, so CXL is capacity only.

At the opposite extreme from CXL sits the wafer-scale engine introduced in section 2.2.1. Its on-wafer fabric removes package- and board-level transfers for mapped operations, but it does not make communication free. Infrastructure planning instead shifts toward capacity, placement, and injection bandwidth.

Our 175B running model needs 350 GB for FP16 weights alone, far beyond the 44 GB of on-wafer SRAM. Cerebras addresses this through weight streaming: external MemoryX units feed weights to the wafer over a 1.2 TB/s path while the wafer executes each layer, decoupling model capacity from the on-wafer memory. Weight streaming was designed for training. Activations stay on the wafer while weights stream in layer by layer and gradients stream back to MemoryX, which performs the optimizer update. The approach works when each layer's computation is large enough to hide the streaming time. The wafer trades the communication wall for a streaming-bandwidth wall.

The lesson for infrastructure planners is not that wafer-scale systems replace GPU fleets. It is that memory proximity and memory capacity trade against each other. WSE-style designs buy extraordinary local bandwidth by putting the working set near the arithmetic, while CXL buys flexible capacity by moving memory farther away. HBM sits between those extremes: off-chip but on-package, smaller than host memory but fast enough for the active computation. The right architecture is the one whose memory tier matches the workload's reuse pattern.

2.9.3 Reconfigurable topologies and optical circuit switching

Beyond the package, optical circuit switching (OCS) moves the fabric topology and power boundary. Micro-electro-mechanical systems (MEMS) mirror arrays steer light between fiber ports without converting it to electrical form. A pod's physical

topology can therefore be rewired for each job and around failed hardware, as in Google's TPU v4 pods. Millisecond-scale reconfiguration, however, limits OCS to job-level allocation rather than per-message routing. Section 3.5.5 develops the mechanism, the TPU v4 deployment, and its fault-isolation limits.

The common theme is relocation rather than elimination. CXL pushes capacity outward into a fabric where PCIe bandwidth becomes the limiting discipline, whereas wafer-scale integration pulls communication inward onto silicon where on-wafer capacity and yield take over. In the same way, advanced packaging, with 2.5D interposers such as TSMC's CoWoS and 3D stacking such as SoIC, compresses die-to-die distance past the reticle limit. It leaves the rack to absorb the resulting power density, which must be checked against the package and cooling budgets. Optical circuit switching, in turn, removes the optical-electrical-optical conversion inside the switch only to make reconfiguration latency the new boundary. Infrastructure planning therefore still begins by identifying where the next byte moves, how quickly it must arrive, and what physical system must be built so that movement does not dominate the workload.

2.10 Fallacies and Pitfalls

Because the bottlenecks move rather than disappear, compute infrastructure teams often optimize the visible specification while missing the binding physical constraint. Each fallacy and pitfall below turns a node, rack, pod, or facility lesson into an operational warning.

Fallacy: *More GPUs always means faster training.*

Section 1.8 warned against reading a compute budget as a wall-clock prediction. The hardware form of the same error assumes that training time scales linearly with GPU count, so that doubling the GPUs halves the training time. In practice, communication overhead grows with cluster size, and this chapter's modeled scaling efficiencies show how fast.

Amdahl's law bounds speedup when a fixed workload has a fixed serial fraction. Distributed training also incurs communication, pipeline, and I/O costs that can change with partitioning and scale; these are not all an invariant serial fraction. For a 175B-parameter model with 350 GB of gradients, the AllReduce at each training step must combine contributions across the participating group. It can do so through ring or tree exchanges; direct transfers between every pair are not required.

Even for a carefully engineered fabric, the modeled scaling efficiency of the running model falls from 0.87 at 256 GPUs to 0.83 at 1,024 GPUs and 0.56 at 8,192. Growing from the reference cluster to the 8,192-GPU scenario of section 2.7 therefore multiplies the hardware 8× but the speed only 5.4×, and 44 percent of the larger cluster's locally achievable throughput is lost to communication and pipeline bubbles. That run still finishes in days, so the scale is worth buying for a deadline, but each added GPU returns less than the one before it; without an engineered fabric and overlapped communication, the curve flattens far sooner.

The correct approach is to profile useful compute time, exposed communication time, and idle time at the current scale before buying the next pod. If the added GPUs mostly increase exposed communication, procurement is buying idle time rather than training progress. Section 6.4.1 turns this local ratio into a scaling-efficiency estimate before committing to procurement.

Pitfall: *Planning training throughput from peak FLOP/s alone.*

Peak FLOP/s describes only one roofline ceiling. At the H100 FP16 ridge point of approximately 295.2 FLOP/byte, the bandwidth and arithmetic ceilings meet; lower-intensity operations cannot reach the arithmetic peak through more compute alone. In the chapter's batch-1 weight-streaming estimate, decode near 1 FLOP/byte uses well under 1 percent of the arithmetic peak. Prefill and training supply more reuse, yet even well-tuned large training runs commonly sustain only 30–50 percent of peak once memory-bound attention and normalization kernels, activation recomputation, dependencies, and communication are counted. Procurement needs those measurements for the intended execution phase.

Fallacy: *Power and cooling constraints can be handled after accelerator purchase.*

Teams that plan GPU purchases from compute requirements without verifying that the target facility can deliver the required power and cooling run into hard physical limits with long lead times. A single rack of four DGX H100 systems requires 33.5 kW of power. Upgrading a data center's electrical infrastructure (new transformers, switchgear, and UPS capacity) and its cooling plant (chillers, piping, pumps) are construction projects planned in months, not days. Even seemingly simple changes, such as upgrading the PDU in a single rack from 20 kW to 60 kW, can require new cabling and circuit breaker panels. Organizations that order hardware without confirming facility readiness risk having millions of dollars of GPUs sitting in shipping containers in the parking lot while the building is retrofitted. Accelerators can arrive faster than a facility can be upgraded to power and cool them, which makes this mismatch a practical planning risk.

Pitfall: *Buying a newer accelerator without checking the workload's arithmetic intensity.*

Suppose a team deploys B200 GPUs (4,500 TFLOP/s FP8 peak) for an inference workload serving a 7B-parameter model at batch size 1, where an arithmetic intensity of approximately 1 FLOP/byte places the workload deep in the memory-bound region. The B200's memory bandwidth (8 TB/s) is 2.4× higher than the H100's (3.35 TB/s). Comparing B200 FP8 against H100 FP16/BF16-class throughput gives a peak arithmetic ratio of about 4.6×, but also changes the precision convention. At a fixed weight footprint, the bandwidth-only model instead predicts a gain of about 2.4×. The low intensity limits the fraction of arithmetic peak that this model can use, though it does not measure idle time; the comparison that matters is bandwidth per dollar at the measured serving rate, and the larger arithmetic peak alone does not establish better value.

Fallacy: *Air cooling is sufficient for AI workloads.*

Operators of legacy facilities may assume that adding fans and chiller capacity is sufficient for any denser AI rack. In practice, the cooling choice depends on the system's heat-rejection design and the facility's available airflow, pressure, inlet temperature, and containment. Engineered air remains viable for some dense configurations, while higher rack densities can require direct liquid cooling to avoid thermal throttling or exceeding facility limits.

Fallacy: *All GPU-hours are equivalent.*

A common error in cost comparisons is to treat one GPU-hour on an H100 as interchangeable with one GPU-hour on an A100 or V100. Under the same dense FP16 peak convention, H100 offers 3.2× the arithmetic rate of A100 and 7.9× that of V100. If a workload sustained the same fraction of those peaks with the same operation count and target quality, 10,000 V100 GPU-hours would correspond to approximately 1,264 H100 GPU-hours. That is a conditional compute-only comparison, not a predicted training time, because memory, communication, numerical recipes, and software can change sustained efficiency. Procurement must compare measured cost per useful computation or per completed run, rather than rental price or peak FLOP/s alone.

Pitfall: *Upgrading the network before identifying the training bottleneck.*

A network upgrade from 200 Gb/s to 400 Gb/s InfiniBand changes training time only through the communication it accelerates on the critical path, the mirror image of the faster-accelerator fallacy in section 1.8. In a no-overlap example with 20 seconds of computation and 2 seconds of communication, doubling transfer bandwidth reduces the estimated step from 22 to 21 seconds, an improvement of 4.5 percent. That result assumes the communication term scales with bandwidth and other terms remain fixed. Adding GPUs or optimizing kernels requires a separate estimate because either can change communication and overlap. The Fleet Law keeps those costs visible when comparing investments.

Fallacy: *Average power draw is sufficient for cooling design.*

Accelerator power draw varies across communication, memory, and compute phases. A workload average below the configured sustained envelope does not establish the cooling requirement because synchronized compute phases can raise many devices toward that envelope together. Thermal design must use the vendor's sustained design target under the intended inlet and cooling conditions, while the electrical path must separately tolerate documented transients. Otherwise thermal throttling can reduce sustained throughput without producing a crash or explicit application error.

Pitfall: *Selecting accelerators by HBM capacity without checking bandwidth.*

Capacity and bandwidth answer separate feasibility questions, and a model that fits in HBM but cannot be served within its latency target is as unusable as one that does not fit. Consider two hypothetical options for a 70-billion-parameter model: (a) 192 GB of HBM2e at 2.04 TB/s, and (b) 80 GB of HBM3 at 3.35 TB/s.

Option (a) holds the 141 GB FP16 weight payload, whose streaming floor is 141 GB/2.04 TB/s = 69.2 ms. Option (b) cannot hold 141 GB in its 80 GB capacity, but the 71 GB INT8 payload fits before other live state is counted. Its weight-transfer floor is 71 GB/3.35 TB/s = 21 ms, a 3.3× ratio between the two estimates. That ratio combines faster memory with fewer bytes; option (a) could also use a validated INT8 recipe. Selection must compare like-for-like quality, complete live-state capacity, and measured latency at the intended concurrency.

Fallacy: *Data loading can be fixed after deployment.*

Teams that optimize only GPU kernels and communication can still find their accelerators waiting for input. The data loading pipeline must sustain the cluster's consumption rate across storage, preprocessing, and host-to-GPU transfer. The chapter's pre-tokenized language-model example needs modest raw bandwidth, but tokenization, sequence packing, and shuffling can change the host-side demand. Size CPU workers, buffering, and storage concurrency from the actual pipeline. Local NVMe staging and prefetching are useful when they relieve the measured bottleneck; neither substitutes for testing the complete path at fleet concurrency.

Pitfall: *Buying homogeneous clusters without modeling workload diversity.*

Uniform hardware simplifies support and placement, but that benefit must be weighed against the useful work existing devices can still perform. For our 175B model, training and low-batch decode stress different resources. Separate pools can exploit that difference without placing mismatched devices in the same tightly synchronized group.

The A100's 2.04 TB/s and the H100's 3.35 TB/s supply different bandwidth ceilings. Retaining older devices for an inference pool can reduce cost when their measured throughput, power, and support costs compare favorably at the required latency. The distinction is between *job-level* balance within a synchronized group and *cluster-level* hardware uniformity. A heterogeneous fleet can preserve balanced groups, but its matching benefit must cover the added scheduling and operational complexity.

Pitfall: *Treating commissioning and burn-in as schedule slack.*

Commissioning is part of the system build, not a buffer that can be consumed when hardware delivery slips. Burn-in tests, cable validation, firmware qualification, thermal soak, and NCCL stress runs are the first time the node, rack, network, and facility layers operate as one machine. Compressing that phase turns installation defects into production failures, where each debugging cycle idles the full fleet rather than a small acceptance-test window.

2.11 Summary

Training our 175B-parameter model exposes a constraint cascade: accelerator capacity and throughput shape the node, node power shapes rack cooling, rack density shapes pod layout, and pod topology and reliability determine how much useful work the fleet sustains. At the device level, the generality tax (principle 1)

explains the trade between flexibility and workload-specific efficiency. A GPU delivers 10–100× the matrix throughput of a CPU on suitable workloads, but that specialization pays only when the workload and software stack can use the dedicated arithmetic over the deployment's lifetime. The roofline in section 2.3.2 identifies the binding compute or memory ceiling, while the bandwidth hierarchy in section 2.5.1 guides where communicating work belongs. Together, these models connect software choices to the physical limits of the fleet.

Our 175B-parameter model connects the decisions at each level. Its low-batch decode estimate requires about 350 billion floating-point operations per token, but moving the 350 GB FP16 weight payload through one hypothetical 3.35 TB/s HBM path takes over 100 ms. A feasible partition changes that path budget as well as solving capacity. At the node level, training state exceeds 2 TB, requiring additional sharding or reductions in resident state. At the rack level, 32 accelerators at 700 W each, plus modeled host and network overhead, require 33.5 kW of qualified power and cooling capacity. The reference cluster coordinates 1,024 GPUs, while the worked pod scenario uses eight times that number. Communication, failure recovery, and sustained utilization determine how much of the purchased capacity becomes completed work. The model's size exposes these interactions, but the same accounting applies whenever a workload crosses physical resource boundaries.

The method transfers beyond this model. At each level, identify the binding constraint, quantify its effect, and propagate the consequence upward. A faster accelerator is counterproductive if cooling cannot remove its heat; a denser rack is futile if the grid cannot supply it; and a wider network is wasteful if the workload cannot use its bandwidth. Infrastructure engineering is thus a quantitative discipline for tracing chip-level choices into rack power, facility cooling, network topology, reliability, and ownership cost.

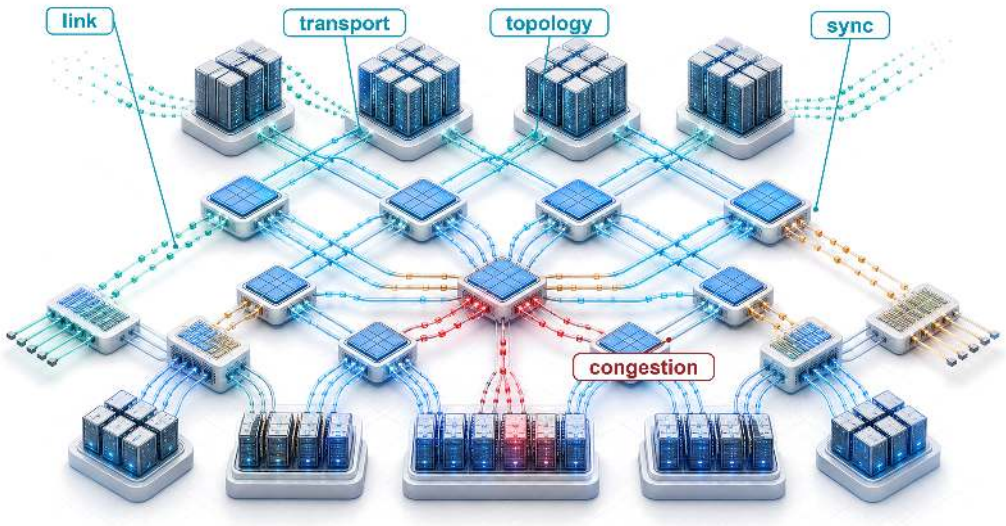
Key Takeaways: The data center is the computer

- **Capacity and bandwidth are separate tests**: Capacity decides whether model state fits; bandwidth decides how fast low-reuse phases run. For single-request LLM decode, weight traffic commonly sets the latency floor. The ridge point (I_{ridge} = peak FLOP/s divided by memory BW) separates bandwidth- from compute-bound operation, but batch shape, fusion, precision, reuse, and the modeled memory level determine where each training or inference phase lies.
- **Bandwidth hierarchy guides parallelism placement**: The 9× per-direction bandwidth gap in the NVLink–InfiniBand example favors keeping frequent tensor-parallel exchanges inside the fast interconnect domain. Pipeline and data parallelism can span slower links, but their traffic and synchronization still have to fit the workload's time budget.
- **A node aggregates private memories**: Eight accelerators multiply HBM capacity, but each device's memory stays private, so the running model's

2.8 TB of persistent training state forces tensor parallelism, optimizer sharding, activation checkpointing, and memory tiering to be combined.

- **Peak vs. sustained**: Capacity planning must use sustained throughput measured with a consistent model-FLOP convention, precision, system scale, and workload shape, not peak specifications.
- **Rack power and cooling bound installable compute**: Watts per rack, delivery losses, and cooling class, not FLOP/s, set how much compute a facility can install and sustain; at pod scale, network topology, cooling, and power delivery must be co-designed for the dominant workload.
- **Failure exposure grows with fleet size**: With independent failures and a per-GPU MTTF of 50,000 hours, the 10,000-GPU example has a mean interval of about five hours between GPU failures. Recovery and checkpoint storage therefore belong in infrastructure planning from the start.
- **Price useful work, not hardware**: GPU-hours from different generations, an FP8 peak that doubles advertised capacity, and bandwidth per dollar for decode compare only through sustained throughput on the target workload. Power, cooling, facilities, and utilization then set the lifetime cost of that useful work, so hardware price alone cannot settle a purchase.

Applied through C³, choosing liquid cooling for a dense accelerator rack changes more than heat removal. It raises the compute a rack can hold, which concentrates communication onto fewer top-of-rack links and adds coordination work for power capping, failure isolation, and maintenance. In the Fleet Law's accounting, the hardware in this chapter fixes the per-device rate behind T_{compute}/N and the link bandwidths behind $T_{\text{comm}}(N)$, while rack and pod reliability decide how often synchronization and recovery interrupt the step. Removing one physical ceiling therefore requires checking the rest of the fleet again; otherwise the investment creates capacity that the workload cannot use.



What's Next: From silicon to wires

Physical infrastructure spans from Tensor Core transistors to megawatt data-center substations. A fleet of disconnected nodes, however, is not yet a computer; it is a warehouse of expensive accelerators. The network fabric turns those nodes into a unified training system by carrying gradients, activations, and checkpoints between them. At every scale above the node, this chapter met the same limit in a new form. The bandwidth hierarchy showed a 9× cliff between NVLink and InfiniBand, and the pod showed why usable bandwidth depends on the communication pattern and where it is placed. Every training step of our 175B model ends by combining gradients across all 1,024 GPUs of the reference cluster, so the slowest required transfer sets when the next

step can begin. Chapter 3 starts from that synchronization and climbs from signaling on a single link through transport protocols, switch topology, and congestion behavior to the integrated cluster. At each level it asks whether the fabric lets those GPUs train as one coherent machine or leaves them waiting as isolated devices.

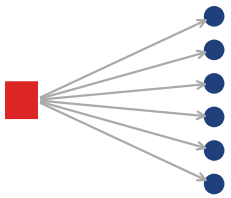
Purpose

Why can the network connecting accelerators matter more than the accelerators themselves at scale?

A single accelerator can perform trillions of operations per second, but distributed training requires devices to exchange results before dependent work can proceed. When network capacity cannot keep pace with computation, accelerators sit idle, and adding more devices can increase the waiting instead of shortening the run. The resulting cost extends beyond the network equipment: an inexpensive connection can leave expensive compute capacity unused throughout a long experiment. Single-node intuition is insufficient because data that once traveled through a local interconnect must now cross cables, switches, and shared paths. A fast connection between two machines does not establish that the same performance will hold when the entire fleet communicates at once. The arrangement of those paths determines which groups can exchange data together and where competing transfers accumulate. Large transfers need sustained bandwidth, while frequent dependent exchanges can remain limited by the time required to start and complete each message. A delayed participant can hold up others even when most links appear healthy. Network design therefore has to follow the workload's



communication pattern, and validation must reflect the traffic that will actually run. Choices about placement, sharing, and failure recovery affect whether available bandwidth becomes useful progress or recurring delay. In C^3 terms, the fabric connects compute through communication, while coordination determines when the fleet must wait for that communication to finish.

Learning Objectives

- Explain how synchronized collective traffic inverts data-center assumptions about flows, loss, and oversubscription
- Model network communication cost using the α-β framework and identify bandwidth-dominated vs. latency-dominated regimes
- Compare high-performance transport protocols by latency, loss-recovery behavior, and operational complexity
- Compare network topologies using BW_{bisect}, hop count, and the workload's collective communication pattern
- Evaluate congestion-control mechanisms and their impact on tail latency during distributed training
- Compare network partitioning and traffic-isolation mechanisms for concurrent training and inference workloads
- Diagnose network performance bottlenecks using RDMA counters, link-level telemetry, and bandwidth testing tools

3.1 The Synchronization Backbone

Chapter 2 traced the bandwidth hierarchy down to the node boundary, where each GPU's NVLink bandwidth narrows to a single external network port. How much that narrowing costs depends on what the training job must push through the port, and how often. Consider the running instance of Archetype A (GPT-4/Llama-3), a 175B-parameter GPT-3-class dense transformer partitioned across the 1,024 GPUs of the reference cluster. Each training step must combine gradient contributions so that corresponding model replicas apply the same update. This operation, called AllReduce, returns the combined result to every participating worker. The model has 350 GB of gradient data at two bytes per parameter, the 16-bit gradients of mixed-precision training that this chapter assumes throughout (FP32 gradients would double the figure). That model-wide figure is not what any one GPU sends. When a reduction partitions the gradient across all 1,024 ranks, each rank owns a 1/1,024 share, a few hundred megabytes, which is the gradient-shard size the transport examples below use; the job's tensor, pipeline, and data-parallel split (chapter 6) sets each GPU's actual payload. Worked examples that switch to another model, precision, or payload state their parameters explicitly. A delayed transfer on the step's critical path can leave the other 1023 GPUs waiting at a job-wide synchronization boundary. The fabric's contribution to training time therefore depends on which transfers the next computation needs and how much of their cost remains exposed. In that role the fabric is not auxiliary infrastructure; it is the synchronization backbone that decides whether the cluster trains as one machine.

One slow link stalls every peer that waits on it.

WITHIN the multi-tier fleet hierarchy framed by figure 1.4, the fabric turns isolated accelerator nodes into a coherent training system. Accelerators, power delivery, cooling, racks, and pods define what each node can compute in isolation; the fabric determines whether the nodes can act together

before communication cost overwhelms computation. That design space organizes into a **five-level model** of co-dependent tiers, developed in section 3.2.1.

At scale, communication cost can dominate computation cost. The fleet-law decomposition in section 1.5.4 makes this explicit: the nonoverlapped communication term $T_{\text{comm}}(N) - T_{\text{overlap}}$ determines how much of each training step is exposed to the network fabric. The fabric influences the layers above it by determining whether communication can run while independent computation continues, which collective algorithms are viable, and how network partitions interact with node failures. That concurrency, communication-computation overlap, is what the T_{overlap} term credits, because transfer time that proceeds behind useful arithmetic does not lengthen the step.

↪ How layer-by-layer scheduling achieves that overlap, and how much communication it still leaves exposed, is developed in section 5.10.

A collective is a communication operation performed by a group of workers. Its name specifies the result each worker receives, while an algorithm determines the messages that produce that result. The physical network fabric carries three recurring collective communication patterns:

- **AllReduce**: Combines corresponding values from all participants and returns the same result to each; synchronous training uses a sum, followed by normalization, to average gradient contributions across workers.
- **AllGather**: Collects a distinct portion from each participant and returns the concatenated collection to every participant, as required when reconstructing a sharded parameter tensor.
- **AllToAll**: Lets each participant send a distinct portion to every other participant, an exchange central to expert parallelism when workers host different expert subnetworks and must route tokens to their assigned destinations.

Collective communication algorithms orchestrate these patterns, while the fabric layer supplies the physical wires and switches that carry them. The distinction matters because the fabric's physical properties (bandwidth, latency, and topology) determine which patterns are efficient and which become bottlenecks.

↪ The full set of collective primitives, with the output contract each one guarantees, is developed in section 5.4.1.

> **Systems Perspective 3.1: The network as a gradient bus**
>
> In a single machine, the memory bus moves data between the processor and memory. In a distributed training cluster, the network fabric serves an analogous role as the gradient bus that carries contributions between workers. When those exchanges limit progress, the job encounters the network wall mapped across the pod tier in figure 2.1. Protocols, topologies, congestion control, and collective schedules determine how effectively the job uses the available paths. This bus has a narrow segment. Since NVLink appeared, the external ports that join machines have offered less bandwidth than the interconnect inside each machine in every generation (figure 3.1). How much of that gap a job actually feels depends on its message sizes, port provisioning, routing, and contention, so the link ratio bounds the problem rather than predicting a transfer time.

↩ Communication dominance at scale, the network wall, is established in section 1.2.3.

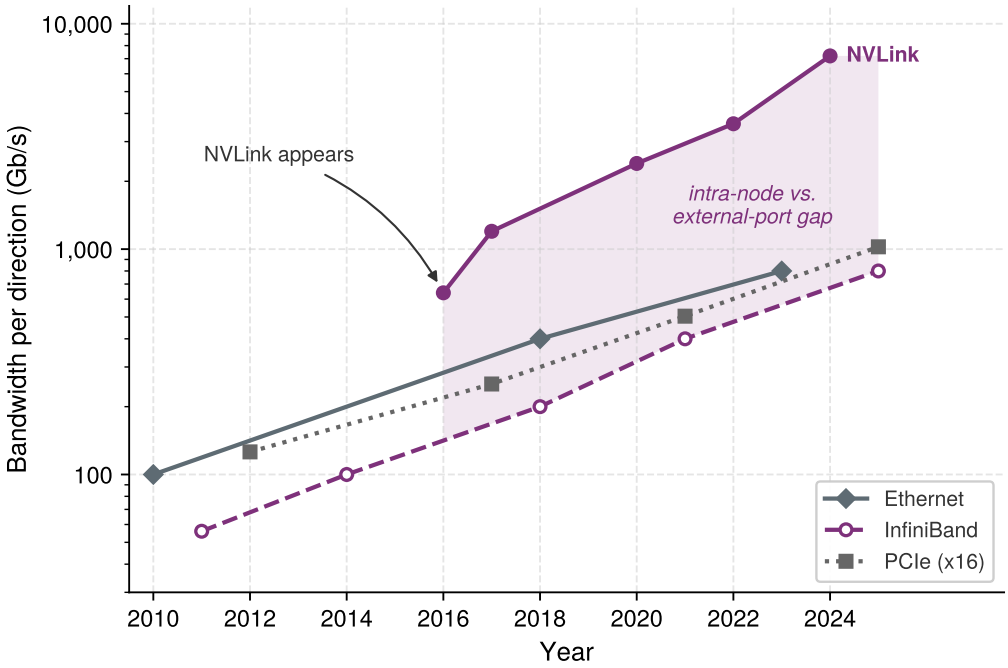


Figure 3.1: Historical Network Bandwidth Scaling: Intra-node NVLink, inter-node InfiniBand and Ethernet, and the PCIe host bus, plotted per direction on a common log scale by the year each generation first shipped, 2010 to 2025. The aggregate NVLink budget exceeds the external-port budgets in these configurations; collective completion time also depends on payloads, provisioning, routing, and overlap. Rates and first-product years from IEEE 802.3, InfiniBand Trade Association, PCI-SIG, and NVIDIA specifications and product announcements.

The reference hardware gives the gradient bus analogy a concrete scale. A single H100 has a precision-specific FP16 peak of 989 TFLOP/s and memory bandwidth of 3.35 TB/s. Each GPU's NVLink ports together provide 900 GB/s of bidirectional bandwidth to its peers within the node. The comparison that matters is per GPU and per direction. In the reference node each GPU has its own network interface card (NIC) with one NDR InfiniBand port, so a tensor leaving the node through that GPU drops from 450 GB/s of NVLink bandwidth to 50 GB/s at the port. This 9× gap is the node boundary's cliff that the bandwidth hierarchy of section 2.5.1 already identified. The model-wide 350 GB gradient state does not all pass through every 50 GB/s port; partitioning and the collective schedule determine each port's traffic. Converting that gap into a step-time estimate requires the workload's local payloads and communication dependencies.

Which traffic must cross that gap depends on how the job is partitioned. The same hierarchy keeps tensor parallelism, with its per-layer exchanges, inside the NVLink domain and lets pipeline stages and data-parallel replicas span nodes, the combination called 3D parallelism whose schedules are developed in section 6.6.1. The fabric adds one lever to that placement. Each data-parallel replica can sum gradients over several microbatches before an exchange (gradient accumulation), reducing how often it must cross the node boundary at the cost of changing the batch and update schedule.

↪ The network hierarchy ratio between intra-node and inter-node bandwidth, with the reference NVLink and InfiniBand values behind it, is developed in section C.2.

Exposed communication leaves gaps between dependent compute phases. Two assumed training schedules on a common 230 ms axis, each containing 100 ms forward and backward compute phases, make that cost visible (figure 3.2). The 8-GPU intra-node case assumes a 1 ms AllReduce and spends 99.5 percent of the step in those compute phases; the 64-GPU inter-node case assumes a 30 ms AllReduce and spends 87 percent in computation. The two AllReduce durations are illustrative inputs chosen to show the effect, not values derived from the link rates above, and the percentages are shares of the schedule rather than measured arithmetic utilization.

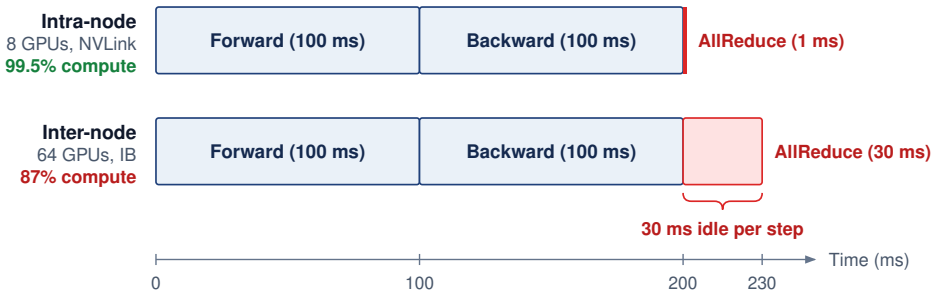

Figure 3.2: The Bandwidth Cliff in a Training Step: Illustrative timelines on a common millisecond axis for the same compute phases: an 8-GPU intra-node job (top) with an assumed 1 ms AllReduce, and a 64-GPU inter-node job (bottom) with an assumed 30 ms AllReduce. These durations illustrate an exposed communication cost rather than predict a particular fabric. The AllReduce phase (red) grows from a thin sliver to a larger share of the step. Without overlap, model computation waits during AllReduce. The compute phases occupy 99.5 percent and 87 percent of these illustrative schedules, a gap of 12.5 percentage points; these shares are not arithmetic utilization measurements.

In Fleet Law terms, the widened red block is the part of $T_{\text{comm}}(N)$ that no T_{overlap} has hidden. In the inter-node schedule it is 30 ms of every 230 ms step, about 13 percent, and that share applies to every accelerator-hour the cluster spends for the life of the run. Network fabric design therefore belongs at the center of distributed-training design rather than at its edge, and keeping that exposed window small requires rethinking the traffic assumptions that govern conventional data-center fabrics.

3.2 How ML Networking Inverts Data-Center Assumptions

A conventional cloud network built for millions of independent web requests breaks down when a training job releases its gradient exchanges in lockstep at the end of a backward pass. Statistical multiplexing relies on traffic peaks not all coinciding, whereas synchronized workers demand the same switch paths at the same microsecond. Web services also have dependency chains and tail-latency requirements, but a bulk-synchronous training job binds every participating worker to a single shared completion boundary.

The ML networking inversion in table 3.1 concerns this change in traffic dependencies. Synchronous collective phases can generate correlated bursts and long-lived flows whose completion gates the next computation. Fabric validation must therefore measure collective completion under the expected load; average

per-flow throughput alone does not establish that the job can meet its step-time budget.

Table 3.1: ML Networking Inverts Traditional Data-Center Assumptions: The comparison contrasts independent-request traffic with synchronized collective phases. Correlated demand and shared completion boundaries change the fabric's capacity and latency requirements.

Workload pattern	Traditional data-center assumption	ML reality
Traffic pattern	Independent requests can arrive asynchronously	Collective phases can release correlated bursts
Flow type	Many short transfers can share available paths	Large collective transfers can create persistent "elephant" flows
Performance metric	Per-request completion and throughput	Collective completion and exposed step time
Loss tolerance	Recovery delays affected requests	Recovery can delay dependent workers at a barrier
Congestion	Statistical multiplexing relies on noncoincident peaks	Shared paths and fan-in can concentrate synchronized traffic

The bulk synchronous parallel (BSP)[1] model, the lockstep at step barriers already met at the scale of one node (section 2.5), makes the dependency in table 3.1 explicit. In the synchronous training example, all 1,024 GPUs must complete the required gradient exchange before the next step can proceed. A 100 ms transfer delay adds 100 ms to that step only if it extends the critical path by the full interval; other computation or communication may hide part of it. At a barrier that waits for the last required result, **tail latency**, the slow end of the completion-time distribution (commonly reported as its 99th percentile, p99), decides when the step ends, so at such a barrier the tail cannot be dismissed as an outlier.

[1] **BSP (bulk synchronous parallel)**: Proposed by Valiant (1990) as a bridging model between parallel hardware and software. Synchronous data-parallel training follows the same barrier structure (Goyal et al. 2017; S. Li et al. 2020).

Definition 3.1: Bulk synchronous parallel (BSP)

Bulk synchronous parallel (BSP) is a parallel execution model in which every worker completes a local computation phase, exchanges the data required by the next phase, and then waits at a global barrier before any worker begins the next phase, which makes the slowest participant the pacing constraint for the entire cluster.

1. **Significance**: The slowest required computation or communication determines when a superstep can complete. Faster workers wait at the barrier, so a localized delay can consume idle accelerator time across the entire participating group.
2. **Distinction**: BSP organizes execution into synchronized supersteps; it does not itself prescribe a learning algorithm or a particular exchange pattern. Synchronous data-parallel updates match a single-device reference only under compatible global batches, update rules, and numerical assumptions.
3. **Common pitfall**: Removing barriers does not by itself establish faster time-to-quality. Asynchronous training trades waiting against stale updates, and the convergence and wall-clock comparison depends on the workload and update schedule.

↩ Synchronous tight coupling, the shared step barrier that lets the slowest worker pace a training fleet, is established in section 1.2.1.

The flow inversion compounds this problem. Traditional networks are designed for fairness among millions of "mice flows,"[2] yet ML training is dominated by a few "elephant flows" corresponding to the gradient AllReduce. The full 175B model has 350 GB of gradient state at the assumed precision, but a sharded job distributes that state across workers. Each collective operates on its participating group and local payload; its algorithm determines how much each worker sends. Standard flow control and routing mechanisms like equal-cost multi-path (ECMP), which hash each flow onto one of several equal-cost paths, are poorly suited to this traffic pattern. A static hash cannot subdivide one elephant flow across all available links, and it can inadvertently map multiple elephant flows to the same link, creating massive congestion while other links sit idle.

[2] **Elephant and mice flows**: The model-wide gradient size is not the size of one network flow. A collective can split each worker's local gradient shard across channels and transport connections; the resulting long-lived flows can still collide under ECMP when their static hashes select the same path.

The loss inversion completes the picture. TCP was designed to recover across an unreliable network, and an occasional retransmission delays only the request it belongs to. In a synchronous collective, a lost packet delays the transfer that every waiting worker needs, and some NICs that implement remote direct memory access (RDMA), called RDMA NICs or RNICs, recover by resending everything after the missing packet rather than only the lost region (Go-Back-N-style recovery). ML fabrics therefore aim to make loss rare and recovery bounded, either by preventing buffer overflow at the link layer or by building transports that recover quickly from it. Level 2 (section 3.4.3) develops both approaches.

Correlated demand also makes **oversubscription**, provisioning less uplink capacity at a switch tier than the downlink capacity it serves (written as a downlink:uplink ratio such as 2:1), a workload decision. A fabric with spare capacity under independent requests can become saturated when a collective releases traffic across the same cut. Designing for that traffic requires tracing the constraint from the wire through transport, topology, and congestion control to the job's synchronization boundary.

3.2.1 The five-level model

Provisioning fast NICs or buying a non-blocking switch tier in isolation routinely fails to speed up training: a 400 Gb/s link still stalls if host TCP copies starve the PCIe bus, an unaligned rack layout exhausts the copper link budget, or static ECMP hashing piles two elephant flows onto one spine port. Tracing why a collective slows down requires following the packet across five coupled layers, from serializer/deserializer (SerDes) signaling and copper or optical reach at Level 1 to the integration of a production cluster at Level 5 (figure 3.3). Each level is developed at the point where its physical or protocol limit becomes the binding constraint.

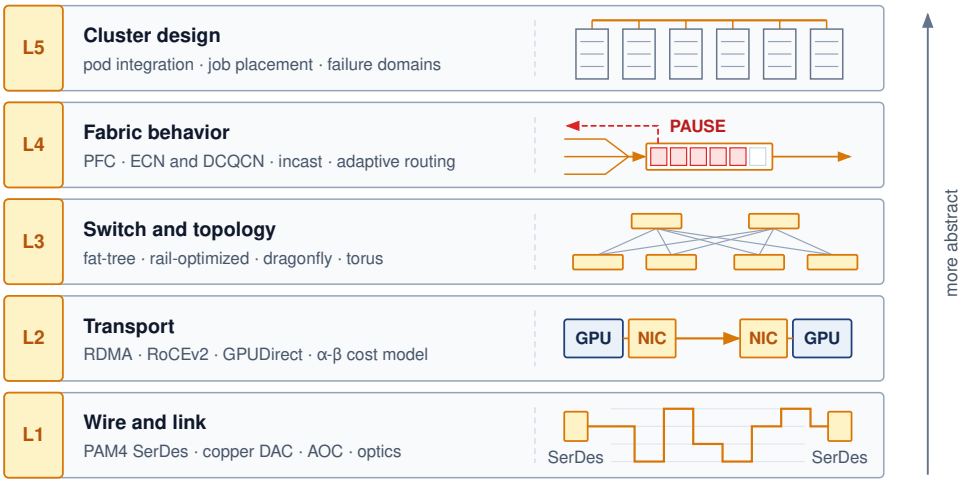

Figure 3.3: The Five-Level Network Model for ML Training: Read from the bottom up, each level builds on the one below and becomes more abstract. Level 1 moves bits over wires and optics; Level 2 turns links into reliable, low-overhead transfers between accelerators; Level 3 arranges switches into a topology; Level 4 governs how the fabric behaves under load and congestion; and Level 5 integrates all of them into a production cluster.

Each inversion of table 3.1 traces back to a specific physical or protocol constraint, and the five levels locate where each one is paid:

- **Level 1: wire and link** (section 3.3). Signal integrity (PAM4, SerDes), forward error correction, and the reach of copper and optics impose hard constraints on per-hop latency and cluster geometry.

- **Level 2: transport** (section 3.4). InfiniBand and RDMA over Converged Ethernet (RoCE) provide RDMA primitives; the α-β model quantifies the latency-vs.-bandwidth trade-off for different message sizes.
- **Level 3: switch and topology** (section 3.5). Fat-trees, rail-optimized designs, and dragonflies achieve the BW_{bisect} needed for global collectives through different structural trade-offs.
- **Level 4: fabric behavior** (section 3.6). Link-level flow control and end-to-end congestion control determine whether theoretical bandwidth translates to realized throughput; adaptive routing and incast behavior determine whether that throughput survives real collective traffic (Alizadeh et al. 2010; Zhu et al. 2015; Li et al. 2019; Gangidi et al. 2024).
- **Level 5: cluster design** (section 3.7). Production supercomputers like the NVIDIA SuperPOD and Meta Grand Teton integrate these layers into a unified gradient bus (NVIDIA 2023; Meta Engineering 2024).

The levels are not an inventory of networking topics; they are the causal chain that turns synchronous ML traffic into infrastructure requirements. Large gradient messages first stress the wire and transport, then force topology choices that preserve bisection bandwidth, then expose congestion behavior that ordinary enterprise networks can hide, and finally determine whether the whole cluster behaves like one training machine.

The traffic pattern determines which fabric metric matters. A global reduction stresses bisection bandwidth and the slowest path; a point-to-point pipeline transfer sits on the critical path, so its full transfer time and hop count matter; an expert exchange stresses path diversity and egress balance; and checkpoint or tenant traffic stresses isolation from the synchronization path (table 3.2). The remaining levels develop each of these pairings in turn.

Table 3.2: Traffic Patterns Determine Fabric Metrics: Workload semantics translate into different physical bottlenecks, so no single link-rate benchmark predicts training performance. The table is a map of what follows; the mechanisms in its right two columns (transport offload, adaptive routing, virtual lanes, and the rest) are developed at Levels 2 through 5.

Traffic pattern	Fabric pressure	Metric that predicts performance	Primary design response
Global reduction	Sustained traffic across a cluster cut	delivered bisection bandwidth; slowest-path completion time	non-blocking capacity, rail alignment, topology-aware collectives
Pipeline point-to-point	Critical-path activation handoffs	startup latency plus size/bandwidth; hop count	short paths, direct placement, transport offload
Expert AllToAll	Many simultaneous worker pairs	path utilization; egress queue depth; tail latency	adaptive routing, path diversity, balanced expert placement

Traffic pattern	Fabric pressure	Metric that predicts performance	Primary design response
Checkpoint and multi-tenant traffic	Bursts competing with training flows	per-class bandwidth; pause duration; interference	traffic classes (virtual lanes, QoS), admission control

Mapping workload semantics to physical constraints shows why ML fabric design must proceed from the physical layer up. Before higher-level topologies or routing protocols can organize traffic, the physical layer must reliably deliver bits between endpoints without excessive signal attenuation or prohibitive power consumption. Level 1 begins where all fabric architecture originates: at the physical wire.

3.3 Level 1 Wire and Link

At 400 Gb/s and beyond, the physics of signal transmission imposes hard limits on cable length, power consumption, and error rates. Signal attenuation in copper and chromatic dispersion in fiber dictate how far an accelerator can sit from its switches before communication fails. Every higher-level protocol and topology is ultimately constrained by what the physical wire can carry; these limits shape the geometry of the entire cluster. To meet throughput demands without raising the signaling rate into worse attenuation, link designs must carry more bits in each transmitted symbol.

3.3.1 Signal integrity and PAM4

Achieving 400 Gb/s and higher line rates requires balancing signaling speed against channel loss and detection errors. The **symbol rate** counts transmitted symbols per second; consecutive symbols need not produce a voltage transition. Raising the symbol rate raises the frequencies the channel must carry, and copper loses more signal at higher frequencies. Carrying more bits in each symbol, by using more than two signal levels, raises the bit rate without that penalty, and PAM4 is the scheme high-speed links use to do it.

Definition 3.2: PAM4 signaling

PAM4 signaling is a modulation scheme that represents two bits per symbol with four signal levels, doubling the raw bit rate relative to binary signaling at the same symbol rate.

1. **Significance**: PAM4 increases the raw BW available at a given symbol rate. The reduced separation between levels makes error-control design part of that gain. High-speed Ethernet uses forward error correction (FEC), including Reed-Solomon RS(544,514), with processing latency that depends on the physical-layer (PHY) design and implementation (Anslow 2016; Yin et al. 2022). FEC contributes to the fixed path budget

modeled by the α term in section 3.4.4; it is one component alongside propagation, switching, and endpoint processing.

2. **Distinction**: At equal symbol rate and voltage swing, NRZ (Non-Return-to-Zero) binary signaling carries one bit per symbol with greater separation between levels. PAM4 carries two bits per symbol with smaller level spacing; the link must compensate through its signal-quality and error-correction design.
3. **Common pitfall**: Doubling bits per symbol does not guarantee twice the usable payload throughput or a fixed latency penalty. Coding overhead, channel quality, and the chosen PHY implementation determine delivered performance.

The price is noise margin. With four levels packed into the same voltage swing, the gap between adjacent levels in PAM4 shrinks to one third of the NRZ gap (figure 3.4), making the link highly susceptible to noise. Consequently, high-speed links operate near the physical limits of reliable detection and require **forward error correction (FEC)** at the physical layer, commonly using Reed-Solomon RS(544,514)-family codes in high-speed Ethernet designs (Anslow 2016; Ethernet Alliance 2025). FEC processing is an implementation-dependent latency term; IEEE 802.3df operator material treats roughly 100 ns of host-side FEC with the RS(544,514) code (called KP4 in the standard) and hundreds of nanoseconds of end-to-end module latency as meaningful at AI/HPC fabric timescales (Yin et al. 2022). Because each switch on a path decodes and re-encodes the signal, the FEC cost accumulates with the number of switches a packet traverses. A path's length is its **hop count**, counted as switch traversals or as inter-switch links; where the two counts differ, each example states which one it uses. A packet that traverses three switches, the leaf-spine-leaf route of a two-tier fabric, incurs a scenario budget of 300 ns–600 ns of one-way FEC latency, or 600 ns–1200 ns for a round trip. Against the 350 GB gradient of the 175B job, a few hundred nanoseconds are negligible, because bulk transfers are governed by bandwidth. The cost lands instead on small, latency-bound messages, such as the control handoffs that coordinate pipeline stages, and on collectives whose many sequential steps each pay it. This physical-layer latency sets a floor on the fabric's fixed startup latency, formalized in section 3.4.4 as the α term, that no software optimization can remove.

Doubling line rate without doubling the symbol rate therefore trades signal-to-noise ratio (SNR) for bandwidth, and forward error correction is what lets the link operate that close to the channel limit. Because that tighter margin leaves less room for channel attenuation, it also shortens the distance a passive copper cable can span before the link must switch to optics.

3.3.2 Reach and medium for copper and optics

Past one to three meters, passive copper attenuates high-frequency PAM4 signals beyond what even FEC can recover, forcing any link that exits a rack onto active optical cables or pluggable optics at a steep jump in cost and power. The choice

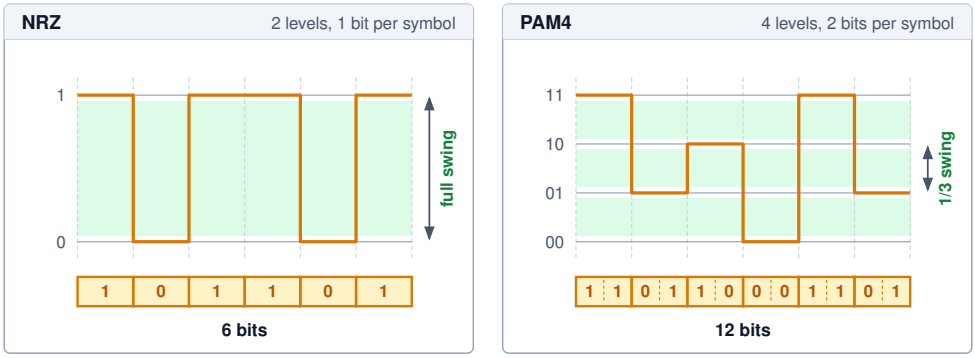

Figure 3.4: From NRZ to PAM4 Signaling: Both panels send six symbols in the same time over the same total voltage swing. NRZ (left) uses two levels and carries one bit per symbol, 6 bits in all; PAM4 (right) uses four levels and carries two bits per symbol, 12 bits in all, doubling the data rate without raising the symbol rate. The cost is noise margin: adjacent PAM4 levels sit one third as far apart (arrows), so high-speed links need forward error correction (FEC), which adds to the fabric's fixed α latency.

of physical medium therefore determines how far a link can reach before latency, power, and cabling budgets reshape the cluster geometry, and the recurring cable and optics options differ along exactly those attributes (table 3.3).

Table 3.3: Cable and Optics Placement Trade-Offs: Common interconnect media occupy different reach, latency, and cost points, so cluster designers use copper inside racks and optics as distance begins to dominate placement.

Medium	Reach	Cost profile	Latency impact	Typical placement
DAC (direct attach copper)	1 to 3 meters, shrinking as lane rate rises	Lowest cost (~$50) and no optical module power	Lowest media latency; no optical conversion, though high-speed lanes still pay FEC	Within a rack
AOC (active optical cable)	3 to 30 meters	Higher cost (~$500) from permanently attached transceivers (the modules that convert between electrical and optical signals)	Electrical/optical conversion adds latency on top of the forward error correction (FEC)	Rack-to-rack or row-scale links
Pluggable optics	More than 30 meters	Highest module and power cost, but replaceable optics and fiber cords	Optical conversion adds latency on top of FEC; distance enables topology reach	Network core and pod-scale links

The high-speed copper and optical paths considered here both include FEC, so choosing optics does not by itself remove error-correction overhead. The ranges in table 3.3 describe representative placements rather than fixed boundaries between media. Optical interconnects can extend the layout beyond a passive copper channel's budget, while pluggable optics also permit separate replacement of modules and fiber. Reach, delivered latency, power, and serviceability jointly determine the choice.

Systems Perspective 3.2: The cost of distance

In an ML fleet, distance is money. Assuming two spine-layer optical links per accelerator, a cluster of 10,000 GPUs requires ~20,000 optical links at the spine layer alone. At $500 per complete link, that represents $10 million in cabling. For power, count one selected spine-side pluggable module per link at 20 W per module, giving 400 kW for those endpoints alone. Each optical link also has a module at its opposite end; this subtotal excludes those modules, switch electronics, and cooling, so it is not the full fabric power budget. The cost dictates cluster geometry: architects pack accelerators as densely as possible (70–100 kW per rack) to maximize cheap copper and minimize expensive optics.

3.3.3 SerDes, link budget, and power

Driving thousands of high-speed links across a cluster burns tens of kilowatts just to serialize bits onto the wire, rivaling a noticeable share of the accelerators' own thermal budget. Every port depends on a **serializer/deserializer (SerDes)** circuit that converts parallel data from the switch application-specific integrated circuit (ASIC) into a serial stream, and its power cost accumulates across the provisioned ports. For the 1,024 GPUs reference cluster, assume a full-BW_{bisect} fabric with roughly 3,000 high-speed links across its host and switch tiers. Count one selected switch-side port per link in this power subtotal. Each counted 400 Gb/s port is assigned 25 W, more than the 20 W pluggable-module figure in the cost-of-distance estimate because it also counts the switch-side SerDes that drives the module. The model totals 75 kW, equivalent to 10.5 percent of the accelerators' combined thermal design power. This comparison isolates the assumed power of the selected switch-side ports, excluding the opposite endpoints and the rest of the switch chassis; it does not establish total fabric power or the fraction of measured cluster energy consumed by networking.

The **link budget** allocates the signal loss a path can tolerate while meeting its error target. Losses are counted in decibels (dB), a logarithmic power ratio in which every 10 dB is a further tenfold attenuation (3 dB is roughly a halving), so the losses of cables and connectors in series add directly. In this simplified accounting, a lane has a 30 dB allowance. A 3-meter DAC cable contributing 18 dB of loss and connectors contributing 2 dB leave 10 dB of margin. Higher signaling frequencies increase copper loss, so preserving reach can require more signal conditioning, a different cable, or optics. Aggregate port speed alone does not determine cable

reach; lane rate, channel construction, and active components matter. The design must meet both the signal-quality target and the power budget before the transport layer can rely on the link.

3.4 Level 2 Transport and the Performance Model

Closing the physical link budget delivers raw bits between adjacent ports, but a single AllReduce across 1,024 GPUs still stalls if host software sits in the path of every transfer or if a dropped packet triggers a multi-millisecond recovery pause. Turning raw wire rate into predictable step time requires a transport layer that offloads memory-to-memory delivery and bounds loss recovery (a contract met either through a physically lossless fabric or through loss-tolerant endpoint recovery), together with a performance model that separates fixed per-message startup latency from sustained link bandwidth.

3.4.1 RDMA and GPUDirect

A conventional kernel TCP path charges the host for every byte it moves. Interrupt processing, protocol work, and payload copies consume CPU cycles and memory bandwidth that the training process also needs for data loading and preprocessing, and the charge grows with aggregate I/O as many streams or NICs drive a host at 400 Gb/s link rates. Modern TCP stacks reduce the charge with segmentation offload, receive-side scaling, zero-copy interfaces, and careful non-uniform memory access (NUMA) placement, so a single stream need not exhaust a server's memory bandwidth. They do not remove it, and the contention becomes harder to provision predictably as nodes add NICs.

Definition 3.3: Remote direct memory access (RDMA)

Remote direct memory access (RDMA) is a networking technology that offloads transport processing to network interface hardware, allowing access to registered remote memory without per-transfer kernel processing of the payload.

1. **Significance**: RDMA can reduce end-to-end message latency from tens of microseconds for a kernel TCP path to low-single-digit microseconds on a tuned fabric, shrinking the fixed startup cost that every message adds to the Fleet Law's communication term $T_{\text{comm}}(N)$.
2. **Distinction**: Unlike a conventional kernel TCP path, RDMA offloads transport processing to NIC hardware and permits user-space access to registered memory. The resulting CPU-core and memory-bandwidth savings depend on the host, NIC, I/O path, message size, and software configuration rather than on link rate alone.
3. **Common pitfall**: RDMA is an access and offload model, not one loss-recovery algorithm. Reliable InfiniBand and RoCE transports detect loss and retransmit (InfiniBand Trade Association 2000). Some RNIC generations use the Go-Back-N-style recovery noted with the loss inver-

sion, which makes a drop expensive (section 3.4.3 quantifies the cost), while other designs support stronger selective recovery or tolerate lossy Ethernet without the link-layer pause mechanism (priority flow control) that many RoCE deployments rely on (Mittal et al. 2018). The requirement is reliable completion with a recovery tail that the synchronized workload can tolerate, not a physically lossless Ethernet fabric in every implementation.

RDMA bypasses the kernel data path. Offloading transport logic to the NIC allows applications to read and write registered remote memory without per-message kernel intervention. For ML, GPUDirect RDMA,[3] the path that dense nodes pair with one NIC per GPU (section 2.5.2), extends this principle to accelerator memory (NVIDIA 2026b). Within a sending node (figure 3.5), GPUDirect RDMA routes an n-byte payload (what one participant sends, not the model-wide gradient state) along the solid green peer-to-peer path through the PCIe switch straight to the RDMA NIC, bypassing host memory entirely. Without this direct memory access (DMA) bypass, the dashed gray staging path must first copy n bytes from GPU memory into a registered host-memory buffer and subsequently read n bytes out to the NIC, generating roughly $2n$ bytes of redundant host-memory bus traffic. The network still transfers the payload, and the PCIe path may comprise multiple DMA transactions; the optimization removes staging copies rather than collapsing the transfer into one transaction.

[3] **GPUDirect RDMA**: Introduced by NVIDIA for Kepler-class GPUs and CUDA 5.0, GPUDirect RDMA enables a direct PCIe path between GPU memory and third-party peer devices such as network interfaces (NVIDIA 2026b). Before GPUDirect, every gradient transfer had to stage through host memory, consuming CPU memory bandwidth that competes with data loading. Eliminating this bounce path is one reason overlapping communication with backward-pass computation is feasible at scale.

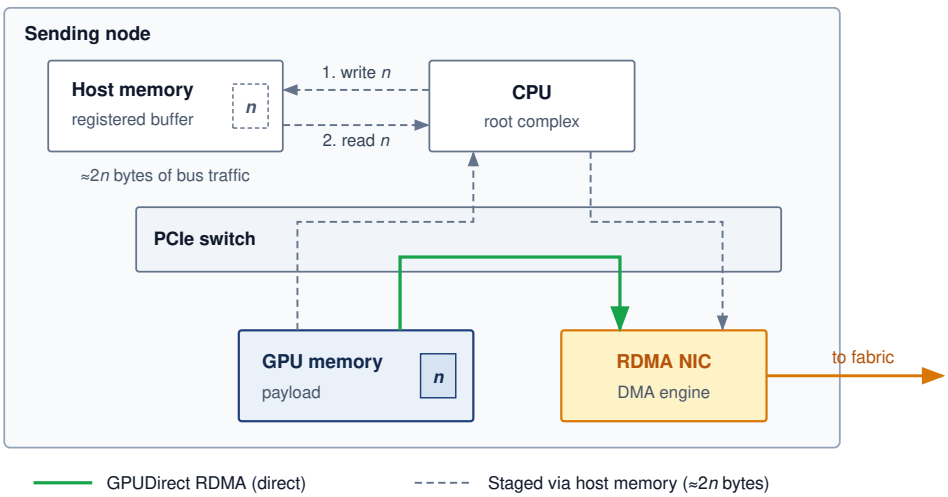

Figure 3.5: GPUDirect RDMA Data Path: Without GPUDirect (dashed), a sending node first writes the n-byte payload from GPU memory into a registered host-memory buffer and the NIC then reads it back out, about $2n$ bytes of host-memory traffic per payload. With GPUDirect RDMA (solid), the NIC reads GPU memory directly over the PCIe peer-to-peer path, so the host-memory bounce disappears.

3.4.2 InfiniBand and RoCE

GPU clusters commonly choose between two RDMA transport stacks, and the decision is a reliability-versus-operations trade-off. Both stacks must keep switch buffers from overflowing under synchronized bursts, and they do so in different places. InfiniBand uses **credit-based flow control**. Each receiver advertises its free buffer space to the sender at the other end of the link in units called credits, and the sender transmits only into space that has been advertised. A buffer therefore cannot overflow; congestion appears as senders waiting for credits rather than as dropped packets. Ethernet was designed to drop packets when buffers fill, so RoCE deployments that want the same behavior add two mechanisms. Priority flow control (PFC) lets a filling switch port send a PAUSE frame that stops its upstream neighbor for one traffic class, and explicit congestion notification (ECN) marks packets that pass through a filling queue so that their senders slow down before a pause is needed. InfiniBand thus builds losslessness into the link layer, while RoCE assembles it from switch configuration and end-to-end congestion control (table 3.4); section 3.6.1 develops PFC's failure modes.

Table 3.4: RDMA Transport Stack Trade-Offs: InfiniBand and RoCE expose RDMA semantics through different operational contracts, one built around native losslessness and the other around Ethernet compatibility.

Stack	Fabric behavior	Operational burden	Typical fit
InfiniBand (IB)	Purpose-built HPC switched fabric (InfiniBand Trade Association 2000) with credit-based flow control, so losslessness is native at the link layer	a central subnet manager computes routes, and virtual lanes (VLs), separate buffer and credit pools on one link, isolate traffic	Dedicated training clusters where predictable tail latency outweighs Ethernet ecosystem flexibility
RoCE (RDMA over Converged Ethernet)	RoCEv2 carries RDMA semantics by encapsulating InfiniBand transport headers in UDP/IP packets	PFC-based deployments suppress loss with PFC, ECN, and routing policy (Guo et al. 2016; Gangidi et al. 2024); PFC-free designs instead place more burden on end-to-end congestion control and loss recovery (Mittal et al. 2018)	Multi-vendor Ethernet fleets that can absorb more congestion-control tuning

The InfiniBand[4] row reflects a protocol heritage that favors hardware-managed losslessness over Ethernet compatibility, while both RDMA stacks share the same user-space bypass across the user-space, kernel, and hardware boundary (figure 3.6). The conventional copied TCP/IP path on the left uses two software copies across kernel buffer boundaries and runs the protocol in software. The RDMA stack on the right traces a single amber bypass arrow from the collective

[4] **InfiniBand**: Formed in 1999 from the merger of two competing server I/O standards (Future I/O and NGIO), InfiniBand was originally designed to replace PCI as a general-purpose system interconnect. Its pivot to HPC networking preserved the credit-based, hardware-managed flow control that server I/O demanded, and that heritage is why InfiniBand provides native losslessness without the PFC fragility of Ethernet-based RDMA fabrics.

communication library (such as the NVIDIA Collective Communications Library, or NCCL) and the user-space **verbs API** straight to the RDMA NIC, which keeps the operating system off the active data path.

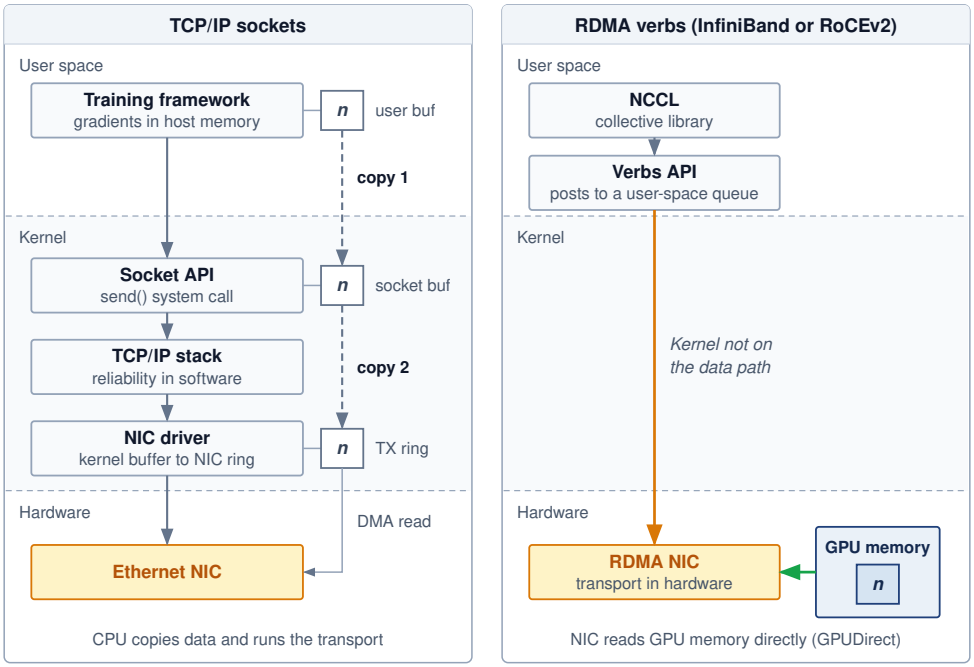

Figure 3.6: Traditional TCP/IP vs. RDMA Verbs Stacks: Read each stack top to bottom through the user-space, kernel, and hardware bands. In the illustrated copied TCP/IP socket path (left), a send enters the kernel through a system call, the payload is copied into kernel socket buffers and again toward the NIC's transmit ring, and the CPU runs the transport protocol in software. With RDMA verbs over InfiniBand or RoCEv2 (right), the collective library posts work requests from user space, the kernel stays off the data path, and the RDMA NIC runs the reliable transport in hardware, reading GPU memory directly through GPUDirect instead of staging a host copy.

3.4.3 Reliable delivery and loss recovery

By routing the user-space verbs API directly to hardware (figure 3.6), the architecture decouples collective library calls from the operating system, leaving the transport hardware and fabric to arbitrate reliable delivery and packet loss. Reliable connected transports in both InfiniBand and RoCE detect loss and retransmit (InfiniBand Trade Association 2000); credits and PFC exist to make that retransmission rare (Guo et al. 2016; Gangidi et al. 2024). Losslessness is therefore a deployment contract rather than a property of RDMA as a family. Designs that operate over lossy Ethernet without PFC shift more responsibility to endpoint congestion control, packet reordering, and selective recovery (Mittal et al. 2018).

Recovery granularity therefore matters. On an RNIC with **Go-Back-N**-style recovery and no out-of-order retention, a lost packet invalidates every packet that arrives after it, and the sender must retransmit from the missing sequence point. The penalty is everything the sender transmitted between the lost packet and the moment it learned of the loss, so it equals link rate times detection delay. If the

receiver's negative acknowledgment reaches the sender after one 5 µs round trip, a sender at 50 GB/s has meanwhile sent 250 KB, all of which it must send again; a drop 900 MB into a 1 GB transfer wastes that window, not the 900 MB already delivered. When detection instead waits for a retransmission timeout, the delay, and with it the resent window, grows with that timeout. An RNIC with selective recovery retransmits only the missing packets, so the same physical loss produces a shorter tail (Mittal et al. 2018). Because the window is line rate times detection delay, resending it takes about as long as detecting the loss did, so a faster link resends more bytes per drop without shortening the stall. Either way the stall spans many packet wire times, and a synchronous collective exposes the slowest recovery to every waiting worker. Fabric designers can reduce that tail by suppressing drops with PFC, by using a loss-tolerant transport with bounded endpoint recovery, or by combining congestion control and admission policy so queues rarely overflow. Each choice moves state and failure modes between switches and endpoints.

3.4.4 The α-β performance model

Even on a lossless RDMA path with zero packet drops, doubling the link rate barely speeds up a few-kilobyte pipeline control handoff while cutting a multi-hundred-megabyte gradient transfer nearly in half. Separating those two behaviors requires a cost model that distinguishes fixed per-message overhead from per-byte transmission rate. The α-β model (principle 5) decomposes message transfer time as $T(n) = \alpha + n/\beta$, where n is the message size in bytes, α is the fixed startup latency, and β is the sustained bandwidth in bytes per unit time (Hockney 1994). The physical topology influences both parameters through path length and available capacity. A collective built from many sequential rounds of messages pays α once per round, so its startup cost can grow with the number of participants even when the underlying fabric provides short physical paths.

The model reveals two regimes that call for different engineering responses. When $n < \alpha\beta$, the startup cost α exceeds the transmission cost, placing small control messages deep in the latency-bound region, whereas when $n > \alpha\beta$, the n/β term dominates and large gradient transfers sit deep in the bandwidth-bound region. Near the crossover both terms matter, and where a collective lands also depends on how its algorithm divides the payload into messages and schedules them across rounds.

For the modeled NDR InfiniBand path with $\alpha = 1.5$ µs and $\beta = 50$ GB/s, the crossover point $n^* = \alpha \cdot \beta \approx 75$ KB. Measured startup latency and delivered bandwidth vary with the NIC, switch path, software stack, and contention, so these parameters describe a scenario rather than a protocol constant. Far below the crossover, more bandwidth removes only a small part of transfer time; far above it, lower startup latency removes only a small part. Shorter paths can lower α, while additional delivered path bandwidth raises β; their value depends on the message sizes the workload actually exchanges.

↪ The same decomposition, multiplied by each schedule's round count and traffic factor, is developed for collective algorithms in section 5.5.

↪ The crossover message size that separates the latency-dominated and bandwidth-dominated regimes, with a worked InfiniBand NDR example, is developed in section D.1.1.

Napkin Math 3.1: The alpha-beta crossover

Problem: A fabric designer is comparing a modeled InfiniBand NDR path (1.5 µs, 50 GB/s) against a modeled RoCE path over slower Ethernet (5 µs, 12.5 GB/s). The comparison deliberately bundles a higher-latency stack with a slower link, so a third path, RoCE on a 400 Gb/s link, separates the two effects. For a 4 KB control message and a 350 MB gradient shard, which part of $T(n) = \alpha + n/\beta$ dominates, and why does the first path help for different reasons in each regime?

Math: Apply $T(n) = \alpha + n/\beta$ for a 4 KB control message and a 350 MB gradient shard.

1. **Small message** (4 KB):
   - InfiniBand: $1.5\,\mu s + 4\,KB/50\,GB/s = 1.5 + 0.08 = \mathbf{1.58}\,\mu s$
   - RoCE (100G): $5.0\,\mu s + 4\,KB/12.5\,GB/s = 5.0 + 0.32 = \mathbf{5.32}\,\mu s$
   - **Result**: Under these assumed path parameters, the NDR path is 3.4× faster because its modeled α is lower.
2. **Large message** (350 MB):
   - InfiniBand: $T = \alpha + n/\beta = 7.0$ ms
   - RoCE (100G): $T = \alpha + n/\beta = 28.01$ ms
   - **Result**: Under these assumed path parameters, the NDR path is 4× faster because its modeled β is higher. That factor is the ratio of the two line rates, so it measures the faster link rather than the transport.
3. **Same line rate** (RoCE at 400 Gb/s, RoCE α):
   - Small message: 5.08 µs, still 3.2× the NDR time, because α alone separates the stacks.
   - Large message: 7.0 ms, essentially the NDR time, because at equal β nothing but a few microseconds of α separates them.

Systems insight: This scenario places the crossover ($n^* = \alpha\beta$) near 75 KB. Because gradients are megabytes to gigabytes, their transfers are usually bandwidth dominated, whereas pipeline coordination can remain latency dominated. A higher line rate produces little benefit for a message whose startup term dominates; transport processing, topology, and hop count then govern the improvement.

The two message sizes in notebook 3.1 map directly onto the 175B training job. For the 4 KB control message that notifies a pipeline stage its next microbatch is ready ($T(n) \approx 1.58$ µs on NDR), the transmission term contributes only 5.1 percent of the total, so faster links offer little benefit. For the 350 MB shard that each of the 1,024 GPUs owns from the 350 GB gradient ($T(n) \approx 7.0$ ms), transmission

dominates, and doubling bandwidth to 100 GB/s approximately halves the transfer time.

Across the full range of message sizes, each path traces a flat latency-dominated plateau that bends into a linear bandwidth-dominated regime (figure 3.7). On the modeled NDR path, the knee at 75 KB marks where transmission time overtakes the 1.5 µs startup latency; the 100 Gb/s RoCE path sits on a higher floor of 5 µs and bends near 62.5 KB. The exact positions reflect the assumed α and β scenario parameters rather than invariant protocol constants. On both paths, startup latency governs sub-kilobyte control handoffs, whereas multi-megabyte gradient shards sit well inside the bandwidth-bound regime.

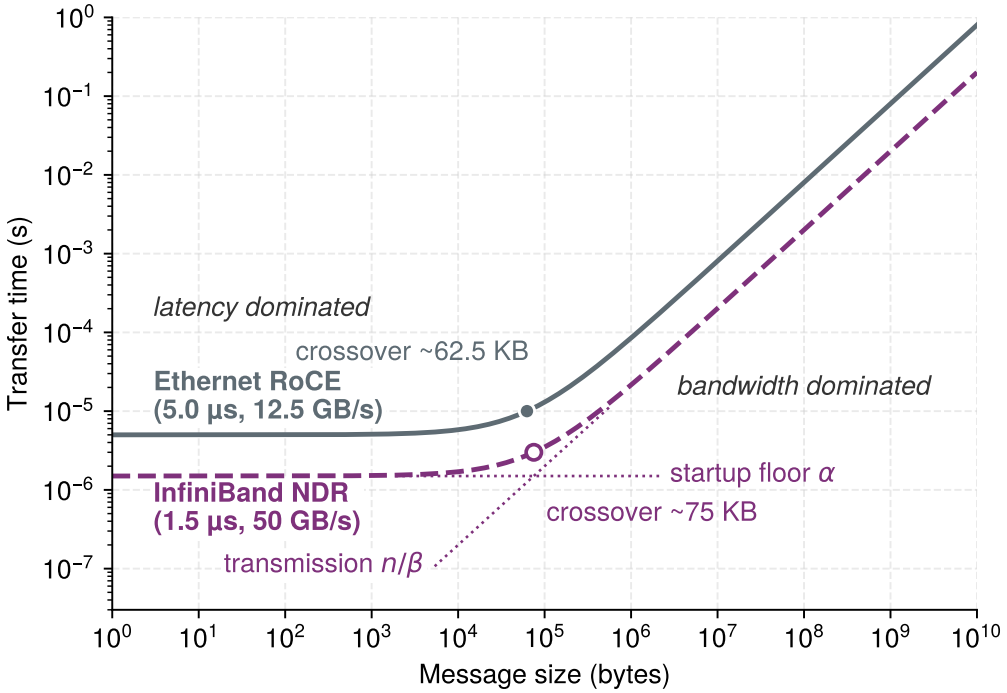

Figure 3.7: The α-β Crossover: Modeled transfer time as a function of message size for an NDR InfiniBand path and a 100 Gb/s RoCE baseline using the scenario parameters in the text. Small messages are latency dominated (flat region), while large messages are bandwidth dominated (linear region); on the InfiniBand path the dotted asymptotes show the knee sitting where the two terms are equal. Measured crossover points vary with the end-to-end path.

A measured collective shows both regimes and where the two-parameter model needs care. NVIDIA publishes the full output of the standard NCCL AllReduce benchmark on one node of eight H100 GPUs connected by NVLink, sweeping message sizes from 8 bytes to 16 GB (NVIDIA 2026a). The two-parameter model can be built from two summary values of that sweep, the median time of the small messages as α and the delivered rate of the largest message as β, and set beside the measured time (figure 3.8). The small messages sit on a floor of about 17 µs regardless of size, and the largest messages approach 274 GB/s of algorithm bandwidth, defined as the tensor size divided by completion time. Because an eight-GPU ring AllReduce sends $2(8-1)/8 = 1.75$ bytes across each GPU's links per tensor

byte reduced, multiplying by that factor gives 480 GB/s of bus bandwidth, the benchmark's hardware-normalized rate on the physical links. Between the two extremes, the model places the knee near 5 MB, but the measured time runs up to 1.7× the model's prediction for messages of 8 to 128 MB. Across that middle range, chunks are not yet large enough to fill every parallel NVLink channel and amortize per-round protocol overhead, so delivered bandwidth is still ramping toward its peak. The model is therefore close at the two ends and optimistic in the middle, and that middle range is where the gradient buckets of data-parallel training often fall.

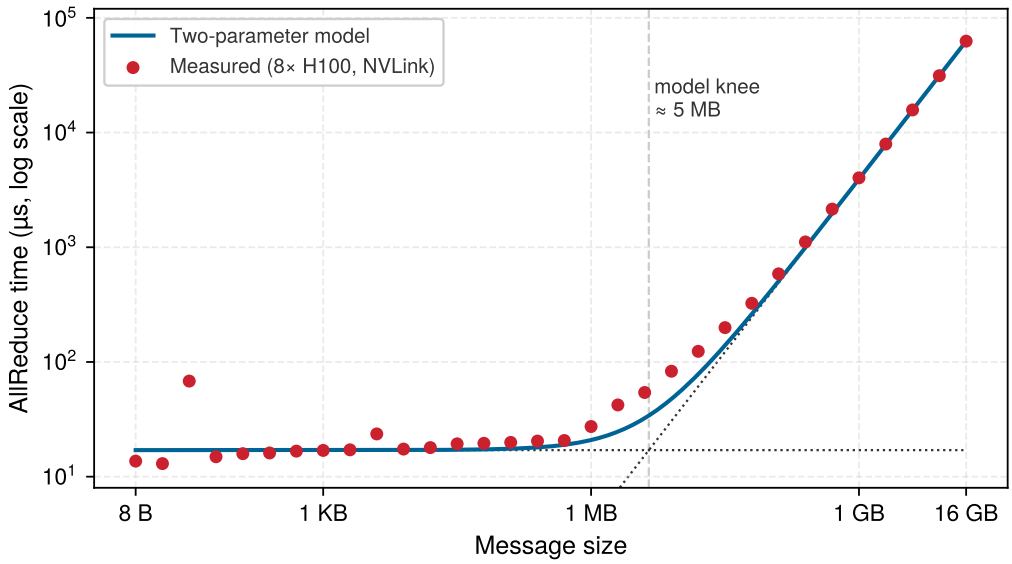

Figure 3.8: Measured AllReduce Time against the Two-Parameter Model: NCCL AllReduce time on one node of eight H100 GPUs over NVLink for message sizes from 8 bytes to 16 GB, on logarithmic axes (points), with the two-parameter model built from the measured small-message floor and the largest message's delivered bandwidth (solid line) and its two asymptotes (dotted). The model is close at both ends; between roughly 1 MB and 1 GB the measurement runs above it. One early small-message point is a timing outlier. Data from NVIDIA (2026a); whether NVLink SHARP was enabled for this run is not stated.

Checkpoint 3.1: Protocol selection

Consider the 175B job on the 1,024-GPU reference cluster. Its gradient exchanges move messages of hundreds of megabytes, while its pipeline stages coordinate through frequent control messages of a few kilobytes.

- ☐ **Protocol fit**: use the α-β crossover to recommend a transport stack, and justify the choice for both the large gradient messages and the small control messages.
- ☐ **RoCE requirements**: compare the infrastructure required by PFC-based and PFC-free RoCE designs with InfiniBand's credit-based fabric.

- ☐ **Line rate vs. startup cost**: explain why moving the control messages from a 100 Gb/s path to a 400 Gb/s path with the same α would barely change their transfer time.

Beyond classifying individual transfers, the same model identifies when communication overtakes computation. A ring AllReduce passes chunks around a logical cycle of participants, in a ReduceScatter phase and then an AllGather phase, with no requirement that the physical switches form a ring. The scaling laws that push training toward more parameters (section 1.3) enlarge, in direct proportion, the gradient that every data-parallel step must reduce. The α-β cost of each transfer, multiplied by the ring's round count and traffic factor, then decides when that collective outlasts the step's computation. At that point the network becomes the pacing constraint for the entire job.

The α-β model quantifies the speed of a single link, but the 175B-parameter model requires 1,024 GPUs to work in concert. Scaling these transport primitives from a pair of nodes to a warehouse-scale supercomputer demands a **network topology**: a specific pattern of connections that maximizes $\text{BW}_{\text{bisect}}$ while minimizing the hop count and cabling cost for global collective operations.

↪ The ring AllReduce derivation, and the schedules that compete with it, are developed in section 5.6.3.

3.5 Level 3 Switch and Topology

A cluster can have thousands of fast links at the edge and still starve its AllReduce operations if the cross-sectional capacity at the narrowest point in the switching hierarchy is insufficient. The physical arrangement of switches determines whether that cross-section throttles collective communication or sustains full line-rate exchange across all participating workers. Two properties govern this capability: bisection bandwidth $\text{BW}_{\text{bisect}}$ and whether the fabric is non-blocking, a constraint captured by the bisection bandwidth theorem (principle 6). Bisection bandwidth quantifies the worst-case throughput ceiling that the topology imposes on global collectives.

Definition 3.4: Bisection bandwidth

Bisection bandwidth is a network topology metric defined as the minimum aggregate link capacity crossing any partition that divides the cluster into two equal halves, representing the worst-case throughput ceiling for traffic that must cross that partition, including global collectives.

1. **Significance**: Bisection bandwidth $\text{BW}_{\text{bisect}}$ directly sets the cluster-scale bandwidth ceiling for global synchronization. A 1,024-GPU fat-tree with 400 Gb/s links at 1:1 subscription provides $\text{BW}_{\text{bisect}} = 512 \times 50\,\text{GB/s} = 25.6\,\text{TB/s}$ per direction; a 4:1 oversubscribed spine reduces this to 6.4 TB/s, increasing the transfer-time lower bound for a fixed cut-crossing payload by 4×. Actual AllReduce slowdown depends on rank placement, the collective schedule, and which links are saturated.

2. **Distinction**: Unlike aggregate bandwidth (the sum of all edge link speeds, which can be high even in a poorly connected topology), BW_{bisect} measures global connectivity. A star topology with 1,000 edge links all meeting at one central switch has high aggregate bandwidth but BW_{bisect} limited by that switch's backplane capacity.
3. **Common pitfall**: A frequent misconception is that adding more leaf switches always increases BW_{bisect}. In a three-tier fat-tree, oversubscribing the spine layer (giving each spine switch fewer uplinks to the core than downlinks to its leaves) reduces BW_{bisect} below the edge-link total regardless of how many leaf switches are present.

ML training includes global collectives and AllToAll phases that can drive traffic across topology partitions, making full BW_{bisect} a useful capacity target. A smaller cut becomes a bottleneck when the workload's crossing traffic exceeds what it can deliver within the communication budget, and rank placement together with the collective schedule determines how much traffic crosses that cut.

Bisection bandwidth measures cut capacity; a non-blocking fabric provides paths that can sustain simultaneous input-output pairings at line rate with suitable routing. Full BW_{bisect} and balanced uplink capacity support that goal, but routing must also spread traffic across the available paths. In the oversubscribed designs considered here, reducing a cut's capacity reduces its effective BW_{bisect}, increasing the transfer-time bound for a fixed payload that saturates it, whereas a collective that keeps most traffic within each half need not experience the same slowdown.

↪ A slower cut lengthens the training step only when the extra transfer time cannot hide behind computation. The communication-to-compute diagnostic that tests this is developed in section B.4.1.

Definition 3.5: Non-blocking fabric

Non-blocking fabric is a network with sufficient internal path capacity to support any permutation of input-output port pairs simultaneously at full line rate under a suitable routing assignment.

1. **Significance**: In ML fleets, a non-blocking fabric can support full-rate permutation traffic with suitable routing, preserving the available BW_{bisect} term for global collectives. A 2:1 oversubscribed spine halves the effective BW_{bisect}, doubling the communication time when that cut is the saturated bottleneck and dropping scaling efficiency $\eta_{scaling}$ accordingly. In a scenario workload assumed to spend 30 percent of each step communicating, doubling that share while the computation share stays fixed lengthens each step, and the longer step costs roughly 23.1 percent of total cluster throughput. This definition uses 2:1, a common data-center compromise, whereas the bisection definition above and notebook 3.2 use 4:1, a cost-optimized spine; the notebook writes out the throughput formula behind both results.
2. **Distinction**: The guarantee concerns a permutation, in which each input and output belongs to one pairing. It does not promise full line rate from

every sender to every receiver at once, nor does it make an arbitrary routing assignment free of contention.

3. **Common pitfall**: A frequent misconception is that non-blocking means zero congestion. Endpoint congestion (incast) can still occur if multiple senders simultaneously target the same receiver port, regardless of how much internal fabric capacity is available.

Fat-trees build on Clos-style non-blocking network principles to supply full BW_{bisect} (Clos 1953), rail-optimized networks trade some global routing flexibility for lower cabling cost, and dragonfly topologies reduce optical link counts while introducing workload-placement constraints (Kim et al. 2008). This trade-off between guaranteed bisection bandwidth and cabling cost drives every topology decision in large-scale ML clusters, as the comparisons in section 3.5.2, section 3.5.3, and section 3.5.4 show, and every switched design begins at the first-hop switch that aggregates a rack or rail of servers.

3.5.1 Top-of-rack (ToR) and the failure domain

Consider a rack containing four nodes with eight GPUs each: if all 32 accelerators attach to a single top-of-rack (ToR) switch with no alternate path, losing that switch disconnects the entire rack from the job at once. Because the ToR aggregates every server link in the rack, it becomes a shared failure domain, one level of the physical hierarchy defined in section 2.5.5, and recovery then depends on available paths, surviving state, and the job's recovery policy. This one-switch-per-rack wiring is the simpler baseline used here to teach radix and failure domains. The reference cluster itself wires each GPU to a rail switch, a layout developed in section 3.5.3. That layout reshapes the failure domain, because losing one rail switch cuts one GPU in each of many nodes rather than every GPU in one rack.

The switch **radix**,[5] its number of ports, determines how many endpoints and uplinks it can connect. In the reference allocation, a 64-port switch assigns 32 ports to servers, one for each of 32 GPUs, and 32 ports to the spine. With equal port rates, the 1:1 ratio avoids oversubscription at that boundary; delivered throughput still depends on forwarding and the paths beyond it. The 1,024 GPUs-GPU cluster therefore requires approximately 32 such endpoint groups, although the physical rack count also depends on node density and the cabling layout.

The same boundary shapes state placement. To survive a rack-wide outage, a job needs recoverable state outside that rack and a way to resume on available capacity. Topology-aware scheduling must therefore consider both fast communication paths and the failures that several nearby resources share.

3.5.2 Fat-tree (Clos) networks

The ToR provides non-blocking bandwidth within a single rack, but connecting the reference cluster's 32 endpoint groups into a cluster that preserves full BW_{bisect} across every possible communication pair requires a topology that scales cross-sectional capacity with cluster size. The fat-tree (also called a Clos network)

[5] **Switch radix**: High-end switches such as NVIDIA Quantum-2 offer a radix of 64 ports, each at 400 Gb/s. As model scale pushes toward 100,000 GPUs, higher radix (128 or 256 ports), larger local accelerator domains, or accepted topology constraints are the main ways to avoid adding switch tiers, each of which adds switch latency and cost.

↪ Nested failure domains, and why redundant state must span them to survive a correlated rack or ToR outage, are developed in section 7.3.4.

achieves this by adding parallel spine switches at each tier, so the aggregate uplink capacity always matches the total edge bandwidth feeding into it. In this vocabulary, leaf switches attach servers or racks, spine switches connect leaves within a pod, and core switches connect multiple pods when a third tier is needed; other sources call the leaf and spine tiers edge and aggregation. A pod here is a switching domain, the group of leaves that one set of spines joins, which can be narrower than the multi-rack pod of section 2.7. A multi-rack pod in that sense can contain several fat-tree pods.

Definition 3.6: Fat-tree

Fat-tree is a hierarchical ML cluster network topology in which the number of parallel paths (and therefore aggregate cross-sectional capacity) increases at each switch tier toward the spine, providing full $\text{BW}_{\text{bisect}}$ and multiple equal-cost routes between any two nodes (Al-Fares et al. 2008).

1. **Significance**: A k-ary fat-tree built from radix-k switches supports $k^2/2$ hosts in a standalone two-tier configuration and $k^3/4$ hosts in a three-tier configuration with full $\text{BW}_{\text{bisect}}$. With 64-port switches, a standalone two-tier fabric supports 2,048 GPUs and a three-tier fabric supports 65,536 hosts. This is a capacity bound for suitable routing and admissible traffic; it does not eliminate endpoint contention or guarantee that a particular AllReduce implementation reaches line rate.
2. **Distinction**: Unlike a standard tree (where bandwidth at the root is a single bottleneck shared by all leaves), a fat-tree replaces each root with multiple spine switches whose combined uplink capacity matches the total edge bandwidth, eliminating the bottleneck.
3. **Common pitfall**: A frequent misconception is that fat-trees guarantee zero network cost. They require $\mathcal{O}(N \log N)$ switches and dense cabling, so a non-blocking three-tier fat-tree at the 4,000-GPU scale needs hundreds of switches and more than ten thousand links before a single accelerator is purchased.

A three-tier radix-4 fabric ($k = 4$) shows the non-blocking structure at a scale small enough to draw (figure 3.9), with four core switches interconnecting four dashed pod modules. Leaf and spine switches split their ports between the tiers below and above; core switches use all their ports to connect pods. Each tier boundary therefore carries 16 links. The highlighted route traverses five switches and is one of $(k/2)^2 = 4$ equal-cost routes from a GPU in Pod 1 to Pod 4. Parallel paths supply the capacity, while routing must distribute traffic across them to use it.

The fat-tree[6] is a common default for ML clusters because a non-blocking design can provide full $\text{BW}_{\text{bisect}}$ across arbitrary partitions. This capacity benefits global AllReduce even though implementations such as rings and trees do not require

[6] **Fat-tree (Clos network)**: The underlying multi-stage switching theory was invented by Clos (1953) at Bell Labs to minimize the number of electromechanical crosspoints in telephone exchanges. Leiserson (1985) at MIT generalized the concept as the "fat-tree," where the tree is "fat" because link bandwidth increases toward the root, proving it could emulate any network of equal hardware volume. The same cost-minimization logic that drove 1950s telephony now drives ML cluster design: minimize switch count while guaranteeing non-blocking connectivity for global AllReduce.

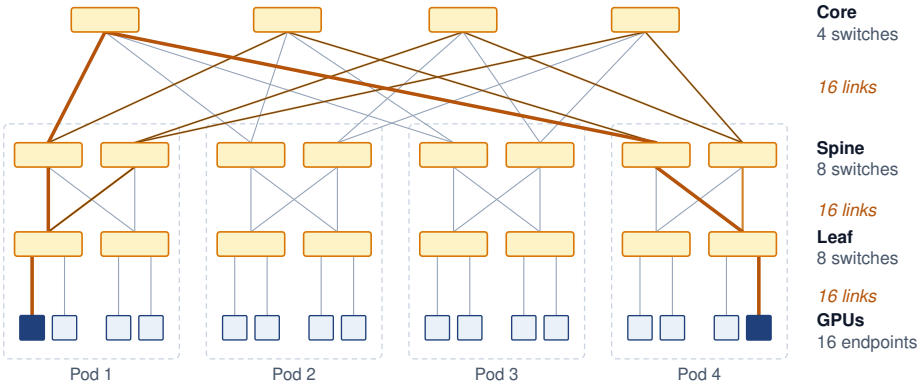

Figure 3.9: Non-blocking Fat-Tree Topology: A three-tier fat-tree built from radix-4 switches ($k = 4$) connects $k^3/4 = 16$ GPUs through four pods. Leaf and spine switches split their ports equally between the tiers below and above; core switches use all their ports to connect pods. Each tier boundary carries 16 links, supporting full $\text{BW}_{\text{bisect}}$ with suitable routing. The highlighted leaf-spine-core-spine-leaf route between pod 1 and pod 4 is one of $(k/2)^2 = 4$ equal-cost paths (the other three are drawn lighter), and exploiting those alternatives without excessive reordering requires compatible switch and endpoint mechanisms.

every pair of ranks to communicate at once. The number of hosts that the guarantee can cover depends on switch radix and tier count.

A fat-tree built from switches with radix k supports $N_{\text{hosts}} = k^3/4$ hosts at three tiers. A standalone two-tier non-blocking fabric can instead use k leaves, each with $k/2$ host ports and $k/2$ uplinks, connected to $k/2$ spines. Each spine uses all k ports to reach the leaves, providing $k^2/2 = 2{,}048$ host ports for radix-64 switches. In the three-tier design, each spine switch reserves half of its ports for the core tier and uses the other $k/2$ ports to connect to leaves, so one pod has $k/2$ leaves and $(k/2)^2 = 1{,}024$ host ports. Because each radix-k core switch connects one port to each pod, the core tier can join up to k pods for the full $k \times (k/2)^2 = k^3/4$ host capacity. These are different port allocations and switch counts rather than two ways of counting the same fabric, and while the 1,024-GPU reference cluster fits within a standalone two-tier design, the distinction matters as soon as a cluster outgrows that limit. A 4,096-GPU deployment cannot join two fully populated standalone 2,048-host fabrics at their spines, because every spine port is already occupied by a leaf connection. Instead, it is built as four 1,024-host pods of the three-tier design, joined through a core tier. A concrete bisection estimate shows how quickly oversubscription at that spine or core boundary turns into synchronization delay.

Napkin Math 3.2: Bisection bandwidth: The cost of oversubscription

Problem: A cluster designer is choosing between a "non-blocking" (1:1) fat-tree and a "cost-optimized" (4:1) spine for a $300M cluster of 1024 GPUs. This is a separate economics scenario rather than the running 175B job: each GPU contributes a 5 GB gradient payload, and the workload is assumed to spend

$f = 30$ percent of each step communicating. That share is a scenario input. It is larger than the 13 percent of the illustrative schedule in figure 3.2 and far smaller than the exposed share in the introduction's GPT-3 synchronization example (section 1.5.5), which assumes pure data parallelism with no overlap; none of the three is a measured share of the reference job. How much slower will the AllReduce be on the cheaper network, and what does that cost?

Math: Bisection bandwidth (BW_{bisect}) is the minimum pipe diameter between halves of the cluster. Assume a unidirectional ring whose ranks alternate between the two halves of the cluster. Every ring edge then crosses the cut, with $N_{GPU}/2$ senders in each direction. Assume balanced routing, no competing traffic, and negligible startup latency. ReduceScatter plus AllGather contributes a traffic factor $2(N_{GPU}-1)/N_{GPU}$ = 1.998 per GPU; multiplying by $N_{GPU}/2$ gives the bytes crossing the cut in each direction. A ring that groups ranks within each half would have fewer crossing edges and a different cut-load bound.

1. **Non-blocking (1:1)**: $BW_{bisect} = 512 \times 50$ GB/s = 25,600 GB/s per direction.
   - Time: 5,115 GB / 25,600 GB/s $\approx$ 0.200 s.
2. **Oversubscribed (4:1)**: BW_{bisect} = 25,600 GB/s divided by 4 = 6,400 GB/s per direction.
   - Time: 5,115 GB / 6,400 GB/s $\approx$ 0.799 s.
3. **Throughput**: If the communication share stretches by the slowdown factor r while computation stays fixed, then relative throughput $= \frac{1}{(1-f)+fr} = \frac{1}{0.70+0.30\times4} = \frac{1}{1.90} \approx 0.53$, a loss of about 47.4 percent of cluster throughput.
4. **Cost**: That loss times the $300M capital cost is about $142.1M.

Systems insight: For this cut-saturating placement, saving money on core switches creates a 4× bottleneck for global synchronization, and on a $300M cluster that bottleneck idles about $142.1M of compute. The same formula gives the 23.1 percent loss of the 2:1 spine in the non-blocking definition. This is an equivalent-capacity cost under the stated workload assumptions, not a direct equipment loss. Oversubscription must be evaluated against the collective traffic actually crossing the constrained cut.

The subscription ratio at each tier therefore determines whether a fat-tree can sustain global collectives, and the tier count determines how far it can grow. Scaling beyond the 2,048-host two-tier limit requires a three-tier architecture with core switches, enabling the fabric to reach 65,536 hosts, but the added scale carries both cost and latency. Each of the k pods contains $k/2$ leaf switches and $k/2$ spine switches (k^2 switches across all pods), and their $k/2$ spines each send $k/2$ uplinks into $(k/2)^2 = k^2/4$ core switches. A non-blocking $k = 64$ three-tier tree therefore

requires $5k^2/4 = 5{,}120$ switches across the core, spine, and leaf layers. At $10,000 to $50,000 per switch, the switching layer alone represents $51M to $256M. Typical hop counts also rise, from two inter-switch links and three switch traversals for intra-pod traffic (leaf-spine-leaf) to four inter-switch links and five switch traversals for inter-pod traffic (leaf-spine-core-spine-leaf), adding serialization delay and switch processing time to the α latency term across thousands of synchronization steps. Rail-optimized topologies respond to both pressures by matching the physical cabling pattern to the collective communication pattern.

Checkpoint 3.2: Fat-tree topologies

These questions check whether hierarchical switch-fabric trade-offs are clear:

- ☐ **Radix and scale**: compute the maximum number of GPUs a radix-64 two-tier fat-tree can connect without core switches.
- ☐ **Non-blocking ratio**: explain why a non-blocking fabric requires a 1:1 subscription ratio at every tier of the network.
- ☐ **Tier vs. latency**: determine how α (startup latency) changes when moving from a two-tier to a three-tier fat-tree.
- ☐ **Aggregate vs. bisection**: distinguish aggregate bandwidth from $\text{BW}_{\text{bisect}}$ and identify the metric that matters for AllReduce.

3.5.3 Rail-optimized topology

When tensor-parallel groups stay inside each node's high-bandwidth NVSwitch domain, data parallelism exchanges gradients only between GPUs that hold the same model shard in the same local slot position across nodes, yet a standard fat-tree wires all eight GPUs of a node into a shared ToR switch. A **rail-optimized topology** instead cables external network ports by local slot position (figure 3.10): GPU 0 in every node connects to the Rail 0 switch, GPU 1 connects to Rail 1, and so on across the cluster.

This slot-aligned wiring exploits the stratified traffic that 3D parallelism produces. Because each node holds a tensor-parallel group, each data-parallel replica assigns the corresponding model shard to the same local GPU slot (where the slot number is a local rank within a node, distinct from the worker's global rank in the distributed job). During data-parallel AllReduce, GPU 0 on one node synchronizes its shard's gradients with GPU 0 on other nodes, but rarely communicates with GPU 1. Isolating each local rank onto its own rail switch fabric removes same-rank traffic from shared rack switches and, when a rail fits on a single switch, shortens the path between corresponding GPUs. A simple hop-count estimate shows the payoff.

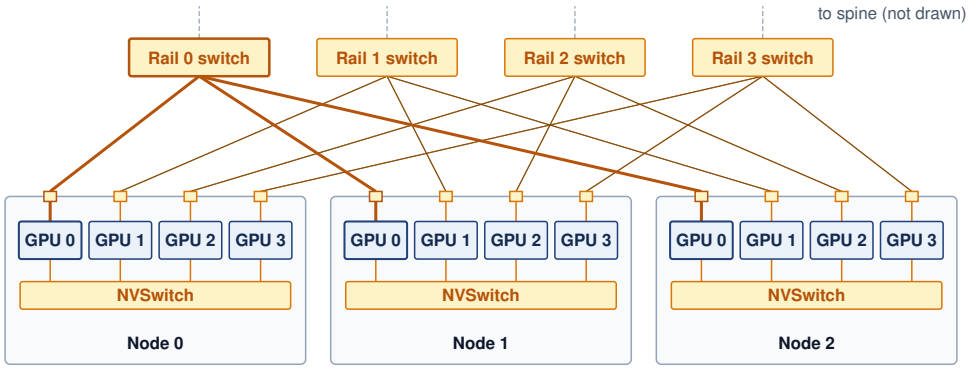

Figure 3.10: Rail-Optimized Physical Wiring: In dense accelerator nodes such as the DGX H100, each GPU's network port is cabled by local slot position: GPU 0 in every node connects to the rail 0 switch, GPU 1 to the rail 1 switch, and so on. Three nodes and four of each node's eight GPUs are drawn, with the rail 0 cables emphasized; further nodes attach to the same rail switches. Tensor-parallel traffic stays on each node's NVSwitch, same-rank data-parallel traffic stays on its own rail, and a spine layer (not drawn) bridges the rails for cross-rank traffic.

Napkin Math 3.3: The rail-optimized dividend

Problem: A team is synchronizing per-rank data-parallel gradients across 128 nodes. In a standard fat-tree, each message between same-rank GPUs traverses its source leaf switch, a spine switch, and the destination leaf switch (3 switch traversals). In a rail-optimized network built from rail switches with at least one port per node, all corresponding GPUs sit on the same rail switch (one traversal). On the reference cluster that requires rail switches with more ports than the radix-64 switch used so far, so the estimate describes a higher-radix design. How much latency dividend does the rail design earn when a rail fits on one switch?

Math: This estimate counts only the switch-traversal contribution to communication latency (α), using the same assumed delay for each traversal.

1. **Standard latency**: 3 traversals $\times$ 0.6 µs = 1.8 µs.
2. **Rail-optimized**: 1 traversal $\times$ 0.6 µs = 0.6 µs.
3. **Result**: 3× lower latency.

Systems insight: For synchronous data-parallel AllReduce, this 3× reduction applies to the modeled switch-latency contribution, not to total collective time. Its effect on scaling efficiency (η_{scaling}) depends on payload size, delivered bandwidth, compute time, and overlap. The single-switch rail in this example avoids the spine traversal for same-rank traffic. The dividend is conditional. On the reference cluster's radix-64 switches each rail outgrows one switch and regains the extra traversals, so what rails reliably buy there is isolation, developed below.

The hop saving is only part of the case for rails. Large language model fleets adopt the pattern because it matches how their parallelism plan divides traffic.

Lighthouse 3.1: Archetype A (GPT-4/Llama-3): The rail-optimized fleet

Archetype A's use of 3D parallelism generates two distinct traffic patterns that pull in opposite directions: (1) large, bandwidth-hungry gradient averaging for data parallelism, and (2) high-frequency, latency-sensitive activation exchanges for tensor parallelism. Keeping tensor parallelism inside each node's NVLink domain leaves data-parallel gradient traffic on the fabric, and rails give each same-rank data-parallel group its own switch network. A rail can provide a single switch hop between nodes when its endpoint count fits the available switch ports. Larger rails require additional switching stages, so rail alignment alone does not guarantee single-hop communication. Either way, the lesson for Archetype A is that how the fabric is wired to the parallelism plan matters as much as how many accelerators it connects.

For the cluster of 1,024 GPUs spanning 128 nodes, this creates 8 parallel networks of 128 GPUs each, requiring at least one switch port per endpoint in each rail. A single-switch realization therefore needs a radix at least as large as the rail endpoint count; the earlier radix-64 switch cannot realize this rail alone, which is why notebook 3.3 assumed higher-radix rail switches. Built from radix-64 switches instead, each rail becomes a small two-tier fabric that preserves rank alignment but adds hops. For the bandwidth-hungry gradient exchanges of data parallelism, the larger benefit is isolation: each rail carries only its own rank's traffic, so the eight rail networks operate concurrently without competing for shared spine capacity. When a rail fits on one switch, the shorter path also trims the startup cost a ring pays on every round. That same isolation creates a sharp trade-off, because traffic that must reach GPUs of different ranks (such as expert routing in mixture of experts (MoE), or pipeline-stage handoffs that do not align with the rail wiring) requires bridging across rails. Large clusters therefore often employ a hybrid approach, using rail-optimized leaves for same-rank data-parallel traffic while bridging the rails with a full fat-tree spine to support cross-rank communication patterns.

Checkpoint 3.3: Rail-optimized networks

These questions check whether workload-specific network-design trade-offs are clear:

- ☐ **Rail beneficiary**: identify the dimension of 3D parallelism (tensor parallelism, pipeline parallelism, or data parallelism) that benefits most from a rail-optimized design.
- ☐ **Switch hops**: explain when a rail-optimized network reduces the number of switch hops for gradient exchanges compared to a standard fat-

tree, and what it still provides when a rail needs more ports than one switch offers.

- ☐ **Traffic isolation**: explain the traffic isolation benefit of placing all GPU 0s on one rail and all GPU 1s on another.
- ☐ **Core switch need**: classify the claim as true or false: a rail-optimized network eliminates the need for high-bandwidth core switches connecting different rails.

3.5.4 Dragonfly and torus alternatives

At tens of thousands of endpoints, a non-blocking three-tier fat-tree forces a third layer of core switches and tens of thousands of long optical cables into the budget, driving network capital expenditure into the tens or hundreds of millions of dollars. Two alternative topologies attack that cost wall from opposite directions: tapering the global switch tier or removing external fabric switches altogether. A **dragonfly**[7] topology organizes high-radix routers (the dragonfly literature's name for switches) into fully connected groups joined by global optical links. Each group has a routers, and each router has p terminal ports and h global channels. The ratio of h to p sets how much global bandwidth each group receives relative to the traffic its terminals can inject, so global bandwidth is a design parameter rather than a fixed percentage of aggregate injection bandwidth. The balanced configuration analyzed by Kim et al. (2008), $a = 2p = 2h$, is one setting of that knob. The routers in a group are fully connected, and the groups are joined by global links. A minimal route between two groups therefore takes at most one local hop to the router holding the right global link, one global hop, and one local hop in the destination group. No minimal path exceeds three router-to-router hops, regardless of system size. Short paths come cheaply, but performance for jobs spanning groups depends on the chosen p/h ratio, routing, and traffic matrix, because every inter-group transfer shares the provisioned global links.

A **torus** topology connects each node directly to its neighbors in a multidimensional grid, most commonly a 3D torus where every node links to its six adjacent peers (up/down, left/right, front/back). The design offers full local bandwidth with minimal switching hardware, because every neighbor is a single hop away. However, global communication requires traversing the diameter of the mesh ($\mathcal{O}(N^{1/3})$ hops), making latency scale poorly with cluster size. Google adopted this architecture for its Tensor Processing Unit (TPU) pods because the collectives that dominate its training workloads can be scheduled as rings along each torus dimension, a nearest-neighbor pattern that maps naturally onto the physical grid. The limitation becomes apparent with MoE, which relies on AllToAll communication patterns. On a torus, these random permutations can congest the limited $\text{BW}_{\text{bisect}}$ of the mesh and degrade performance relative to a non-blocking switch fabric.

The trade-off becomes concrete for the 4,096-endpoint deployment that the three-tier fat-tree reached with four pods. Arranged as a $16 \times 16 \times 16$ torus with wraparound links, the same endpoints need no external switching stages. Splitting

[7] **Dragonfly topology**: Introduced by Kim et al. (2008) at ISCA 2008, the dragonfly uses high-radix routers grouped into fully connected "supernodes." For systems with at least 16,000 terminals, the architecture achieves a 52 percent network-cost reduction relative to a folded Clos (the fat-tree of section 3.5.2) of equivalent bandwidth, though global optical link oversubscription can create AllToAll bottlenecks during MoE token routing.

the cube in half across one axis cuts a 16×16 plane of interior links and an equal plane of wraparound links, so only $2 \times 16^2 = 512$ links cross the bisection, against 2,048 in the non-blocking fat-tree. With 50 GB/s per link and direction, the torus offers 25.6 TB/s across the cut against the fat-tree's 102.4 TB/s, a 4× gap. Because wraparound links cap the distance along each 16-node axis at 8 hops, the torus's worst-case path across all three axes crosses $3 \times 8 = 24$ neighbor hops against the fat-tree's five switch traversals. Because a cubic torus's cut grows only as $N^{2/3}$ while its endpoint count grows as N, that capacity gap widens at fixed link rate. Whether the gap matters depends on the traffic. A ring AllReduce scheduled along each torus dimension moves data only between neighbors and combines contributions before forwarding them, so it leans little on the narrow cut. An MoE AllToAll or an embedding exchange instead sends a large share of its traffic between distant endpoints and drives it straight into the cut, with the exact pressure set by placement and message sizes. Consequently, the collective schedule and traffic matrix determine whether the torus's lower cross-sectional capacity limits completion time.

At the scale of the 1,024-GPU reference cluster, the four families range in cut capacity from 25.6 TB/s in the non-blocking fat-tree down to 6.4 TB/s in a 3D torus, while an assumed interconnect cost runs from \$1.5/Gb/s for the switchless torus to \$4/Gb/s for the tapered dragonfly (figure 3.11). The cheapest capacity is also the least capacity, which is the trade every topology decision prices. The dragonfly's assumed cost per Gb/s is the highest here because its savings come from replacing long optical runs and switch tiers at large scale, which Kim et al. (2008) reports for systems of at least 16,000 terminals; at 1,024 GPUs it has few such runs to replace. Radix, endpoint count, link speed, routing mechanisms, and equipment pricing all shift these trade-offs; the topology family alone dictates neither raw cross-sectional capacity nor operational capital cost.

↪ AllToAll schedules and their cost at scale, where every rank sends a distinct share to every other rank, are developed in section 5.8.

3.5.5 Optical circuit switching and reconfigurable topology

Every topology compared in figure 3.11 is fixed when the facility is cabled, locking the cluster into a single physical graph regardless of which workload runs on it. A statically cabled Clos hierarchy (section 3.5.2) fixes the oversubscription ratio and bisection pattern whether the active job is pipeline-dominated, data-parallel, or AllToAll expert-routed. A statically cabled torus (section 3.5.4) is equally rigid: it fits dimension-ordered rings, but it congests under MoE AllToAll traffic and cannot rewire its links to match the job.

Switching those multi-tier fabrics electrically also extracts a recurring power tax at every hop. Each electrical packet switch inspects headers and chooses an outgoing link only after an Optical-Electrical-Optical (OEO) conversion: incoming photons hit a photodiode, high-speed SerDes circuits deserialize the electrical signal, switch ASICs buffer and route packets across crossbars, and output SerDes drive lasers to re-transmit light over optical fiber. At 800 Gb/s and 1.6 Tb/s per-port data rates, SerDes and transceiver electronics consume significant energy (section 3.3.3), and every additional switch tier repeats that conversion cost for each bit that crosses it. Changing the physical connections between node groups

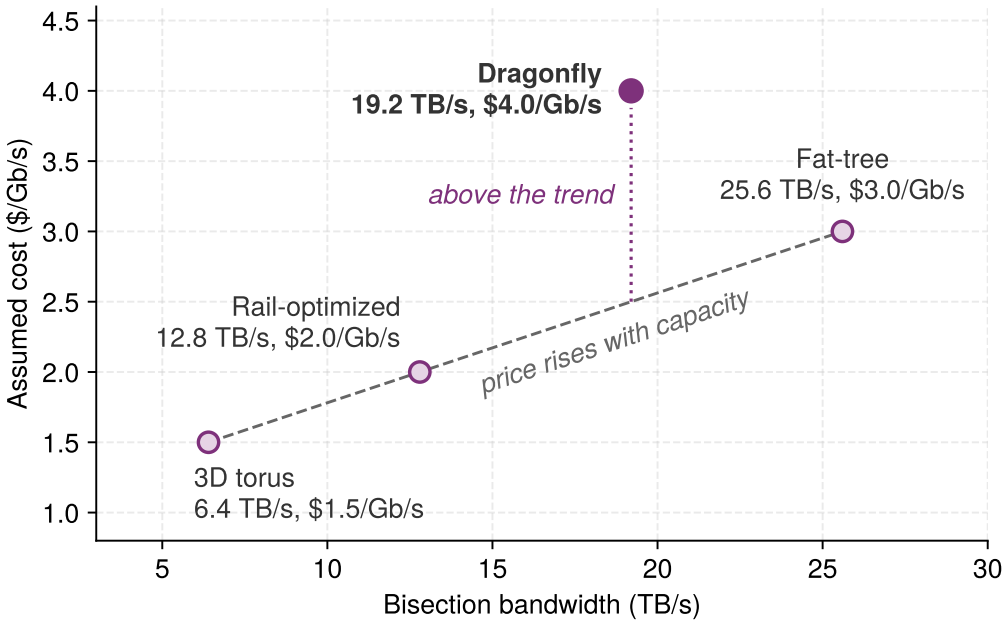

Figure 3.11: An Illustrative Bandwidth-Cost Scenario for ML Network Topologies: BW_{bisect} (TB/s, horizontal axis) against assumed cost per Gb/s (vertical axis) for four topology configurations on a 1,024-GPU cluster: fat-tree (25.6 TB/s, $3/Gb/s), dragonfly with tapered global links (19.2 TB/s, $4), rail-optimized with a 2:1 bridging spine (12.8 TB/s, $2), and a 3D torus (6.4 TB/s, $1.5). The bandwidths follow from the stated structures at one link rate; the costs are scenario inputs that illustrate the comparison method rather than universal properties of each topology family.

in light, for the duration of a workload allocation rather than packet by packet, avoids both static wiring and per-hop OEO conversion.

Definition 3.7: Optical circuit switching

Optical circuit switching (OCS) is a physical networking architecture that routes optical signals directly using Micro-Electro-Mechanical Systems (MEMS) mirror arrays without Optical-Electrical-Optical (OEO) conversion, enabling dynamic, software-defined topology reconfiguration and high energy efficiency at warehouse scale.

1. **Significance**: An optical circuit bypasses packet-by-packet electronic processing in the switching path. The complete system still consumes power for actuators, control, and transceivers. Its compatibility across line rates depends on optical loss, wavelengths, and endpoint budgets, so protocol transparency does not imply unrestricted upgrades.
2. **Distinction**: Unlike electrical packet switches (which inspect headers, buffer packets in SRAM, and make nanosecond routing decisions per packet), an OCS establishes semi-static physical optical circuits with millisecond-scale switching latency (10–30 ms), making it suitable for topology-level reconfiguration rather than dynamic packet routing.

3. **Common pitfall**: Assuming OCS replaces packet switching entirely. OCS operates at circuit granularity: it configures cluster-scale topologies (such as 3D tori or job-specific sub-clusters) and routes around hardware faults, while packet switching or accelerator-native interconnects handle fine-grained, intra-step message routing.

Google's TPU v4 supercomputer (Jouppi et al. 2023) deployed optical circuit switching in production. Instead of wiring 4,096 chips into an inflexible electrical fat-tree, the system groups accelerators into $4\times4\times4$ node cubes and routes the inter-cube links through an array of 3D MEMS optical circuit switches (codenamed Palomar).

The optical layer serves two purposes, adapting the topology to the workload and recovering from faults. For workload adaptation, the physical interconnect can be reconfigured to match the communication structure of the running model. A training run using 1D pipeline parallelism can configure its slice as an elongated cylinder to streamline stage-to-stage transfers. Conversely, a 2D or 3D tensor-parallel partition can configure a compact cubic 3D torus that minimizes average hop count, while an MoE workload can maximize bisection bandwidth across specific expert groups.

Optical switching also supports fault isolation by changing connections around unavailable hardware where spare connectivity permits. The capability matters because in a statically cabled torus, a single failed link or node can break a ring along an entire dimension and degrade every job that spans it. With optical circuit switching, the mirrors can be redirected to bypass the failed cube or fiber and splice healthy cubes into a complete, smaller torus slice without manual recabling. The fabric manager must first detect the fault, choose a feasible allocation, and establish the new circuits, which means circuit-switching time is only one part of recovery; a training job may also need to rebuild its process groups and restore state before computation resumes, so optical reconfiguration latency alone does not specify recovery time.

The trade-off is switching latency. Because MEMS mirrors physically rotate to steer collimated light beams, reconfiguration occurs on a mechanical timescale that is much longer than packet forwarding in an established electrical path. Circuit setup changes connectivity, while packet forwarding uses connectivity already in place. Consequently, OCS raises the power and protocol ceiling of the switching layer while leaving reconfiguration latency as the binding constraint, so it is deployed for job-level topology allocation and fault isolation, not for per-message dynamic routing. Within that limit, OCS turns the choice of topology from a decision fixed when the fabric is cabled into one made for each job.

Each topology comparison so far has considered one traffic pattern at a time. In practice, clusters serve multiple workloads with different communication patterns, and topology selection must balance their competing demands.

Checkpoint 3.4: Topology selection for your workload

The choice of network topology dictates the upper bound of training efficiency. Warm up by matching each single-workload pattern to its ideal topology, then design a fabric that must serve several at once.

Single-workload picks

- ☐ **AllReduce bandwidth**: select the topology that maximizes BW_{bisect} for a standard data-parallel job dominated by AllReduce.
- ☐ **MoE traffic**: select the topology that best sustains a mixture-of-experts model's AllToAll-dominant, bursty communication, in which any rank may send to any other.
- ☐ **Neighbor locality**: select the topology that best fits a ring AllReduce scheduled along each dimension of the machine, where every transfer goes to a physical neighbor.

Designing for a mixed cluster

You are designing the network for a new ML cluster that will run two primary workloads: (1) training a 175B-parameter language model using 3D parallelism (tensor, pipeline, and data parallelism), and (2) serving a mixture-of-experts model that relies heavily on AllToAll communication to route tokens to the correct experts.

- ☐ **Training topology**: select the topology (fat-tree, rail-optimized, or hybrid) that best matches tensor parallelism within groups of 8 GPUs and data parallelism across all nodes, then justify the choice.
- ☐ **MoE topology**: revise the topology choice for unpredictable AllToAll traffic where any GPU may need to communicate with any other GPU.
- ☐ **Oversubscription risk**: identify which workload suffers more under 2:1 spine-layer oversubscription and propose a scheduling strategy to mitigate the impact.

Topology provides the structural capacity for the cluster of 1,024 GPUs to communicate, but structure alone does not guarantee performance. When the 1,024 GPUs synchronize contributions to the model's 350 GB gradient state, that theoretical capacity collides with the reality of **fabric behavior**: congestion control and routing dynamics determine whether this traffic flows smoothly or gridlocks under the strict synchronization of the BSP model.

3.6 Level 4 Fabric Behavior, Congestion, and Routing

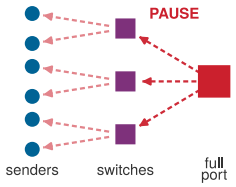
A collective can finish late even when the topology provides full BW_{bisect}. Levels 1 through 3 determine how long a transfer takes on an unloaded path; fabric behavior determines how much longer it takes once the job's own synchronized traffic loads that path. Competing flows can concentrate on one output path, and the BSP barrier introduced in section 3.2 exposes any delay that extends the

last required transfer. The relevant paths are those used by the participating workers; a congested link elsewhere in the fleet need not affect the job. In the Fleet Law (equation 1.3), measured transfer durations contribute to $T_{\text{comm}}(N)$, while residual waiting at synchronization contributes to $T_{\text{sync}}(N)$, the point where the communication axis of C^3 hands its cost to the coordination axis. A timeline must assign each interval consistently so the same congestion delay is not counted twice.

The p99 tail latency introduced with the BSP barrier helps expose delays that an average hides, but a particular barrier waits for its last required participant, not for a percentile. Evaluating a fabric therefore requires both transfer-time distributions and the collective completion times they produce under load.

3.6.1 Priority flow control (PFC)

The BSP weakest-link property means that even a single dropped packet can trigger a retransmission timeout that stalls the global barrier for milliseconds, a delay that can rival the entire communication phase of a training step. PFC-based RoCEv2 fabrics prevent the drop in the first place by running PFC, the pause mechanism introduced with the RDMA stacks (section 3.4.2), in lossless mode, so that upstream senders stop before any buffer saturates (Guo et al. 2016; Gangidi et al. 2024).



Definition 3.8: Priority flow control

Priority flow control (PFC) is a link-layer mechanism used by RoCEv2 ML cluster fabrics to prevent switch buffer overflow. When a port's queue depth crosses a configured threshold, the switch sends PAUSE frames to an upstream sender, which throttles injection on a per-priority basis without dropping packets.

1. **Significance**: In PFC-based RoCEv2 deployments, PFC is the foundation for a lossless Ethernet service. A PFC PAUSE frame must reach the upstream sender before the buffer overflows, so each pause threshold must leave headroom for the data still in flight during roughly one link round trip.
2. **Distinction**: Unlike standard IEEE 802.3 flow control, which pauses all traffic classes on a link, PFC operates per priority class, allowing latency-sensitive control messages to continue flowing while only pausing the congested gradient data queue.
3. **Common pitfall**: A frequent misconception is that PFC solves congestion. It transforms packet loss into congestion spreading. PFC itself places no bound on how far PAUSE frames propagate, so a single faulty transceiver can pause traffic far from its own link unless a watchdog intervenes.

The danger of PFC lies in its cascading nature. When a switch port's buffer fills, it sends a PAUSE frame upstream, which can move congestion into the upstream

switch and trigger another PAUSE frame. A slow receiver, routing hot spot, or true fan-in burst can therefore pause links unrelated to the original queue. This behavior, known as **congestion spreading**, is the primary operational risk of PFC-based lossless Ethernet, and the flows it stalls without ever touching the congested queue are called **victim flows**. Fan-in is one trigger, but it is not intrinsic to every collective. A bandwidth-optimal ring exchanges data point to point, although multiple ring flows can still collide at a shared egress or an oversubscribed cut and create a hot spot without a single aggregation receiver (section 3.6.5).

PAUSE frames climb back tier by tier and stall senders far from the full port.

3.6.2 Lossless fabric hazards and watchdog recovery

While priority flow control provides the illusion of a lossless physical layer, relying on link-layer backpressure introduces structural failure modes that do not exist in loss-tolerant packet-switched networks. When switch queues cannot drop packets to relieve congestion, pressure propagates backward through the network graph, creating two distinct hyperscale failure modes: buffer-dependency deadlocks and PFC storms.

Definition 3.9: Cyclic buffer dependency deadlock

Cyclic buffer dependency deadlock is a permanent distributed lockup in a lossless network, whether its backpressure uses PFC PAUSE frames or InfiniBand credits. A set of switch port queues forms a closed dependency cycle, and each queue holds packets destined for the next queue while backpressure from that same queue pauses it.

1. **Significance**: A single such deadlock permanently halts traffic across all participating ports and upstream links, requiring manual intervention or watchdog timeouts that discard packets to recover. InfiniBand fabrics prevent it through deadlock-free routing and virtual-lane assignment, and PFC-based Ethernet fabrics need the same discipline in their routing and priority configuration.
2. **Distinction**: Unlike a PFC storm (which is a transient cascade of backpressure triggered by a slow-draining endpoint), a buffer-dependency deadlock is a static, self-sustaining topological cycle that cannot resolve itself even after traffic injection stops.
3. **Common pitfall**: Assuming multi-stage Clos (fat-tree) fabrics are inherently immune to deadlocks. Dynamic multipath routing, link failures, and address resolution flooding can introduce cyclic forwarding dependencies across switch tiers.

3.6.2.1 The graph mechanics of buffer-dependency deadlocks

In a lossless network, a switch cannot forward a packet to downstream buffer b_j if b_j is full; instead, it holds the packet in upstream buffer b_i and awaits credit or pause clearance. A directed buffer dependency graph $G = (V, E)$ formalizes this relationship. Each vertex $b_k \in V$ represents a packet buffer or virtual lane queue

at a switch port. A directed edge $(b_i, b_j) \in E$ indicates that a packet currently occupying buffer b_i requires buffer b_j along its routing path to make forward progress.

A directed cycle in the buffer dependency graph is a necessary condition for a cyclic buffer dependency deadlock (definition 3.9), but a cycle alone does not establish that progress has stopped. The cyclic dependency in equation 3.1 becomes a deadlock when the occupied buffers cannot drain and every participant waits for its successor:

$$b_1 \to b_2 \to \ldots \to b_k \to b_1 \tag{3.1}$$

When each buffer in the cycle fills beyond its configured pause threshold, each port asserts a PFC PAUSE frame to its predecessor. Because no buffer can advance a packet into a paused successor, no buffer can drain, and no port can de-assert its PAUSE signal. The entire cycle freezes permanently. A four-switch ring whose queues (b_1 through b_4) are completely full shows this mutual protocol interlock (figure 3.12). Solid gray arrows trace packet forwarding dependencies advancing clockwise ($b_1 \to b_2 \to b_3 \to b_4 \to b_1$), while dashed red PAUSE frames propagate counterclockwise. Each full queue pauses its upstream predecessor while waiting for its downstream successor to drain, permanently freezing all four queues until an external watchdog intervenes to drop frames.

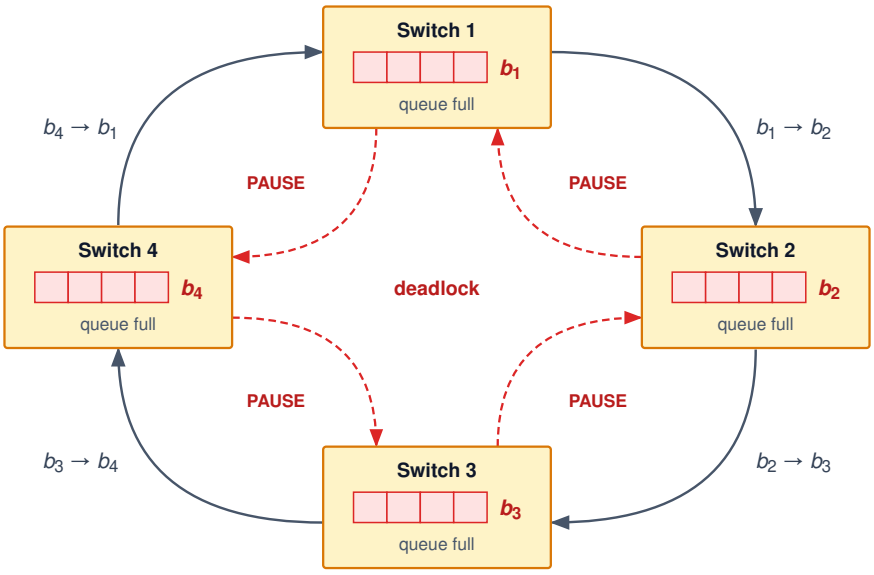


Figure 3.12: A PFC Deadlock from a Cyclic Buffer Dependency: Four switch queues form the cycle of equation 3.1. Follow the solid arrows clockwise: each full buffer holds packets that need space in the next. The dashed PAUSE frames run counterclockwise, so each full queue pauses its upstream predecessor while awaiting space in its downstream successor, and no queue can drain until a watchdog drops packets.

Routing changes and flooding can create the dependencies needed for deadlock. During link failure or Border Gateway Protocol (BGP) convergence, inconsistent

forwarding tables can create transient loops. A lossy IP network eventually discards a looping packet when its time-to-live expires; a lossless class has no such release, so looping traffic can fill the buffers along the loop and hold them. If traffic occupies a cycle of mutually blocked queues, backpressure can prevent progress until recovery breaks the dependency. Multicast or broadcast replication can also fill queues whose dependencies intersect, while cross-connects and asymmetric failover paths can introduce cycles absent from the intended hierarchical route. None of these conditions alone proves a deadlock; the occupied buffers and pause states must form the closed waiting cycle described by the model. Microsoft's production RoCE deployment encountered the flooding trigger directly (war story 3.1).

War Story 3.1: Microsoft's PFC deadlock (2016)

Context: A team led by Chuanxiong Guo at Microsoft Research deployed RoCEv2 across Microsoft's data centers, a fleet operating at the scale of tens of thousands of servers, to support latency-sensitive services. Their design provided a lossless fabric with PFC, and the team developed a Differentiated Services Code Point (DSCP)-based PFC mechanism to extend the deployment beyond virtual local area network (VLAN) boundaries (Guo et al. 2016).

Mechanism: PFC interacted with Ethernet flooding to create a cyclic buffer dependency. A dead server with an incomplete mapping between an IP address and a media-access-control address caused upstream switches to flood lossless packets to every port; PFC PAUSE frames then propagated upstream in response to the flooded traffic, forming a closed loop of paused buffers.

Impact: Lossless traffic through the switches in the cycle stopped entirely and stayed stopped, because no buffer in the dependency loop could drain without outside intervention.

Fix: Microsoft blocked broadcast and multicast traffic from entering lossless traffic classes, and dropped lossless packets when the corresponding Address Resolution Protocol (ARP) entry was incomplete rather than falling back to flooding.

Systems lesson: PFC backpressure is a structural vulnerability of lossless Ethernet at hyperscale. RoCE fabrics require packet-class discipline, PFC pause telemetry, and hardware-level safeguards because a mechanism designed to avoid packet loss can itself become the failure mode. ML training fabrics built on RoCE inherit this risk directly. A single incomplete ARP entry can freeze the lossless class that carries a multi-thousand-GPU training run's gradients, with the cluster appearing healthy while no gradient flows between workers.

3.6.2.2 PFC storms and victim flows

In contrast to a static topological cycle, a **PFC storm** is a dynamic, runaway amplification phenomenon triggered when a single "slow drainer" (an accelerator stalled

by memory bus saturation, operating system preemption, or a degraded transceiver with elevated bit error rates) fails to consume packets at wire speed. The attached ToR switch queue fills and sends a PAUSE frame to the sender. Because multi-port switches aggregate traffic from many sources across shared packet buffers, the paused queue blocks buffer allocation for unrelated packets (head-of-line blocking). The spine switches feeding that ToR then fill their buffers and pause the other leaf switches that send through them, and each additional tier widens the set of paused links until traffic between node pairs that never communicated with the stalled worker also stops. These victim flows turn one slow endpoint into a job-wide barrier delay, because every data-parallel worker whose path crosses a paused spine port now arrives late at the barrier. Because a degraded transceiver is one such slow drainer, a component-exposure calculation shows how often a cluster should expect at least one, even though exposure alone does not estimate the probability of a PFC storm.

Napkin Math 3.4: Probability of at least one transceiver degradation

Problem: A 4096-GPU RoCE cluster, larger than the reference cluster, is in operation. If the probability that a given transceiver begins degrading on a given day is 0.001 percent, what is the chance that at least one transceiver degrades on a given day?

Math: Assume independent transceiver-degradation events with the same per-device probability.

1. **Total exposure**: 4096×3 link tiers = 12,288 links, or 24,576 transceivers.
2. **Probability of zero transceiver degradations**: $\Pr(\text{no degradation}) = (1 - 0.00001)^{24{,}576} \approx 0.782$.
3. **Probability of at least one degradation**: $\Pr(\text{at least one degradation}) = 1 - 0.782 = \mathbf{0.218}$ (about 21.8 percent).

Systems insight: Under these assumptions, a large RoCE cluster has a 21.8 percent daily chance of at least one degraded transceiver. This result motivates hardware telemetry and automated remediation, but estimating fabric-wide freeze risk additionally requires the conditional probability that a degradation triggers and propagates a PFC storm.

3.6.2.3 Watchdog recovery and the lossy alternative

Switches can use **PFC watchdog timers** to detect prolonged pause states and trigger recovery without a full reboot. The configured threshold T_{watchdog} must fit the deployment's pause and recovery budgets; a range such as 50–200 ms is a configuration example, not a universal requirement. Exceeding it indicates stalled progress, not proof of a cyclic deadlock. Depending on the implementation, mitigation can disable pause handling or discard affected traffic so blocked queues can drain. The transport must then recover any lost data, with the completion penalty determined by retransmission behavior, outstanding traffic, and the collec-

tive's dependencies. On an RNIC with Go-Back-N-style recovery (section 3.4.3), each discarded packet also costs the in-flight window behind it, so breaking a pause converts a stalled queue into a retransmission tail that the waiting collective absorbs.

This systemic brittleness is driving hyperscale operators toward next-generation architectures such as the Ultra Ethernet Consortium (UEC) (Ultra Ethernet Consortium 2025), detailed in section 3.10.1, and loss-tolerant RDMA designs (Mittal et al. 2018). Designs that combine packet spraying with congestion control and selective retransmission can operate without link-layer PFC. Removing PFC removes its pause-based deadlocks and storms, but endpoint recovery must still bound the completion-time penalty of congestion and loss.

3.6.3 End-to-end congestion control with DCQCN and HPCC

Because link-layer PFC fires only when a switch buffer is already near exhaustion, relying on pauses alone invites the cascades and watchdog drops of section 3.6.2. Keeping queues below those thresholds requires end-to-end congestion control, which throttles sender injection rates before buffers fill. For a BSP workload with a completion-time target, this rate control is a *latency requirement* rather than an *optional throughput optimization*: delaying a required transfer extends the synchronization boundary, so the controller must balance delivered throughput against queueing and recovery tails.

The first widely deployed solution, **DCQCN**,[8] operates as a reactive feedback loop using ECN (Zhu et al. 2015). When a switch's queue depth exceeds a configured threshold, it marks the ECN bit in the packet header. The receiver echoes this mark back to the sender via a congestion notification packet (CNP), prompting the sender to reduce its injection rate using a multiplicative-decrease algorithm. DCQCN is widely supported, but production AI collectives expose a tuning problem because the feedback loop takes a full network round trip to take effect. Setting the ECN threshold high leaves too little buffer headroom for synchronized bursts to slow down before hitting the PFC pause threshold, whereas setting it low causes senders to throttle aggressively on brief queue spikes and underutilize the link. Consequently, ECN thresholds and NIC firmware behavior trade off PFC avoidance, throughput, visibility, and tail latency rather than offering one stable optimum (Gangidi et al. 2024).

HPCC[9] uses in-network telemetry (INT) to give the sender more information about path load (Li et al. 2019). Switch measurements of queue occupancy and transmitted traffic let the controller estimate an appropriate injection rate rather than react only to a binary congestion mark. That information still arrives after a feedback delay, so the controller must account for changing load and avoid overreaction. The evaluated design reduces queue buildup and tail latency, but requires switch telemetry support and compatible endpoint processing. DCQCN needs less detailed switch feedback, trading that simpler deployment requirement against a different tuning problem.

[8] **DCQCN (data center quantized congestion notification)**: Introduced by Zhu et al. (2015) (Microsoft and Mellanox) at SIGCOMM 2015 for large-scale RDMA fabrics, its binary ECN/CNP feedback loop is simpler to deploy than telemetry-rich schemes. However, it creates a delicate tuning surface for training collectives: Meta's 2024 RoCE deployment showed that aggressive ECN marking reduces PFC pauses but degrades collective completion time (Gangidi et al. 2024).

[9] **HPCC (high precision congestion control)**: Introduced by Li et al. (2019) (Alibaba) at SIGCOMM 2019, HPCC requires programmable switch ASICs that append INT metadata to packets at line rate, a hardware dependency that limits the fabrics able to deploy it.

3.6.4 Adaptive routing

Throttling senders with DCQCN or HPCC relieves a filling queue only by slowing the flows that cross it, even when parallel spine links sit idle. That imbalance is the ECMP hash-collision problem from section 3.2: because static flow hashing,[10] which works well for millions of small flows, pins each persistent elephant flow to a fixed path, an 8-flow AllReduce across 4 equal-cost paths can place 4 flows on one link while another carries none. In a synchronized training step, that overloaded link then determines completion time and can halve useful bandwidth.

Adaptive routing mitigates this problem by allowing switches to select among eligible output paths using congestion information rather than only a static hash. The implementation is protocol- and device-dependent. Packet-level spraying[11] can send packets of one connection over different paths, so the receiver may observe reordering. Compatible endpoint support must accept out-of-order placement or restore the transport's required ordering; the presence of InfiniBand alone does not guarantee arbitrary spraying across every path.

Ethernet fabrics can also employ **flowlet switching**, which changes a flow's path between bursts separated by a gap large enough to preserve packet order across the candidate paths, so its usefulness depends on how often the workload leaves such gaps relative to path delay differences. MoE expert exchanges illustrate why path diversity matters: a dense exchange among 64 expert-parallel ranks contains at most $64(64-1) = 4{,}032$ directed remote rank pairs after excluding self-transfers, with active traffic governed by expert placement and token-routing sparsity. Where static-hash collisions concentrate that traffic onto a few links, adaptive routing spreads it across the provisioned $\mathrm{BW}_{\mathrm{bisect}}$. Archetype B (DLRM at Scale) creates similar exchanges when batches of embedding requests and results move among table shards, although batch and shard placement determine the traffic matrix rather than every individual lookup requiring a global exchange.

3.6.5 The incast problem in ML

Congestion control and adaptive routing manage flows that traverse the interior of the fabric. A different failure mode occurs at the edge, where the traffic pattern itself overwhelms a single port regardless of how much capacity the fabric interior provides.

Definition 3.10: Incast

Incast is a many-to-one ML cluster traffic pattern in which a large number of senders simultaneously transmit data to a single receiver port. It concentrates line-rate traffic from multiple sources into a single switch queue, and it can overflow the buffer if the burst outlasts the available buffering and control response, even when the rest of the fabric is uncongested.

1. **Significance**: Flat aggregation, synchronized storage reads, or other fan-in phases can direct many senders toward one receiver. The deliberately worst-case scenario here assumes a RoCE fabric whose ports all run

[10] **ECMP (equal-cost multi-path)**: ECMP selects a path by hashing on the 5-tuple (source/destination IP, source/destination port, protocol), which means the same flow always takes the same path. This determinism is a feature for packet ordering but a liability for ML. Because a single AllReduce ring produces a small number of persistent flows, hash collisions are not transient statistical events but hot spots that last as long as those flows do.

[11] **Packet spraying**: Unlike standard Ethernet (which hashes flows to single paths to avoid reordering), packet spraying sends individual packets of a single flow across multiple paths. This can improve use of the available $\mathrm{BW}_{\mathrm{bisect}}$ by AllReduce elephant flows when the transport can tolerate or repair reordering. The Ultra Ethernet Consortium (UEC) specification design explicitly includes multi-path packet spraying and flexible ordering to reduce the ECMP collision problem for AI/HPC traffic (Ultra Ethernet Consortium 2025).

at 400 Gb/s. In it, 256 senders each transmit at 50 GB/s toward one switch egress, producing 12.8 TB/s of offered load against a 400 Gb/s port. A 32 MB buffer then overflows in about 2.5 µs under the stated assumptions, after which the switch either drops packets or, in a PFC deployment, pauses its upstream neighbors. The example is a stress bound, not the traffic matrix of a ring AllReduce.

2. **Distinction**: Unlike general congestion (which occurs on shared internal links when aggregate traffic exceeds link capacity), incast is an endpoint bottleneck. It occurs even if every internal spine and leaf link is completely uncongested, because the bottleneck is the single destination port, not the fabric interior.
3. **Common pitfall**: Incast is not necessarily rare or unpredictable. Training jobs create it on a schedule, whenever many GPUs read dataset shards from or write checkpoints to the same storage node, and in the aggregation step of a tree or hierarchical reduction, where several ranks send partial sums to one parent. A gradient ring is different; its point-to-point flows can still collide at a shared egress, but that is a hot spot rather than many-to-one incast. The severity depends on the collective algorithm, topology, routing, and oversubscription, so it must be measured and mitigated rather than treated as an edge case.

In a worst-case incast, 12.8 TB/s of offered traffic from 256 senders converges on a single 400 Gb/s (50 GB/s) egress (figure 3.13). Each sender injects at 50 GB/s. The buffer fills over a finite interval; control feedback can reduce arrivals, drops can discard excess traffic, or backpressure can move the queueing upstream. Whether that pressure spreads depends on shared queues and the paths carrying the traffic. Let the aggregate arrival rate to one egress be λ_{arr}, the egress service rate be μ, and the instantaneous queue occupancy be $Q(t)$. While a burst persists and $\lambda_{\text{arr}} > \mu$, the queue grows at the net rate

$$Q(t) = \min(Q_{\max},\, Q(0) + (\lambda_{\text{arr}} - \mu)t)\,,$$

where $Q_{\max}$ is the finite buffer capacity. The ratio $\rho_{\text{egress}} = \lambda_{\text{arr}}/\mu$ distinguishes a drainable workload from sustained overload: for $\rho_{\text{egress}} < 1$, idle intervals can drain the queue; as long-run ρ_{egress} approaches one, less slack remains to absorb bursts; and for $\rho_{\text{egress}} > 1$, occupancy must reach a control threshold or the buffer limit if the overload persists. This is a packet queue, distinct from the request queues of an inference server. Serialization and propagation set the unloaded path latency, whereas queued bytes add approximately Q/μ of waiting time.

⇄ **Contrast:** Request queues, whose arrival and service rates set serving latency rather than switch buffer occupancy, are developed in section F.1.1.

In the deliberately worst-case incast above, ρ_{egress} is 256×, so the 32 MB buffer fills in about 2.5 µs. Once full, that buffer represents 640 µs of egress waiting time. By contrast, the bandwidth-delay product for the 400 Gb/s egress and an illustrative 5 µs feedback round trip is only 250 KB; it measures data in flight on the path, not the buffering needed to absorb an arbitrary fan-in burst. ECN must mark

early enough for feedback to arrive before exhaustion; PFC can prevent a drop, but its backpressure can spread congestion. A larger buffer extends the reaction window at the cost of a larger tail-latency bound.

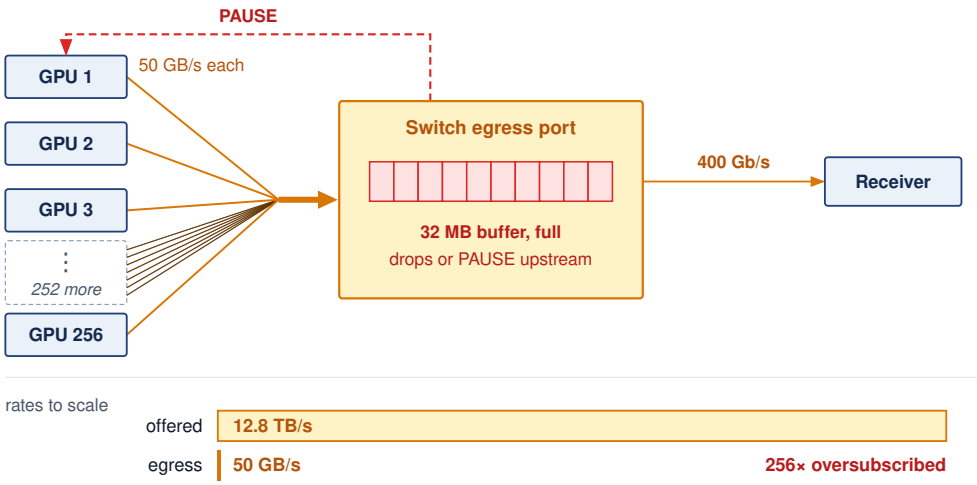

Figure 3.13: A True Incast Burst: This deliberately worst-case fan-in scenario sends 256 sources at 50 GB/s toward one 400 Gb/s (50 GB/s) egress with a 32 MB buffer. The 12.8 TB/s offered load oversubscribes the destination egress by 256×. Flat aggregation or synchronized reads can create this pattern; bandwidth-optimal ring AllReduce does not, because each rank exchanges point-to-point chunks.

Synchronized ML traffic is susceptible to both true fan-in and shared-egress hot spots. When a layer finishes backward computation, many ranks can inject traffic at once, and flat or hierarchical aggregation phases can create true fan-in. Production clusters mitigate both cases along three complementary dimensions:

1. **Time.** Layer-staggering triggers each gradient bucket's AllReduce as soon as backpropagation produces it. Final-layer gradients reduce while earlier layers are still computing, so communication is spread across the backward pass instead of released as one synchronized burst. The same staggering is communication-computation overlap, so it also hides transfer time behind the backward computation that remains.
2. **Space.** Collective algorithm selection bounds fan-in at individual switch ports. Hierarchical and rail-local reductions aggregate gradients in stages so that no single port must absorb all senders at once, and topology-aware placement keeps concurrent ring flows off oversubscribed ports.
3. **Priority.** Quality of service (QoS) classification tags gradient traffic with the highest service class to reduce interference from background storage or management traffic; shared links, buffers, and arbitration still constrain isolation.

These mitigations spread the burst in time, space, and priority, but they do not eliminate congestion or tail latency. The question becomes how to build end-to-end clusters that perform despite these realities.

3.7 Level 5 Cluster Design and Case Studies

The final level of the stack is cluster design, where wires, transport, topology, and congestion control combine into a coherent system. The goal of cluster design is to provide an end-to-end gradient bus that makes thousands of distributed GPUs feel like a single machine. At this level, the abstraction layers collapse into concrete engineering decisions: which cables to buy, how to wire the racks, which protocol to deploy, and how to validate that the resulting fabric delivers the bandwidth the training job expects. Two representative large-scale architectures, one built on InfiniBand and one on Ethernet, illuminate the trade-offs that define ML infrastructure (NVIDIA 2023; Meta Engineering 2024; Gangidi et al. 2024).

3.7.1 The GPU-to-GPU "gradient bus"

In a well-designed cluster, the network fabric acts as a scheduler-aware extension of the system bus, not a passive pipe. The ~9× per-direction cliff between NVLink and one external port, measured at the start of this chapter, is the gap the cluster must hide. Communication-computation overlap, which the Fleet Law credits as T_{overlap}, is the first mechanism for hiding it, through the same layer-staggered AllReduce launch that spreads incast bursts in section 3.6.5. Overlap cannot hide the last mile of the exchange, because the gradients computed at the end of backpropagation have little computation left behind which to hide their transfer (section 5.10).

Placement is the second mechanism, because it decides which communication crosses each boundary. The placement that the bandwidth hierarchy of section 2.5.1 sets, tensor parallelism inside the NVLink domain with pipeline stages and data-parallel replicas spanning nodes, becomes a wiring rule at cluster scale, because each fabric tier must be provisioned for the traffic placed on it. The links between nodes must meet the pipeline's activation-transfer budget, which physical adjacency alone does not guarantee. The full fabric carries the data-parallel exchanges, which gradient accumulation makes less frequent and overlap partly hides. Production designs therefore differ mainly in how they provision that outermost tier, as the two that follow show.

3.7.2 NVIDIA DGX SuperPOD architecture

The NVIDIA DGX SuperPOD, a concrete implementation of the gradient bus, provisions the outermost tier by obtaining losslessness from the link layer and aligning the wiring with the data-parallel ranks, so that the fabric's tail behavior depends on hardware mechanisms rather than on congestion tuning. It connects DGX H100 nodes using an NDR InfiniBand network (NVIDIA 2023). Each node acts as a dense compute island, with eight H100 GPUs connected via NVSwitch to provide 900 GB/s of internal bandwidth. Externally, each GPU pairs with a ConnectX-7 NIC delivering 400 Gb/s of injection bandwidth. Across a standard scalable unit of 32 nodes (256 GPUs), this yields an aggregate injection bandwidth of 12.8 TB/s (256×50 GB/s), the rate the scalable unit can offer the fabric when every GPU transmits at once.

This architecture connects all five levels of the network model into a single chain. At the wire (Level 1), it standardizes on 400 Gb/s NDR links, choosing

copper or optics by the reach between each node and its leaf and between leaf and spine. Because those links run InfiniBand's native credit-based flow control at the transport layer (Level 2), they provide a lossless medium without the pause-cascade fragility of Ethernet PFC. Above the transport, the topology (Level 3) arranges the switches as a rail-optimized fat-tree, aligning GPU rails across each scalable unit so that same-rail traffic stays close while cross-rail traffic traverses the spine layer (replacing the simpler per-rack ToR allocation used earlier to illustrate switch radix). When cross-rank traffic climbs to the spine, hardware-based adaptive routing (Level 4) selects among spine paths to preserve bisection behavior. Finally, at the cluster level (Level 5), additional switching joins multiple SuperPOD scalable units into larger fleets (NVIDIA 2023): for the 175B-parameter model, four SuperPOD scalable units wire together so that 1,024 GPUs function as a single synchronous instrument.

3.7.3 Meta Grand Teton platform

Meta's Grand Teton clusters take the opposite approach, accepting Ethernet's congestion-tuning burden in exchange for multi-vendor supply and shared operations. Meta disclosed two Grand Teton-based 24,576-H100 clusters: one using RoCE over an Arista/OCP Ethernet fabric and one using NVIDIA Quantum-2 InfiniBand, both with 400 Gb/s endpoints. Meta used both for Llama 3 training and reported ongoing Llama 3 training on the RoCE cluster (Meta Engineering 2024). Ethernet lets Meta source switches from multiple vendors and reuse the optical infrastructure and management tooling of its front-end serving fleet, avoiding the operational silo of a dedicated InfiniBand island.

Meta's RoCE study shows how Level 4 choices affect the complete fabric. It describes PFC watchdogs for long-duration pause events, iterative routing designs beyond plain ECMP, future-oriented flowlet switching experiments, and a 400G deployment in which DCQCN tuning proved difficult enough that Meta proceeded without DCQCN while relying on PFC plus higher-layer collective controls (Gangidi et al. 2024). The lesson is to validate the combination of endpoint behavior, routing, and flow control under the intended collective traffic. Large-transfer throughput alone does not establish small-message latency or recovery tails, and those results cannot be inferred from the Ethernet or InfiniBand label. Small-message latency matters in training through frequent small exchanges, which expose startup cost even when a full step lasts seconds, and in serving to a degree set by model partitioning, request shape, and service-level objectives (SLOs).

These case studies close the five-level stack by showing how the physical wire, transport protocol, topology, and congestion controls become one production fabric. The remaining operational problem is not how to build a single fast cluster, but how to share that expensive substrate across teams and workloads without sacrificing the predictable performance that training demands.

3.8 Network Virtualization

When a single training job leaves racks or spine links idle between runs, operators carve the cluster among multiple tenants and jobs, only to discover that a neighbor's checkpoint burst or evaluation sweep can starve a synchronous AllReduce across shared NICs and switch buffers. Network virtualization must make sharing compatible with bandwidth allocations, latency targets, and access isolation. These requirements interact because tenants still share physical links and buffers. A proposed policy might reserve 80 percent of the cluster's BW_{bisect} for training and allocate the remaining 20 percent to inference and preprocessing. Enforcing that policy requires admission control and compatible scheduling along the relevant paths; a virtual NIC or separate traffic class alone does not guarantee the end-to-end share.

3.8.1 Hardware NIC virtualization with SR-IOV

Routing multi-tenant traffic through a hypervisor's software virtual switch reintroduces the exact host-CPU overhead and microsecond jitter that RDMA was built to bypass. Cloud providers instead expose NIC resources to virtualized GPU instances through **single-root I/O virtualization (SR-IOV)**, a standard that allows a physical NIC to present multiple **virtual functions (VFs)**. Each VF exposes its own hardware queues, doorbell registers, and DMA mappings, which software can assign to a workload. A directly assigned VF can remove host software mediation from the active DMA path, while drivers and virtualization software still configure access and manage the device. Performance depends on the NIC, I/O placement, and competing traffic. Because VFs share physical resources, placement logic must reserve NIC capacity and QoS policy alongside GPUs rather than treat the network as an unbounded pool.

However, hardware-level isolation still needs explicit bandwidth policy. SR-IOV exposes multiple VFs that share the NIC's physical resources; administrators can add per-VF or per-group QoS policies to cap or guarantee bandwidth, such as assigning eight VFs 50 Gb/s each on a 400 Gb/s NIC. For the 175B-parameter model training on a multi-tenant cluster, that configured partitioning can prevent a neighboring tenant from stealing bandwidth, but it also enforces a hard ceiling on peak throughput. The training job must be architected to operate within this slice, as no amount of software optimization can burst beyond the configured VF limit.

3.8.2 Traffic isolation and quality of service

Per-VF rate caps bound what each tenant injects at the NIC, but traffic from different tenants still merges on the fabric's shared switch buffers and spine links. When the 175B model is midway through a gradient AllReduce and a neighboring job initiates a 100 GB checkpoint save, that burst occupies a 400 Gb/s port for 2 s at full line rate. It can also claim a large share of the shared spine links for that interval, which stretches every AllReduce whose traffic crosses them. To prevent this noisy-neighbor effect inside the fabric, high-performance switches rely on

quality of service (QoS) mechanisms that enforce fairness at the packet and queue level.

InfiniBand isolates traffic through virtual lanes (VLs), which maintain separate credit and buffer state within a physical link across up to 16 lanes (one of them reserved for subnet management) (InfiniBand Trade Association 2000). If a storage burst exhausts the credits of its own lane, a gradient lane with available credits can continue transmitting, even though both lanes still share link bandwidth and arbitration. Ethernet and RoCE fabrics achieve a similar separation through device-dependent **traffic class** mappings and queue policies, where **enhanced transmission selection** allocates service among traffic classes and switches may also partition buffer and forwarding resources into **network slices**. Across both stacks, these mechanisms reduce interference only when classification, resource allocation, and scheduling agree along the entire path, because shared priorities or buffer pools can still couple tenants.

Virtualization solves the sharing problem but makes performance diagnosis harder. When a training job slows down on a multi-tenant cluster, the cause could be a physical link degradation, a noisy neighbor exceeding its bandwidth allocation, or a misconfigured QoS policy. Systematic monitoring is essential to distinguish these cases.

3.9 Monitoring and Debugging

Network performance problems in ML clusters are insidious because they show up as **silent waste** rather than explicit failures. A degraded transceiver causing a 10 percent reduction in effective bandwidth might slow each training iteration by only 2–3 percent. The slowdown is small because the lost bandwidth stretches only the exposed communication share of the step (the 30 percent assumed in the oversubscription estimate, less whatever overlap hides), and stretches it by roughly the inverse of the bandwidth that remains. A drift that small is easily masked by the natural variance of checkpointing or data loading. Over a 30-day training run on 1,024 GPUs, this invisible drag accumulates to roughly 15,000–22,000 wasted GPU-hours, burning about $30,000–$44,000 at $2/GPU-hour without triggering a single alarm. Traditional IT monitoring tools like SNMP or ICMP ping measure connectivity, not the sustained throughput required by RDMA. Effective observability requires a three-layer approach: **physical monitoring** (FEC errors, signal attenuation), **transport monitoring** (PFC pause frames, retransmission rates), and **application monitoring** (NCCL algorithmic bandwidth) (Jeaugey 2017; Gangidi et al. 2024). The three layers retrace the five-level model from the top down. Application monitoring observes the collective that Level 5 integrates, transport monitoring observes the Level 2 recovery and Level 4 congestion machinery, and physical monitoring observes the Level 1 wire. Only by correlating signals across these layers can operators detect that a "slow training run" is caused by a single degraded cable in one rack.

3.9.1 Link-level telemetry

A marginal cable or overheating transceiver rarely drops the link outright; instead, it accumulates symbol errors, triggers transmit discards, or retrains to a slower link state while the job keeps running. Catching that physical drift requires polling switch and NIC port counters, which report transmitted and received data, transmit discards, symbol errors, and link-down events; on InfiniBand a utility such as `perfquery` reads them, and Ethernet/RoCE devices expose the equivalent telemetry through their own management interfaces (Linux man-pages project 2026). Data counters measure utilization, discards warrant investigation against the port's traffic and recovery policy, and symbol errors and link-down events are evidence of a degrading signal. Correlating those counters with link rate, lane state, and transport behavior narrows the cause; a counter alone does not identify a defective cable or transceiver.

Polling link state alongside traffic counters can reveal **silent degradation**. A link operating at HDR (200 Gb/s) rather than the expected NDR rate (400 Gb/s) can remain connected while offering half the expected bandwidth. A link that trains with two of its four lanes active after a connector fault fails the same way: it stays up while its bandwidth is halved. Both cases are visible only when negotiated rate and lane state are compared with the deployment baseline. For 1,024 GPUs and roughly 3,000 links, the assumed 0.1 percent point-in-time degradation probability gives 3 degraded links in expectation and, under independent events, a 95 percent probability of at least one degradation. This probability measures something different from the daily figure in notebook 3.4. That notebook asks how often a new degradation begins; this one asks how many degraded links are present at any moment. Standing prevalence is roughly the onset rate times how long a degraded link stays in service, and silent degradation, by definition, stays in service until someone looks, so prevalence can far exceed what a small daily onset rate suggests. Both rates are scenario assumptions rather than measured fleet data. A job slows when an affected path limits its required traffic; fleet-wide exposure alone does not determine the job's slowdown. When the degraded link lies on a ring AllReduce's path, however, the cost reaches every participant, because each round waits for its slowest hop and the whole ring proceeds at the pace of that one link.

↪ Gray failure, the general case of a component that degrades without failing, and why a synchronous job feels it as a straggler, is developed in section 7.9.5.

3.9.2 Bandwidth and latency validation

Clean port counters and an active 50 GB/s NDR link state still do not guarantee that a node pair can deliver that rate to a training job: a degraded PCIe path, a cross-socket NUMA bounce, or a congested spine cut can throttle RDMA transfers without incrementing a single physical error counter. Active validation must therefore measure the bandwidth and latency the job can actually achieve across the complete host-to-host path. Pairwise tests such as `ib_write_bw` can populate an **all-pairs bandwidth matrix**, or a sampled subset for a large fleet (linux-rdma project 2026). A low-throughput pair identifies a path to investigate. Comparing the affected pairs with routing and physical telemetry helps distinguish a shared switch or cable problem from endpoint limitations.

For latency-sensitive synchronization, `ib_write_lat` runs a ping-pong test with small RDMA writes and reports half the measured round-trip time as one-way latency. Values such as 2 µs, 5 µs, or 100 µs must be compared with a baseline for the same endpoints, message size, path, and load; they are not universal fault thresholds or evidence of a particular fallback. Application-level tests such as `nccl-tests` then exercise collective communication across the intended worker group. Point-to-point results establish a path baseline, while collective tests reveal costs from concurrent traffic and scheduling that isolated pairs cannot expose.

3.9.3 Systematic debugging workflow

When a training job reports lower-than-expected throughput, the diagnostic order should preserve the layer model rather than starting with cables. The following sequence moves from application symptoms toward physical causes:

1. **Check GPU utilization**: Rule out compute bottlenecks with accelerator telemetry (`nvidia-smi`, for example). High SM utilization alone does not rule out a network bottleneck, because communication kernels can also keep SMs active. Correlate utilization with the compute and collective portions of the step timeline. Low utilization does not automatically implicate the fabric, however. A starved input pipeline (data loading or storage) produces the same symptom, so confirm the data path is keeping the accelerators fed before investigating the network.
2. **Inspect collective-library logs**: Enable the library's debug output (`NCCL_DEBUG=INFO` in NCCL, for example) to reveal which network transport was selected, the detected bandwidth between nodes, and any fallbacks to slower protocols.
3. **Run point-to-point tests**: Run a pairwise bandwidth test (such as `ib_write_bw`) between specific nodes in the job. A single degraded link can bottleneck the entire ring in a ring AllReduce.
4. **Check PFC/ECN counters**: Inspect switch counters along the path. Sustained PFC activity indicates persistent congestion that should be investigated at the scheduler or routing level.
5. **Validate physical layer**: Check symbol errors and CRC counts to identify failing transceivers or cables.

In this order, application symptoms identify the failing path, transport counters show whether congestion or fallback is involved, and physical telemetry confirms whether the wire itself is degrading. Applying the sequence to a concrete slowdown shows how each layer narrows the search before any hardware is replaced.

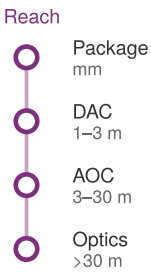
> Checkpoint 3.5: Diagnosing a training slowdown
>
> Your 175B model training job has been running for 3 days on the 1,024-GPU reference cluster. You notice that the iteration time has gradually increased

from 4.2 s to 4.8 s (a 14 percent slowdown). The GPU utilization reported by `nvidia-smi` has dropped from 92 percent to 85 percent.

- ☐ **First diagnostic**: choose the first diagnostic step, name the tool that confirms whether the bottleneck is communication-bound or compute-bound, and cite the evidence that distinguishes the two.
- ☐ **Physical layer**: identify physical-layer causes that could explain a 50 percent bandwidth drop when `ib_write_bw` finds one node pair at 24 GB/s instead of the expected 48 GB/s, and verify them using switch counters.
- ☐ **Collective impact**: estimate the impact on overall AllReduce time when the degraded link lies in the ring AllReduce path, then evaluate whether a hierarchical reduction that routes less of the collective through that link would help.

3.10 Network Technologies That Move the Ceiling

Monitoring keeps deployed fabrics honest, but it cannot push past the physical ceilings it measures, such as the reach and power limits that copper approaches at high signaling rates. New fabric technologies earn attention only when they move one of those bounds. As clusters scale toward 100,000 nodes, the durable design variables are power per bit, reach, and the ratio of compute to memory to network capacity, not the product names attached to a particular roadmap.



3.10.1 Protocol convergence and link density

Standard RoCEv2 forces operators to wrestle with fragile PFC pause thresholds and ECMP hash collisions that were never designed for synchronized elephant flows, while InfiniBand locks the fabric into a single-vendor stack. The Ultra Ethernet Consortium (UEC) addresses these reliability and load-balancing limits for AI/HPC traffic over Ethernet. Its Ultra Ethernet Transport design combines packet spraying across multiple paths, flexible ordering, multiple transport delivery services, congestion-control changes, and telemetry (Ultra Ethernet Consortium 2025). The architectural question is how the selected service delivers the required completion and ordering semantics under congestion or loss. Packet trimming (cutting an overflowing packet down to its header instead of dropping it, so the receiver learns of the loss at once), retry, and endpoint recovery should therefore be judged by their effect on completion-time tails and resource cost. Whether the design reproduces a lossless-fabric mechanism is not the test.

Higher switch capacity attacks hop count as well as raw bandwidth. XDR InfiniBand pushes 800 Gb/s per port, and Ethernet roadmaps include 800GbE and 1.6TbE link speeds (NVIDIA 2026f; Ethernet Alliance 2025). Ethernet switch silicon with 1.6 Tb/s ports pushes aggregate capacity to 102.4 Tb/s in current Tomahawk 6-class designs (Broadcom Inc. 2025). A single 1.6 Tb/s port delivers the bandwidth of 4 400G ports, so the same ASIC can instead expose 4 times as many 400G ports. Spending that capacity on radix rather than port rate is what

flattens the topology, because fat-tree host count grows as $k^2/2$ at two tiers and $k^3/4$ at three. A cluster that previously required three tiers of switches may then be served by two when radix, port rate, and placement constraints line up, potentially reducing the number of optical links and switching stages. The transceiver savings require explicit port and cable accounting; removing one tier does not automatically halve the module count, and the latency benefit depends on the resulting paths and traffic.

3.10.2 Optical interconnects

Each extra meter pushes the fabric from copper toward optics.

Pushing ports from 400 Gb/s to the 800 Gb/s and 1.6 Tb/s rates of section 3.10.1 doubles per-lane signaling from the 100 Gb/s class of current NDR and 800G Ethernet links to the 200 Gb/s class, which sharply increases the insertion loss per meter of passive copper. As that usable reach shrinks, in line with the link-budget example in section 3.3.3, the SerDes must spend more energy per bit on equalization to recover the signal. Active electrical cables, which add retimer chips to regenerate the signal mid-cable, extend that reach but add latency and power of their own, leaving optical interconnects as the primary lever on power per bit and reach.

Co-packaged optics (CPO) places optical engines close to the switch or accelerator on a shared package substrate. Moving the optical engine from the switch faceplate to the package shortens the SerDes-to-optics electrical path from centimeters of board trace to millimeters, which reduces the signal-conditioning burden before transmission over fiber. The receiving optical engine converts the signal back to electrical form. Fiber still introduces propagation delay and has a loss budget; packaging the optics closer to the processor does not remove those constraints.

Co-packaged optics therefore changes the electrical portion of the link budget while retaining the reach advantages of optical transmission. Usable reach still depends on the fiber, connectors, optical power, and receiver design. The relevant comparison holds payload capacity and error targets fixed, then measures the power saved by the shorter electrical path against the packaging and maintenance costs of integration. The power side of that comparison can be estimated port by port for a single switch.

> Napkin Math 3.5: The optical dividend
>
> **Problem**: Calculate the power savings of moving a 51.2 Tb/s switch from pluggable transceivers to co-packaged optics.
>
> 1. **Pluggable architecture**: 128 ports $\times$ 20 W = 2.56 kW for optics alone.
> 2. **CPO architecture**: 128 engines $\times$ 10 W = 1.28 kW.
> 3. **Savings**: The savings reach 1.28 kW of power per switch.
>
> **Systems insight**: Across 1,000 switches, the assumed pluggable modules consume 2.56 MW. The modeled CPO configuration saves 1.28 MW, equivalent to the reference power budget of roughly 1,800 H100 GPUs. That equivalence

measures the scale of the saving; using it for additional accelerators also requires compute capacity, power delivery, and cooling in the right locations. Optics power constrains both operating cost and the equipment a facility can support.

The spine example for 10,000 GPUs assigns 400 kW to pluggable optics. That subtotal counts only the selected spine-side endpoints. Applying the same fractional saving to those endpoints would require a CPO implementation with the assumed per-port power and capacity; opposite-end optics remain outside the comparison. Integration also changes serviceability: replacing a failed optical component may involve a larger assembly than swapping a pluggable module. The energy benefit must be evaluated alongside packaging, repair, and spare-capacity costs.

For ML infrastructure, CPO could flatten the bandwidth hierarchy by narrowing the gap between intra-node and inter-node bandwidth. If inter-node links achieve bandwidth comparable to NVLink-class local fabrics (hundreds of GB/s per GPU), the bandwidth penalty for extending tensor parallelism beyond a single node would shrink. Cross-node tensor parallelism would then become economical for more workloads, provided that startup latency and collective frequency also fit the step-time budget.

However, CPO introduces new challenges. Optical components are sensitive to temperature (laser wavelength shifts with temperature, requiring active thermal management), and integrating photonics on the same package as a 1,000 W GPU creates a hostile thermal environment for the optical components. The manufacturing processes for silicon photonics and CMOS transistors are similar but not identical, requiring separate fabrication steps that increase package cost and complexity. Hybrid integration, which places the photonics chiplet on a cooler region of the package substrate and thermally isolates it from the GPU die, is one way to manage that environment, at the cost of a longer electrical path than full co-location.

3.10.3 Disaggregated and composable architectures

Narrowing the gap between package-level and rack-level interconnects also tempts architects to relax the fixed compute-to-memory ratio of the server node itself, which otherwise leaves compute or memory underused when workloads need different resource ratios. Compute Express Link (CXL) memory pooling allows supported hosts to access assigned memory capacity through a CXL path, while disaggregated designs make some resource allocations independent of the chassis boundary. This changes which links lie on the workload's critical path. It does not merge CXL memory access, NVLink communication, and InfiniBand transport into one interchangeable service; each path retains its own supported operations, bandwidth, and latency.

↩ CXL memory pooling, which makes node memory capacity less rigid but remains a capacity tier rather than a high-bandwidth memory (HBM) replacement, is established in section 2.9.1.

A composed node therefore needs a new traffic budget. The α-β distinction between startup and transfer cost remains useful, but each path requires its own

parameters and access model. Remote memory traffic can compete with other transfers, and fine-grained dependent accesses can expose latency that a bulk-bandwidth estimate hides. Disaggregation improves resource flexibility only when these added costs fit the workload's execution budget. Composition relocates the synchronization backbone onto new paths rather than eliminating it.

3.11 Fallacies and Pitfalls

Designing and operating high-performance fabrics for ML requires unlearning assumptions from traditional data-center networking. The following fallacies and pitfalls capture the most common errors that stall training and degrade cluster productivity.

Fallacy: *More bandwidth always means faster training.*

Engineers assume upgrading from HDR (200 Gb/s) to NDR (400 Gb/s) will yield proportional gains, but the α-β model (section 3.4.4) reveals this is only true in the bandwidth-dominated regime. For small models or the small-message phases of pipeline parallelism, the startup term α (1.5 µs in this chapter's NDR scenario, including NIC processing, switch hops, and FEC) dictates performance. If a workload is latency-bound, a 2× bandwidth increase may deliver only a small fraction of the line-rate gain while adding substantial power and transceiver cost.

Consider a 10 KB message (typical for control synchronization). On 200 Gb/s InfiniBand, it takes 1.90 µs. Upgrading to 400 Gb/s reduces this to 1.70 µs, a 10.5 percent improvement despite doubling the link rate.

Fallacy: *Lossless Ethernet is as reliable as InfiniBand.*

RoCE over Ethernet can achieve throughput comparable to InfiniBand for large transfers, but lossless operation depends on the configuration and interaction of PFC, ECN, routing, buffers, and NIC behavior (section 3.6.1). A forwarding loop, cyclic buffer dependency, or firmware defect can trigger a PFC storm, where PAUSE frames spread beyond the original queue. InfiniBand's per-hop credit mechanism avoids this specific reactive PAUSE-frame cascade, but the fabric still requires deadlock-free routing, sound virtual-lane configuration, and congestion management (InfiniBand Trade Association 2000). Both fabrics require validation and telemetry; RoCE adds particular sensitivity to the configuration of Ethernet losslessness. Procurement should therefore compare complete transport stacks rather than link rates, because the stack determines where flow-control state and operational risk reside even when nominal rates match.

Pitfall: *Accepting data-center oversubscription ratios for synchronous training.*

Oversubscription relies on the traffic crossing a shared boundary fitting its available capacity. Bulk-synchronous training can violate that assumption with coordinated bursts. In the cut-saturating scenario of section 3.5.2, 4:1 oversubscription increases the modeled communication bound by 4×. Applied to a $300M cluster with the assumed 30 percent communication fraction, the resulting idle-capacity estimate exceeds $142.1M. This is an equivalent-capacity comparison under the stated schedule, not an equipment loss or a universal penalty for every collective.

Fallacy: *TCP bandwidth tests are sufficient for ML fabric validation.*

Standard benchmarks like `iperf` measure kernel-based TCP/IP performance. TCP throughput depends on host processing, offloads, and tuning as well as wire speed; it has no fixed throughput ceiling independent of that configuration. An RDMA training job exercises a different data path, so a low TCP result does not establish that the RDMA path is slow, and a high TCP result does not validate collective performance. Validation protocols must use RDMA-specific tools from the `perftest` suite to match the workload's data path.

Pitfall: *Relying on adaptive routing instead of topology-aware placement.*

Adaptive routing can distribute traffic across available paths, but it cannot increase their total capacity. For a 1,024-GPU job spanning two oversubscribed spine groups, the group-to-group links become limiting when the collective sends more crossing traffic than those links can carry within its time budget. Placement can reduce that traffic, and routing can reduce path imbalance. Both must be evaluated against the actual collective schedule.

↪ Topology-aware gang placement that keeps collective traffic off contended cross-rack paths is developed in section 8.6.2.

Fallacy: *Network fabric problems always appear as hard failures.*

Network performance issues in ML clusters often show up as subtle training slowdowns rather than errors, because jobs continue to run while gradients arrive late. The silent-waste estimate in section 3.9 shows how a small bandwidth loss accumulates into wasted GPU-hours over a long run without raising a single alarm. Detection therefore depends on comparing delivered throughput with a baseline, not on waiting for an error.

Pitfall: *Treating PFC and ECN counters as optional production details.*

Discard counters and PFC pause durations should be correlated with collective completion time and the affected paths. Rising values can reveal queue pressure or recovery activity, but they do not establish a failing transceiver or predict an inevitable job failure. Physical error counters, traffic load, routing, and configured watchdog actions help distinguish the causes and select a response.

3.12 Summary

The five-level model of figure 3.3 bridges physical reach, transport primitives, switch topologies, congestion dynamics, and cluster integration into a single system contract. A fabric must provide both enough capacity for the workload's traffic and predictable completion at its synchronization boundaries. InfiniBand and RoCE distribute this responsibility differently across links, endpoints, and operational policy; the production cases show why neither port rate nor protocol name determines delivered performance.

Three numerical anchors show how to apply the model. One GPU's NVLink bandwidth exceeds its own external port's per-direction bandwidth by 9×; the modeled NDR path has equal startup and transmission costs near 75 KB; and the 4:1 oversubscribed cut increases the fixed-payload transfer bound by 4×. Each result depends on its stated configuration and traffic assumptions. In the Fleet Law, transfer time contributes to $T_{\text{comm}}(N)$ and residual synchronization waiting

to $T_{\text{sync}}(N)$; consistent timeline accounting prevents counting one delay in both. The communication and coordination axes of C^3 meet where those dependencies determine useful compute progress.

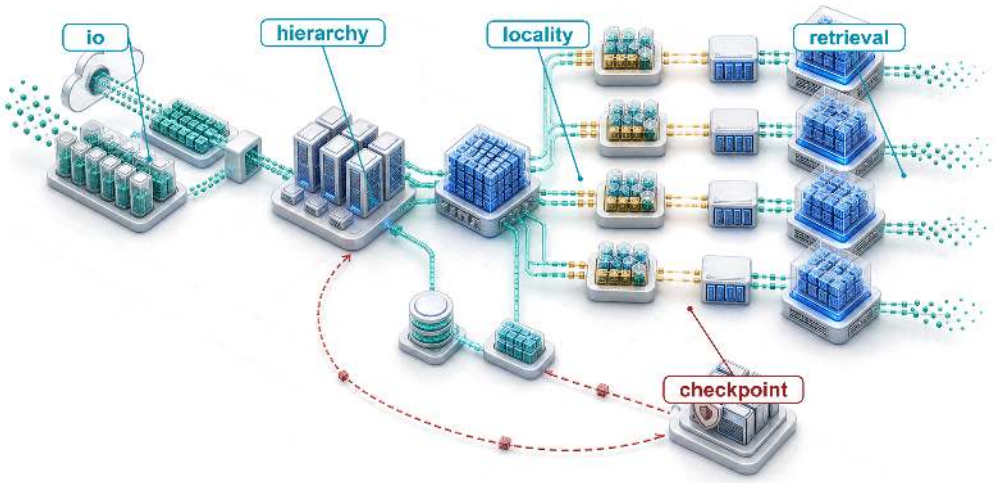
The same model guides design and diagnosis. Message sizes determine whether startup latency or bandwidth dominates; communication patterns determine which paths must carry that traffic. During operation, application throughput, transport counters, and physical telemetry distinguish inadequate capacity from contention or a degraded component. These measurements also test whether a proposed optical or composable architecture removes the binding constraint or merely moves it.

Key Takeaways: The fabric decides useful compute

- **Synchronous training inverts data-center traffic**: A bulk-synchronous step releases a few large, correlated flows whose completion gates a barrier, so the fabric is judged by collective completion time and its p99 tail rather than by average per-flow throughput. Static ECMP hashing turns flow collisions into persistent hot spots.
- **Link speed is not fabric speed**: For traffic that crosses a fabric cut, available capacity bounds transfer time (principle 6). Workload placement and collective schedules determine how much data must cross, so advertised port speed alone cannot predict useful training throughput.
- **Latency and bandwidth bind differently**: The α-β model of section 3.4.4 separates startup cost from per-byte transfer cost, with $n^* = \alpha \cdot \beta$ marking the regime change. Message-size distributions, not vendor peak numbers, determine whether to optimize software latency or hardware bandwidth.
- **Reliable delivery moves the risk**: RDMA transports need reliable completion and bounded recovery, not one universal lossless-fabric mechanism. InfiniBand normally suppresses loss with link-level credits; many RoCE deployments use PFC and ECN, while PFC-free designs place more recovery responsibility at the endpoints. Each choice trades hardware flexibility against tail latency and operational complexity.
- **Topology must match traffic**: Fat-trees buy flexible bisection bandwidth, rail-optimized designs give same-rank AllReduce traffic its own isolated switch network, and dragonfly or torus designs trade cabling and locality differently. The right fabric depends on whether the workload stresses AllReduce, AllToAll, or multi-tenant sharing.
- **Losslessness and load create their own failures**: PFC prevents drops by pausing senders, which can spread one slow drainer's congestion to victim flows or freeze a lossless class in a cyclic buffer dependency. Under synchronized load, end-to-end congestion control is a latency requirement, adaptive routing repairs hash collisions without adding

capacity, and incast is spread in time, space, and priority rather than eliminated.

- **Telemetry saves GPU-hours**: PFC counters, link error rates, bandwidth baselines, and application throughput must be correlated across layers. Without that observability, a degraded transceiver or congestion storm silently converts a high-end fleet into a queue of waiting accelerators.



At fleet scale, the interconnect is part of the computer. Its value lies in how much useful computation it allows the participating accelerators to complete together. A fabric decision therefore has to be judged against the workload's communication pattern and synchronization schedule, because additional capacity helps only where those dependencies expose a communication limit.

What's Next: From wires to data pipelines

A fabric that completes every collective on time still leaves two flows of bytes unaccounted for. Each step needs its next input batch in place before the accelerators ask for it, and the fleet's training state must outlive the next hardware failure, which at this scale means writing multi-terabyte checkpoints on a schedule. Those checkpoint bursts are the traffic class this chapter isolated from the synchronization path, and for text pretraining they can outweigh the training corpus itself. Chapter 4 treats storage as the fleet's fuel line, sizing the tiers and pipelines that deliver inputs ahead of demand and persist model state without stalling the step.

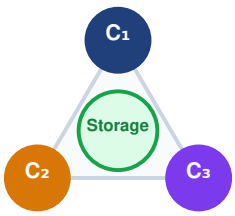
Purpose

Why does storage become the invisible bottleneck that prevents accelerators from reaching their potential?

A training job can leave expensive accelerators idle even when its models fit in memory and its network has ample capacity, because the next batch must arrive before computation needs it and a saved checkpoint must remain usable when a worker fails. Storage becomes an invisible bottleneck whenever accelerator benchmarks begin with data already in place, excluding the work needed to deliver inputs and preserve results. A pipeline that keeps one machine busy can stall once many workers compete for the same data source. A burst of checkpoint writes from one job can delay input reads for others, which turns a local pause into lost progress across the fleet. Adding compute increases demand without expanding the shared system's ability to serve it. How severely that contention hurts depends on the workload: compact training inputs may be easy to deliver even when saving model state dominates storage traffic, whereas larger samples can make continuous input delivery the limiting factor. Bringing data closer to the accelerator reduces those delivery delays, though it adds staging traffic, capacity cost, and the obligation to preserve complete versions, since a fast local save provides little protection if the

only copy disappears with the failed machine. Storage decisions therefore govern both how quickly the fleet advances and how much of that progress survives disruption. In C^3 terms, storage design coordinates data movement and durable state so that available compute produces recoverable progress.



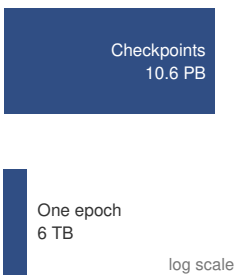
Learning Objectives

- Compare storage demands of full-corpus training, checkpoint writes, and model serving across local and shared tiers
- Calculate input bandwidth and mean cache service time from workload demand and tier behavior
- Design shard packaging, prefetching, locality, and direct-storage paths that keep fleet accelerators fed when small files or slow tiers would starve them
- Select checkpoint staging and replication strategies that balance pause time, recovery risk, and storage cost
- Specify storage commit and replay contracts that preserve correctness when distributed pipeline stages fail, including the provenance that generated training data must retain
- Analyze serving-time storage workloads, from bulk model loads and rollout bursts to retrieval indexes bound by random-access IOPS
- Evaluate staging and tiering choices by total delivery cost, including transfer fees and idle accelerators

4.1 The Fuel Line

The dense accelerator nodes of chapter 2 pack eight GPUs delivering petaFLOP/s of aggregate compute, and the InfiniBand fabrics of chapter 3 connect thousands of such nodes at hundreds of gigabits per second. Within the multi-tier fleet stack of figure 1.4, data storage completes that physical foundation, staging training data, model weights, optimizer state, and intermediate checkpoints at the right distance from the accelerator. An engine without fuel is expensive sculpture. The engineering question is how to deliver that fuel fast enough that the accelerators of a training cluster never starve. The running cluster for that question is 256 eight-GPU nodes, 2,048 accelerators in all, deliberately twice the 1,024-GPU (128-node) reference cluster used elsewhere in this book, because the larger fleet makes the pressure on shared storage easier to see. Every worked number for the 175B job uses this running cluster; a side scenario with a different workload or fleet size names its own scale where it appears.

Consider the running example for the storage analysis, an instance of Archetype A (GPT-4/Llama-3). A 175-billion parameter language model trains on 1.5 trillion tokens of text: roughly 3 TB in compressed source form, or 6 TB once represented as 4-byte token IDs. That token budget is set upstream of storage. Under the compute-optimal scaling results of section 1.3, the training-token count grows in proportion to parameter count, so each step up the model-size curve enlarges both the corpus the fleet must hold and the bytes each epoch must read. This corpus already sits below the compute-optimal allocation for a 175B-parameter model, so a compute-optimal run would raise both figures further. The run makes a single pass (one epoch) over this corpus, reading every selected token once



Storage is the physical substrate spanning Compute (C_1), Communication (C_2), and Coordination (C_3).

in an order determined by the shuffle seed. No small "hot" subset dominates access. Meanwhile, each accelerator processes its local batch in roughly 200 ms, then waits for the next. If storage cannot deliver data within that 200 ms window, the accelerator sits idle, and the organization pays for silicon that produces heat instead of gradients.

The problem is deceptive because storage technology has improved substantially. Non-Volatile Memory Express (NVMe) drives achieve 7 GB/s of sequential throughput, a figure that would have seemed out of reach a decade ago. An H100 moves data internally through high-bandwidth memory (HBM) at 3.35 TB/s, roughly 479× the sequential bandwidth of a single NVMe drive. This ratio contrasts two tiers; it is not the rate at which storage must supply training inputs, because HBM bandwidth also carries repeated weight, activation, and tensor traffic during computation. The storage feed requirement is instead determined by the input-batch bytes each accelerator needs per iteration. Dividing those bytes by the compute window gives one worker's required delivery rate; summing across workers gives the fleet demand. That rate must be evaluated at each tier using the representation stored there, since compressed inputs and decoded tensors occupy different numbers of bytes. A hierarchy becomes useful when the durable source cannot meet that rate or its latency varies enough to interrupt computation. Faster tiers stage upcoming batches while the durable tier supplies capacity and preserves the source data.

The storage problem joins physics with economics. Physics favors the memory closest to the accelerator, which offers the highest bandwidth in the smallest capacity; economics favors shared storage, which pools far more capacity at lower cost per byte behind additional interfaces and service queues. Device technology, interconnects, and contention then determine the rate a particular consumer actually receives. The engineering task is to place and move data so that the accelerator receives each batch before it is needed. The resulting design problem is quantitative. It asks how fast each tier must be, how deep the pipeline must run, and which bytes are worth keeping close to the accelerator. Improving arithmetic throughput alone does not improve input delivery or checkpoint persistence. Those paths require their own bandwidth and latency budgets.

The canonical training-data footprint for this example is roughly 9 TB across the hierarchy, combining the example's compressed corpus and tokenized shards. Additional shuffled or packed variants can raise the staging footprint, but the per-epoch training read over 4-byte token IDs is 6 TB. This chapter adopts one resumable mixed-precision Adaptive Moment Estimation (Adam) checkpoint contract: FP16 model weights, FP32 master weights, and two FP32 Adam moments, for 14 bytes per parameter. This is the 16-byte training state of section 2.5.3 without its 2-byte FP16 gradients, which are recomputed after restore, while scheduler, random-number-generator, and data-loader metadata are negligible at this scale. The resulting checkpoint is 2,450 GB every 10 minutes. Over a 30-day training run on the 256-node cluster, the storage system must deliver 6 TB of tokenized training data in the run's single epoch, absorb 10.6 PB of checkpoint writes, and

Over the run, checkpoint writes exceed one epoch of training-data reads by more than 1,000 times.

stage model weights for evaluation runs. The sections that follow use this same contract for every checkpoint size, duration, retention total, and lifetime-write calculation.

Those numbers force the storage path. ML access patterns first invert the assumptions behind conventional storage systems. That inversion forces a hierarchy from HBM to cold archive. The hierarchy then requires a pipeline equation that sizes delivery and direct data paths that remove host copies. It also requires a checkpoint protocol for the dominant write traffic, commit boundaries that keep every versioned artifact reproducible (generated training data included), and economics that decide which bytes belong at each tier. Serving-time model loading and retrieval indexes are variations on the same fuel-line problem, and devices that move the boundaries between tiers close the chapter. In each workload, the storage system must place the right representation at the right distance before the accelerator asks for it.

4.2 How ML Workloads Invert Storage Assumptions

A database administrator moving to an ML infrastructure team would find that the 175B running example's multi-terabyte sequential scans and multi-terabyte checkpoint bursts invert many familiar storage design principles. Transactional databases emphasize small random accesses and strong consistency, issuing thousands of 4 KB reads per second to serve user queries. Storage designs for that regime combine caching algorithms that assume recently accessed records will soon be requested again, write-ahead logs that support point-in-time recovery, and redundant array of independent disks (RAID),[1] which trades capacity and performance for fault tolerance. Full-corpus pretraining breaks the locality and access-size assumptions behind that stack while retaining the need to protect durable state; fine-tuning, curriculum learning, hard-example mining, recommendation features, and retrieval introduce their own skewed working sets, so each inversion below is a property of the workload rather than of ML as a whole.

Full-corpus pretraining inverts these assumptions when samples are packaged into sequential shards, allowing the pipeline to stream through datasets that span hundreds of terabytes. Individual accesses are large (megabytes rather than kilobytes) because models consume batches of images or text sequences, while immutable, versioned training shards avoid read-write conflicts during a run even though checkpoint publication and live feature updates still require explicit consistency guarantees. Image and video workloads can demand hundreds of gigabytes per second for days or weeks, whereas compact tokenized text can require much less input bandwidth even when checkpoint writes dominate total traffic. The mismatch between what storage was optimized for and what ML actually needs creates the **I/O wall** (principle 7): when storage throughput cannot deliver training data as fast as accelerators consume it, GPUs idle regardless of their computational power. For bandwidth-heavy image and video inputs, that wall arrives when accelerator count grows faster than provisioned storage throughput,

[1] **RAID (redundant array of independent disks)**: A Berkeley taxonomy of drive-combining strategies that trade redundancy, capacity, and I/O performance (Patterson et al. 1988). RAID 0 stripes data without redundancy and can suit a disposable cache backed by a durable source. A drive failure then requires restaging; redundancy may still be worthwhile when that recovery cost or the required availability justifies it. Unreplicated checkpoints and sole dataset copies require a different durability contract.

making the *data pipeline*, not the *model*, the limiting factor whenever a fixed input service time cannot keep pace with faster compute.

↪ How storage stalls surface as communication or coordination bottlenecks in the C^3 taxonomy is developed in section B.4.6.

> **Systems Perspective 4.1: The moving I/O bottleneck**
>
> Hold the batch representation and storage path fixed while improving compute throughput. The batch now finishes sooner, leaving less time to deliver the next one. Prefetching can overlap delivery with execution, but it cannot overcome a sustained service-rate deficit. This compute-to-storage imbalance does not imply that every larger model is input bound: a model that performs more computation on the same batch can instead give storage more time. The design must follow workload service times, not advertised peak-throughput trends.

A normalized example isolates the effect. Suppose input delivery takes one quarter of the original compute time and overlaps perfectly with computation, so each batch takes the longer of the two service times. Doubling compute speed halves batch time, and quadrupling it halves batch time again, at which point compute and delivery take equal time. Beyond that point the pipeline is delivery bound. A sixteenfold faster accelerator still raises batch throughput only fourfold, and the remaining compute sits idle behind the input path. That plateau is an I/O wall for this workload and allocation. Faster storage, a more compact representation, or additional independent input paths can move it; deeper prefetching alone cannot.

The first inversion is access pattern. Where database workloads issue *random access patterns* that benefit from seek-time optimization, full-corpus pretraining performs large *sequential scans*. An epoch in the running example reads each selected sample once, in the order produced by shard and buffer shuffling, so the pattern resembles video streaming more than database queries. Storage systems optimized for random IOPS[2] waste capabilities on this workload, whereas systems optimized for sequential throughput excel. The penalty for the wrong pattern is large. A Gen4/Gen5 NVMe drive delivers roughly 7–14 GB/s for sequential reads, while small 4 KB random reads can fall near 0.5 GB/s, an order-of-magnitude to 30× drop. Hard drives pay an even steeper 100× throughput reduction because mechanical seek times dominate random access.

The shuffling that ML training requires adds a complication rooted in the requirements of stochastic gradient descent. Stochastic gradient descent requires that each mini-batch be drawn approximately uniformly from the training distribution; presenting samples in a correlated order (all samples from the same document, all images from the same class) biases the gradient estimates and slows or destabilizes convergence. True global shuffling would satisfy this requirement perfectly, but it requires random access across the entire dataset, destroying the sequential access pattern that storage hardware demands. Even for a multi-terabyte corpus, random per-sample seeks are I/O-prohibitive. A dataset of 1 trillion 4-byte tokens (about 4 TB) stored as individual elements on NVMe and accessed at random would take hundreds to thousands of hours to read at the drive's random-read IOPS

[2] **IOPS (input/output operations per second)**: The metric that dominated storage procurement for decades because database workloads issue millions of small random reads. ML training inverts this priority: a pipeline streaming 256 MB shards sequentially needs sustained GB/s throughput, not per-operation speed. Provisioning storage by IOPS rating for an ML workload over-spends on random-access capability the pipeline never exercises.

rate, rather than about ten minutes of sequential streaming. The practical solution is therefore a compromise that shuffles the order of large data shards and then shuffles samples within each shard's local buffer. This preserves sequential I/O, but adequate mixing depends on shard composition and buffer size, a dependence section 4.4.2 turns into a validation step for the loader.

The second inversion is working set size. Traditional applications rely on temporal locality: a web server repeatedly accesses popular pages, and a cache holding the top 10 percent of content serves 90 percent of requests. In the chapter's full-corpus pretraining scenario, the 6 TB serialized corpus has no "popular" token range; each selected token is consumed once per epoch. A cache of any practical size holds only a small fraction of the corpus, and most samples are effectively "cold" when accessed. This access pattern makes traditional recency caching much less effective. A least recently used (LRU)[3] cache can approach a 0 percent hit rate for a cyclic scan larger than the cache, because each sample is evicted before its next access. With independently reshuffled epochs, cross-epoch hits are low but nonzero and depend on the cache fraction and sample order.

[3] **LRU (least recently used)**: An eviction policy that discards the entry unused for the longest time, effective when recently accessed data is likely to be accessed again soon. Under independent reshuffling, some samples retained from the end of one epoch may be reused early in the next, so teams should measure that reuse before allocating DRAM that could otherwise serve as prefetch buffers.

Other training policies create different locality. Multi-task or curriculum learning, hard-example mining, and filtered sampling access some subsets more frequently during particular phases. This temporary working set lets the NVMe tier exploit locality. Large-scale pretraining jobs that repeatedly scan a fixed corpus remain the scenario for the hierarchy derived here; systems serving another sampling policy should measure its reuse distribution before adopting the same cache design.

The third inversion is write pattern. Transactional systems generate continuous streams of small writes, each immediately durable. ML systems generate occasional large writes when saving checkpoints. A 175B parameter model checkpoint, including optimizer state, occupies roughly 2,450 GB. Saving it every 10 minutes generates concentrated bursts that saturate bandwidth for seconds, followed by long idle periods. These synchronized bursts, called checkpoint storms and defined formally in definition 4.5, must be absorbed by the shared file system without disrupting ongoing training reads. The bursty write pattern is particularly challenging because all nodes in the cluster write their checkpoint shards simultaneously. If 256 nodes each write 10 GB, the parallel file system receives 2.4 TB of writes in a single burst, which blocks training if the job writes synchronously to that tier. Local staging and asynchronous replication can shorten this pause, as section 4.6 develops. When checkpoint and gradient traffic share one fabric, traffic isolation also keeps the burst from delaying the job's collectives.

↩ Traffic isolation and quality-of-service mechanisms are established in section 3.8.2.

The fourth inversion is subtler. The read/write ratio shifts by lifecycle phase. During the intervals between checkpoints, the input pipeline reads continuously. Across a complete run, however, the read/write ratio depends on input size, epoch count, checkpoint size, and save frequency. The running language-model example produces far more checkpoint bytes than training-input bytes despite spending most of its time between saves. During data preprocessing, both reads and writes are heavy, and the access pattern more closely resembles a MapReduce job than a

training loop: tokenization, deduplication, and shuffling scan the raw corpus once (large sequential reads) and write intermediate artifacts (large sequential writes). The next stage then scans those artifacts again. A 3 TB compressed text corpus typically expands to 6 TB of tokenized shards before the first training epoch begins, loading each storage tier differently from the read-only training phase that follows. No single storage configuration optimizes for all phases, which is why ML systems require a multi-tier hierarchy rather than a single storage technology.

A fifth inversion emerges when comparing training and inference workloads. *Training* reads datasets sequentially and writes checkpoints in bursts. Weight-resident *inference*, by contrast, performs one large model read at startup and then serves requests from HBM. Its storage challenge is cold-start latency: the time required to load a model when scaling up or recovering from failure. The binding constraint flips from sustained dataset throughput to a bulk read whose duration depends on which tier supplies the weights. Retrieval, state offload, and models larger than aggregate HBM create additional serving-time I/O, so this weight-resident case is a baseline rather than a universal inference pattern. Section 4.9 derives the load times and connects that baseline to the retrieval workload that follows.

Serving at fleet scale also creates a fan-out read burst. A serving cluster with 100 replicas of the 175B running model holds 35 TB of FP16 weights, and a model rollout must deliver a new version to every replica within minutes while the old version keeps serving. The burst is the checkpoint storm in reverse. Instead of many nodes *writing* to shared storage at once, many nodes *read* the same data at once.

Table 4.1: ML Workloads Invert Traditional Storage Assumptions: The five inversions of full-corpus training and serving. Where databases optimize for random IOPS with cacheable working sets, ML training streams sequentially through datasets that exceed all cache levels and writes state in bursts, its read/write balance shifts by lifecycle phase, and serving replaces dataset streaming with bulk model loads.

Workload pattern	Traditional assumption	ML reality
Access pattern	Random access	Sequential streaming
Working set	Fits in cache, with strong temporal locality	Exceeds all cache levels; low locality in full-corpus scans
Write pattern	Continuous small writes	Bursty large writes
Read/write ratio	Balanced	Phase-dependent (read-only to write-dominated)
Training vs. inference	One access pattern for all phases	Corpus streaming in training; bulk model loads and fan-out in serving

Together, the five inversions collected in table 4.1 reduce to one procurement rule, which is to optimize for streaming reads and bursty writes rather than database-style random IOPS. An organization provisioning storage for ML based on database-era heuristics will over-invest in random IOPS for sequential training

shards, under-invest in the sustained bandwidth those shards require, and fail to account for the bursty write patterns that checkpointing creates.

Checkpoint 4.1: Storage workload analysis

Consider the storage subsystem for a new ML training cluster with 512 GPUs. The primary workload will train large language models on a 10 TB text dataset.

- ☐ **Database heuristics**: use the five storage workload inversions to name at least three database optimization strategies that would be counter-productive for this workload.
- ☐ **Epoch reads**: calculate the total data volume read when each training epoch reads the full 10 TB dataset once and the cluster trains for 100 epochs, then compare it to a typical database workload.
- ☐ **Checkpoint bandwidth**: calculate the minimum write bandwidth required when the model saves a 500 GB checkpoint every 15 minutes and each save must complete within 30 seconds.
- ☐ **Write duty cycle**: calculate the percentage of time the storage system spends in "write mode" vs. "read mode" under bursty checkpoints every 15 minutes.

Translating these five inversions into a concrete architecture requires separating how a dataset is packaged from how fast each storage tier must serve it. The required delivery rate depends on workload demand rather than parameter count alone: it equals the aggregate input bytes consumed during a delivery window divided by that window, a rate that representation, batch size, parallelism, and compute time jointly set (section 4.4) and that prefetching alone cannot sustain when demand exceeds a tier's allocated share. In the running example, the 1.5 trillion tokens of training data produce roughly 6 TB of sequential token-ID reads per epoch from a 3 TB compressed source corpus. Stored as one file per sample, that corpus would spend its storage budget on file opens rather than payload bytes, the metadata bottleneck that section 4.3.6 develops as the small file problem. Preprocessing the corpus into large sequential shards (Aizman et al. 2019) amortizes open, seek, and close costs across many tokens without changing the payload byte rate (section 4.3.5). Where those shards should live, and how close to the accelerator, is the question the storage hierarchy answers.

4.3 The ML Storage Hierarchy

No single storage device can hold a petabyte-scale training corpus, absorb multi-terabyte checkpoints, and still feed an accelerator at terabytes per second. HBM supplies high local bandwidth at limited capacity, whereas object storage pools durable capacity behind a much slower service and client path. A multi-tier hierarchy combines these resources rather than requiring one technology to meet every demand. Each tier offers a different balance of bandwidth, latency, capacity, and cost. The hierarchy extends the familiar processor memory hierarchy across

nodes. The new fleet-level decision is how local staging reduces demand on shared storage while preserving a durable, consistently versioned source. Comparing the tiers fairly requires stating each resource at its own scope, per accelerator, per node, or as an aggregate shared service (table 4.2).

Table 4.2: Extended Memory Hierarchy for ML Systems: HBM bandwidth is per accelerator, host DRAM and local NVMe are per node, and parallel-file-system and object-storage figures are aggregate service rates. These different scopes are not directly comparable tier ratios; divide shared bandwidth among active clients and account for each client path before sizing prefetching and caching. Memory costs are acquisition dollars per GB, while storage costs are recurring dollars per GB-month; comparing them requires an explicit amortization period and utilization assumption.

Storage tier	Typical capacity	Bandwidth	Latency	Illustrative cost basis
GPU HBM	80 GB	3.35 TB/s	~273 ns	~$15/GB acquisition cost
Host DRAM	512 GB–2 TB	200 GB/s	~100 ns	~$3/GB acquisition cost
Local NVMe SSD	4–30 TB	7–25 GB/s	~100 µs	~$0.10/GB/month provisioned
Parallel File System	100+ PB	1+ TB/s aggregate	~1 ms	~$0.03/GB/month provisioned/service
Object Storage	Very large pool	100 GB/s aggregate	~50 ms	~$0.02/GB/month service
Archive/Cold Storage	Very large pool	1 GB/s	Minutes to hours	~$0.004/GB/month service

HBM's advantage over host DRAM in table 4.2 is *bandwidth*, not *latency*, because its lead comes from wide stacked interfaces rather than faster cells (section 2.3.1). The latency cliff between adjacent tiers opens only at NVMe and below, where the physical distance from the accelerator grows from millimeters to meters. The storage hierarchy model (principle 8) therefore governs storage tiering and pipeline design: the local tiers exchange bandwidth for capacity, while shared tiers aggregate many devices and expose a different client path. Because per-client bandwidth depends on allocation and contention rather than a fixed factor between tiers, data format choices, caching strategies, prefetch buffer sizing, and tiering policies all exist to manage the movement of data upward through the hierarchy so that the accelerator never starves.

The rest of the chapter numbers the six tiers by distance from the accelerator, from Tier 0 (HBM) through Tier 1 (host DRAM), Tier 2 (local NVMe), Tier 3 (parallel file system), and Tier 4 (object storage) to Tier 5 (archive). Distance alone hides an important distinction, because each tier's bandwidth figure describes a different

scope: per accelerator, per node, or a shared service divided among its clients (figure 4.1).

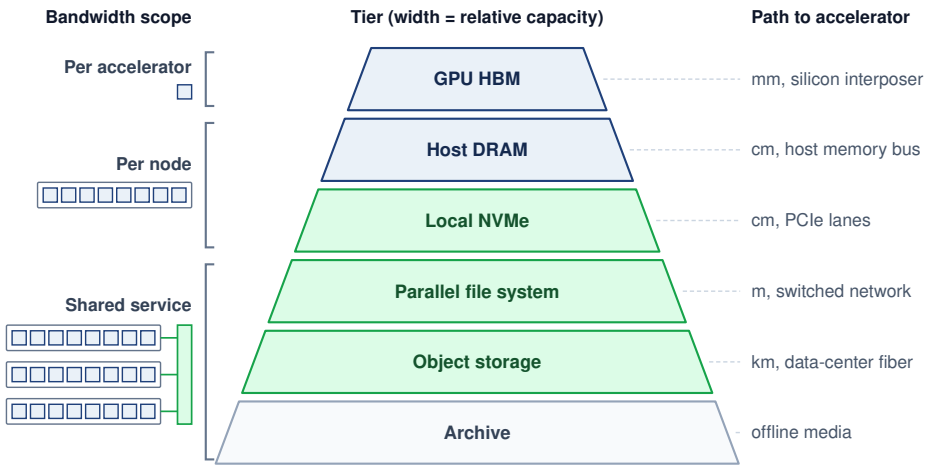


Figure 4.1: ML Storage Hierarchy: The six tiers of table 4.2 stacked by distance from the accelerator, with band width showing schematically how capacity grows toward the base; the table carries the numbers. The left brackets give the scope of each tier's bandwidth figure, and each glyph shows what shares it: one accelerator, the accelerators of one node, or many nodes drawing on one aggregate shared service. The right column gives the physical path each byte travels to reach the accelerator. Blue memory tiers are bought per GB; green storage tiers are rented or provisioned per GB-month; the gray archive tier is offline media.

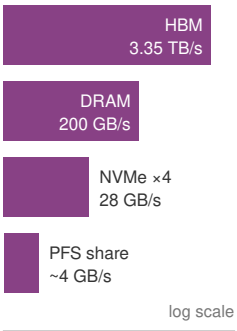

The physical tiers of figure 4.1 govern the trade-off among access distance, capacity, and cost. Shared services can aggregate more bandwidth than an individual local device, so the ordering is not a monotonic ranking of aggregate throughput. This trade-off is not arbitrary; it reflects the physics of data proximity. HBM sits on the same silicon interposer as the accelerator, connected by thousands of parallel traces measured in millimeters, whereas host DRAM connects to the CPU memory controller and reaches the accelerator across the host-device interconnect, and local NVMe reaches across the circuit board over PCIe lanes. Beyond the node, the parallel file system traverses meters of cable and network switches, while object storage may span kilometers of fiber between data centers. Distance, protocol overhead, and contention can increase access latency, while media technology and provisioning determine capacity cost. Distance is therefore a guide rather than a measurement; only the complete client path establishes all three properties for a given consumer.

The engineering challenge is to deliver each batch to HBM before the accelerator needs it. Return to the running example: the durable corpus lives in object storage (Tier 4) as a 3 TB compressed source copy plus 6 TB of tokenized training shards, but the accelerator needs each batch in HBM (Tier 0) within 200 ms. The chapter's reference design fixes one path between them. At job start, each node copies its share of the tokenized shards from object storage to its local NVMe (Tier 2). The single training epoch then reads from that local copy, prepares batches in host DRAM, and transfers them to HBM. The parallel file system (Tier 3) holds checkpoints rather than training inputs. Streaming the shards directly from object

storage, or serving them from a parallel file system, are the alternatives the chapter weighs against this design, and the hierarchy describes placement choices, not a requirement that every byte visit every level.

4.3.1 Bandwidth cliffs between tiers

Stepping down one level from a single accelerator's HBM (3.35 TB/s) to the whole host's DRAM (~200 GB/s) drops bandwidth by roughly 16.8×, and that comparison still understates the cliff on an eight-GPU node because all eight accelerators share the same host-memory bandwidth. Comparing adjacent tiers requires making the scope of each rate explicit—per accelerator, per node, or across a shared service—as bracketed in figure 4.1. Between host DRAM and NVMe, the ratio is roughly 7.1× (200 GB/s vs. ~28 GB/s from a 4-drive RAID-0). Between NVMe and a parallel file system, the ratio depends on the per-node allocation: if a 1 TB/s aggregate parallel file system (PFS) serves 256 nodes, each node receives roughly 4 GB/s, a 7× reduction from the local RAID-0 stripe. Object-storage throughput likewise depends on the client path and allocation; there is no fixed ratio to a parallel file system.

Per-client bandwidth falls roughly 7 to 17× at each step from HBM to a node's share of the parallel file system.

As section 4.1 established, a cliff is not a feed requirement; the feed rate remains input-batch bytes divided by iteration time, summed over distinct consumers. What the cliffs decide is where buffering must sit. Along the chosen path, host DRAM can buffer prepared batches and NVMe can cache shards from shared storage. Each buffer must cover the delay of the tier below it while that tier sustains the consumption rate; durable repositories need not act as intermediate buffers.

The same hierarchy can be analyzed as a cache rather than as six isolated devices. If a request hits the hot tier with probability h, taking T_{hot}, and otherwise falls through to a colder tier, taking total end-to-end miss-path time T_{cold} (including the failed hot-tier lookup), its mean service time is

$$\mathbb{E}[T] = hT_{\text{hot}} + (1-h)T_{\text{cold}}. \tag{4.1}$$

For fixed-size records served serially, the corresponding effective bandwidth is the record size divided by $\mathbb{E}[T]$. The arithmetic makes small miss rates consequential: with a 95 percent hit rate and a cold-tier access 100× slower than a hot-tier access, $\mathbb{E}[T] = 5.95T_{\text{hot}}$, so the effective request rate is only about one-sixth of the all-hot rate. Concurrent requests and prefetching can overlap service, so this mean is a sizing baseline rather than a fleet-throughput or latency guarantee. Correlated misses or a heavy-tailed cold tier can drain the prefetch buffer even when the average satisfies the pipeline budget, so production designs must check a tail percentile and miss bursts as well as $\mathbb{E}[T]$.

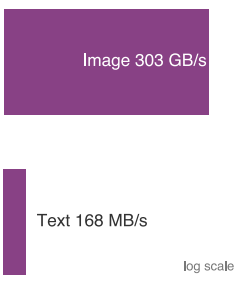

Image training demands 1,800× the storage bandwidth of text.

The batch-volume arithmetic also explains why increasing cluster size creates storage pressure. Aggregate demand is each consumer's batch bytes divided by its compute window, summed over consumers, so at a fixed per-node rate it grows linearly with node count. The per-node rate itself spans orders of magnitude across data modalities, as text and image training on the running cluster show.

Napkin Math 4.1: Text vs. image bandwidth

Problem: How much aggregate storage bandwidth does a 2,048-GPU cluster require for text training vs. image training?

Setup: Compare two declared batch representations at the same compute window and number of independent input consumers. The result depends on batch volume and rate, not modality alone. Both jobs are generic ones sized to the running cluster, not the 175B running job. Each GPU consumes one per-GPU batch every step, a pace that fits a model far smaller than 175B parameters.

For text training, the demand is low. With a per-GPU batch of one packed sequence of 4,096 tokens and a 200 ms step time, the aggregate bandwidth is:

$$2{,}048 \text{ GPUs} \times 4{,}096 \text{ tokens/GPU} \times 4 \text{ bytes/token} \div 0.2\text{s} \approx 167.8 MB/s$$

This is easily served by a single network-attached storage node.

Image training demands far more. Using a common batch size of 256 per GPU (ImageNet at 224×224, roughly 116 KB/image), the aggregate bandwidth is:

$$2{,}048 \text{ GPUs} \times 256 \text{ images/GPU} \times 115.7 \text{ KB/image} \div 0.2\text{s} \approx 303.2 GB/s$$

Systems insight: Under the stated batch representations and compute times, image training requires 1,800× higher input bandwidth than text training. The text example is *volume-heavy* but *bandwidth-light*. One network-attached storage server can carry its input feed, so its storage design is shaped by total corpus volume and, as later sections show, by checkpoint traffic. The image example is *bandwidth-heavy*, with a feed that exceeds any single storage server and calls for the aggregate bandwidth of many servers or of local caches. Whether either demand becomes an actual bottleneck still depends on the measured delivery rate of the path that serves it.

The 175B running job sits lower still. Its 6 TB epoch spread over the 30-day window averages about 2.3 MB/s for the whole cluster, corpus bytes divided by run length, roughly 70× below the notebook's generic text job. Each token of a 175B model carries so much computation that the corpus trickles in, which is why the running example's storage design is shaped by checkpoint traffic rather than by its input feed.

The image result is a floor for visual data rather than a ceiling. At about 303.2 GB/s across 256 nodes, the image job already consumes nearly a third of a 1 TB/s parallel file system built from 100 data-serving nodes (the architecture section 4.3.6 develops). Higher-resolution images and video clips, at megabytes per sample rather than the roughly 116 KB of a compressed ImageNet image, raise the per-

node demand by an order of magnitude or more, and a fleet several times larger multiplies it again. Demand at that scale exceeds what a shared file system of this size can serve, so the architecture must rely on local NVMe caching to take repeated reads off shared storage.

The bandwidth cliff between tiers also has implications for the data format at each level. Computation consumes float16 tensors, packed token IDs, or other supported representations, while NVMe and object storage can retain compressed records. Compression reduces bytes stored and transferred but adds decoding work. The chosen format must let CPU or GPU decoding keep pace with consumption; maximum compression can reduce end-to-end throughput when decoding becomes the limiting stage. A host-decoded path stages the resulting tensors in DRAM, while a GPU-decoded path moves the transformation and its resource demand to the accelerator.

The format challenge intensifies for multi-modal training, which combines text, images, audio, and video in a single model. Serialized sizes span orders of magnitude, from 4 bytes per text token to roughly 116 KB per compressed image to megabytes per short video clip, depending on representation, compression, resolution, and duration, and each modality requires its own decoding and augmentation work. A multi-modal training job must manage these parallel streams and provision for their combined service demand. For a corpus containing 3 TB of text, 50 TB of images, and 200 TB of video, video dominates retained capacity. Its bandwidth contribution also depends on how frequently training samples it and how many bytes each sampled batch reads. Corpus size alone determines neither the delivery rate nor the modality's contribution to model quality.

Tracing how each tier meets these bandwidth and format constraints begins at the top of the pyramid and steps outward from the accelerator to the archive. That descent starts where computation actually consumes bytes: HBM, the tier fast enough to keep accelerator arithmetic fed but far too scarce to hold the full training corpus.

4.3.2 Tier 0 GPU HBM

The scarcest resource in the system sits closest to the arithmetic. On the H100 used here, HBM holds the active weights and activations served to the accelerator, while caches and on-chip buffers reuse portions of that state. Its stacked packaging supplies 3.35 TB/s of aggregate bandwidth, the top of the cliffs just measured. That bandwidth is what makes large-scale deep learning feasible, because a matrix multiplication involving billions of parameters reads those parameters from memory on every forward and backward pass. What HBM lacks is room.

↩ High-bandwidth memory packaging, the 3D stacking and through-silicon vias behind this bandwidth, is established in section 2.3.1.

For placing the unpartitioned running model, the immediate constraint is *capacity*. Once state fits, HBM bandwidth can still limit execution. The node-memory budget of section 2.5.3 already shows how far one 80 GB device falls short of the 175B running example: the FP16 weights alone, 350 GB, need at least five H100 accelerators. The mixed-precision contract this chapter checkpoints also retains 700 GB of FP32 master weights, so weights, gradients, master weights, and Adam moments occupy 2.80 TB before activations and communication buffers. State that

does not fit in one HBM pool must be split across accelerators or kept outside HBM and fetched when needed. Splitting it across the cluster makes the run possible, but every shard becomes a separate piece of state that lower tiers must stage, save, and restore in step with the others. HBM scarcity is what forces the rest of the hierarchy to exist, and HBM is the destination that every lower tier exists to serve.

Because HBM capacity is so limited relative to both model size and dataset size, the accelerator processes data in batches. Each batch occupies a fraction of HBM for the duration of one forward-backward pass, then is discarded to make room for the next. The rate at which batches must be supplied sets the bandwidth requirement for all lower tiers.

The razor-thin margin is a defining feature of large model training, visible in the HBM budget that each 80 GB H100 carries while the fleet trains the 175B parameter model (table 4.3). The table treats partitioning as a storage layout, and the chapter keeps this one layout throughout. Tensor parallelism splits the model weights eight ways inside each node, so every node holds one complete copy of the weights spread across its GPUs. Optimizer, master-weight, and gradient state are additionally sharded across the 256 nodes, so each GPU holds only its slice of that state rather than a full replica. Sharding optimizer and gradient state across data-parallel replicas while each replica keeps its weights is the second stage of the Zero Redundancy Optimizer (ZeRO), a training technique in its own right; its third stage also partitions the weights. Here only the resulting per-GPU slices matter, because they set the storage pressure HBM sees.

↪ Sharded data parallelism (ZeRO and FSDP), which partitions optimizer, gradient, and weight state across workers, is developed in section 6.3.3.

Table 4.3: HBM Memory Budget for 175B-Parameter Training: Per-GPU allocation when splitting a 175B model eight ways inside the node and sharding optimizer and gradient state across 256 nodes. The optimizer, master-weight, and gradient rows are per-GPU shards after both levels of partitioning. The resulting budget occupies most of a 80 GB HBM device, leaving limited buffer for the incoming data pipeline. Any delay in fetching the next batch from host memory risks starving the accelerator.

Component	Size per GPU
Model Weights (FP16, 8-way shard)	43.75 GB
Optimizer State (node-sharded)	0.7 GB
FP32 Master Weights (node-sharded)	0.34 GB
Activations (variable by sequence length)	10–20 GB
Gradient Buffers (FP16, node-sharded)	0.2 GB
Communication Buffers (NCCL)	2–4 GB
Total Occupied	**56.9–68.9 GB**

Even with aggressive partitioning, the total memory footprint reaches 56.9–68.9 GB in decimal gigabytes, about 66.3–80.3 percent of the HBM pool (the device's nominal 80 GB is a binary capacity, slightly larger than 80 decimal gigabytes). The remaining headroom shrinks further once fragmentation and framework workspaces are included, and that headroom is all the incoming data pipeline has to work with. An input batch and its activations occupy HBM for one training

step, while model weights and optimizer state persist across steps. Prefetching the next batch therefore competes with the live training footprint for scarce capacity; a deeper input queue is useful only if the memory budget can accommodate it.

From the data pipeline's perspective, Tier 0 is not a storage tier to be managed but a constraint to be satisfied. The pipeline's purpose is to ensure that the batch the accelerator needs *next* is already resident in HBM before the *current* batch's computation completes. If it arrives late, the accelerator stalls. If it arrives early, it consumes HBM that could hold activations. The tension between "just in time" and "just too late" defines the pipeline's buffer management strategy, quantified in section 4.4.

4.3.3 Tier 1 host DRAM

One level below HBM, host DRAM serves as the staging area for the data pipeline. Every byte of training data that reaches the accelerator passes through host DRAM first (unless GPUDirect Storage bypasses it, as described in section 4.5). A typical training node contains 512 GB to 2 TB of system memory shared across the host CPU and its peripherals. While the bandwidth between host DRAM and the accelerator is limited to what PCIe Gen 5 (about 64 GB/s per direction, 128 GB/s bidirectional) can provide, host DRAM plays three roles in the ML storage hierarchy. It is the prefetch buffer, a home for embedding tables too large for HBM, and the augmentation workspace. Only CPU-accelerator superchips with a coherent NVLink-class host link raise that path toward the 900 GB/s that NVLink provides between accelerators. The data loader occupies two of these roles at once, because its augmentation stage and the prefetch buffer it fills both live in host DRAM.

The data loader pipeline that runs in host DRAM works as it does on a single node: reader threads fetch compressed samples, workers decode and augment them, and a collation stage assembles batches in pinned, or page-locked, memory for the host-to-accelerator direct memory access (DMA) transfer. At fleet scale, these stages compete with the node's other demands for the same host DRAM.

↪ The single-node overlap techniques behind this loader (prefetching, pinned host buffers, and double buffering) are collected for reference in section A.2.1.

Host DRAM's most critical function is serving as a prefetch buffer. When the accelerator finishes processing batch k, batch $k+1$ should already be assembled in host memory, ready for transfer to HBM. The depth of this prefetch buffer determines how much I/O variance the pipeline can absorb without stalling.

Recommendation workloads, the regime of Archetype B (DLRM at Scale), place a different demand on host DRAM: hosting embedding tables that can exceed 100 GB, far too large for HBM. These tables reside in host DRAM and are accessed through lookups that fetch only the rows needed for the current batch. The bandwidth between host DRAM and HBM becomes the critical bottleneck for these workloads, and some systems go further, pooling embedding tables in the DRAM of dedicated CPU servers and returning only the requested rows over remote direct memory access (RDMA).

Host DRAM also provides the augmentation workspace that the CPU pipeline requires. Data augmentation operations (resizing images, tokenizing text, applying noise) execute on the CPU and require temporary memory for intermediate results. A training pipeline that applies five augmentations to a 256-image batch at 116

KB per image needs tens of megabytes of working space for each augmentation stage. Although modest per-batch, this memory accumulates when multiple data loader workers run in parallel. GPU-side decoding with libraries such as the NVIDIA Data Loading Library (DALI) moves decode and augmentation onto the accelerator, so smaller compressed bytes cross the host link and host DRAM bandwidth demand falls. The work then consumes HBM capacity and compute cycles instead, which helps an input-bound job and hurts a compute-bound one.

The three roles interact in subtle ways. The prefetch buffer and the augmentation workspace compete for the same physical DRAM, and embedding tables consume capacity that could otherwise serve as deeper prefetch queues. A node with 512 GB of DRAM hosting a 200 GB embedding table has only 312 GB remaining for prefetching and augmentation. If the data loader uses 8 workers, each maintaining a decode buffer of 1 GB, the effective prefetch capacity drops further. System architects must balance these competing demands by profiling the actual memory consumption of each pipeline stage and provisioning DRAM accordingly.

The physical layout of DRAM also matters. On a dual-socket node, each socket's DRAM forms a non-uniform memory access (NUMA) domain local to the GPUs on that socket's PCIe root complex, and reaching the other socket's DRAM crosses the inter-socket link, with a penalty that depends on the processor, topology, and concurrent traffic (section 2.5.1.1). NUMA-aware allocation keeps each data loader worker and its prefetch buffer in the same NUMA domain as the GPUs it serves; the gain should be measured on the target node rather than assumed.

Host DRAM sits below the first cliff of section 4.3.1, and the host-to-GPU interconnect adds a separate cliff, with effective transfer bandwidth depending on whether the node uses PCIe or NVLink. In the conventional path that stages payloads through host memory, a depleted DRAM prefetch buffer leaves the accelerator waiting for lower tiers. The direct path of section 4.5 removes that staging copy when the data layout and devices support it. In the running example, the 256-node cluster requires each node's host DRAM to sustain a continuous flow of decoded, augmented batches ready for PCIe transfer. If the NVMe-to-DRAM read pipeline falls behind by even a few hundred milliseconds, the prefetch buffer drains and the accelerator idles until the next batch arrives.

4.3.4 Tier 2 local NVMe

When the working set exceeds host DRAM, the system falls to Tier 2: the local NVMe drives attached directly to the compute node. NVMe[4] provides a high-performance protocol designed specifically for solid-state drives, achieving 7 GB/s of sequential throughput per drive. NVMe's deep queues and PCIe lanes, rather than faster flash, explain why it delivers 10× to 50× the throughput of SATA SSDs (capped near 550 MB/s by the link) with identical NAND flash, provided the loader keeps many asynchronous reads outstanding. With four drives in a RAID-0 configuration, a single node can sustain roughly 28 GB/s of sequential reads before overhead, sufficient to stream the 6 TB serialized dataset from local disk in about 3.6 minutes under ideal sequential conditions.

[4] **NVMe (Non-Volatile Memory Express)**: A storage protocol designed for SSDs, connecting directly to the CPU via PCIe lanes. Its many deep command queues, replacing the single 32-command queue of the older SATA interface, are what allow a multi-worker ML data loader to keep enough requests outstanding to saturate the drive's bandwidth.

In ML training, local NVMe acts as a warm cache, storing data shards fetched from distributed storage. Workers can reread resident shards across epochs without fetching them over the network again. The savings depend on reuse, cache capacity, and whether remote reads cross a charged transfer boundary (section 4.8). Staging pays an initial transfer cost and provisions local capacity in exchange for avoiding later remote reads; it does not eliminate storage cost or read latency.

The warm cache pattern requires careful capacity planning. A training node with four 7.68 TB NVMe drives provides approximately 30.7 TB of local storage. For the running example, the 6 TB serialized dataset fits comfortably on a single node's local storage, with room for checkpoint staging and temporary augmentation buffers. A multi-modal training job combining 20 TB of images, 10 TB of text, and 5 TB of audio totals 35 TB, exceeding local capacity by about 4.3 TB and forcing the pipeline to stream from the parallel file system for at least part of the dataset. The design trade-off is between provisioning more local NVMe (which increases node cost) and accepting network-dependent reads (which risks latency spikes).

The I/O wall takes a deceptive form at this tier. The HBM-to-NVMe ratio of section 4.3.1 does not set demand, so the question here is whether the stripe meets the input-batch rate, not whether it approaches HBM. Pipelining overlaps that delivery with compute (section 4.4), while GPUDirect Storage (section 4.5) can remove host payload copies when those copies limit throughput. The wall is easy to miss because NVMe performance is excellent by historical standards. A storage engineer accustomed to HDD-era throughput of 150 MB/s might view 28 GB/s from a local RAID-0 stripe as more than enough. Whether 28 GB/s suffices depends on the batch representation and consumption rate. Compact text may fit within this budget, while image or video inputs may require more bandwidth; overlap hides transfer time only when sustained supply keeps pace with demand.

Local NVMe also supports local checkpoint staging. Writing a consistent snapshot locally and replicating it to shared storage in the background can shorten T_{write}, the time training pauses to save a checkpoint, when the shared write would otherwise be slower. Resuming after a local save accepts a period during which a node failure can destroy the new shard. The storage design must therefore specify both the exposed pause and the later durability boundary, while retaining a previous recoverable generation. Section 4.6 develops this trade-off and its timing model.

The same local NVMe tier also pays for itself by recovering utilization lost to remote-read latency. When congestion on a shared file system drains the host prefetch buffer and exposes I/O wait on every step, staging shards onto node-local flash converts that exposed remote wait into reclaimed accelerator compute time.

Napkin Math 4.2: Return on investment of local NVMe caching

Problem: A vision-model training pipeline, a separate workload from the 175B language model, runs each step in 800 ms on the 1,024-GPU reference cluster. It reads from a shared parallel file system, and even with prefetching,

congestion bursts on that shared service drain the loader's buffer and leave an average of 150 ms of exposed I/O wait per step. Assume that serving the same shards from local NVMe leaves only 10 ms of exposed wait per step, the residue of local tail latency that the prefetch queue does not cover. How much does adding local NVMe SSDs to each node improve GPU utilization?

Math: GPU utilization here means the fraction of step time spent in computation, an active-time fraction rather than model FLOPs utilization.

1. **Remote Only**: 800 ms / (800 ms + 150 ms) $\approx$ 84.2 percent.
2. **Local Cache**: Prefetching from local NVMe removes the congestion bursts of the shared service, leaving the assumed local residue.
    - New Util: 800 ms / (800 ms + 10 ms) $\approx$ 98.8 percent.

Systems insight: Local storage can act as a *GPU utilization multiplier*. In this scenario, adding a $500 NVMe drive to a node whose accelerators each cost $30,000 recovers 14.6 percent of the GPU's capacity that was previously wasted on I/O wait. Across the 1,024-GPU cluster, that utilization gain is equivalent to adding 149 GPUs worth of useful work without buying that many more accelerators. The gain is exactly the exposed remote wait that local reads remove, so it is large only when shared-storage congestion leaves a wait of this size; where it does, local NVMe is not auxiliary but the physical buffer that decouples expensive compute from unpredictable shared storage.

A practical concern at this tier is SSD endurance. NAND flash memory can sustain a limited number of write-erase cycles before the cells degrade. Enterprise NVMe drives are rated for 1 to 3 drive writes per day (DWPD) over a 5-year lifespan. For a 7.68 TB drive at 1 DWPD, this means the drive can absorb 7.68 TB of writes per day, or roughly 14 PB total over its lifetime. ML training workloads are predominantly read-heavy (the dataset is written once and read many times), which is favorable for SSD endurance. However, checkpoint writes can be intensive: if each node saves its roughly 10 GB share of the running example's checkpoint every 10 minutes, that is about 1.4 TB per day of checkpoint writes spread across the node's drives, well within a four-drive node's 1 DWPD budget. The risk emerges when local NVMe is used as a staging buffer for both checkpoint writes and dataset caching: the combined write volume from initial dataset staging plus repeated checkpoint saves must remain within the drive's endurance rating.

4.3.5 Data formats for training

Local NVMe can stream 28 GB/s per node, but packaging determines how much of that bandwidth reaches the loader. The same multi-terabyte dataset stored in different formats can yield I/O throughput that differs by over 100$\times$ on identical hardware, because each format charges a different access cost: per-file metadata, unnecessary feature reads, or sequential shard traversal. A directory containing one JPEG per sample pays a separate file open and metadata lookup for every

image. At roughly 10 to 50 microseconds per open in the kernel's file-system layer, a node reading 8,000 images per second spends 80 to 400 ms of CPU time per second on opens alone, before it decodes a single byte. On a shared file system the same operations also queue at a metadata service, the fleet-scale form of this cost that section 4.3.6 develops as the small file problem. A standard ImageNet training pipeline makes the cost of the wrong format visible.

Napkin Math 4.3: The ImageNet bottleneck analysis

Problem: A ResNet-50 training job on ImageNet (1.28M, ~116 KB average) targets 1000 images/s. Can individual JPEG files on an HDD sustain that rate, or does the job need NVMe?

Math:

1. **Raw Bandwidth**: 1000 images/s $\times$ 116 KB = 116 MB/s.
2. **HDD reality**: A 7200 RPM hard disk drive (HDD) delivers 100 IOPS at random reads. Sustaining 1000 images/s requires 10× more IOPS than the disk provides.
3. **Result**: When every image is a separate random read, shuffling individual files on an HDD will starve the GPU, capping utilization at about 10 percent before decode, seek, and file-system overheads.

Systems insight: Two fixes work, and they remove different limits. NVMe answers a random read in roughly 100 µs rather than the milliseconds of a mechanical seek, so even one outstanding request covers the 1000 images/s that the HDD's 100 IOPS cannot. Alternatively, converting the dataset to a sequential format (TFRecord/WebDataset) removes the random reads altogether and turns the HDD problem into a bandwidth one, in which the job needs 116 MB/s, within the roughly 150 MB/s that one HDD streams sequentially.

The first format choice is the record layout. Row-oriented formats, such as CSV or JSON lines, store successive records together and are easy to inspect and debug. They can stream many records from one file, although parsing text and reading unused fields consume CPU cycles and bandwidth.

A second choice solves a different storage problem. Columnar formats like Apache Parquet and Apache Arrow avoid unnecessary reads when tabular features can be selected before transfer. They organize data by column rather than by row, which allows for excellent compression as data within a column is typically of the same type and has lower entropy. Column pruning lets the reader fetch only required features. Predicate pushdown applies filters at the storage reader and can skip groups of records using their metadata, further reducing unnecessary I/O. These formats are well-suited for tabular ML tasks and feature engineering but are less natural for unstructured data like images or audio, which are treated as atomic blobs.

A third choice addresses the training access pattern directly. Sequential streaming formats reduce per-sample metadata to the cost of opening a shard. TFRecord, Mosaic's StreamingDataset format (Databricks 2026), and WebDataset[5] group many samples into large, contiguous binary files called shards. WebDataset uses standard `tar` archives, in which each sample keeps its image, label, and metadata entries while the loader streams the archive in order. A data loader opens a single shard and streams its contents sequentially, amortizing the open over thousands of samples. The `tar`-based formats have the added advantage of being valid targets for HTTP byte-range requests, making them ideal for streaming data directly from object storage without downloading the entire file first.

[5] **WebDataset**: A data format that repurposes standard POSIX tar archives for ML training. The design insight is that tar's sequential header-then-data layout, invented in 1979 for tape backup, maps perfectly onto the streaming access pattern that ML data loaders need.

A key trade-off within streaming formats is the presence of an index. TFRecord readers often rely on a separate index file that records each sample's byte offset within a shard, while HDF5 embeds its index in the file itself. This enables efficient random access within a shard but introduces a metadata dependency: the index must be read and held in memory. WebDataset is indexless, because each record in the `tar` archive contains its own header specifying its size, allowing for purely sequential streaming without any external metadata. The trade-off is that indexless formats cannot efficiently seek to an arbitrary sample within a shard, a capability that matters for curriculum learning or active learning workloads that require nonsequential data access.

Compression integration also varies across formats, and it trades storage bytes against CPU decoding work. Parquet integrates compression at the column level, exploiting type homogeneity for high ratios. WebDataset and TFRecord typically leave compression to the individual sample: a WebDataset of images stores already-compressed JPEG files, while a text dataset might apply zstd compression per shard, and the host CPU pays for that decompression. Consider two illustrative codecs on the same corpus: a lighter codec compresses 3:1 and produces 1.5 GB/s of decoded output per CPU core, while a denser codec compresses 4:1 and produces 0.5 GB/s per core. These are scenario assumptions, not fixed properties of named codec levels. At the 28 GB/s local NVMe rate, multiplying that read rate by each compression ratio yields potential decoded output rates of 84 GB/s and 112 GB/s, respectively, provided CPU decoding keeps pace. Dividing each uncompressed output rate by its per-core decoding speed requires 56 versus 224 cores, so the denser codec needs 4× as many cores because it produces one-third more uncompressed bytes from the same storage read while decoding each byte at one-third the per-core speed. Running each codec at the drives' full output is the worst case, an upper bound on decode work; a node needs only enough cores to decode its own share of demand. The generic text job of notebook 4.1 asks the entire cluster for about 167.8 MB/s, which a single core of either codec covers, so these core counts bind only for image and video feeds whose decoded demand per node approaches the drives' rate. With fewer cores than that demand requires, decoding limits delivery before storage saturates, so compression is chosen from the measured corpus, decoder, and available CPU budget rather than from the compression ratio alone.

For the running example, the 1.5 trillion token dataset is stored as roughly 2,000 shards of 3 GB each in a custom binary format. Each shard contains a small header (token count, vocabulary size, byte order) followed by a contiguous array of 4-byte token IDs. The number of `open()` calls per epoch is therefore the number of shards, not the number of tokens (trillions), an approximately 750,000,000× reduction in metadata operations that makes streaming from both local NVMe and remote storage feasible at training scale. When staged on POSIX storage such as local NVMe or a parallel file system, the data loader memory-maps the shard and indexes directly into the token array by position, achieving near-peak read bandwidth with zero per-sample metadata overhead. When the same shards are read directly from object storage, the loader uses HTTP ranged GET streaming and an explicit local buffer rather than memory mapping. The formats differ chiefly in the access cost each one imposes per sample on the storage path (table 4.4).

Table 4.4: Data Format Comparison for ML Training: Per-sample overhead determines whether the storage hardware's bandwidth is realized or wasted on metadata operations.

Format	Overhead/sample	Random access	Streaming	Compression
Individual files	≈ 50 µs (open/stat/close)	Yes	Poor	Per-file
Parquet	≈ 1 µs (row group seek)	Yes (row group)	Good	Column-level
TFRecord	≈ 0.1 µs (index lookup)	With index	Excellent	Per-record
WebDataset (`tar`)	~0 (sequential)	No	Excellent	Per-sample
Raw binary (tokens)	0	Yes (byte offset)	Excellent	None needed

Packaging removes the per-file cost within one node, but no node-local format gives every node the same view of the data. That requirement belongs to the next tier.

4.3.6 Tier 3 parallel file systems

Local NVMe drives cannot give 256 training nodes a single namespace for shared datasets or a globally visible home for checkpoints that survive a node crash. A parallel file system provides that shared tier across the cluster.

Definition 4.1: Parallel file system

Parallel file system (PFS) is a distributed storage architecture for ML training clusters that stripes data across many storage servers to provide aggregate throughput exceeding the capacity of any single device.

1. **Significance**: A PFS aggregates storage I/O bandwidth ($BW_{storage}$) across object storage servers (OSS). Twenty OSS nodes delivering 10

GB/s each offer 200 GB/s aggregate. When the client and network sustain that full rate, a 10 GB striped shard loads in about 50 ms rather than the 1 second a single 10 GB/s server would need. The rate that enters the data-movement term D_{vol}/BW of the single-machine iron law recalled in section 1.5.4 is the bandwidth that reaches the actual consumer, not the aggregate rating.

2. **Distinction**: Unlike network-attached storage, where every I/O request routes through a single server, a PFS client receives stripe location metadata from a dedicated metadata server (MDS) and then reads data directly from multiple OSS nodes in parallel. The MDS and OSS paths are architecturally separated, so data bandwidth scales with OSS count while metadata operations scale with MDS count.
3. **Common pitfall**: A frequent misconception is that a PFS has unlimited throughput if enough OSS nodes are added. In reality, every open, stat, and create passes through the MDS, whose service rate is finite and does not grow with the number of OSS nodes; a one-time burst of 10,000 opens does not by itself establish sustained saturation. The MDS becomes a throughput bottleneck when the aggregate metadata-operation arrival rate exceeds its service rate, regardless of spare bandwidth at the OSS nodes.

A Lustre-style parallel file system decouples metadata lookups from bulk data movement (figure 4.2), separating two concerns that traditional file systems handle together (Schwan 2003). Metadata servers (MDS) manage the namespace (persisting file layouts and attributes on metadata targets, or MDTs): file creation, directory listings, permission checks, and lock management. Object storage servers (OSS)[6] manage the actual data blocks, each serving a stripe of every large file. When a client opens a 10 GB training shard, the MDS tells the client which OSS nodes hold which stripes, and the client reads from all of them in parallel. A Lustre[7] deployment with 100 OSS nodes, each providing 10 GB/s, delivers an aggregate 1 TB/s.

This abstract architecture has concrete implications for performance tuning. When a training job creates a new dataset directory on Lustre, the administrator configures the stripe count (the number of object storage targets, or OSTs, a file is spread across) and stripe size (the chunk size written to each OST) for that directory (Lustre Wiki 2017). For large sequential-read training shards, administrators may choose wider striping and multi-megabyte stripe sizes so a single file can draw bandwidth from multiple OSS nodes. Lustre's striping guide treats wide striping as useful for very large files or files accessed by many clients, while smaller files often use fewer stripes to reduce overhead (Lustre Wiki 2019). A 4 GB data shard striped across 100 OSTs with 4 MB stripes places roughly 10 stripes on each OST. When a data loader reads large contiguous ranges, the Lustre client can issue parallel read requests to the OSS nodes holding those stripes, aggregating their bandwidth. The client also maintains its own read-ahead buffer, prefetching the next several stripes

[6] **OSS (object storage server)**: In parallel file system terminology, "object" means a chunk of striped file data managed by an object storage target, a usage that predates cloud object storage (S3, GCS) by over a decade. Confusing the two is a common source of miscommunication: when a Lustre administrator says "add more OSS nodes," they mean adding data-serving capacity to the parallel file system, not provisioning cloud buckets.

[7] **Lustre**: A portmanteau of "Linux" and "cluster," developed at Carnegie Mellon University and first deployed in production in 2003. Lustre is common in HPC and ML infrastructure because its architecture scales aggregate bandwidth linearly with the number of OSS nodes, the same property that makes it a natural choice for training clusters where a single job may demand hundreds of GB/s of sustained read throughput.

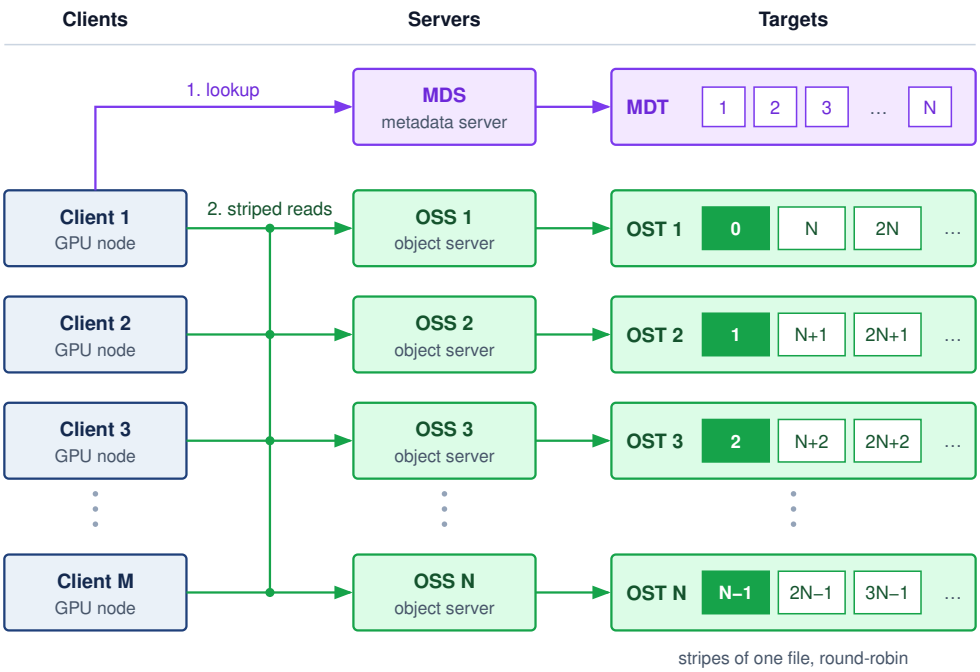

Figure 4.2: Parallel File System Architecture: A client makes one metadata request (MDS → MDT) to learn a file's stripe map, then reads the stripes directly from the object storage servers (OSS → OST) in parallel. Each OST holds every Nth stripe of the file in round-robin order, so consecutive stripes (dark) sit on different servers and one client reads them at once. The shared data path lets every client draw on every OSS, so aggregate bandwidth grows with the number of servers while metadata traffic stays on a separate path.

while the application processes the current ones. This file-system-level read-ahead is distinct from the data loader's application-level prefetch buffer; the two layers of prefetching compound to provide deep latency hiding, making the physical distance to the OSS nodes nearly transparent to the training process.

The separation between metadata and data paths is what enables the aggregate bandwidth that ML workloads demand. In GPFS[8] (IBM Spectrum Scale), the architecture takes a different approach: it stripes data and metadata across shared disks and coordinates concurrent access through token-based distributed locking (Schmuck and Haskin 2002). The result is not a simple MDS/OSS split; it is a shared-disk design whose metadata and data placement can be distributed while the lock protocol preserves consistency across clients. The trade-off is greater complexity in lock management, which must scale to thousands of nodes.

The data path scales with the number of object storage servers, but every file still begins with a request to the metadata service, and that service has a finite operation rate. That finite rate is the source of the small file problem. The per-open cost that section 4.3.5 charged to one node's CPU now lands on a metadata service shared by the whole fleet. Each `open()` system call requires a metadata lookup, lock acquisition, and attribute fetch. When a dataset of millions of 10 KB images is stored as individual files and 10,000 workers, a fleet several times the running cluster, each open a new file every few samples, the aggregate open rate exceeds

8 **GPFS (General Parallel File System)**: Developed by IBM Research starting in 1998, now marketed as IBM Spectrum Scale. For ML checkpoint writes, its token-based distributed coordination can reduce reliance on a single dedicated metadata path, but it also makes lock behavior part of the performance envelope.

the few hundred thousand operations per second an MDS typically serves. The MDS becomes the serialization point, and delivery collapses to its operation rate long before the data links saturate.

Definition 4.2: Small file problem

Small file problem is an ML data-loading pathology in which per-file operations overwhelm a storage system's metadata service.

1. **Significance**: `open`, `stat`, and `close` requests from 10,000 workers can serialize at the metadata service, idle the cluster, and reduce effective I/O bandwidth ($BW_{storage}$).
2. **Distinction**: This is a metadata request-rate and latency (L_{lat}) problem, not a bulk bit-rate problem.
3. **Common pitfall**: Faster SSDs do not fix this format problem. Packing samples into sequential containers such as TFRecord or Parquet amortizes metadata operations across many samples.

At production scale, the metadata bottleneck can collapse an otherwise high-bandwidth file system. When a cluster migrates from aggregated containers back to individual sample files, metadata request queues saturate long before the underlying storage servers or network links reach their byte-rate limits.

Example 4.1: The metadata meltdown

Scenario: A large-scale training cluster migrates from a preprocessed sequential dataset to 200 million raw image files stored individually on a parallel file system provisioned for 500 GB/s aggregate bandwidth.

Diagnosis: The file system delivers less than 1 percent of rated throughput. Millions of per-second `stat()` and `open()` calls overwhelm the metadata servers, choking data loaders despite abundant network and storage bandwidth.

Systems lesson: Metadata contention limits delivery when operation demand exceeds metadata service capacity. Bundling 200 million raw images into 50,000 large tar shards (for example, WebDataset) reduces the file count by 4,000× and amortizes per-file operations across samples. Packaging alone does not prevent startup contention if loaders still enumerate files with per-file `stat()` calls; distributing a precomputed dataset manifest removes those repeated lookups from the hot path. Measure metadata operation rate alongside byte bandwidth to determine which service limits delivery.

Striping and aggregation solve different problems: striping distributes large files across data servers, whereas aggregation, the shard packaging of section 4.3.5, reduces the number of files the MDS must track. Realized bandwidth then depends on the reader. A read contained within one stripe uses a single server, while enough concurrent reads spanning stripes can draw from several servers at once. Wider striping therefore helps only when read sizes and concurrency exploit those paths, and small files usually need fewer stripes.

Parallel file systems provide a shared namespace and lock management that support coordinated checkpoints (Schmuck and Haskin 2002), but the two ML write patterns need different guarantees from them. Immutable training shards remove conflicts with concurrent writers once the dataset version has been published, so readers need only agree on which completed version belongs to the run. A checkpoint needs more: file-system locks coordinate individual writes, and a completed write to one file does not establish that the other shards are complete, so a multi-file generation needs an application-level publication protocol, developed in section 4.6.

The performance of a parallel file system depends on the *balance* of load across OSS nodes as well as their *number*. If a shard uses 10 of 100 equally provisioned OSS nodes, those servers offer at most 10 percent of the system's aggregate server bandwidth. Realized delivery can be lower because of client limits, request size, or insufficient concurrency. Conversely, when many concurrent readers draw on shards striped across all 100 servers, demand spreads over every server and realized bandwidth can approach the system's rating, provided the clients and network keep pace. Placement and access scheduling therefore matter alongside the number of storage servers, and a simple shard-assignment calculation shows how an imbalance can arise even when aggregate storage capacity looks ample.

Napkin Math 4.4: The thundering herd: Shard contention

Problem: A dataset is split into 1,000 shards on a shared file system. If 32 workers each pick a shard at random to start their next epoch, what is the probability that at least two GPUs "collide" on the same shard, creating a potential read hotspot? A shard collision does not imply a server collision unless the placement maps each shard to a distinct server.

Math: This is a variant of the "Birthday Problem" in probability.

1. **Probability of No Collision**: $\approx e^{-n_{\text{workers}}^2/(2K_{\text{shards}})} = e^{-32^2/2{,}000} \approx 0.60$.
2. **Probability of Contention**: $1 - 0.60 = 40\%$.

Systems insight: With 32 workers and 1,000 shards, the 40.1 percent collision probability identifies a potential storage-shard hotspot. Whether that collision delays workers depends on shard placement, caching, and available service capacity. Coordinating shard assignments can reduce this source of tail latency when assignments spread demand across independently serving devices while preserving the intended sampling policy.

At the scale of thousands of nodes, tail latency (Dean and Barroso 2013a) can dominate exposed input wait. If a training step requires data from 100 storage servers and each independently has a 1 percent chance of being slow, the probability that all 100 respond quickly is $0.99^{100} = 0.366$, meaning over 63 percent of these request sets contain at least one slow response. Shared congestion can correlate delays, changing that probability. A slow response delays the step only when prefetching fails to hide it and the required input lies on the step's critical path. When it does, the delay is not confined to one worker, because synchronous data-parallel training waits for every worker at the next collective, so one late fetch stretches the whole fleet's step.

Systems can mitigate tail latency through hedged requests: after a chosen delay, the client issues a redundant read to another replica and uses the first valid response. The trigger delay trades faster tail completion against extra work (Dean and Barroso 2013b). An independence model can multiply the probabilities of two slow replicas, but shared congestion and the later start of the hedge invalidate a simple squared-probability latency guarantee. Issuing a hedge at the median response time would duplicate roughly half of requests before accounting for cancellation; that load can worsen the congestion the scheme aims to avoid. A hedge therefore pays off only when its trigger sits in the measured tail and the duplicate traffic it adds stays within the spare service capacity.

↪ Tail latency as a serving constraint, where routing and load balancing decide which requests miss the p99 target, is developed in section 10.11.

The effectiveness of hedged requests depends on the replicated data layout. If both replicas reside on OSS nodes that share the same network switch, a switch failure makes both copies simultaneously unavailable. Effective hedging requires failure-domain-aware placement: replicas should reside in different racks, connected through different top-of-rack switches, so that the failure of any single component affects at most one replica.

In production clusters, the parallel file system is a shared utility, simultaneously servicing many concurrent training jobs with different I/O patterns. At any given moment, a large language model job might be streaming sequentially through text shards, a computer vision job might be reading random image shards, and a checkpoint storm from a third job could be saturating write bandwidth. This concurrency gives rise to the noisy neighbor problem, where one job's I/O pattern severely degrades performance for all other jobs. A checkpoint save that consumes a disproportionate share of the PFS's internal network bandwidth causes read latency for other jobs to spike, potentially stalling their training pipelines. PFS administrators mitigate this through I/O scheduling policies (quality-of-service tiers, bandwidth quotas per job), but these policies add administrative complexity and can reduce peak single-job throughput.

A related challenge is namespace isolation. Different teams and workloads require different storage configurations. A team training on millions of 100 KB images first needs to aggregate samples to reduce metadata operations; increasing stripe count does not remove per-file metadata work. A team working with large video shards can use wider striping when read sizes and concurrency exploit the additional data paths. Misconfigured striping for one team's workload can create hotspots that degrade performance for the entire shared file system. The impact of sharing is easy to quantify. A PFS with 1 TB/s aggregate bandwidth, shared across 10 concurrent training jobs, provides only 100 GB/s per job on average. If one job's checkpoint storm consumes 400 GB/s for 10 seconds, the remaining nine jobs share 600 GB/s, a 33 percent reduction that can trigger data stalls in their accelerator pipelines.

Checkpoint 4.2: Parallel file system design

Consider a training cluster with 512 nodes, each running 8 GPUs. The training job requires 400 GB/s of aggregate read bandwidth.

- ☐ **OSS count**: calculate the number of OSS nodes required when each Lustre OSS delivers 10 GB/s.
- ☐ **Metadata cost**: calculate the time required to open 200 million 116 KB image files sequentially when each `open()` call takes 50 µs on the MDS, then state the practical implication.
- ☐ **Shard count**: calculate the number of metadata operations needed to read the full dataset when images are bundled into 4 GB tar files.

Parallel file systems solve the shared-namespace problem for active training clusters, but their cost per byte is too high for the organization's complete data holdings. The petabytes of raw training data, historical checkpoints, and preprocessed datasets that an ML organization accumulates over years require a tier optimized for capacity and durability rather than bandwidth.

4.3.7 Tier 4 object storage

Keeping petabytes of raw corpora, preprocessed shards, and historical checkpoints on a parallel file system would pay high-bandwidth server rates for data that sits mostly at rest. At petabyte scale, object storage provides the durable, lower-cost foundation of the hierarchy. Services like Amazon S3 and Google Cloud Storage organize data in object namespaces where objects are retrieved by keys rather than by POSIX directory paths (Amazon Web Services 2026c; Google Cloud 2026a). Unlike file systems, which organize data in hierarchical directories with metadata-rich operations (rename, link, permission inheritance), object storage treats each object as an opaque blob identified by a unique key. The simpler interface changes the namespace operations exposed to clients; the service still manages metadata for placement, versions, access control, and integrity as capacity grows.

Services such as Amazon S3 publish an "eleven nines"[9] annual durability target (99.999999999 percent). Erasure coding,[10] replication, placement, and repair contribute to storage protection, but a coding scheme alone does not establish a service's durability target. Selecting a source-of-truth tier for training data and checkpoint archives requires checking the chosen service's failure model alongside versioning, lifecycle policy, access control, and recovery testing.

Three different guarantees govern whether that source of truth is usable. Durability asks whether acknowledged data survives failures; availability asks whether the storage service responds when a client needs it; and consistency asks which version a read is allowed to observe when writes overlap or replicas disagree. Replication can improve durability and availability without by itself guaranteeing that a reader sees the newest committed checkpoint. A recovery design must therefore state all three properties instead of treating a durability percentage as a complete reliability contract.

> **Definition 4.3: Erasure coding**
>
> ***Erasure coding*** protects stored data by adding redundant fragments, with the Reed-Solomon scheme considered here encoding d data and m parity blocks so that any d remaining fragments recover the original.
>
> 1. **Significance**: Coding can protect against fragment loss with less capacity overhead than full replication. A 4+2 Reed-Solomon code stores four data fragments and two parity fragments, tolerating two unavailable fragments at 1.5× storage overhead instead of the 3× overhead of triple replication. Actual durability also depends on failure correlation, placement, detection, and repair.
> 2. **Distinction**: Unlike replication (which stores complete copies), erasure coding uses mathematical encoding (for example, Reed-Solomon) to distribute redundant information across different failure domains (disks, racks, or sites).

[9] **Eleven nines (99.999999999 percent durability)**: A design target of 11 nines annual durability corresponds to an expected loss probability of about 10^{-11} per object-year; for one million objects, that is about one expected object loss per 100,000 years.

[10] **Erasure coding**: Built on Reed-Solomon codes (Reed and Solomon 1960), which use maximum-distance-separable coding to recover the original data from any sufficient subset of encoded fragments. In storage systems, Reed-Solomon-style codes and later local-reconstruction variants trade storage overhead against repair bandwidth and degraded-read cost (Plank 1997; Huang et al. 2012). Local-reconstruction codes, for example, read fewer surviving fragments to rebuild a lost one, cutting repair traffic at the price of a little extra capacity.

3. **Common pitfall**: A frequent misconception is that erasure coding is "free durability." In reality, it is a latency-compute trade-off: reconstructing data after a failure requires additional CPU cycles and increases the p99 latency of the storage read.

Erasure coding lets the service recover data without requiring the training application to manage fragments. In the form considered here, the service retains the original d data fragments alongside parity, so healthy reads can use the data fragments directly. When a required fragment is unavailable, reconstruction uses surviving data and parity fragments. The object interface hides that recovery procedure, but additional I/O, network traffic, and decoding can remain visible as longer read latency. Protection against data loss does not imply unchanged service time during a failure.

Object storage also costs less per byte. At a representative \$0.02/GB/month, its recurring capacity rate is 5× lower than the local-NVMe rate assumed here, and section 4.8 converts that ratio into annual costs for a 100 TB dataset. Comparing it with HBM acquisition cost additionally requires a hardware lifetime and utilization assumption. This cost advantage makes object storage a common home for the organization's training data lake, where raw data, preprocessed datasets, and archived model artifacts can reside durably.

Request latency also matters. Design estimates use 50 to 100 ms for an object GET as a representative planning range rather than a universal service guarantee. Much of that delay is the price of the indirection that provides durability. The service looks up the object's location in a distributed metadata index, determines which fragments to read, fetches them from potentially different storage nodes, and reconstructs data when a fragment is unavailable, all on top of the client network path and queueing. Large transfers amortize per-request overhead across more bytes, while small transfers can spend most of their elapsed time on that overhead. Request size and concurrency therefore enter the delivery budget alongside aggregate bandwidth.

The remedy is the shard packaging of section 4.3.5, applied here to request latency rather than metadata operations. Formats like WebDataset (Aizman et al. 2019) or Mosaic Streaming (Databricks 2026) bundle samples into multi-gigabyte shards that transform high-latency random access into high-bandwidth sequential streaming. Rather than issuing billions of small GET requests, the data loader issues hundreds of large reads in parallel, each fetching an entire shard that contains thousands of samples. With sufficient parallelism and colocated network capacity, object storage can sustain high aggregate throughput, enough to feed large training clusters for some workloads. The streaming pattern works by assigning each data loader worker a subset of shards and having it read them sequentially. Within each shard, samples are stored contiguously, so the worker decodes them in order and shuffles them in a local buffer. This approach achieves pseudo-random access across the dataset while maintaining sequential I/O at the storage level.

The architecture of a streaming data loader for object storage differs from a local-storage loader in important ways. A local-storage loader can use memory-mapped I/O to treat the dataset as a virtual memory region, relying on the operating system's page fault mechanism to load data on demand. This approach is elegant but incompatible with object storage, which does not support the POSIX file system interface that memory mapping requires. Instead, an object-storage loader must explicitly manage HTTP connections, issue ranged GET requests for specific byte ranges within shards, handle retries on transient failures, and manage a local buffer pool for decoded samples. Libraries like WebDataset and Mosaic Streaming encapsulate this complexity, presenting a simple iterator interface to the training loop while managing the HTTP transport and buffering internally.

Applying this streaming architecture to the running example makes the design concrete as an alternative to the staged path the chapter adopts. Instead of copying shards to local NVMe at job start, the cluster would read them from the object store throughout the run. The tokenized training set is stored in an S3-like object store as roughly 2,000 shards of 3 GB each. The streaming architecture assigns each of the 256 compute nodes a unique subset of roughly 8 shards. Within each node, 8 data loader worker processes issue concurrent HTTP `Range` requests to fetch 256 MB chunks from their assigned shards. Across the cluster, this results in 2,048 concurrent requests, allowing aggregate throughput in the 50–100 GB/s range when the object store and network path are provisioned for it, far exceeding the roughly 167.8 MB/s required by the generic text job in the text-versus-image comparison. The running example's average input demand is lower still. At these provisioned service rates, the network between the compute virtual private cloud (VPC) and the object-storage endpoint can limit maximum streaming throughput without making input delivery the running job's bottleneck. Organizations that co-locate compute and storage in the same cloud availability zone can reduce cross-network latency, directly reducing the required prefetch buffer depth and improving overall pipeline efficiency.

That request parallelism is what object storage rewards. Each of the 2,048 GET requests is independent and can be served by a different storage node within the cloud provider's infrastructure, and the count grows with the fleet. With each request fetching a 256 MB chunk of a shard, the aggregate throughput depends on the cloud provider's network capacity, internal bandwidth, and request-rate quotas. The practical limit is often the network bandwidth between the compute cluster and the object storage service, not the storage service's internal media bandwidth.

Many object storage services provide strong read-after-write consistency, which means that a subsequent read of an acknowledged object sees the completed write. Amazon S3 announced strong read-after-write consistency for object writes and overwrites, together with strongly consistent listing, in December 2020 (Amazon Web Services 2020). The relevant contract is the documented behavior of the chosen backend, not a blanket assumption about object storage. Per-object consistency

still does not make a checkpoint spanning many objects atomic, so the publication protocol of section 4.6 applies here as it does on a file system.

The scale of ML datasets makes them vulnerable to silent data corruption: subtle bit flips in the storage medium or during network transfer that can introduce training artifacts nearly impossible to diagnose. Object storage services provide per-object checksums that verify integrity on upload, copy, or download; Amazon S3, for example, documents checksum options including CRC-family and cryptographic hashes (Amazon Web Services 2026a). Parallel file systems often rely on underlying RAID or erasure coding for physical integrity but may not provide end-to-end checksums visible to the application. A well-engineered large-scale ML pipeline computes and stores a checksum for each data shard during preprocessing and verifies it when the shard is first loaded by a training worker. The verification overhead is negligible compared to the cost of training on corrupted data, and checkpoints need the same check, because a flipped bit in restored state can make training diverge silently after recovery.

↪ Detecting and verifying silent data corruption across the fleet, including in restored checkpoints, is developed in section 7.5.

Training datasets can contain sensitive information, including personal data, proprietary text, and licensed images. Storage design must carry the organization's access and retention policies through every copy. Object services expose identity policies and encryption options; parallel file systems provide POSIX permissions and access-control lists. Audit coverage and enforcement depend on the configured platform, not the tier's name. Versioned manifests should identify derived shards and retained copies so that access reviews, retention decisions, and deletion workflows can locate the relevant artifacts; a deletion request, for example, must reach every immutable preprocessed shard derived from the deleted record. Storage controls protect stored bytes; evaluating what a trained model retains requires additional model-level analysis.

The transition from Tier 4 to Tier 5 is driven primarily by economics. Data that is accessed rarely should move to archive storage when retrieval latency and governance requirements allow it, because archive capacity is cheaper still.

4.3.8 Tier 5 archive and cold storage

Archive services such as S3 Glacier preserve rarely accessed lineage—superseded checkpoints, raw source corpora, and training logs—over multi-year horizons so that a deployed model can still be reproduced or audited years after its run ends. At a representative \$0.004/GB/month, archive storage is 5× cheaper than the \$0.02/GB/month object-storage assumption used in section 4.3.7, trading that lower capacity rate for retrieval latency measured in minutes to hours and making this tier unsuitable for operational access. The record at stake is training data provenance: the link from a deployed model to the exact data versions, hyperparameters, and preprocessing that produced it. The organization's governance policy determines which records to retain and for how long, and the storage design must keep them identifiable and retrievable for that period; archive serves when its retrieval delay meets the requirement, while records needed during frequent investigations may justify a warmer tier.

Automated lifecycle policies govern the transition of data between tiers based on access recency. As one illustration of how such automation is expressed, a time-based rule for ML infrastructure might move checkpoints as follows. The most recent three checkpoints remain on the parallel file system for fast recovery. Checkpoints older than 72 hours are transitioned to object storage, and checkpoints older than 90 days are transitioned to archive storage. Checkpoints older than two years are deleted unless flagged for regulatory retention. S3 Lifecycle rules provide the same general transition/archive/delete mechanism for object lifetimes (Amazon Web Services 2026b). The running example's checkpoint retention in section 4.6 adopts a count-based variant of the same idea, where the transition rule keys on checkpoint count rather than age. Without automation, teams either hoard data on expensive tiers (wasting budget) or delete data too aggressively (losing reproducibility). The lifecycle policy encodes the organization's cost-recovery trade-off in a declarative rule that requires no manual intervention.

For the 175B model training run, the archive tier holds the complete training lineage: the raw 3 TB compressed source corpus, the 6 TB serialized shard set, all preprocessing scripts, the final checkpoint, and a sampled subset of intermediate checkpoints. Capacity must include every retained full checkpoint as well as both corpus representations; table 4.5 computes that total for the declared retention policy. A round dataset-only allowance would underprovision the archive. The asymmetry between archive cost and compute cost makes retention inexpensive relative to the run it documents; failures to archive usually reflect missing lifecycle ownership, unclear retention policy, or retrieval-process neglect rather than raw capacity cost.

Archive storage services offer multiple retrieval speed tiers, each with different pricing. In an S3 Glacier-style service, standard retrieval may complete within hours at moderate cost, expedited retrieval may complete within minutes at a higher cost, and bulk retrieval may trade still more latency for the lowest retrieval price (Amazon Web Services 2026d). The choice of retrieval tier depends on the urgency of the use case. Forensic analysis of a production incident warrants faster retrieval; annual compliance audits can use slower bulk retrieval. Designing the lifecycle policy requires understanding the storage cost, the expected retrieval frequency, and the urgency for each class of data.

The six tiers now have their roles, capacities, and prices, but a role does not say how fast bytes must climb the hierarchy. That rate is set by the accelerators consuming them, and it is the next quantity to derive.

4.4 The Data Pipeline Equation

Whether a training job streams from object storage or reads from local NVMe, each worker's next batch must reach HBM before the current compute step finishes; falling short starves the fleet's accelerators, while provisioning far above demand strands capital in idle storage bandwidth. Sizing the hierarchy therefore begins by turning the accelerator consumption rate into a required byte rate. The data

pipeline throughput equation in equation 4.2 quantifies the bandwidth the pipeline must sustain for a target training rate:

$$\mathrm{BW}_{\mathrm{required}} = N_{\mathrm{GPU}} \times \eta_{\mathrm{target}} \times \frac{D_{\mathrm{vol}}^{(\mathrm{batch})}}{T_{\mathrm{compute}}} \tag{4.2}$$

where N_{GPU} counts accelerators consuming distinct local input batches, η_{target} is the target fraction of wall-clock time spent computing (typically 0.8 to 0.95), $D_{\mathrm{vol}}^{(\mathrm{batch})}$ is one local batch in bytes, and T_{compute} is its uninterrupted compute time. This utilization is an active-time fraction, not model FLOPs utilization. If iteration time already includes stalls, multiplying by utilization again would count the slowdown twice. Eliminating sustained input stalls requires supplying batches at the full compute rate; the target fraction sizes a lower accepted training rate. Devices that cooperate on one batch do not each require an independent storage read, so their shared input must be counted once at the tier being sized. The text-versus-image comparison of notebook 4.1 already applied this equation with $\eta_{\mathrm{target}} = 1$; the equation makes the target fraction explicit, and the service chain below adds the requirement that every stage, rather than the accelerator-facing endpoint alone, meet the resulting rate.

The demand equation sizes the accelerator-facing endpoint, but bytes must traverse the complete service chain. Let r_j denote the measured service rate of stage j, including object-store reads, network transfer, decoding and augmentation, host-memory copies, and host-to-device transfer. Express all rates in the same output-equivalent bytes per second, using each stage's expansion or compression ratio; raw compressed-read bandwidth cannot be compared directly with decoded-tensor bandwidth. With bounded buffers and no sustained backlog, the pipeline can deliver at most

$$r_{\mathrm{pipeline}} = \min_j r_j, \qquad r_{\mathrm{pipeline}} \geq \mathrm{BW}_{\mathrm{required}}. \tag{4.3}$$

Capacity at one tier cannot compensate for a slower downstream stage. Compression may raise the storage-read rate while lowering the decode rate; additional loader workers may raise decoding throughput while saturating the host-memory or PCIe stage. The end-to-end inequality in equation 4.3 therefore turns the chapter's hierarchy into a testable contract. Measure every stage under representative concurrency, then provision or overlap the stage whose service rate is the minimum.

The throughput equation in equation 4.2 exposes four levers on storage demand, and none of them is free. Reducing the accelerator count (N_{GPU}) lowers aggregate input demand by reducing the number of distinct consumers, but it lowers training throughput with it, whereas lowering target utilization (η_{target}) relaxes the delivery rate only by accepting idle accelerators. Decreasing the per-batch data volume ($D_{\mathrm{vol}}^{(\mathrm{batch})}$) through a more compact representation of the same samples helps only while decoding keeps pace. Shrinking the batch itself changes the training configuration and its statistical efficiency. Conversely, increasing compute time (T_{compute})

gives storage longer to deliver each batch, at the cost of proportionally longer iterations. This is also why a faster accelerator can expose an input bottleneck that a slower one hid. The equation therefore sizes the pipeline for a chosen training configuration; deliberately slowing useful computation does not improve delivery.

The consequences of falling short are captured by the **data stall ratio**, defined in equation 4.4 as the fraction of each training step where the accelerator waits for data:

$$\text{Data Stall \%} = \frac{T_{\text{step}} - T_{\text{compute}}}{T_{\text{step}}} \times 100 \tag{4.4}$$

The data stall ratio covers one worker's input path with communication excluded, so its T_{step} is compute plus exposed input wait. The Fleet Law of section 1.5.4 carries no input-wait term, so it implicitly treats the next batch as already resident. Whatever input wait the loader fails to hide adds to the distributed step on top of $T_{\text{comm}}(N)$ and $T_{\text{sync}}(N)$, as compute (C_1) capacity that sits idle while storage catches up. In a real distributed job, the gap $T_{\text{step}} - T_{\text{compute}}$ also contains exposed communication and synchronization, so the ratio implicates storage only when that gap is measured as time spent waiting on the input queue, separately from collectives and barriers. Without overlap, step time adds compute and I/O time. Pipelining reduces step time to the longer of the two durations and stall time to the positive difference between I/O and compute.

Napkin Math 4.5: The data stall ratio

Problem: A GPU processes a batch in 200 ms, but storage takes 250 ms to deliver the next batch. What fraction of each training step is the accelerator idle, and how much does pipelining I/O with compute reduce that stall?

Without pipelining (sequential I/O then compute):

$$T_{\text{step}} = T_{\text{IO}} + T_{\text{compute}} = 250 + 200 = 450 \text{ ms}$$

$$\text{Stall \%} = \frac{250}{450} = 55.6\%$$

With pipelining (I/O overlapped with compute):

$$T_{\text{step}} = \max(200, 250) = 250 \text{ ms}$$

$$\text{Stall \%} = \frac{250 - 200}{250} = 20\%$$

Systems insight: Even with pipelining, the accelerator is idle 20 percent of the time. To eliminate the stall entirely, the next batch must arrive within the 200 ms compute window, either by increasing effective storage bandwidth or by adding parallel I/O streams. Deeper prefetch buffers cannot help here,

because the delivery time exceeds the compute window on every step rather than merely in the tail.

The data stall ratio measures time lost waiting for inputs relative to the chosen iteration window. Acceptable stall time depends on the fleet's cost and throughput objectives; a threshold is a policy choice, not a universal storage-health boundary. Instrument batch-ready times and accelerator execution in the same trace to distinguish input starvation from synchronization, CPU preprocessing, and other idle intervals. General profiling tools can expose these events, but an idle accelerator alone does not identify storage as the cause.

A storage pipeline that met its budget at launch can drift out of it as datasets grow, jobs contend, and drives age, so it requires continuous monitoring to keep silent bottlenecks from eroding training efficiency. Key metrics to track in real time include per-tier bandwidth utilization (NVMe, network, object storage), prefetch buffer depth (how many batches are queued and ready), the data stall ratio per GPU, the parallel file system's metadata operation rate, and NVMe drive health indicators (wear level, temperature, error counts). Alert thresholds should trigger before stalls become visible in training loss curves. An undetected 5 percent increase in data stall ratio across the 1,024-GPU reference cluster (half the running cluster) for just one week wastes about $17,203 in idle compute (1,024 GPUs $\times$ $2/GPU-hour $\times$ 168 hours $\times$ 5 percent). Comprehensive storage monitoring is therefore a first-order economic concern rather than an operational nicety.

↪ An I/O-wait efficiency target for the fleet Data axis is developed in section B.10.4.

Diagnose a storage stall at three levels. The application timeline identifies when the accelerator waits; per-worker rates and queue depth identify the pipeline stage that falls behind; device and shared-server counters show which resource limits that stage. Correlating those observations distinguishes a byte-bandwidth shortage from metadata contention or insufficient decoding capacity. Because a small development dataset may hide the contention and accumulated state of a production run, a pipeline stress test should use representative data volume and concurrency and run long enough to expose queue depletion, resource leaks, and memory pressure before the loader is coupled to an expensive training job.

The terms in equation 4.2 explain why the chapter's workloads place such different demands on the same cluster. In the bandwidth comparison of notebook 4.1, image classification with ResNet-50 on ImageNet combines large compressed samples (116 KB per image on average) with short iteration times (100 to 200 ms), pushing $D_{\text{vol}}^{(\text{batch})}/T_{\text{compute}}$ high, whereas language-model pretraining packs 4,096 4-byte token IDs into 16 KB per sequence even though total volume over the run still reaches trillions of tokens. Recommendation model training, the Archetype B (DLRM at Scale) workload, combines both access modes: embedding lookups require high-IOPS random access to the embedding table while the dense layers stream sequential training batches. Which storage tier binds therefore follows the workload's access profile rather than cluster size alone. Archetype C (Federated MobileNet) falls outside this shared-storage analysis, because its raw training data

stays on the devices that produce it; there is no central corpus to stage, and its storage constraints become per-device capacity and upload limits.

↪ On-device training data and federated updates are developed in chapter 11.

MLPerf Storage measures these profiles on production storage systems. Each submission emulates a set of accelerators that consume samples with a fixed per-sample compute time, so the storage system, not a real GPU, sets the pace, and reports the read throughput the system sustained while keeping the emulated accelerators at least 90 percent busy (70 percent for CosmoFlow) (MLCommons 2024; Devarajan et al. 2021). Across the 124 passing results of the closed division in the 2024 round, sustained throughput grows in proportion to the number of emulated accelerators, as the N_{GPU} term of equation 4.2 predicts (figure 4.3, panel a). Per accelerator, the median demand differs about 15× across workloads, and ResNet-50, although demanding among image-classification jobs, is the lightest of the three because its samples are small 2D images while 3D U-Net reads whole medical volumes. An emulated H100 needs about 2.8 GB/s for 3D U-Net on medical volumes, 0.55 GB/s for CosmoFlow, and 0.18 GB/s for ResNet-50 (figure 4.3, panel b). Emulating H100s instead of A100s raises every workload's demand by 1.6–2×, because the faster accelerator shortens T_{compute} while the bytes per batch stay the same. A storage tier sized for one accelerator generation is therefore undersized for the next, even when the dataset and the model do not change.

In an ideal overlapped pipeline, the bandwidth-to-demand ratio bounds the compute active-time fraction (figure 4.4). With input demand defined as batch bytes divided by uninterrupted compute time, the frontier ramps linearly through bandwidth-starved operating points before flattening at the supply-equals-demand saturation knee (ratio = 1). The active fraction is the smaller of one and available bandwidth divided by that demand, assuming no other bottleneck.

Below matching supply, bandwidth increases raise the ideal active fraction proportionally. Above it, more bandwidth does not improve this ideal compute stage, although headroom can help absorb contention and variable delivery. The markers show how far apart the chapter's workloads sit. Served by the whole 1 TB/s parallel file system, the text job of notebook 4.1 has about 6,000× more bandwidth than it consumes, the image job only 3.3×, and the pipeline of notebook 4.5 sits left of the knee at 80 percent active time. Real systems can fall below the curve because of preprocessing, latency tails, or synchronization. The graph identifies a workload service-rate boundary; it does not establish that every job needs every storage tier.

Because $\text{BW}_{\text{required}}$ grows linearly with N_{GPU}, adding compute nodes against a fixed shared file system moves any workload leftward along figure 4.4 until supply equals demand; past that saturation knee, additional GPUs add cost without raising training throughput, and equation 4.2 locates that limit from the storage tier's measured bandwidth. Even to the right of the knee, however, the frontier in figure 4.4 assumes that storage reads and CPU preparation overlap computation completely and that latency spikes never empty the input queue. Achieving that overlap in practice requires pipelining the loader stages and sizing a prefetch buffer deep enough to absorb tail delays.

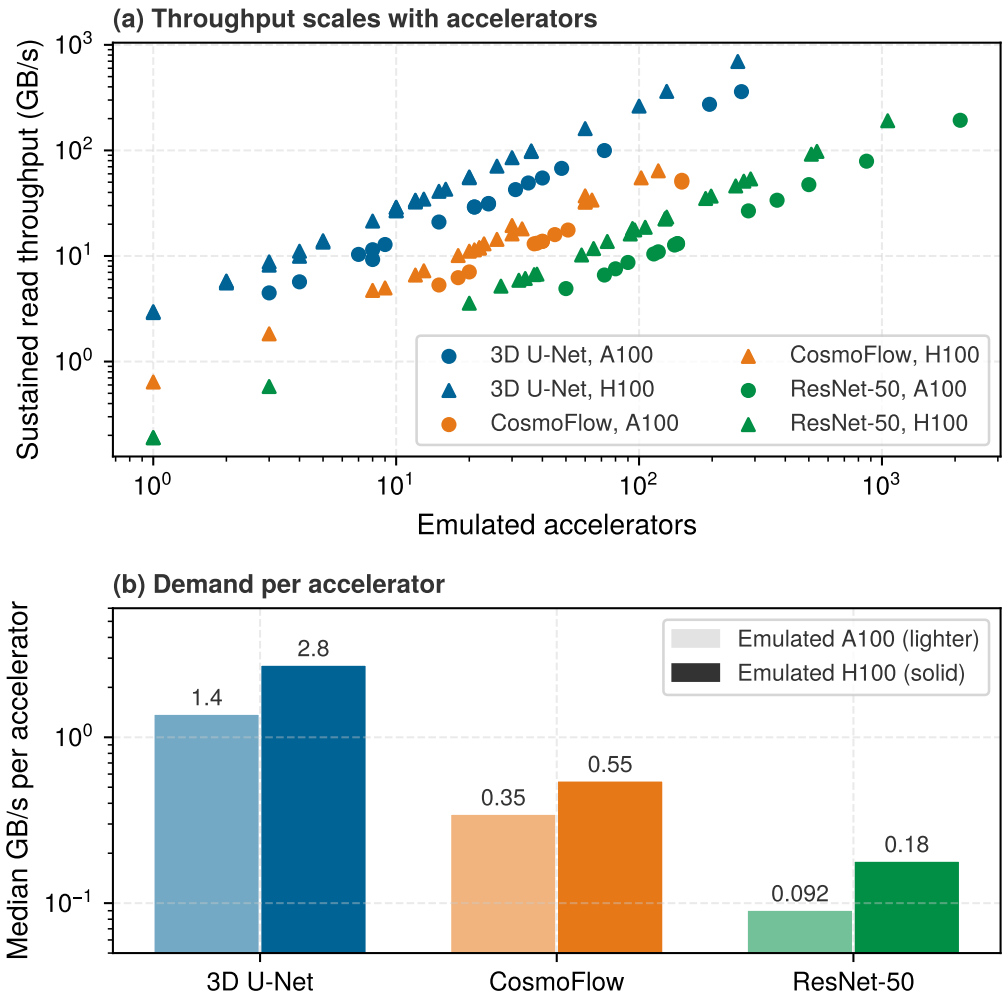

Figure 4.3: Measured Storage Demand per Accelerator: (a) Read throughput sustained by each passing closed-division MLPerf Storage v1.0 submission against its number of emulated accelerators, on logarithmic axes, by workload (color) and emulated accelerator (marker); throughput grows in proportion to the accelerator count. (b) Median throughput per emulated accelerator for each workload and accelerator, on a logarithmic axis. Accelerators are emulated with a fixed per-sample compute time and must stay at least 90 percent busy (70 percent for CosmoFlow); the values measure storage systems under that load, not real GPUs. Data from MLCommons (2024).

4.4.1 Pipelining and prefetching

When a data loader waits until the GPU finishes batch k before reading and decoding batch $k+1$, the accelerator sits idle across the entire storage read and CPU preparation window on every step, as panel (a) of figure 4.5 shows. Pipelining removes that synchronous stall by staging and preparing batch $k+1$ on host resources while the GPU trains on batch k, turning the sum of input and compute time into their maximum (section A.2.1). When delivery keeps pace and enough prepared work sits in host memory to absorb latency variation, four batches finish in about the time sequential loading needs for two (panel (b)); at fleet scale, the open question is how deep that buffer of prepared work must be.

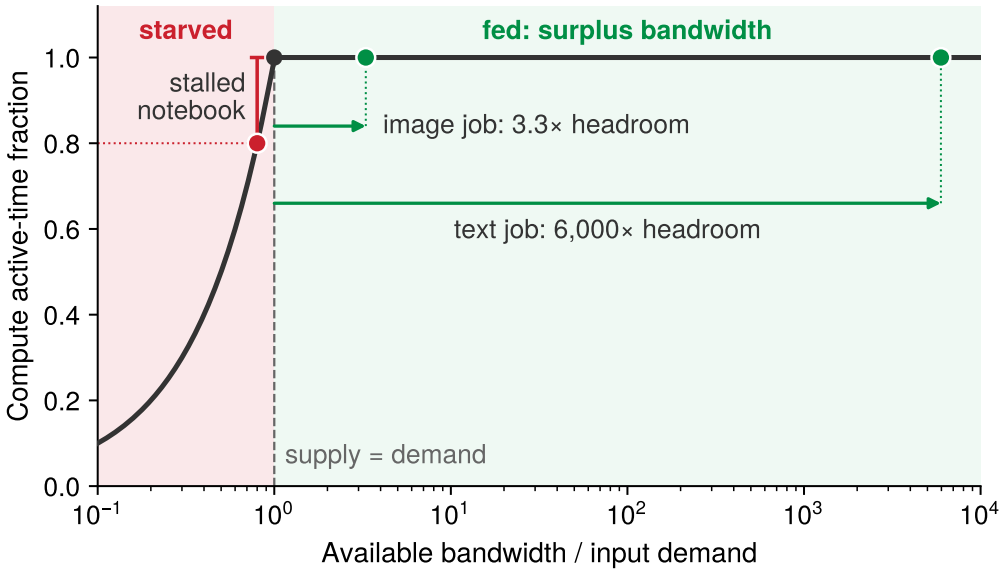

Figure 4.4: The Data-Stall Frontier: In the ideal overlapped pipeline, the compute active-time fraction is min(1, available bandwidth / input demand), plotted against a logarithmic bandwidth ratio. Markers place three of the chapter's workloads on the curve: the data-stall notebook's pipeline, whose delivery time exceeds its compute window, and the image and text jobs of the text-versus-image bandwidth comparison, each served by the whole parallel file system; arrows from the knee measure each fed job's bandwidth headroom. The curve is an ideal service-rate bound, not an empirical utilization curve or a claim about a storage technology.

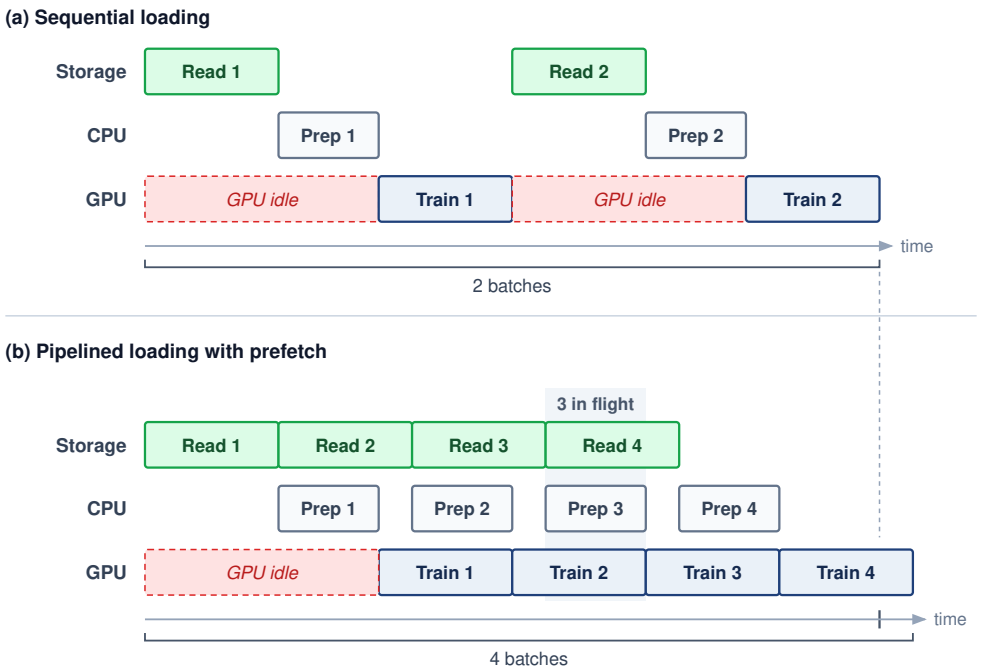
Pipelining converts a sequential bottleneck into overlapped execution (figure 4.5), but continuous saturation requires a prefetch buffer deep enough to absorb variance in I/O latency. Stage durations need not be deterministic if ready batches cover the delays. Storage systems experience I/O jitter: variation in read latency caused by contention and background work. NVMe drives suffer occasional latency spikes during internal garbage collection (when the controller reorganizes NAND flash blocks) or wear-leveling operations. Parallel file systems incur spikes when multiple training jobs contend for the same OSS nodes, when the MDS processes a burst of metadata operations, or when background scrubbing detects and repairs bit errors. Object storage likewise exposes delays from shared-service contention and maintenance.

A single slow I/O creates a "bubble" when it exhausts the pipeline's ready work. If the CPU is preparing batch $k+1$ with no additional batches ready, a delayed read can leave batch $k+1$ unavailable when the GPU finishes batch k. The GPU then idles until the batch is ready. A longer queue tolerates a longer interruption, and delivery faster than consumption can refill it afterward. Rather than preparing just one batch ahead, the CPU maintains a queue of N_{prefetch} preloaded batches.

A buffer sized to the measured p99 I/O delay needs enough ready batches to cover that delay without draining:

$$Q_{\text{prefetch,min}} = \left\lceil \frac{T_{\text{IO,p99}}}{T_{\text{compute}}} \right\rceil \tag{4.5}$$



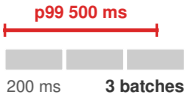


Figure 4.5: Pipelined Data Loading: Both panels share one time scale, with illustrative stage durations. Sequential loading (a) leaves the GPU idle while each batch is read and prepared. Pipelined loading (b) reads and prepares batch $k+1$ while the GPU trains on batch k, so four batches finish in about the time sequential loading needs for two (dashed line). The shaded column marks one instant with three batches in flight. The overlap hides storage latency only while delivery keeps pace with compute and the prefetch buffer is deep enough to absorb variance.

The prefetch depth equation in equation 4.5 estimates how many ready batches cover the selected latency window. Outstanding reads contribute to replenishing that buffer but do not count as ready batches until they complete. The equation assumes that the long-run data supply rate is at least as high as the accelerator's consumption rate; prefetching absorbs latency variance, not a sustained bandwidth deficit. When average throughput is sufficient but p99 latency exceeds compute time, deeper prefetching absorbs delays within the provisioned window; rarer or correlated delays can still cause stalls. When sustained delivery is lower than demand, identify the limiting stage before choosing more storage bandwidth, additional decoding capacity, a different representation, or local staging. The equation uses the p99 delay rather than the mean because a buffer sized for the mean drains whenever a slow read arrives, and the tail-latency arithmetic of section 4.3.6 shows that when a step depends on many servers, some read is slow on most steps. Even the p99 window leaves rarer events and correlated interruptions to test.

If object-storage reads take 500 ms at the 99th percentile and compute takes 200 ms, then $Q_{\text{prefetch,min}} = 3$ batches; provisioning five ready batches adds a margin. A data loader's configured work-ahead count (for example, a per-worker prefetch factor) is not a count of ready batches, because some of that work may still be loading or preprocessing. The quantity that protects the accelerator is

A 500 ms p99 read spans 2.5 steps of 200 ms, so three ready batches must cover it.

completed-queue occupancy and its refill rate, measured against the delay window on whichever tier serves the reads.

To illustrate the memory cost of prefetch buffer depth, return to the image job of notebook 4.1. Each GPU processes its batch in roughly 200 ms, and once its 256 images are decoded into $224 \times 224 \times 3$-byte tensors, the collated batch occupies about 40 MB per GPU. Reading from local NVMe, the p99 I/O latency for that batch is approximately 50 ms. Under the p99-window model, the minimum ready-buffer depth is $\lceil 50/200 \rceil = 1$ batch, and this example provisions a depth of 2. Reading from a parallel file system, the p99 I/O latency rises to roughly 200 ms due to network jitter and contention, requiring a minimum depth of $\lceil 200/200 \rceil = 1$, with an illustrative provisioned depth of 3. Reading from object storage, the p99 latency can exceed 500 ms, requiring a depth of at least 3, with an illustrative provisioned depth of 5 or more. These numbers translate directly into host DRAM consumption. At 40 MB per batch, a depth-5 prefetch buffer per GPU consumes 200 MB, and 8 GPUs per node consume 1.6 GB. At 40 MB per batch with a depth of 1, the same node needs only 320 MB. Measured delivery delays, batch size, and the chosen protection window determine this memory budget. Queue occupancy and refill rate must still be tested under correlated delays.

The representation decides whether that depth is cheap. Text barely registers, because a per-GPU batch of a few packed 4,096-token sequences occupies tens of kilobytes, so even a deep text queue is negligible. Decoded images are where depth costs memory. The 256-image batch above is roughly 39 MB before rounding, and a buffer of 8 such batches consumes about 308 MB per GPU, modest against a node's 512 GB of DRAM even after multiplying by the GPUs on the node. Higher-resolution images and video raise the per-batch size by an order of magnitude or more, at which point the prefetch buffer competes with embedding tables and other DRAM consumers.

Prefetching and the storage hierarchy together form a layered defense against stalls. The prefetch buffer in host DRAM absorbs I/O variance from NVMe reads. The local NVMe warm cache absorbs network variance from shared storage (whether a parallel file system or an object store). The parallel file system read-ahead cache absorbs variance from disk seeks across the OSS cluster. Because each layer adds latency tolerance at the cost of memory or storage capacity, the system designer must check each active path against the interruption window it is intended to absorb and verify that sustained delivery replenishes the consumed batches. The running example's shards come from object storage, whose 500 ms p99 against a 200 ms step would call for 3 ready batches if every read went to that tier. Once the shards are staged on local NVMe, every training read is a local hit, and the prefetch buffer needs to absorb only the 50 ms local p99, which a single ready batch covers.

Checkpoint 4.3: Data pipeline design

A training cluster the size of the book's reference cluster runs 1,024 GPUs with 128-image batches (116 KB per image after compression, 150 ms per iteration).

- ☐ **Bandwidth requirement**: with the pipeline bandwidth requirement of equation 4.2, which scales accelerator count and target utilization by bytes per iteration, calculate the required aggregate storage bandwidth at 90 percent target utilization.
- ☐ **Checkpoint contention**: determine whether 800 GB/s aggregate parallel-file-system bandwidth is sufficient, then recalculate when checkpoint writes consume 20 percent of that bandwidth.
- ☐ **Prefetch depth**: calculate the minimum prefetch buffer depth in batches needed to absorb 300 ms p99 object-storage latency.
- ☐ **Host memory**: calculate total prefetch buffer memory when each decoded batch occupies 10 MB in host DRAM at the depth calculated in (3).

4.4.2 Multi-worker data loading

A single CPU core cannot keep a high-throughput accelerator fed, even when the storage hardware is fast enough, because of the CPU work required between the storage read and the GPU transfer. For image training, decoding a 116 KB JPEG image into a $224\times224\times3$ raw tensor costs several milliseconds of CPU time. One measurement decoded full-resolution ImageNet images at about 530 per second across the four virtual CPUs of a cloud inference instance (Kang et al. 2020), and each augmentation, such as a random crop, flip, or color jitter, adds further work per image. The image job of notebook 4.1 feeds each GPU 256 images every 200 ms step, more than 1,000 images per second. At 1,000 images per second per GPU and 8 GPUs per node, a single core would need to decode and augment 8,000 images per second, tens of times what a single core can sustain. The solution is multi-worker data loading, where W worker processes each read from storage, decode, augment, and enqueue batches independently. The effective I/O throughput scales approximately linearly with W until one of three bottlenecks is reached: the storage device's bandwidth saturates, the PCIe bus between host and device saturates, or the workers exhaust host CPU cycles.

The worker count W is tuned as on a single node, by profiling the data stall ratio, since too few workers starve the GPU and too many waste CPU on contention. At fleet scale, every core given to loading is a core the training runtime, communication threads, and operating system cannot use, so dividing host CPU between data loading and training orchestration is itself a capacity planning exercise. How those workers exploit concurrency then depends on which tier serves their reads. On local NVMe, workers issue concurrent reads to the same RAID array and rely on NVMe's deep command queues to expose device parallelism until shared drive or controller capacity saturates. On a parallel file system, they distribute reads

across different OSS nodes to aggregate server bandwidth. On object storage, they issue concurrent HTTP GET requests to distinct shards.

Multi-worker loading must also preserve shuffle quality without giving up I/O efficiency. Under the shard-level and within-shard shuffling of section 4.2, the loader assigns contiguous groups of the shuffled shard list to each worker, and the adequacy of that mixing depends on how the shards were built. A corpus whose shards are internally homogeneous, such as one source or one class per shard, needs finer shards or a larger shuffle buffer, so the layout should be validated against the loss curve of a fully shuffled baseline on a subset before the run commits to it.

The shuffle buffer size creates a memory-randomness trade-off. A larger buffer provides better randomness (because samples are drawn from a larger pool) but consumes more host DRAM. For the running example with text data, a shuffle buffer of 10,000 sequences at 2,048 tokens each, with each token represented as a 4-byte integer, consumes roughly 82 MB. This is negligible relative to the 512 GB of host DRAM. For image data, where each decoded image occupies 151 KB, a shuffle buffer of 10,000 images consumes 1.5 GB, still manageable but a nontrivial fraction of the prefetch budget. The data loader designer must balance shuffle buffer size against prefetch depth, since both compete for the same host DRAM capacity.

The data loading pipeline, from storage read through decode, augmentation, and transfer to accelerator, is the complete fuel delivery system for the training engine, and when any stage becomes the bottleneck the accelerator starves. Local reads can reduce network and shared-storage wait, which makes shard placement across nodes the next decision when that path limits delivery.

4.4.3 Data locality and placement

Even when a node has enough CPU workers to decode batches at full speed, fetching every shard across a shared storage network exposes the training loop to fabric congestion and remote service queues. Placing shards on node-local NVMe avoids that shared-network contention, whereas keeping them in a remote parallel file system or object store preserves a single shared pool that any node can read without copying data ahead of time. Because local NVMe's advantage depends on both the node's drive stripe and the per-client bandwidth the remote tier can sustain, placement decisions must compare measured client rates rather than assume a fixed local-to-remote ratio.

The staging decision determines where the job pays for data movement, whether before training starts, during the first epoch, or on every epoch. The simplest strategy is static placement, or *prestaging*. At the beginning of a training job, the orchestrator assigns a fixed subset of data shards to each node, and the node copies its shards from shared storage (the object store in the running example, a parallel file system in many on-premises clusters) to local NVMe drives before the first iteration. Reads remain local while the assigned shards fit and the sampling policy uses that assignment, which gives the highest steady-state throughput at the cost of the longest startup delay. Staging a 10 TB dataset across 256 nodes at 500 MB/s per node takes roughly 80 seconds under ideal conditions, and contention on

shared bandwidth can extend that stall to several minutes. A changed dataset or assignment requires restaging, so the placement policy must preserve the intended sample distribution as well as local throughput.

The alternative is dynamic placement, or *on-demand staging*, where nodes fetch shards from shared storage when the data loader first accesses them and retain them locally for reuse. This removes the upfront delay and supports datasets larger than aggregate local NVMe capacity and sampling policies that change the active subset over time, but the first epoch pays the full network-read cost. Cache misses consume shared-storage bandwidth and expose remote latency unless prefetching hides it; cache hits retain the benefit of local reads, so the pattern pays off when later epochs reread the cached shards.

Streaming keeps data off local storage entirely, reading records from the parallel file system or object store on every epoch. It has no startup delay and needs no local NVMe capacity, but every epoch absorbs the network-read cost again. On transfer cost alone, streaming suits single-epoch pretraining, which reads each byte once, and datasets that exceed the cluster's aggregate local capacity. The single-epoch running example stages anyway, for reasons of latency tails rather than transfer fees, as section 4.8 shows.

The cache view of equation 4.1 puts a number on that trade. Take the multimodal job of section 4.3.4, whose 35 TB corpus overflows a node's 30.7 TB of local NVMe. If the job samples uniformly and the cache holds that fraction of the corpus, about 88 percent of reads hit the 28 GB/s local stripe and the remaining 12 percent fall through to the node's 4 GB/s share of the parallel file system. Taking the time to deliver one byte as the service time, a serial loader averages the time per byte across hits and misses rather than averaging the two bandwidths directly, so the harmonic mean delivered rate is about 16 GB/s, only 58 percent of the all-local rate. A miss rate near one in eight costs about two-fifths of the bandwidth because each missed byte takes 7× as long as a hit, and that mean is the optimistic case; misses that cluster in time drain the prefetch buffer faster than the average suggests.

A more advanced approach is locality-aware scheduling. The scheduler keeps track of which data shards are cached on which nodes' local NVMe drives. When it starts a new job or replaces a failed node, it prefers a node that already has the required data cached, rather than treating all nodes as interchangeable. This uses the principle of data gravity,[11] co-locating compute with data to minimize transfer times. Scheduling avoids a staging copy only when an available node holds the required, validated shard versions. The next requirement is therefore to identify the cached contents precisely enough to reuse them safely.

For the 6 TB serialized dataset distributed across 256 nodes, each node is responsible for approximately 23.4 GB of data. If a node fails, its replacement must restage that shard subset from shared storage. Drawn at the uncontended 4 GB/s per-node share of the chapter's parallel file system, the copy takes about 5.9 seconds. At an effective 400 MB/s per-node rate, which recovery contention can impose and which is also the order of the per-node share of the 50–100 GB/s object-store streaming path described in section 4.3.7, the same copy stretches to about 58.6 seconds. If

[11] **Data gravity**: A metaphor treating large datasets as massive objects that attract compute. The gravitational analogy is apt: moving a 100 TB dataset out of one cloud provider to another costs roughly $9,000 in egress fees and takes hours, while launching compute next to the data is near-instantaneous. In ML fleet design, data gravity means the storage location of the training dataset often dictates the physical placement of the entire training cluster.

the orchestrator can instead schedule the replacement workload on an idle node that already has the data cached from a previous run, staging time is zero and training resumes as soon as the replacement joins. The saving is modest per event but recurs. At a per-GPU mean time between failures of 50,000 hours, the 256-node cluster sees about 1 node failure per day, and each contended restage idles the whole synchronous job for the copy time above. Larger fleets fail proportionally more often, although each node's share of the corpus shrinks as the node count grows.

The pipeline equation, the prefetch queue, the loader workers, and shard placement together determine which bytes reach host memory and when. On the conventional path, however, every one of those bytes is also copied by the CPU through host DRAM before the accelerator's DMA can start, and at high request rates that copy competes with decoding for the same cores. No amount of orchestration removes that copy; only a direct data path between storage and accelerator does.

4.5 GPUDirect Storage and the CPU Data-Copy Bypass

Even when the storage tier has enough raw bandwidth, the traditional data path for loading training data routes every shard read through three hops: storage → host DRAM → GPU HBM. Data is first read from NVMe into a kernel buffer in host DRAM by a DMA transfer, then copied by the CPU into the data loader's user-space buffer, and finally transferred over PCIe to GPU memory by the GPU's DMA engine. Each hop adds latency and consumes host resources because the CPU must orchestrate every transfer, manage buffer allocation, and handle interrupts from both the storage device and the GPU. For a single transfer, this overhead is negligible, but when eight GPUs on a node each demand thousands of small transfers per second, the aggregate CPU load for payload movement alone can saturate multiple cores and starve the data augmentation stage. GPUDirect Storage (GDS),[12] which removes that host-memory bounce copy for local or RDMA-attached NVMe while the CPU still submits and coordinates I/O through the software stack, pays off whenever that host copy limits throughput.

[12] **GDS (GPUDirect Storage)**: Part of NVIDIA's GPUDirect family, which also includes GPUDirect RDMA (network adapters writing directly to GPU memory) and GPUDirect Peer-to-Peer (inter-GPU memory access); GDS extends this data-copy-bypass approach to NVMe storage. With RDMA and GDS, payload data can traverse the path remote storage → network → GPU memory without a CPU-mediated bounce copy, while the CPU still issues and coordinates the operations.

Definition 4.4: GPUDirect Storage

GPUDirect storage (GDS) is a technology that enables a direct DMA path between NVMe storage devices and GPU memory, bypassing the system-DRAM bounce buffer and CPU payload copies while retaining CPU submission and control.

1. **Significance**: It eliminates the "bounce buffer" through system memory. In the small-transfer model detailed in notebook 4.6, the assumed active CPU service per request falls by 75 percent. That model estimates CPU capacity savings, not an end-to-end latency guarantee. Whether the storage link saturates depends on the remaining bottlenecks.

2. **Distinction**: Unlike traditional I/O, where payload data is staged through host buffers and copied between them, GDS provides direct memory access between the storage controller and the accelerator. CPU-issued I/O calls and kernel storage drivers remain in the control path.
3. **Common pitfall**: A frequent misconception is that GDS makes all storage "faster." The direct path depends on supported storage and interconnect configurations; it does not eliminate media latency, network latency, or queueing.

The software layers in the traditional I/O path contribute control overhead as well as payload-copy work. Direct I/O and pinned buffers can avoid some copies even without GDS. The correct baseline is therefore the actual data path rather than a fixed number of copies for every read. The direct path changes the payload route without eliminating the software control path. The application registers a GPU memory region for direct DMA (through the cuFile API in NVIDIA's implementation), and later reads move payload from NVMe into GPU memory without an intermediate system-memory buffer. The file system and kernel storage drivers still handle submission and completion.

The benefit from GDS matters when host payload movement is a limiting stage after other pipeline work is accounted for. In figure 4.6, the conventional path takes two DMA hops through intermediate host-DRAM bounce buffers, while GDS takes a single direct DMA transfer. The direct path eliminates the CPU payload-copy stage, but the dashed control link shows that the host CPU still orchestrates transfer submission and completion.

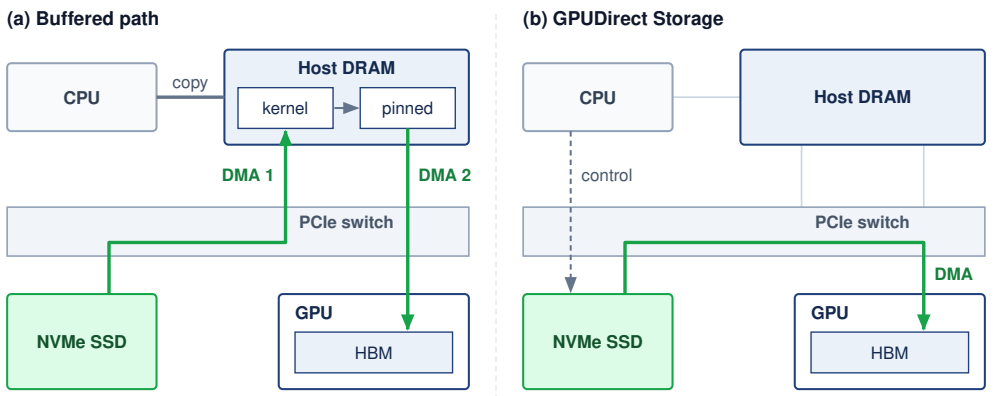

Figure 4.6: Traditional vs. GPUDirect Storage Path: Both panels draw the same node: CPU and host DRAM above a PCIe switch, NVMe and GPU below it. Green routes are DMA transfers of payload bytes. In the buffered path (a), payload climbs into host DRAM and comes back down, and the CPU copies every payload from the kernel buffer to a pinned buffer before the accelerator's DMA can start. In the GDS path (b), NVMe transfers directly into GPU memory, and the dashed CPU link shows the submission and completion work that remains.

GDS benefits depend on the bottleneck, request sizes, alignment, concurrency, and storage topology. Removing host bounce buffers can improve throughput when those copies limit the path; it does not imply that the smallest transfers

benefit most. Small I/O may remain submission- or latency-limited and require concurrency to approach the available bandwidth. Benchmarks of the direct path therefore measure I/O size and per-device behavior as well as throughput. The benefit appears only in an end-to-end comparison of the pipeline with and without the direct path, and the clearest case is the one where host CPU time per request is the limiting stage.

Napkin Math 4.6: The CPU bypass dividend

Problem: A training node with 8 GPUs loads 116 KB images at 8,000 images/s per GPU (64,000 images/s total). That rate is deliberately aggressive, several times the per-GPU image rate of notebook 4.1, to isolate the case in which per-request CPU work is the limiting stage. Assume active CPU service of 120 µs per request on the buffered path and 30 µs on the direct path. These illustrative service times exclude time blocked on I/O; compare the implied CPU load rather than treating elapsed transfer latency as CPU time.

Traditional path: In the assumed buffered implementation, each image requires a DMA from NVMe to DRAM, a host copy from kernel to user space, and a PCIe transfer to GPU. At 64,000 images/s with 120 µs of CPU time per image, the CPU spends 7.68 seconds of CPU time per wall-clock second, consuming roughly 8 cores worth of processing just for data movement.

GDS path: Each image is transferred directly via DMA from NVMe to GPU. At 30 µs of CPU time per image (for initiating the DMA), the CPU spends 1.92 seconds of CPU time per wall-clock second, freeing roughly 6 cores for data augmentation.

Systems insight: Under the assumed CPU-service costs, bypassing payload copies releases processing capacity for preprocessing. The calculation does not predict end-to-end transfer latency, nor prove that preprocessing or storage throughput can sustain this request rate.

GDS has practical limitations: not all NVMe controllers support peer-to-peer PCIe transfers, and the data must already be in a format that the GPU can consume directly (raw pixel values, token IDs, or formats handled by GPU decoders, rather than arbitrary compressed JPEG or gzip streams). In practice, many pipelines use a hybrid approach: CPU-side decoding for compressed formats followed by a normal pinned-memory GPU transfer, while GDS is reserved for direct reads of GPU-consumable data from supported local or remote storage.

The architectural evolution from CPU-mediated copies to direct storage access reflects a broader trend of removing CPU payload copies from the critical data path wherever possible. RDMA allows network payloads to move without CPU copying, while GDS provides the same bypass for storage payloads. Together, RDMA and GDS let data flow from remote storage (such as NVMe over Fabrics, or NVMe-oF), through the network fabric, and into GPU memory without a host-memory bounce copy. The CPU still submits and coordinates the operation, while more of

its capacity remains available for data augmentation, pipeline orchestration, and error handling.

The GDS design principle also extends to checkpoint writes: whereas a host-staged path transfers checkpoint bytes from GPU HBM through host DRAM to NVMe, a supported direct path can bypass that host staging for a 2,450 GB checkpoint. Removing the copy reduces T_{write} only when that movement contributes to the exposed pause; snapshot consistency, serialization, storage service, and durable publication remain separate requirements.

↩ RDMA and kernel-bypass network paths are established in section 3.4.1.

4.5.1 The complete data path

Combining GDS with the multi-tier hierarchy, the complete data path connects the tiers for the running example. At the beginning of the training job, the 6 TB serialized shard set, derived from the 3 TB compressed source corpus, is staged from object storage into the cluster's local NVMe caches, with each node receiving its assigned shard subset during setup. The data loader workers read tokenized shards from NVMe, assemble packed sequences in pinned host DRAM, and transfer those batches to the accelerator. With GDS enabled, token IDs that are already in a GPU-consumable layout can be loaded directly into GPU memory without CPU payload copying; compressed formats still require CPU or GPU decompression before use.

During steady-state training on the host-staged path, CPU data loader workers read from local NVMe and fill a prefetch queue in host DRAM. The GPU receives batches from this queue via PCIe DMA; the supported GDS alternative bypasses that host payload staging. The compute phase (forward pass, backward pass, optimizer step) consumes the batch and updates model state in HBM. Every 10 minutes, the training framework captures a consistent checkpoint, writes it to local NVMe through the chosen path, and copies it to the parallel file system in the background. The checkpoint protocol must still establish when all required shards are safe to publish for recovery.

At the end of the training job, the final model checkpoint is promoted from the parallel file system to object storage for long-term retention. The local NVMe copies are deleted during job cleanup. If the model is deployed for inference, it is loaded from object storage into the serving cluster's HBM, completing the lifecycle of data movement through the hierarchy.

The total number of data copies in this lifecycle is instructive. Each training sample traverses: object storage → NVMe (staging), NVMe → host DRAM (read), host DRAM → GPU HBM (transfer). Each checkpoint traverses: GPU HBM → NVMe (local save), NVMe → parallel file system (async copy), parallel file system → object storage (long-term retention). Every copy consumes bandwidth and contributes latency. The engineering goal is to minimize copies on the critical path (the training loop) and tolerate additional copies on noncritical paths (staging and archival). Both lifecycles cross the same tiers in opposite directions, with synchronous critical-path copies drawn solid and asynchronous background transfers drawn dashed in figure 4.7. For training inputs moving rightward, the active loop waits only on local promotion into HBM (or the optional GDS bypass); for

checkpoints flowing leftward, the exposed pause is confined to the local NVMe save while parallel-file-system replication and archival retention proceed off the critical path.

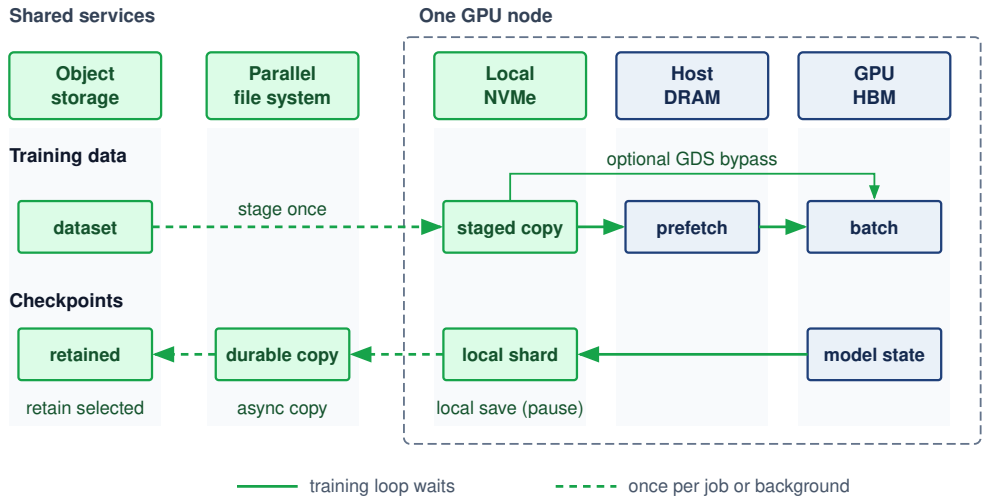

Figure 4.7: The Complete Data Path: Columns are storage tiers, ordered from the durable object store (left) to accelerator memory (right). Training data moves right and bypasses the parallel file system in this running example; checkpoints return left through it. Solid arrows mark copies the training loop waits on; dashed arrows mark copies that run once per job or in the background. The dashed outline is one GPU node: every copy the training loop waits on stays inside it.

Every copy that leaves the node also needs a network, and the choice of network decides whom a storage burst can disturb. Many training nodes carry a small number of storage-facing network adapters on a separate front-end network, in addition to one compute-fabric adapter per accelerator. Routing staging reads and checkpoint copies over that front-end network isolates them from gradient collectives, but it caps each node's storage bandwidth at a few front-end ports. Routing storage over the compute fabric offers far more bandwidth, and remote GDS reads use exactly that RDMA path, but then a checkpoint burst shares switch buffers and spine links with the job's collectives and must be separated by traffic classes. For the running example, each node's fair share of a 1 TB/s file system shared by 256 nodes is roughly 4 GB/s, and copying its roughly 10 GB checkpoint shard within the 10-minute interval needs far less, so a front-end network can carry it. Image workloads that stream hundreds of GB/s across the cluster push designs toward the compute fabric. Through the C^3 lens, storage traffic becomes communication (C_2) load the moment it leaves the node, and the network chosen to carry it decides which collectives a storage burst can delay.

Over the 30-day run, checkpointing writes roughly 10.6 PB of state against a single read of the 6 TB serialized dataset, so checkpoints, not training inputs, are the storage workload to design next. That design must take a multi-terabyte save off the training critical path without ever exposing a checkpoint that cannot be restored.

4.6 Checkpoint Storage

After the 2,048 accelerators of the running cluster have been training for six hours, a power supply failure turns checkpoint storage into the difference between resuming within minutes and repeating hours or days of lost computation. Whether the job recovers cleanly depends on three storage questions: how quickly the most recent checkpoint was saved, where its shards reside, and whether they can be read back intact. Because checkpoints are also the heaviest write workload in the hierarchy, the storage architecture must minimize T_{write}, the time the training pipeline pauses to save a snapshot, while stating when that snapshot becomes durable and visible for restore. The save interval is an input to this storage analysis; selecting it from failure rates and recovery costs is a separate reliability decision derived in section 7.8.1.

Under the resumable mixed-precision Adam contract of section 4.1, the 175B parameter model's 2,450 GB checkpoint comprises 350 GB of FP16 model weights, 700 GB of FP32 master weights, and 1,400 GB for the two FP32 Adam moments, while learning-rate-scheduler state, random-number-generator state, and the data-loader cursor add negligible bytes and gradients are recomputed after restore. When a save triggers, every participating worker process, called a rank, writes its assigned shard at once, producing the checkpoint storm introduced in section 4.2. Keeping that burst tractable requires a coordinated save that writes each unique byte once, whatever the parallel layout. In the running layout of table 4.3, the Adam moments and master weights already exist as distinct per-node slices, while the FP16 weights repeat once per node, so a coordinated save assigns each of the 256 nodes a disjoint 1/256 slice of its local FP16 weight copy to write alongside its unique optimizer slice. Spreading those unique bytes evenly gives each of the 256 nodes about 1/256 of the checkpoint. The third ZeRO stage (ZeRO-3), which partitions the weights as well, makes that even split the natural one, because every rank already owns a distinct slice. Breaking that rule is a real risk even in the running layout, where a save in which every node writes the FP16 weight copy it holds would multiply the weight bytes by the node count. Its cost is clearest in a deliberately extreme thought experiment, a smaller model whose complete resumable state is written once per GPU of the book's reference cluster.

Definition 4.5: Checkpoint storm

Checkpoint storm is a burst of synchronized network and storage traffic that occurs when all nodes in an ML training fleet save model state simultaneously.

1. **Significance**: When each replica writes its own full copy, the naive storm takes $T_{\text{write}} = N_{\text{DP}} \times \text{per-replica state}/\text{BW}_{\text{ingest}}$, where N_{DP} is the number of replicas writing at once and $\text{BW}_{\text{ingest}}$ is the aggregate rate at which the target storage tier absorbs writes. A coordinated save that writes each unique byte once takes unique state/$\text{BW}_{\text{ingest}}$. Under the chapter's checkpoint contract, a 70B-parameter model, smaller than the 175B

Writing one copy per replica takes 1,024 times longer than writing each unique byte once.

running example, stores 140 GB of FP16 weights, 280 GB of FP32 master weights, and 560 GB of Adam moments. With vanilla data parallelism across 1,024 replicas (one per GPU of the book's reference cluster, rather than the chapter's 256-node fleet), naively writing that complete state from every replica generates 1003.5 TB of simultaneous traffic. No 80 GB device can hold a 0.98 TB replica, so the case is a bound on write volume rather than a deployable layout. At 100 GB/s of aggregate storage ingest bandwidth, the write takes roughly 10,035.2 seconds, or over 167.3 minutes of training stall. A coordinated checkpoint protocol writes one logical copy. Replicated data parallelism can select one writer; ZeRO-3 instead distributes that copy across state-owning ranks. In the sharded example the total is roughly 0.98 TB, bringing T_{write} down to roughly 9.8 seconds. Gradients do not appear in either total because recovery recomputes them.

2. **Distinction**: Unlike general I/O contention (which is stochastic and unpredictable), a checkpoint storm is synchronous and periodic: every node writes at the same moment because the training orchestrator triggers checkpoint after a fixed step count. Its predictability makes it both more damaging (all nodes compete simultaneously) and more tractable (it can be prevented by design through staggered scheduling or asynchronous serialization).
3. **Common pitfall**: A frequent misconception is that checkpointing every 100 steps is "low overhead" whatever the save protocol. Under the naive protocol at 70B scale, if each training step takes 10 seconds and a checkpoint storm takes 10,035.2 seconds, checkpointing every 100 steps means spending most of the run on checkpoint I/O rather than useful training.

The severity of a checkpoint storm depends on two factors: the per-node shard size, determined by the model size and the sharding strategy, and the throughput of the first write tier, typically local NVMe. A concrete 175B example shows why the local-write phase, rather than the durable copy to the parallel file system, governs the exposed training pause.

Napkin Math 4.7: Tiered checkpoint staging

Problem: Assume sustained bandwidth, no snapshot-copy, serialization, or coordination overhead, and no interference from background copies. The resulting times are bandwidth lower bounds. A 256-node cluster saves a 175B-parameter checkpoint every 10 minutes. Each checkpoint totals 2,450 GB. Writing each unique byte once and spreading the bytes evenly across nodes, each node saves roughly 9.6 GB.

1. **Per-node write to local NVMe** (4 drives at 7 GB/s each = 28 GB/s): 9.6 GB ÷ 28 GB/s ≈ 0.34 seconds.
2. **Async copy to PFS**: 256 × 9.6 GB ≈ 2.4 TB total. If the PFS provides 1 TB/s aggregate, the storm completes in roughly 2.4 seconds.
3. **Per-node PFS bandwidth**: If all 256 write simultaneously, each gets 1000 GB/s ÷ 256 = 3.9 GB/s.
4. **Training pause**: At least 0.34 seconds for the local NVMe write under this model. The PFS copy overlaps with the next training iteration.
5. **Overhead lower bound**: 0.34 seconds pause every 600 seconds ≈ 0.06 percent training time lost to checkpointing.

Systems insight: Under these 1 TB/s aggregate-PFS assumptions, tiered staging reduces checkpoint overhead from about a 2.4 seconds PFS-direct write to a sub-second local write. The training pause can end at the local snapshot boundary before durable publication, but actual pause includes snapshot creation, serialization, and coordination in addition to this byte-transfer lower bound.

A PFS-direct save of a few seconds every 10 minutes costs well under 1 percent of the run, which can make tiered staging look unnecessary for the running example. The checkpoint-dominance argument of section 4.5.1 concerns bytes moved, not this pause, and the notebook's figure holds only while its assumptions do. The job has the whole 1 TB/s file system to itself; shared among the ten concurrent jobs of section 4.3.6, it receives a tenth of the bandwidth, the same save takes ten times as long, and its burst slows the other jobs' reads. Realized ingest also falls below the rated aggregate once serialization, metadata operations, and stragglers enter. The save interval shrinks as the fleet grows, because a larger fleet fails more often and the reliability analysis of section 7.8.1 then calls for more frequent saves, and a larger model scales every save with it. Tiered staging removes the shared-tier write from the exposed pause when the background copy keeps pace, although local snapshot creation, serialization, writing, and coordination still determine that pause.

Tiered staging insulates the training loop from that shared-tier contention by splitting the save into two phases. In the first phase, as calculated in notebook 4.7, each of the 256 nodes writes its 9.6 GB share of the 2,450 GB checkpoint across 4 local NVMe drives at 28 GB/s, establishing a byte-transfer lower bound on T_{write} of roughly 0.34 seconds before snapshot-copy, serialization, and coordination overhead. Once every required local shard has completed and the captured state is no longer being modified, the training pipeline can resume.

In the second phase, a background process asynchronously copies the local checkpoint to the parallel file system for durability. The copy can overlap training, but it still competes for memory, network, and storage service and must drain before repeated saves create an unbounded backlog. The two phases therefore land differently in the Fleet Law (equation 1.3). The local write is a pause that

every rank takes at the same step boundary, and training resumes only when the slowest writer has finished its shard. That is the shape of a barrier rather than of a transfer between workers, a coordination (C_3) cost, so the pause adds to the synchronization term $T_{\text{sync}}(N)$ of each saving step, the term that already carries barrier and straggler waiting. The background copy belongs to no step's critical path. While it stays hidden and drains before the next save, it adds nothing to the step time; it reappears only as interference, in $T_{\text{comm}}(N)$ when it shares links with collectives or in exposed input wait when it slows shared-storage reads. If a node fails before its copy completes, the new generation may lose a required shard. Replication to peer nodes' NVMe drives can protect against a single-node loss, provided replicas occupy independent failure domains. Waiting for that replication extends the pause beyond the local-only calculation. A design that resumes earlier must retain the previous committed generation until the new one reaches its declared durability boundary.

Durability alone does not make a distributed checkpoint restorable. Each rank writes its checksummed shard under an immutable generation identifier. Only after every shard has persisted does a coordinator publish a manifest naming the complete shard set. That commit uses an atomic primitive of the target tier (a create or rename on a file system, a conditional create or versioned pointer on an object store). A crash can then leave garbage to collect but never an incomplete generation that appears valid.

↪ The commit rule behind this ordering, a two-phase commit over the shard set, and the consistency of the cut that a manifest names are developed in section 7.8.5.

The exposed pause and the durability boundary therefore fall at different moments, as the four concurrent lanes of figure 4.8 align them. Training pauses only during the local NVMe shard write (t_0 to t_1), resuming on live state while the parallel file system absorbs the asynchronous copy (t_1 to t_2) and the coordinator validates checksums before publishing the manifest last (t_3).

4.6.1 Synchronous and asynchronous checkpoint writes

In the two-phase timeline of figure 4.8, the first phase is still synchronous with respect to local flash: across 256 nodes, every node must write and acknowledge its shard of the same completed training step before the completion barrier releases the next iteration, with the commit rules that make that cut consistent developed in section 7.8.5. The slowest local writer therefore sets the exposed pause from t_0 to t_1.

Asynchronous checkpointing shrinks even that local-flash pause by staging the snapshot in host DRAM first. Nodes coordinate the training step to capture, copy each accelerator-resident shard into a dedicated pinned host-memory buffer, and resume training immediately while a background thread writes the buffer to local NVMe. The snapshot buffer must remain immutable until the background write finishes; separate live-state buffers allow training to advance without changing the captured generation. If a node fails during the asynchronous write, its local shard may be incomplete. The job must wait for the required writes or peer replication before declaring this generation durable, even if training has already resumed.

The choice between synchronous and asynchronous checkpointing depends on the pause budget and save frequency. A 1-second pause at 200 ms per iteration costs

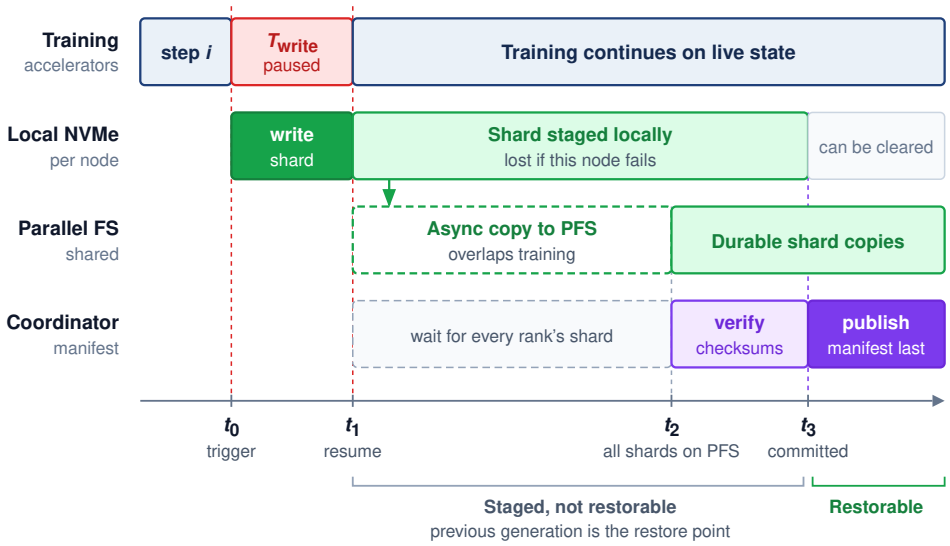

Figure 4.8: Two-Phase Checkpoint Staging: Read the lanes left to right. Training pauses only for the local NVMe write (t_0 to t_1); the copy to the parallel file system overlaps later training steps, and the coordinator publishes the manifest last (t_3). Between t_1 and t_3 the new generation exists only as staged shards, so the previous committed generation remains the restore point.

five iterations; whether that overhead is acceptable depends on how much useful training occurs between saves. Asynchronous checkpointing reduces exposed write time when snapshot buffers and background bandwidth are available, but its buffer capacity, contention, and durability delay also enter the decision.

Checkpoint formats implement the write-once rule of the checkpoint storm as rank-sharded saves, as in DeepSpeed's zero-redundancy checkpointing and PyTorch's Distributed Checkpoint (PyTorch Contributors 2026a). The sharding is what keeps the pause short. Had one node saved the full 2,450 GB itself, its 28 GB/s local stripe would need more than a minute rather than the 0.34 seconds of an even shard. Making each individual save fast, however, creates a cumulative capacity problem once thousands of snapshots accumulate over a multi-week run.

4.6.2 Checkpoint retention and restore

Checkpointing a 175B-parameter model every 10 minutes over a 30-day training run generates roughly 4,320 snapshots of 2,450 GB each, totaling approximately 10.6 PB, enough to fill a typical parallel file system several times over if retained in full. The retention policy this run adopts keeps the three most recent checkpoints on the parallel file system for fast recovery, copies every 100th checkpoint and the final checkpoint to object storage for long-term auditability, and deletes the rest. This policy reduces the parallel file system checkpoint footprint from 10.6 PB to roughly 7.35 TB (three live full checkpoints) while preserving 43 periodic historical snapshots in object storage, plus the final checkpoint when it does not coincide with that schedule, for posttraining analysis.

Incremental checkpointing offers a further optimization for reducing T_{write}. Rather than saving the entire training state every time, an incremental checkpoint

records changed state relative to a declared base or preceding generation. The delta must include changed optimizer and continuation state as well as parameters. For models where a large fraction of parameters are frozen (such as fine-tuning scenarios where only the last few layers are updated), incremental checkpoints can be orders of magnitude smaller than full checkpoints. Restoring a generation requires its base and every intervening delta, so smaller saves add recovery work and dependencies. Periodic full checkpoints bound that chain, and the retention policy must preserve each dependency until no retained generation requires it. A shorter pause matters only if the checkpoint can be read back; the costlier failure is a checkpoint that was written but never verified as restorable.

War Story 4.1: The backup that had not been restored (2017)

Context: On January 31, 2017, a GitLab.com site reliability engineer working a database replication incident accidentally wiped the primary PostgreSQL data directory (GitLab 2017).

Mechanism: All five layered backup paths failed simultaneously: S3 dumps were silently empty due to a version mismatch, Azure disk snapshots were disabled, replication was broken, LVM snapshots were six hours stale, and WAL archiving was unimplemented.

Impact: Six hours of production database writes, user comments, and repository metadata were permanently lost, requiring an 18-hour emergency restoration from a staging snapshot.

Fix: GitLab instituted automated daily backup restoration testing, unified PostgreSQL versioning across environments, and implemented automated WAL archiving to S3.

Systems lesson: Storage reliability is a restore property, not a backup property. A checkpoint, replica, or dump only counts if the team regularly proves that it can be located, validated, and restored under incident conditions. ML systems face the same vulnerability. A model checkpoint written to object storage or a feature store snapshot is useless if silent version mismatches or missing restore tests prevent resuming a multi-day training run after node preemption.

That incident turns checkpoint storage from a capacity question into a restore-design question. Before consolidating the running example's full storage footprint, the following check tests the write rates and staging trade-offs that govern each save.

Checkpoint 4.4: Checkpoint storage design

A training cluster of 256 nodes saves a 175B-parameter model checkpoint every 10 minutes. Each checkpoint is 2,450 GB total, distributed across all nodes.

- ☐ **Per-node state**: calculate the per-node checkpoint size.

- ☐ **Local write**: calculate T_{write} for the local write when each node writes to local NVMe at 28 GB/s.
- ☐ **Async copy**: calculate the per-node write bandwidth and async-copy time when the parallel file system provides 1 TB/s aggregate and all 256 nodes write simultaneously.
- ☐ **Tiered staging**: explain why tiered staging (local NVMe first, then async PFS copy) is faster than writing directly to PFS.

With the checkpoint accounting now derived in full, the running example's storage demands can be consolidated against the same hierarchy. Placing the training dataset, live model state, checkpoints, and archive lineage side by side reveals which direction of traffic dominates the 30-day run.

Systems Perspective 4.2: The 175B model's storage footprint

The running example, a 30-day training run of a 175B-parameter model on 256 nodes, places data on every tier of the hierarchy (table 4.5).

Table 4.5: 175B-Parameter Training Storage Footprint: Volume and primary storage tier for each data category in a 30-day, 256-node training run.

Category	Volume	Primary tier
Training dataset (compressed source)	3 TB	Object Storage
Training dataset (tokenized, per epoch)	6 TB	Object Storage → NVMe cache → Host DRAM
Model weights (FP16)	350 GB	GPU HBM (distributed)
Master weights (FP32)	700 GB	GPU HBM (ZeRO-partitioned)
Adam moments (two FP32 states)	1,400 GB	GPU HBM (ZeRO-partitioned)
Single resumable checkpoint	2,450 GB	NVMe → PFS → Object Storage
All checkpoints (30 days, 10-minute interval)	10.6 PB	NVMe (transient) → PFS (recent) → Object (archive)
Archive (retained checkpoints + dataset)	~116.8 TB	Glacier

The total data moved through the hierarchy is approximately 10.6 PB of checkpoint data plus 6 TB per 1 epoch of training data reads. For a single-epoch language model training run, checkpoint I/O dominates data loading I/O by a factor of over 1,764.

Checkpoints therefore set the run's write budget, while the far smaller training corpus carries a different obligation. Because training quality depends on the exact samples delivered at every step, each byte of that corpus must remain traceable to the source version and transformation code that produced it.

4.7 Versioned Data and Commit Boundaries

If a multi-week training run suffers a sudden loss spike or a deployed model regresses, an engineering team that did not record which shard versions, preprocessing code, and shuffle seeds fed each step cannot tell a model bug from a silent change in the input data. A checkpoint manifest provides one commit boundary per save. The data pipeline that built the training corpus has many, one at every stage that turns raw inputs into processed shards. The storage system must record both the exact bytes read and the preprocessing code, shuffle seed, schema, and integrity checks that produced them before the run began.

Lighthouse 4.1: Archetype B (DLRM at Scale): Feature store latency

While Archetype A (GPT-4/Llama-3) trains on static, versioned shards, Archetype B (DLRM at Scale) trains on live feature streams that change every second as users click and interact. Replaying an exact batch then becomes a point-in-time problem, which a feature store answers by keeping a retained, versioned feature log.

↪ Point-in-time correctness, the leakage it prevents, and the storage cost of retained feature history are developed in section 12.4.3.

Even when the underlying shard files are immutable, a distributed loader produces a stream of consumed samples whose versions and order can shift across epochs during a 30-day run. Dataset versioning provides a "Git for data" record by snapshotting the cryptographic hashes[13] of every data shard, the exact preprocessing code used for tokenization, and the random seeds governing the global shuffle. With that snapshot in place, engineers investigating a mid-run divergence can replay the exact batch that triggered the loss spike and test whether the culprit was a corrupted sample or numerical instability in the optimizer.

At petabyte scale, the data pipeline has to make every transformation reproducible. Raw documents are cleaned, tokenized, packed into training examples, and sharded across storage tiers. Each stage writes an immutable artifact, and each artifact records the input version, code version, schema, and statistical checks it satisfied. Once those dependencies are explicit, the pipeline forms a directed acyclic graph: later artifacts depend on earlier artifacts, and no stage is allowed to rewrite its own history. When a training job starts, the cluster manager verifies that each worker's local NVMe shards match the data snapshot declared for the run. Treating the data pipeline as a graph of versioned artifacts rather than a simple file transfer makes silent data drift detectable and attributable to a specific stage, code version, or input snapshot. Immutability also pays a storage dividend. Because an artifact never changes once written, a manifest can name it by content identifier, and many experiments can reference the same unchanged shards without copying entire datasets.

[13] **Hash cost (SHA-256)**: Verifying the integrity of a 100 TB dataset using SHA-256 consumes approximately 55.6 CPU-core hours at a per-core hashing rate of 500 MB/s. The work parallelizes across shards, but it still competes with decoding for host cores and must read every byte, so the validation step is best pipelined with ingestion rather than run as a separate pass before the fleet starts.

4.7.1 Replay and commit boundaries in data pipelines

When a tokenization worker crashes halfway through building a shard of the running example's corpus, its replacement must decide which raw documents to process again without silently dropping records or writing duplicates. Versioned artifacts identify *what* a pipeline produced, while commit and replay rules determine whether mid-stage failures can alter that result. The storage system's part in that decision is the commit boundary, the point at which a stage's output becomes durable and visible downstream, the same contract that section 4.6 applied to checkpoint generations. That shared contract is why a storage chapter owns these semantics, because whether a replay loses or duplicates data is decided by what the store has committed. The restarted worker compares its input position with the last committed output and replays everything after it, so the work at risk is whatever accumulated past the last commit. Two service-rate effects govern how much accumulates. Records are assigned to workers by a partition key, such as a document's source or a user identifier, and partition skew arises when one key owns disproportionate work and holds its stage open while the rest of the fleet idles. Backpressure propagates a slow downstream stage's limit upstream by slowing admission or bounding in-flight data, a control response to overload rather than another name for slow processing.

Failures near that boundary raise a correctness question, and three guarantees answer it differently. At-most-once processing never replays uncertain work, so a document that was read but whose output was never confirmed is lost. At-least-once processing replays everything after the last confirmed commit, so a document whose output was written but not yet confirmed is written twice. An effectively exactly-once outcome combines replayable inputs with idempotent writes, writes that leave the same result however many times they repeat, or with transactional output keyed by a stable event or transaction identifier (Akidau et al. 2015). Reliable message delivery between workers cannot provide this guarantee on its own, because the duplicate arises from the worker's own replay.

Example 4.2: The acknowledgment gap

Failure trace: A feature-pipeline worker writes the output row for click event `e42`, then crashes before it records that the write succeeded. Its replacement cannot tell whether `e42` was committed. Skipping the event risks losing it. Replaying it with an append writes the feature row a second time, so that click counts twice in every training set built from the table. Writing the row under the stable key `(feature_version, e42)` turns the replay into an overwrite of the same row, so the uncertain event can be reprocessed safely.

Systems lesson: Exactly-once belongs at the output commit boundary, whose record must bind the input position, transformation version, stable identifier, and commit state.

The two replays differ only in how the output is addressed. An append gives every attempt its own row, while a write under a stable key sends every attempt to

the same row, so reprocessing uncertain work leaves the stored result unchanged (figure 4.9).

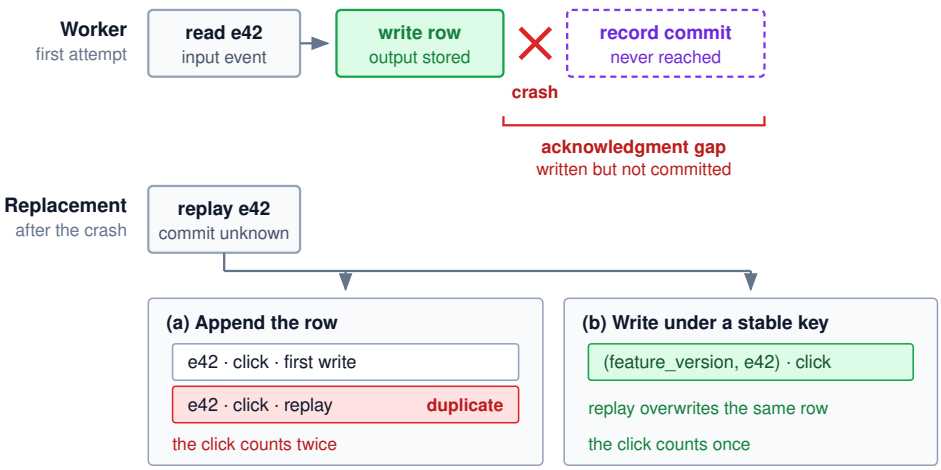

Figure 4.9: The Acknowledgment Gap at a Commit Boundary: A worker stores the output row for event e42 and crashes before it records the commit, so its replacement cannot tell whether the row exists and must replay the event. (a) Appending the replayed row duplicates it, and the click counts twice in every training set built from the table. (b) Writing under the stable key (feature_version, e42) makes the replay an overwrite of the same row, so at-least-once replay produces an effectively exactly-once result.

Streaming adds a time boundary to the contract. Event time records when an event occurred; processing time records when a worker handled it. A pipeline that aggregates clicks per hour must decide when an hour is finished, even though events can arrive late. A watermark is its running estimate that every event up to some event time has arrived, which lets it close that window and emit the result; a late-data policy determines whether later arrivals update, retract, quarantine, or drop the result (Akidau et al. 2015). Watermarks therefore trade freshness against completeness rather than prove that no older event remains.

Each of these mechanisms buys one property at the cost of another. Buffering absorbs finite bursts or temporary slowdowns but increases recovery state and freshness lag; sustained overload still requires backpressure or more service capacity. Aggressive watermarks reduce delay but exclude more late data, while retries help only when writes are safe to repeat. These choices change the stored result, because a feature table closed under an aggressive watermark holds different rows from one closed under a lenient watermark. A reproducible training snapshot must therefore record source and code versions alongside partitioning, replay policy, stable identifiers, watermark state, and late-data decisions. That record is what lets a later feature backfill, a replay of history under new code, rejoin features at the correct points in time without mixing old and new histories.

↪ Feature backfills that replay history under this snapshot contract are developed in section 12.4.5.

4.7.2 The synthetic fuel line

The versioned-artifact contract applies to generated training samples as well as collected ones. When a fleet generates candidate samples, filters them, and verifies

the survivors, each stage adds storage traffic and records that must remain linked to the accepted payload. The pressure to generate comes from the compute-optimal allocation of section 1.3, which grows the token budget with the parameter count. As high-quality human-generated text becomes harder to expand, the fleet encounters the **data wall**: the point where additional training samples must increasingly come from synthesis, simulation, curation, or expensive human collection (Villalobos et al. 2024). This shift from simple collection to managed data generation sends more than payload bytes through the hierarchy. A "synthetic fuel line" must also store the **provenance chain** of every sample: which model generated it, which filters accepted or rejected it, which judge or verifier models scored it, and which downstream run consumed it. That lineage makes repeated reuse of generated material traceable. It supports investigation of **model collapse**, where recursive training on generated data can degrade the learned distribution (Shumailov et al. 2024); retaining provenance alone does not prevent the degradation. The storage design must separately budget retained artifacts and the repeated scans used to assess them.

Napkin Math 4.8: The storage cost of synthetic data

Problem: A 1 TB synthetic dataset retains provenance metadata and undergoes three independent verification scans. How much persistent capacity and pipeline traffic does it require if judge outputs are not retained as full dataset copies?

1. **Raw Payload**: 1 TB.
2. **Provenance Overhead**: 40 percent extra for lineage hashes, generation logs, and reward-model scores.
3. **Verification Traffic**: 3 judge passes each read the payload, producing 3 TB of read traffic. Their scores reside in the provenance metadata rather than in three retained payload copies.
4. **Capacity Result**: Persistent capacity is $1\ \text{TB} \times 1.4 = 1.4\ \text{TB}$, a 1.4× capacity factor.
5. **Traffic Result**: Writing the payload and metadata once and reading the payload three times moves 4.4 TB, a 4.4× traffic factor before generation and judge-model compute are counted.

Systems insight: Verification primarily draws on service rate and compute, while retained provenance consumes capacity. The two costs coincide only when the pipeline materializes each judge output as another full dataset. Synthetic storage must therefore budget bytes at rest separately from bytes moved and record which generator, filters, judges, and downstream runs produced each accepted sample.

Generated data therefore makes lineage part of the payload, so the store must budget retained provenance and verification traffic alongside the samples them-

selves. Every tier that holds those samples, checkpoints, or provenance records also carries a distinct price tag, turning placement across the hierarchy into an economic optimization problem.

4.8 Storage Economics

Checkpoints, training shards, and the lineage that binds them now each have a place in the hierarchy, and every placement carries a price set by the tier that holds the bytes and by how often they cross a billing boundary. ML storage economics is therefore not simply about choosing the cheapest capacity tier; the design objective is to minimize total cost of data delivery, which combines recurring storage charges, cross-boundary transfer fees, and the opportunity cost of idle accelerators.

Applied to one 100 TB training dataset, the per-gigabyte rates quoted earlier for each tier diverge by orders of magnitude: object storage (S3 Standard) costs $24,000 per year, provisioned local NVMe costs $120,000 per year, and archival storage (such as Glacier) drops to $4,800 per year. By contrast, hypothetically provisioning the same capacity as GPU memory at $15/GB would require $1,500,000 in upfront acquisition cost alone, before factoring in amortization, power, or server housing.

The 5× cost difference between local NVMe and object storage motivates placing data on the least expensive tier that meets its delivery and recovery requirements. Device technology contributes to the gradient: HBM uses 3D-stacked silicon with through-silicon vias, and accelerator-adjacent capacity is constrained by packaging and node design. Shared storage pools capacity across clients but introduces network and service dependencies. The cost comparison must include those dependencies rather than infer the cheapest usable path from capacity price alone.

Repeated cross-boundary egress, not storage, dominates cloud cost.

Storage cost, however, is only part of the equation. Data transfer costs can dominate, especially in cloud environments. When compute runs in a different region or cloud from the bucket, as assumed here, reading the 100 TB dataset from object storage to compute instances incurs a transfer charge of $9,000. For multi-epoch training that reads the dataset 10 times, the egress cost alone reaches $90,000, more than the annual storage cost. This inversion, where *reading* data costs more than *storing* it, drives the architecture decision to cache data on local NVMe rather than streaming from object storage each epoch.

The economic analysis changes further when accounting for the opportunity cost of accelerator idle time. The book's reference cluster of 1,024 GPUs, half the chapter's running cluster, at $2/GPU-hour costs $49,152 per day. If input stalls reduce its compute-active fraction from 90 percent to 70 percent, the lost compute time is valued at $9,830 per day. Over a 30 days training run, this amounts to $294,912. That value sets a budget for evaluating a storage upgrade, but the recoverable benefit depends on how much exposed wait the upgrade removes. Capacity that does not relieve the limiting stage yields no corresponding compute-time saving.

Systems Perspective 4.3: The storage cost iceberg

The visible cost of storage ($/GB/month) is the tip of the iceberg. Below the surface lie costs that often exceed the storage cost itself:

- **Egress fees**: The ten-epoch egress charge of $90,000 computed above already exceeds a year of storage.
- **IOPS charges**: Object storage charges per-request fees. S3 Standard GET requests cost about $0.0004 per 1,000 requests, so a dataset of 100M individual files, read once, costs about $40 in GET request fees before data transfer or retrieval charges, even though the storage cost is $2,000/month.
- **Idle accelerator cost**: The $9,830 per day of lost compute computed above dwarfs any storage saving.
- **Retrieval fees**: Archive storage charges retrieval fees ($0.02/GB for Glacier) in addition to egress. Restoring a 100 TB dataset from Glacier costs $2,000 in retrieval fees plus $9,000 in egress.

The economically rational strategy often invests more in storage (local NVMe caching, parallel file system capacity) to reduce transfer costs and prevent accelerator stalls.

The cost iceberg reveals that raw storage capacity can account for less than half of the total expenditure; replication, metadata operations, API calls, and cross-region transfers can collectively dominate the bill at scale. Among those hidden line items, egress is the one that often flips the architecture decision. Unlike capacity charges, which scale with the volume of data stored, egress charges scale with the volume of data read, and ML training reads the full dataset on every epoch.

Napkin Math 4.9: The cost of egress

Problem: A team trains a vision model on a 50 TB image dataset stored in S3. Training runs for 20 epochs. The decision is whether to stream from S3 each epoch or stage to local NVMe.

Option A: Stream from S3

- Storage: 50 TB $\times$ $0.02/GB/month $\times$ 12 months = $12,000/year
- Egress: 50 TB $\times$ 20 epochs $\times$ $0.09/GB = $90,000 per training run
- Total for 4 training runs/year: $12,000 + $360,000 = $372,000/year

Option B: Stage to local NVMe

- Storage (S3 source of truth): $12,000/year
- NVMe capacity (50 TB across cluster): 50 TB $\times$ $0.10/GB/month $\times$ 12 = $60,000/year

- Egress (stage once per training run): 50 TB × 4 runs × \$0.09/GB = \$18,000/year
- Total: \$12,000 + \$60,000 + \$18,000 = \$90,000/year

Systems insight: Local NVMe caching saves \$282,000/year at 20 epochs per run, enough to fund 9 additional H100 GPUs at list price. Including the \$60,000/year provisioned NVMe cost and the once-per-run staging egress, the break-even point is just over 4 epochs per run; by the fifth epoch, local caching is cheaper than streaming from S3 every epoch.

The notebook turns the iceberg into a decision rule: the cheapest storage tier is not always the cheapest delivery path. Object storage can remain the source of truth, but repeated reads make egress, request overhead, and idle-accelerator cost part of the storage design. Multi-epoch vision training may justify staging on local NVMe by the fifth epoch, while single-epoch language-model pretraining may leave the corpus in object storage and optimize the streaming path instead. The running example stages anyway, although it reads its corpus only once, because egress is not what decides it. Each node's share of the shards fits easily on local NVMe, the staging copy happens once before the clock starts, and local reads keep object-store latency tails out of every training step. When compute and bucket share a region, transfer fees largely disappear and the same comparison turns on request charges, latency, and idle accelerators instead. The architecture is therefore chosen from access pattern, read count, and latency sensitivity rather than from \$/GB/month alone.

The cost analysis extends to the parallel file system tier, which occupies a middle ground between NVMe and object storage in both performance and price. A parallel file system capable of delivering 1 TB/s aggregate bandwidth requires roughly 100 OSS nodes, each with multiple NVMe drives and high-bandwidth network connections. Because the throughput target, not the stored capacity, sets that server count, a bandwidth-sized system costs far more than its stored bytes alone would suggest. This expense is justified only if the alternative, streaming from object storage and paying egress fees, is even more expensive, or if the latency requirements of checkpoint writes cannot be met by object storage alone. The break-even analysis depends on the organization's workload mix. A team running a single long training job may find that staging data on local NVMe and bypassing the parallel file system entirely is the cheapest option, while a team running many concurrent short jobs benefits from the shared namespace that a parallel file system provides.

The decision to build vs. buy storage infrastructure hinges on the trade-off between the high capital expenditure of an on-premises parallel file system and the recurring operational expenditure of cloud object storage. A 1-petabyte Lustre deployment, sized for capacity rather than for the 1 TB/s target above, costs roughly \$3–5 million in hardware, plus an additional \$500,000 per year in operational overhead for power, cooling, and engineering support. Storing 1 PB in a cloud

object store at $0.02/GB/month costs $240,000 per year for storage alone. Egress fees for accessing the data, however, dominate the total cost. Reading that petabyte at 10 reads/year adds $900,000 in data transfer fees. Under these assumptions, annual cloud delivery costs $1,140,000; after subtracting $500,000 of on-premises operations, the net savings are $640,000 per year. The resulting hardware break-even is roughly 4.7–7.8 years, and a payback within two years would require a hotter workload with many more full-dataset reads per year, lower capital expense, or non-egress drivers such as checkpoint latency and shared-namespace requirements. For the running example, the 6 TB serialized corpus is much smaller than 1 PB, so the local-storage case is driven more by latency, repeated experiments, and checkpoint staging than by one-year egress savings alone. Read-heavy training fleets also rarely wear out their drives under the DWPD budget of section 4.3.4, so a storage refresh cycle is usually driven by density rather than wear, and its timing belongs to the lifecycle cost analysis of section 12.9.3.

4.8.1 Tiering strategies

The cost structure laid out above turns tiering into a placement policy: keep data only as close to the accelerator as its access frequency and latency requirement justify. A tiering strategy encodes that policy across the hierarchy. Its hot, warm, cold, and archive labels name placement roles for a dataset rather than devices, and they follow the scope brackets of figure 4.1. The node-local pair is the hot tier, and the three shared services become the warm, cold, and archive tiers. The tier sections called local NVMe a warm cache because it sat in front of shared storage; in this placement vocabulary the same drives belong to the hot tier, because they hold the data the running job consumes.

The fastest and most expensive layer is the hot tier (local NVMe + host DRAM), which holds data being actively consumed by the running training job. Datasets are staged from shared storage to local NVMe at job start. This tier is provisioned per-node and is not shared across the cluster, so data that multiple jobs or teams need simultaneously cannot live here alone.

That shared-access requirement is what justifies the warm tier (parallel file system), which holds datasets accessed by multiple jobs or teams, shared checkpoints for fault recovery, and model artifacts under active development. The parallel file system provides the shared namespace necessary for multi-tenant access with strong consistency.

Below the warm tier sits the cold tier (object storage), which serves as the canonical repository for all organizational training data. Datasets are authored and versioned in object storage, then promoted to warmer tiers when needed for training. Object storage also serves as the durable backup for checkpoints after they are staged from local NVMe through the parallel file system.

Data that must be retained for compliance or reproducibility but is not expected to be accessed during normal operations drops to the archive tier (Glacier or equivalent). Lifecycle policies of the kind shown for the archive tier in section 4.3.8 automate both directions of movement. They promote data from cold to warm

when a job requests it, demote it when no job has read it for a configured period, and transition cold data to archive after 90 to 365 days since last access.

In the running example, the 3 TB source corpus and 6 TB serialized shards live permanently in object storage (cold tier), and the staging and cleanup lifecycle of section 4.5.1 moves each node's shards through local NVMe (hot tier) for the life of the job. The parallel file system holds only the job's recent checkpoints, which the retention policy of section 4.6.2 governs.

The economic benefit of automated tiering compounds over time. An organization retaining 50 training datasets of 10 TB each would need 500 TB of parallel file system capacity if all data were left in place. If ten datasets are active concurrently and the other forty can be demoted after their jobs finish, automated tiering reduces the dataset capacity required on the parallel file system to 100 TB, saving $144,000 per year at the parallel file system's per-TB rate. These savings are invisible in any single experiment but substantial when accumulated across the fleet. Tiering and staging thus settle where training data and checkpoints live and what each placement costs; serving reuses the same hierarchy for a different objective, governed by the time to bring a model into HBM and the latency of serving-time state rather than epoch throughput.

4.9 Storage for Serving

Where full-corpus training streams datasets for weeks and writes checkpoints in bursts, the weight-resident serving baseline of section 4.2 reads the model weights once when a replica starts or recovers and then answers requests out of HBM, before KV-cache offload and retrieval indexes add serving-time I/O of their own.

That startup read makes model loading latency, often called cold-start time, the primary storage metric for weight-resident inference: the duration required to load a model from storage into the accelerator's HBM. For the 175B parameter language model, the weights alone occupy 350 GB in FP16 format; loading that footprint sequentially from a single high-performance NVMe drive at 14 GB/s takes 25 seconds, an unacceptable delay for a user-facing application. Loading from a shared PFS at a per-node rate of 4 GB/s takes 87.5 seconds. Reading from object storage at 1 GB/s stretches the delay to 5.8 minutes.

To reduce cold-start time, the model is sharded and loaded in parallel. If the 350 GB model is striped across 8 NVMe drives, each loading a 43.75 GB shard at 7 GB/s, the total load time drops to roughly 6.2 seconds. When using tensor parallelism across 8 GPUs, each GPU loads only its 43.75 GB shard. If the weights already sit in host DRAM, each GPU's own PCIe link could move its shard in about 0.7 seconds, but the 8 transfers share the node's 200 GB/s of host-memory bandwidth, so the full load takes about 1.8 seconds. For the most latency-sensitive applications, organizations maintain warm replicas: one or more copies of the model weights kept preloaded in host DRAM, ready for that host-memory-bound transfer. This trades DRAM capacity for a load of about 1.8 seconds instead of the 6.2 seconds striped NVMe read.

↪ How cold-start time limits autoscaling, and how warm pools trade idle capacity for scaling response, is developed in section 10.13.

These load times describe one replica. The model rollout previewed in section 4.2 asks all 100 replicas to load a new version at once, 35 TB of weights in one burst. If every replica reads from object storage at the 1 GB/s single-client rate, the fleet asks the store for 100 GB/s. A store whose aggregate service matches that figure, the 100 GB/s of table 4.2, finishes the rollout in about 5.8 minutes, no slower than one replica's cold start; any smaller aggregate share stretches the rollout in proportion. Reading from the 1 TB/s parallel file system instead would take about 35 seconds, but only by claiming the whole file system and starving every training job that shares it, the read-side mirror of a checkpoint storm. Serving fleets therefore stage the new version on local NVMe before switching traffic, roll the update across groups of replicas so that the old version keeps serving, or let replicas that have finished loading supply the rest.

During autoregressive generation, the server keeps a per-request record of the attention keys and values produced by earlier tokens so it can generate the next token without recomputing the entire prefix. This record, called the key-value cache (KV cache), grows with sequence length and can consume significant HBM. For long sequences (128K tokens or more), KV cache offloading to host DRAM or NVMe extends the effective context window at the cost of increased latency per generated token, because cache blocks must be moved back into HBM before attention can use them. The storage lesson is that inference maintains an active working set rather than presenting solely a model-loading demand. When serving must also retrieve external context to ground that generation, the storage pipeline faces an entirely different access pattern: low-latency random queries into high-dimensional vector indexes.

↪ KV-cache growth and the HBM capacity wall it creates for serving are developed in section 10.7.1.

4.9.1 Retrieval indexes

An inference request that needs supporting documents cannot wait for a sequential scan of the training corpus. A retrieval system first converts documents into vectors that represent semantic meaning, then finds nearby vectors and returns their source documents as context. The same storage analysis still applies, but the unit of demand becomes a query and its index accesses, and the deadline becomes the serving latency budget. With a graph-based approximate nearest-neighbor (ANN) index, the storage system traverses a high-dimensional vector graph instead of streaming sequential blobs via formats such as TFRecord or Parquet. Other index families shift the storage demand elsewhere. Exact flat search scans every stored vector and is bound by scan bandwidth, inverted-file (IVF) partitioning probes only the few clusters nearest the query, and product quantization (PQ) compresses each vector into short codes so that more of the index fits in memory, at some cost in accuracy.

Systems Perspective 4.4: The IOPS bottleneck in high-dimensional search

For graph-based ANN, this architectural pattern shifts the primary storage bottleneck from sequential read bandwidth to random-access IOPS. The search traverses a high-dimensional graph to find approximate nearest neighbors across billions of embeddings. Its performance is governed by the trade-off among recall, latency, and capacity, where recall is the fraction of the true nearest neighbors that the approximate search returns. Raising recall requires traversing a larger portion of the index, driving up IOPS and latency. The arithmetic of a disk-resident traversal shows why IOPS, not bytes, binds. Each hop that misses DRAM costs one dependent SSD read of roughly 100 µs (table 4.2), and the next hop cannot start until that read returns, so ten such hops already spend a millisecond of the serving budget in storage alone. Throughput is bounded separately. A drive whose 4 KB random reads run near 0.5 GB/s (section 4.2) completes on the order of 10^5 such reads per second, and every concurrent query draws on that same budget, while each read moves only a few kilobytes. A 1,536-dimension embedding in FP32 (4 bytes per value) consumes approximately 6.1 KB, so a billion-document corpus requires roughly 6.1 TB before graph adjacency lists. If those lists add 50 to 100 bytes per node, they add 50 GB to 100 GB, making raw vectors plus minimal graph metadata about 6.2 TB at the high end. Production indexes can be larger once identifiers, graph levels, allocator overhead, deleted-entry slack, and replication are included. In-memory hierarchical navigable small world graph indexes make graph navigation fast when the index fits in DRAM (Malkov and Yashunin 2020). Disk-backed graph indexes such as DiskANN trade DRAM footprint against SSD traversal while targeting high recall and low query latency (Subramanya et al. 2019).

Graph-based retrieval therefore spends storage budget on index levels that keep random traversal inside the serving latency service-level objective. A disk-backed graph is economical only if the extra SSD accesses do not erase the quality gain from searching a larger corpus. Flat, IVF, and PQ designs move that budget toward scan bandwidth, partition probes, or decompression and approximation error. The same hierarchy now supports bulk model loading, request-scoped KV state, and retrieval, each with a distinct service-rate contract. Every design so far also assumes today's six tiers, and the boundaries between those tiers are themselves moving.

4.10 Storage Technologies That Move Tiers

Today's six-tier hierarchy leaves a 1,000× latency cliff between host DRAM (~100 ns) and local NVMe (~100 µs), forces the host CPU to spend cycles decompressing bytes that GPUDirect Storage could otherwise DMA directly, and pauses training while synchronous checkpoints reach flash. Compute Express Link (CXL), the coherent capacity tier of section 2.9.1, targets the DRAM-to-NVMe gap first. Seen

from storage, CXL-attached memory is a "Tier 1.5," slower than host DRAM but byte-addressable, with access latencies of roughly 200 to 500 ns against the roughly 100 µs of an NVMe read. It offers a capacity pool for the structures that the Tier 1 discussion showed competing for host DRAM. For the running example, CXL-attached memory could expand the effective host memory tier from 512 GB to over 4 TB per node. That pool could hold deeper prefetch queues, embedding-table spillover, or a local shard cache as large as the 3 TB compressed source corpus without paying NVMe access latency on every read, though it still falls short of the full 6 TB tokenized training copy on one node.

A different bottleneck appears when CPU-side decoding, not storage bandwidth, throttles the pipeline. The computational storage drive closes that gap by embedding processing elements (field-programmable gate arrays (FPGAs) or simple CPU cores) directly on the SSD controller, enabling decompression, filtering, or format conversion to happen at the storage device rather than consuming host CPU cycles. For ML pipelines where CPU-side decoding is the bottleneck, computational storage could eliminate the CPU from the data path entirely, complementing GDS by offloading work that direct DMA cannot address.

Checkpoint writes impose the pause T_{write} while a consistent snapshot reaches the first storage tier, and shrinking it makes frequent saves less costly. Persistent memory, despite market shifts such as Intel's 2022 wind-down of its Optane memory business (Intel Corporation 2022), remains the architectural idea that attacks that term directly. Byte-addressable non-volatile memory could lower the destination-device latency, but the checkpoint pause still includes snapshot creation, byte transfer, and coordination. A lower device-access latency reduces T_{write} only to the extent that this device lies on the pause's critical path.

These technologies are not yet broadly deployed at the scale of the largest ML clusters, but they illustrate the direction of the storage hierarchy's evolution. The fundamental principle remains unchanged, with faster, more expensive storage closer to the accelerator and slower, cheaper storage at the periphery. What changes is the *granularity* of the tiers and the *size of the gaps* between them.

4.11 Fallacies and Pitfalls

Storage design errors are among the most expensive mistakes in ML infrastructure because they are discovered late, when training begins, and remediation requires either expensive hardware upgrades or time-consuming data reformatting. The following fallacies and pitfalls capture the most common errors that experienced storage engineers make when first encountering ML workloads.

Fallacy: *NVMe is fast enough to feed GPUs directly without pipelining.*

A single NVMe drive delivers 7 GB/s, while an H100 consumes 3.35 TB/s from HBM. The gap is roughly 479×. Even four drives in RAID-0 only close this gap to about 120× before overhead. Without pipelining and prefetching to hide the latency of loading from NVMe to host DRAM to HBM, every batch transfer introduces a stall equal to the transfer time. The HBM ratio measures tier disparity rather than the required input rate, because model state is reused many times for each

batch loaded from storage. The relevant test compares measured input delivery with batch bytes divided by compute time, then checks whether buffering hides transfer latency and jitter. A device can have enough sustained bandwidth and still expose stalls when transfers are serialized with computation.

Pitfall: *Relying on prefetching to hide object storage latency.*

Prefetching hides latency only within the time covered by ready batches; it cannot hide an arbitrarily long interruption. With N_{prefetch} batches ready and constant compute time, a complete interruption of supply exhausts the queue after $N_{\text{prefetch}} \times T_{\text{compute}}$. A slow request need not stall computation if other completed work remains available, but correlated delays can deplete many workers' queues together. Provision buffer depth from measured delivery tails, test correlated interruptions, and verify that the sustained refill rate meets consumption. Local staging can reduce remote exposure when the required shards fit and remain valid.

Fallacy: *Millions of small training files are harmless at scale.*

Storing each training sample as an individual file (one JPEG per image, one JSON per text sample) creates repeated per-file work through operations such as `open()`, `stat()`, and `close()`. Metadata becomes the bottleneck when the resulting request rate exceeds the service's capacity, even if byte bandwidth remains available. Aggregating samples into sequential shards amortizes that work (section 4.3.5). Packaging 10,000 to 100,000 samples per shard can reduce file-level operations by a corresponding 10,000 to 100,000$\times$ when readers consume whole shards. The loader must still implement the intended sampling policy and avoid repeated enumeration.

Pitfall: *Ignoring egress costs when designing the storage architecture.*

Cloud egress costs are invisible during development but can dominate at scale. Under a representative \$0.09/GB cross-boundary egress fee, a training job that reads a 100 TB dataset from object storage 10 times incurs \$90,000 in egress fees, far exceeding the annual storage cost of \$24,000 under the object-storage price assumption in section 4.3.7. These fees apply when reads cross a region, provider, or internet boundary; same-region reads may be free or discounted, which is exactly why the cost stays hidden until a cross-region or multi-cloud topology makes it unavoidable. Teams that prototype with small datasets on object storage and then scale up discover that their storage architecture is economically unsustainable. The fix is to budget egress costs explicitly and to design the data pipeline to minimize cross-tier transfers, typically by staging data on local NVMe at job start rather than streaming from object storage each epoch.

Fallacy: *Average write bandwidth is enough for checkpoint design.*

Checkpoints are written by all nodes simultaneously, creating bursts that can exceed steady-state bandwidth by 10$\times$ or more. When the PFS write lies on the training critical path, sizing it only for average write load extends T_{write} during bursts and reduces effective training throughput. A synchronous PFS-direct design must provision enough burst bandwidth to meet its pause budget. With local

staging, the first tier absorbs the burst and the PFS drains it in the background; the shared tier must then meet the durability deadline and keep up with repeated saves without an unbounded backlog.

Pitfall: *Assuming faster accelerators automatically improve training throughput.*

When an organization upgrades from A100 to H100 GPUs, they expect training time to decrease proportionally to the compute improvement. If the storage pipeline was already marginal on A100s, delivering data just fast enough to avoid stalls, the faster H100 compute hits the I/O wall sooner. The accelerator upgrade reduces T_{compute} without reducing T_{IO}, which means the data stall ratio increases. Every accelerator upgrade must be accompanied by a storage pipeline audit to ensure that the faster compute does not expose a previously hidden storage bottleneck.

Fallacy: *RAID configurations optimized for databases are suitable for ML training.*

RAID selection follows the tier's failure contract. A disposable local cache can use RAID 0 to aggregate drives without parity, provided a durable source remains available and the fleet can tolerate restaging after a drive failure. Redundant layouts can still reduce disruption when restaging is slow or the cache supports an availability objective. A local checkpoint awaiting durable replication is not yet disposable merely because it lives on the same NVMe drives. Treating all ML storage as replaceable input data confuses capacity placement with recovery policy.

Pitfall: *Creating full copies for each dataset snapshot.*

Copying an entire dataset for every version duplicates unchanged content. For a 10 TB dataset with 5 percent of its bytes changed, a full copy retains 9.5 TB of redundant data. Content-addressable storage or delta encoding can reuse unchanged objects or blocks. If the storage granularity isolates the changed bytes, the new payload is roughly 500 GB, a 20× reduction before metadata and redundancy overhead. Rewriting large compressed shards can reduce that saving because a small sample change may replace a much larger stored object. Versioning must therefore preserve lineage while choosing a reuse granularity compatible with the dataset format.

Fallacy: *Compression always helps because it reduces the amount of data to read.*

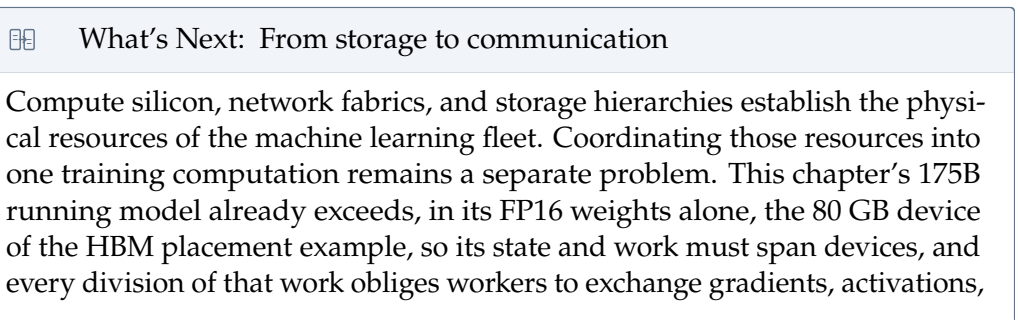
Compression reduces stored and transferred bytes but adds decoding work. If decoding further saturates an already limiting host processor, it makes that bottleneck *worse*, not *better*. If transfer is limiting and decoding has headroom, compression can improve delivery until another stage becomes the limit. Compare candidate representations using output-equivalent stage rates, including CPU or GPU decoding, rather than select the strongest codec from an I/O-bound label alone. The same choice can reduce capacity cost without improving training throughput. These fallacies all return to the same accounting exercise: where each byte lives, how often it moves, and which tier pays the cost.

4.12 Summary

Storage in ML systems is an active, multi-tiered pipeline that supplies accelerator inputs, preserves restorable state, and records the lineage of training and serving artifacts. The hierarchy exists because workloads need different combinations of bandwidth, capacity, latency, durability, and cost, and the demand on it grows with the scaling laws that drive the fleet. Larger models call for more training tokens and carry larger checkpoints, so storage pressure rises at every step up the model-size curve. The data pipeline throughput equation, $\text{BW}_{\text{required}} = N_{\text{GPU}} \times \eta_{\text{target}} \times D_{\text{vol}}^{(\text{batch})} / T_{\text{compute}}$, sizes delivery for a chosen training rate when applied to the representation and distinct input consumers at each tier. Measured against the Fleet Law, storage succeeds when it contributes no exposed time. Prefetching preserves the Fleet Law's assumption that the next batch is already resident. Tiered checkpoint staging shrinks the save pause that surfaces in $T_{\text{sync}}(N)$ to the local write and takes the slow shared-storage copy off the step entirely, so that copy costs step time only when it contends with collectives or input reads. Both spend communication (C_2) and coordination (C_3) capacity to protect compute (C_1).

Treating the hierarchy as a cache makes that sizing workload-specific. The hit rate and the service times of the hot and cold paths determine mean effective throughput, while the tail and correlation of misses determine whether a finite prefetch buffer drains. At the durable tiers, reliability also separates into three contracts: data survival, service response, and the version a reader may observe. These are durability, availability, and consistency, respectively; improving one does not automatically establish the others.

The diagnostic task is to identify which service contract fails before changing the storage tier. Low accelerator utilization can arise from metadata-intensive loading, a depleted prefetch queue, an exposed checkpoint write, or host-memory traffic crossing a contended NUMA link. Measure input wait separately from communication and synchronization before attributing it to storage. Full-corpus scans favor aggregated shards, while graph retrieval and live features require random access and explicit consistency. A depleted input queue can reflect slow storage, metadata contention, or insufficient decoding capacity; GDS helps when host payload copying is the limiting stage while retaining CPU control. Compare remedies by total delivery cost, including transfers and idle accelerators. For checkpoint writes, evaluate the shorter training pause together with the time until a complete generation becomes durable and publishable.



Key Takeaways: Feed the accelerators or waste them

- **Workload demand sizes the delivery path**: Use $\text{BW}_{\text{required}} = N_{\text{GPU}} \times \eta_{\text{target}} \times D_{\text{vol}}^{(\text{batch})} / T_{\text{compute}}$ for the chosen training rate, then check each tier's service rate and buffering (principle 8).
- **Workload determines the storage contract**: Full-corpus scans favor sequential throughput and aggregated shards, and metadata opera-

tions can bind before byte bandwidth does (principle 7). Disk-backed graph retrieval must fit its random I/O within a serving deadline, and synthetic-data pipelines must budget verification traffic separately from retained capacity while keeping the versioned lineage of every accepted sample.

- **Tail latency sets the cache budget**: A high hot-tier hit rate is insufficient when cold misses are orders of magnitude slower. Use equation 4.1 as a mean baseline, then size prefetch buffers from p99 I/O latency and test correlated miss bursts against the compute window.
- **Direct storage removes host payload copies**: GDS retains CPU submission and coordination while bypassing host bounce buffers. The illustrative example assumes 75 percent less active CPU time per request; the benefit depends on whether payload copying limits the workload.
- **Checkpoint recovery is a storage protocol**: Local NVMe staging can shorten pause time, but a restorable checkpoint also needs durable publication, a committed manifest, and verified shards; durability, availability, and consistency remain distinct contracts.
- **Pipeline correctness lives at commit boundaries**: Replay preserves processing completeness only when stable identifiers and idempotent or transactional writes prevent duplicate effects. Event-time watermarks then make the separate freshness-completeness trade-off explicit.
- **Economics drive tiering**: The 5× local-NVMe/object-storage price ratio illustrates the incentive to keep data on cheaper tiers under the stated pricing assumptions (principle 8). Compare total delivery cost, including transfer charges and idle accelerators, before deciding where to stage it.

Checkpoint staging shows the C^3 trade-off in one design decision. Writing first to local NVMe shortens the compute pause, but asynchronous replication adds communication traffic and requires coordination to publish only complete generations. Once the shared-file-system write leaves the critical path, the bottleneck can move to local flash endurance, peer-replication bandwidth, or manifest commit latency. Measuring only the shorter training pause would miss the new recovery boundary.

or parameters across the fabric. Part II moves from physical infrastructure to distributed execution. It begins with the collective operations that carry those exchanges and the cost of each, then partitions neural networks across data, tensor, pipeline, and sequence dimensions, before turning to the hardware failures that a fleet must survive.

↪ The collective operations that carry gradient and activation exchanges, and the cost models that price them, are developed in chapter 5.

DISTRIBUTED ML

Part II

4

Distributed ML Principles

Wiring thousands of accelerators together with high-speed switches and parallel storage does not by itself make them train one model. Without distributed coordination, replicas diverge, partitioned layers stall on missing activations, and a single failed GPU halts the entire cluster. If Part I built the physical substrate, Part II establishes the logic of distribution: the algorithms, protocols, and coordination strategies that make a collection of independent accelerators behave as one machine. The same physics that set the rates in Part I explains why adding accelerators does not always yield linear speedups, and why communication, not computation, is often the hidden bottleneck.

At this scale, the engineering challenge is a trade-off between parallelization and coordination. Partitioning a model reduces per-device memory pressure but requires exchanging intermediate results across partitions. Replicating a model across workers instead requires coordinating their updates. Adding nodes can reduce training time while exposing a job to more component failures, decreasing its mean time between failures (MTBF) when an individual failure interrupts the job. Fault tolerance therefore becomes part of the execution design. These principles decompose the communication cost that the Fleet Law exposes (section 1.5.4) and add the reliability cost of scale.

The following principles preview the trade-offs developed in Part II, and the chapters establish when each mechanism helps and how to measure its cost. The first pressure is the economics of scale itself. Frontier capability demands compute, and each improvement costs more than the last, as the scaling laws of section 1.3 showed. Part I priced the supply of that compute; the first principle states the demand in the form that later chapters cite.

Principle 9: The empirical scaling law

Invariant: Within empirically validated regimes, foundation-model loss ($\mathcal{L}$) follows approximate power-law relationships with a resource quantity X such as training compute, dataset size, or parameter count. The exponent α_{scale} depends on the fitted regime. The single-resource simplification used to illustrate diminishing returns is:

$$\mathcal{L}(X) \propto X^{-\alpha_{\text{scale}}}$$

Implication: Within a fixed scaling regime, reducing loss further requires increasing resources. The diminishing return helps explain the move from single-server training to warehouse-scale clusters. Architecture, data quality, and training methods can change that regime, so a fitted scaling relation guides resource planning without guaranteeing improvements on every task.

That demand for scale turns each training step into a negotiation between faster local work and slower global coordination. Splitting a batch or a model across more workers shrinks the arithmetic each device performs, but it also introduces network transfers and barrier waits that grow with cluster size.

Principle 10: The fleet law (distributed step-time model)

Invariant: Under ideal partitioning of a fixed amount of work across N workers or accelerators, the step-time model adds computation, communication, and synchronization, then subtracts the portion hidden by overlap, with $0 \leq T_{\text{overlap}} \leq \min\left(\frac{T_{\text{compute}}}{N}, T_{\text{comm}}(N) + T_{\text{sync}}(N)\right)$.

$$T_{\text{step}}(N) = \frac{T_{\text{compute}}}{N} + T_{\text{comm}}(N) + T_{\text{sync}}(N) - T_{\text{overlap}}$$

Implication: Scaling is a race between parallelizable compute (which shrinks with N under ideal partitioning), communication overhead, and synchronization overhead. To scale efficiently, algorithms must reduce or amortize $T_{\text{comm}}(N)$ and $T_{\text{sync}}(N)$ (for example, through gradient accumulation, which alters the effective batch and convergence regime, or through compression, which can introduce numerical error). They must also maximize T_{overlap} through communication hiding and pipelined execution.

For data parallelism, the AllReduce that combines every worker's gradients sets the size of the Fleet Law's communication term. Because every replica must receive the full sum of gradients before advancing its weights, the volume moved per rank approaches a constant floor even as more workers join the job.

Principle 11: The AllReduce bandwidth bound

Invariant: An AllReduce of a M-byte tensor across N ranks, built from point-to-point transfers, must send at least $2(N-1)M/N$ bytes from some rank. Ring AllReduce meets that bound, at the price of a startup term that grows linearly with N:

$$T_{\text{ring}} = 2(N-1)\alpha + 2\frac{N-1}{N}\frac{M}{\beta}$$

Implication: The bandwidth term approaches $2M/\beta$ and stops shrinking as workers are added, while each worker's share of the compute keeps shrinking, so under pure data parallelism communication eventually dominates the step. Tree and hierarchical schedules give up some of the ring's byte efficiency for fewer startup rounds when messages are small or N is large.

The Fleet Law and the AllReduce bound predict the time of one step; the scaling efficiency bound measures how far the resulting speedup falls short of ideal. Comparing multi-device runtime against a single-device baseline turns those exposed communication and synchronization terms into a direct measure of cluster return on investment.

Principle 12: The scaling efficiency bound

Invariant: For a fixed amount of training work, adding nodes reduces the computation assigned to each node, but the communication and synchronization terms of the Fleet Law limit the resulting speedup.

$$\eta_{\text{scaling}} = \frac{T_1}{N \times T_N}$$

Here, T_1 and T_N are the times to complete the same work on one and N devices, respectively. The ratio measures achieved speedup as a fraction of ideal linear speedup.

Implication: Perfect linear scaling ($\eta_{\text{scaling}} = 1.0$) is the ideal baseline, not a practical target. Real systems fall short of it by an amount that depends on the workload, the fabric, and the parallelism layout. Under pure data parallelism the shortfall grows with N because the compute term keeps shrinking while the ring's bandwidth term stays near $2M/\beta$, the scaling wall of data parallelism. A statistical limit applies as well, because beyond the critical batch size added data-parallel width buys little further loss reduction. The gap between $\eta_{\text{scaling}} = 1.0$ and the achieved efficiency captures losses from communication and coordination as well as load imbalance or other limits on parallel execution.

Even when communication and coordination are tuned, a larger fleet fails often enough that progress itself must be protected. Without periodic state snapshots, a single device or link failure discards every step completed since the run began.

Principle 13: The Young-Daly checkpoint interval

Invariant: The first-order checkpoint model balances the cost of writing the checkpoint (T_{write}) against the expected cost of reworking lost progress due to system-level failures ($\text{MTBF}_{\text{system}}$). For long runs with approximately constant failure rates and checkpoint write times small relative to MTBF, its optimal checkpoint interval (T^*_{ckpt}) is:

$$T^*_{\text{ckpt}} = \sqrt{2 \cdot T_{\text{write}} \cdot \text{MTBF}_{\text{system}}}$$

Implication: Checkpointing consumes time and storage bandwidth. When more participating components reduce job MTBF, the model favors shorter intervals, and the overhead at the optimum grows roughly as the square root of the component count; faster checkpoint writes can reduce that overhead. Correlated failures, variable write times, and recovery requirements need additional analysis before the interval becomes an operational schedule.

Fault tolerance illustrates why reducing one cost requires checking the others. Saving more often reduces expected rework but increases storage traffic.

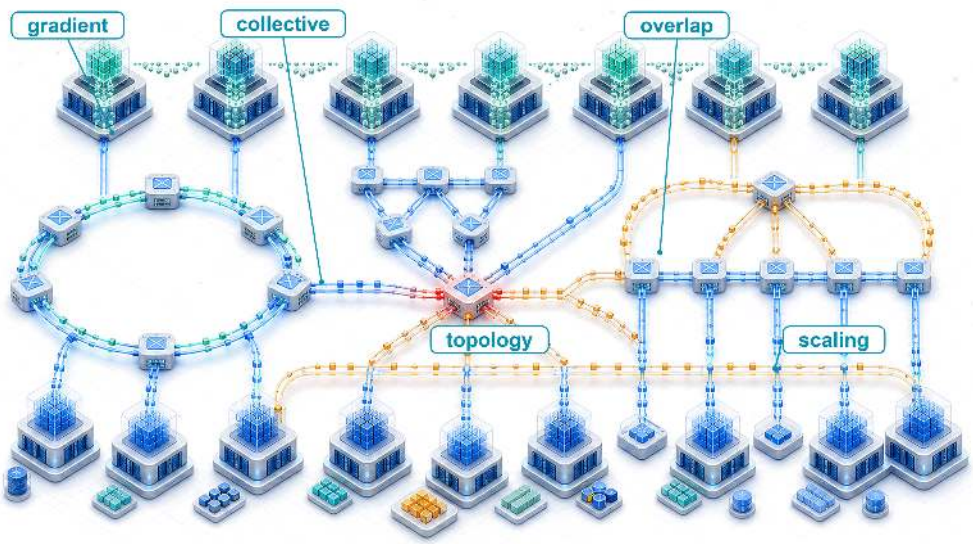
Principle 14: The displacement of overhead

Invariant: Distributed ML optimizations often relocate overhead among Compute, Communication, and Coordination (the C^3 taxonomy). Reducing one term can increase another, so designs must evaluate all three.

Implication: Asynchronous training can eliminate global coordination barriers ($T_{\text{sync}}(N) \to 0$) but may introduce gradient staleness that shows up as additional training iterations ($T_{\text{compute}} \uparrow$). Pipeline parallelism can reduce communication volume relative to finer-grained model partitioning but adds pipeline bubble time ($T_{\text{sync}}(N) \uparrow$). The C^3 taxonomy reveals where each design pays its overhead.

Accounting for overhead inside one job leaves a fleet-level question open, because many jobs compete for the same machines and a share of the fleet is worth something only if the job can run on it. Granting accelerators without the interconnect topology, power, or storage bandwidth a synchronous workload requires only strands those devices in an unusable allocation.

🏛 Principle 15: The feasibility-before-fairness principle



Invariant: A gang allocation for a synchronous job requires atomic allocation (every member is granted at once) and topology-feasible placement (the members sit within the interconnect domains the job's parallelism requires) to complete training steps. Its power and I/O allocation must also support the rate of progress promised at admission. Missing required gang members or placement can prevent execution; insufficient power or I/O capacity can reduce progress below the admitted rate.

Implication: Fairness policies such as dominant-resource fairness divide useful progress, so they can choose only among feasible allocations. A scheduler must first enumerate the feasible bundles and only then apply its fairness policy to them; a fair share of accelerators on which the job cannot run is idle capacity charged to a tenant. Feasibility constraints can deliberately leave accelerators idle, and that idle capacity is the price of keeping every admitted job productive.

Part II develops these previews in dependency order. Collective communication establishes how groups of workers combine and redistribute information across the fabric and what each exchange costs. Distributed training then partitions a workload and decides which of those exchanges its partitions must make. Fault tolerance protects the resulting progress against failure, and fleet orchestration allocates shared resources to jobs with those communication and recovery needs, admitting only allocations the jobs can actually use. Orchestration decides how much of the fleet a job actually holds, and fault tolerance decides how much of that held time becomes retained progress. In Fleet Law terms, collective communication shrinks $T_{\text{comm}}(N)$ and enlarges T_{overlap}. Distributed training decides how T_{compute}/N is divided and what $T_{\text{comm}}(N)$ that division incurs. Fault tolerance and orchestration bound the synchronization and recovery time that no partitioning can remove. The same chapters also set the fleet-level envelope for serving, since replicas draw on the same scheduler, share the same failure rates, and need the same recovery machinery. Together, they develop the algorithmic and operational discipline that turns the physical fleet of Part I into a working distributed system.

5

Collective Communication

Purpose

Why does communication between machines constrain large-scale machine learning systems?

Computation scales by adding processors; communication scales by moving data between them. These scale differently. Adding processors increases available arithmetic capacity, but useful work stalls when the required data does not arrive in time. Exchanging gradients, activations, and parameters can then consume more time than computing them. On one machine, shortening the dominant calculation often shortens the job. Across a fleet, that same improvement may simply make each processor reach its next dependency sooner and wait longer for the others. The cost of that wait includes every reserved accelerator, so a small delay repeated throughout training can consume a substantial budget without advancing the model. Faster links help when transfer capacity is the constraint, but the benefit depends on which physical paths the traffic shares. More bandwidth cannot remove a dependency. Sending less data introduces its own choices about numerical accuracy, memory use, and when the next computation can begin. An exchange must also deliver the correct result to every participant that needs it. A fast transfer that combines the wrong contributions does not preserve a valid

training run. The engineering decision is therefore how to organize communication so that its cost remains compatible with the work it enables. Light-speed delays, bandwidth limits, and the energy cost of movement make that decision as physical as processor design. In C^3 terms, collective communication connects distributed compute through coordinated exchanges whose correctness and exposed cost determine whether the fleet delivers useful scale.

Learning Objectives

- Apply communication cost models to estimate collective duration and message-size crossover points
- Match collective communication primitives and AllToAll schedules to parallelism strategies, topology, message granularity, and skew
- Compare ring, tree, butterfly, double-tree, and hierarchical reduction algorithms using scale-dependent cost models
- Evaluate topology-aware collective schedules under link-bandwidth, rank-placement, and shared-capacity constraints
- Evaluate compression, sparsification, and error feedback by balancing communication savings against convergence risk
- Design overlap strategies with bucket fusion, asynchronous operations, and layer-by-layer gradient scheduling
- Specify matched measurements for calibrating collective cost models across algorithms, process groups, and topologies

5.1 From Parallelism to Communication Patterns

WHEN 10,000 GPUs cooperate on one training update, the splits created by data, tensor, pipeline, and expert parallelism determine which results must cross device boundaries. Workers execute collective operations within participating groups and point-to-point transfers between pipeline stages. In the multi-tier fleet stack of figure 1.4, these exchanges occupy the Distributed Execution row of the Distribution band, where logical parallelism becomes physical traffic.

Every such split assumes that replicas, shards, stages, and experts can exchange gradients, activations, parameters, and tokens quickly enough for the optimizer to see one coherent training run. In data parallelism, each worker holds a full copy of the model and processes its own slice of the batch, so the copies must agree on one combined gradient before every update. Tensor, pipeline, and expert parallelism divide the model itself, so partial results must cross device boundaries within each step. Each of these exchanges is charged to the Fleet Law's communication term $T_{\text{comm}}(N)$, and the part of it not hidden behind computation counts against program goodput, the ratio of a step's ideal execution time to its actual time (section 9.6.1). Every way of splitting the model relocates work onto the network, and this chapter turns those exchanges into schedules whose latency, bandwidth, and topology costs can be computed.

The gap between that assumption and the wire reveals an asymmetry in how computation and communication scale. Computation is local because each GPU works on its own data, so aggregate compute grows with the number of GPUs. Communication is global because keeping the fleet synchronized requires information to cross physical links with finite latency, bandwidth, interconnect topology, and energy. Gradient synchronization is the central case, because every syn-

↪ The partitioning strategies themselves, and the 3D parallelism cube that composes data, pipeline, and tensor parallelism into one configuration space, are developed in section 6.2.

chronous data-parallel step repeats it on the full gradient. Scaling laws (principle 9) make that case harder over time, because the capability they reward comes from more parameters trained on more accelerators, so the gradient to be reduced and the group that must agree on it grow together.

Managing that global traffic begins by separating an operation's result from the schedule that produces it. Section 3.1 named AllReduce, AllGather, and AllToAll as the traffic the fabric must carry; here they become contracts on results. AllReduce[1] combines corresponding tensor elements across participating workers and returns the reduced tensor to every worker. AllGather instead concatenates their shards, ReduceScatter combines contributions but leaves each worker with only a shard of the result, and AllToAll sends different data to different destinations. The parallel decomposition determines which contract each exchange needs; ring, tree, and hierarchical algorithms are alternative schedules for carrying that contract out.

For the initial gradient budget, consider a ring schedule: each worker passes tensor chunks to a neighbor, first accumulating their sums and then circulating the completed chunks. Each phase moves nearly one tensor's worth of data per worker, so the bandwidth budget is approximately twice the gradient size divided by link bandwidth. The detailed round count follows once the transfer model is established.

[1] **AllReduce**: The name comes from MPI and describes the result, not the schedule: a Reduce (combining every rank's data at one root) followed by a Broadcast (returning the combined value to all ranks). A direct gather to the root concentrates raw input traffic there, but a tree can aggregate contributions along the way. The algorithms in section 5.6.3 distribute the reduction without a root.

Definition 5.1: Gradient synchronization

Gradient synchronization is the collective communication step in synchronous data-parallel training in which every worker contributes its locally computed gradient tensor to an aggregate reduction, then receives the same reduced result so all model replicas apply an identical update.

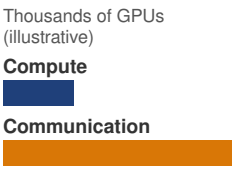
1. **Significance**: Communicating all gradients of a 70B-parameter model in BF16 gives a 140 GB logical payload per replica per step. As a communication-only baseline, suppose every rank reduces that complete buffer. A ring across 1,000 GPUs at 50 GB/s per link has a bandwidth budget of approximately $2 \times 140/50 \approx 5.6$ s of transfer per step. Model partitioning shrinks each rank's share of that buffer, and only the portion of $T_{\text{comm}}(N)$ left exposed after overlap adds to step time in the Fleet Law (equation 1.3).
2. **Distinction**: Unlike a parameter server, which concentrates every worker's gradient at a central aggregator, ring AllReduce spreads the exchange so that each worker sends $2 \times (N-1)/N \times M$ bytes per step, approaching $2M$ however large the cluster grows (section 5.6.1 develops the comparison).
3. **Common pitfall**: A frequent misconception is that ring AllReduce makes every worker exchange data with every other worker. In ring AllReduce, each worker communicates with neighbors according to a schedule, and the per-node communication volume is approximately constant as the cluster grows. The scaling pressure comes from latency

steps, topology, and the gradient volume per step, not from every worker opening a distinct stream to every other worker.

For standard synchronous data-parallel stochastic gradient descent (SGD), gradient synchronization supplies the shared gradient needed for one optimization trajectory. Replicas that apply different local gradients can diverge. To reproduce the intended global-batch update, they must also start from matching parameters and optimizer state, weight local contributions correctly, and apply the same update rule. The AllReduce primitive provides the reduction; convergence follows from the optimization assumptions, not from communication alone. Floating-point reduction order can still change low-order bits.

In general, a model with P parameters contributes $2P$ bytes per data-parallel replica when all gradients are communicated in BF16 (2 bytes per parameter); stored weight precision alone does not determine that choice. For the 70-billion-parameter model in the definition above (a mid-sized dense model smaller than the 175B-parameter running instance of Archetype A, GPT-4/Llama-3), that complete logical gradient is 140 GB, and a ring moves nearly twice its input buffer size per rank.[2] If a replica spans multiple ranks through model parallelism, each corresponding-shard group reduces its own portion rather than this full buffer.

Because every bandwidth term in this chapter scales linearly with payload size, the worked derivations use this compact 70B gradient (or the chapter's reference gradient buffer first priced in the energy estimate of section 5.2) and vary rank count to isolate how each schedule scales, before section 5.7.1 prices the full 175B Archetype A model on this book's reference cluster.



At large scale (hundreds of billions of parameters across thousands of GPUs), gradient synchronization can dominate training step time unless collective communication is systematically optimized. Understanding how to manage that overhead requires modeling data movement as physics rather than as an abstract API call.

5.2 The Physics of Data Movement

Whenever a gradient shard leaves an accelerator, three hardware limits bound its trip before any collective algorithm runs. The speed of light sets a propagation floor[3] of roughly 5 µs per kilometer in fiber. High-frequency signal loss limits how far copper traces can reach before the link must convert to optics (the bandwidth-distance product of section 3.3.2). Host-kernel networking stacks add tens of microseconds of software copy overhead, unless kernel-bypass transports such as remote direct memory access (RDMA) and GPUDirect RDMA strip per-message initiation down to a few microseconds. Collective communication also pays an energy price for every bit moved across those links, which the schedule must respect as firmly as latency and bandwidth.

Moving data consumes energy across storage arrays, interfaces, serializers, transceivers, and switches. A transfer that starts in local SRAM can stay on-package in high-bandwidth memory (HBM), cross to an intra-node peer GPU, or traverse intermediate switches to a remote node. Each step widens the physical account-

[2] **Ring AllReduce**: The algorithm dates to the HPC collective-communication literature; Patarasuk and Yuan analyzed bandwidth-optimal AllReduce algorithms for workstation clusters, Baidu's Andrew Gibiansky popularized ring AllReduce for deep learning in February 2017, and Horovod plus NVIDIA NCCL helped make it a common distributed-training primitive (Patarasuk and Yuan 2009; Gibiansky 2017; Sergeev and Balso 2018; Jeaugey 2017).

Exposed gradient synchronization can dominate step time at scale.

[3] **The speed-of-light constraint**: Light travels through optical fiber at approximately 200,000 km/s, or 200 meters per microsecond. For a rack-to-rack fiber path of 100 meters, propagation alone contributes approximately 500 ns in one direction. Faster switches can reduce other latency components, but reducing this propagation delay requires a shorter path or a different propagation medium.

↩ Kernel-bypass RDMA, which strips the per-message software overhead, and GPUDirect RDMA, which removes the host-memory bounce, are established in section 3.4.1.

ing boundary that an energy estimate must include (figure 5.1). Each boundary activates distinct physical components: on-package links, intra-node crossbars, serializers, optical transceivers, and switch fabrics. Distance alone does not determine energy per bit, and an endpoint-only estimate cannot be compared directly with a complete fabric-path estimate. Locality remains useful because it can avoid transfers and active interfaces; the energy saving must be evaluated under the same workload, utilization, and accounting boundary.

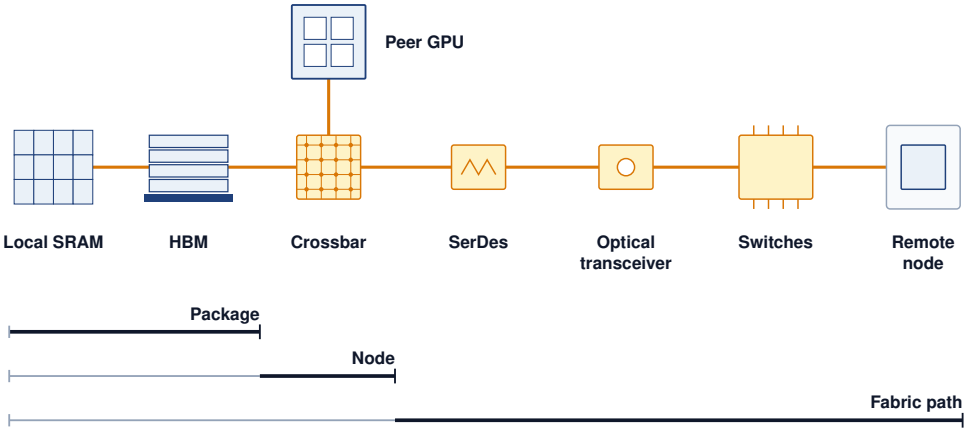


Figure 5.1: Data-Movement Accounting Boundaries: Successively broader paths involve different storage and communication components. The schematic identifies what an energy estimate must include; it assigns no universal distance law or fixed energy multiplier. Compare energy per transferred byte only after specifying endpoints, interfaces, switches, and utilization.

The chapter's reference gradient buffer of 1 GB stands for one large fused reduction, far smaller than a full model gradient but large enough that per-byte transfer, not per-message startup, governs its cost; later examples return to it by name. Reducing it around an illustrative 10,000-rank ring sends approximately twice the payload from every rank. At a fabric-path transfer cost of 35 pJ/bit, a representative midpoint of the range typical of switched fabrics rather than a measurement of any particular one, this gives about 5.6 kJ per reduction, paid again at every synchronous step. The usable rule is that communication energy is the bytes an algorithm sends multiplied by the energy per bit of every boundary those bytes cross. An algorithm that moves fewer bytes, or a placement that keeps more of them inside the node, therefore saves energy as directly as it saves time. The share of the step's total energy that communication represents must be measured at the same accounting boundary as the compute it accompanies. The fabric-path figure charges the serializers, transceivers, and switches between two endpoints. A whole-system estimate that also charges endpoint memory reads, host software, and idle network power assigns each byte crossing the network a much larger cost, so two per-byte figures can be compared only after their boundaries match.

↪ The energy cost of moving a byte across memory, storage, and network boundaries, and why movement can outweigh arithmetic, is developed in section 15.4.2.2.

These constraints govern different parts of a communication budget. Propagation latency sets a floor for every message regardless of size. Link bandwidth caps throughput once a transfer is large enough to fill the pipe. Protocol overhead adds

a fixed per-message cost that penalizes fine-grained exchanges unless a kernel-bypass transport removes it. RDMA's zero-copy path[4] avoids staging each transfer through host memory and the kernel's socket buffers, keeping that per-message cost low. Because the physical fabric fixes these limits, the collective schedule determines how many times the job pays them.

Across this section, the α-β cost model, the LogP processor-overhead extension, and the bisection-bandwidth ceiling have priced single transfers in isolation and exposed the 5,512.7 ms physical floor for a 140 GB gradient synchronization. Which collective operations a training step actually invokes, and how often they hit that latency-or-bandwidth wall, depends on how the workload partitions its parameters, activations, and tokens across devices.

5.3 Parallelism Strategies and Their Traffic

Once a training job splits its batch, layers, or parameters across devices, no rank holds all the state needed to finish a step on its own. A synchronous data-parallel worker computes gradients from its local batch slice, but its optimizer cannot update the weights until every replica's gradients have been combined. Some of those reductions can start as backward layers finish, while earlier layers are still computing. Tensor ownership determines where each tensor must go, and gradient or activation readiness determines when each transfer can start.

How the model is partitioned dictates which tensors cross device boundaries and which ranks must exchange them. For Archetype A (GPT-4/Llama-3), dense gradient contributions are combined within each data-parallel group; in a hybrid layout, that group contains the matching parameter shard from each replica. AllReduce serves the replicated-gradient baseline. For Archetype B (DLRM at Scale),[5] lookup requests travel to embedding-shard owners and the resulting vectors return to the workers that need them. Mixture-of-experts (MoE) routing similarly sends activations to the ranks hosting selected experts and returns their outputs. These destination-specific exchanges motivate AllToAll.

At large scale, these parallelism strategies can be combined. A 3D parallelism layout combines data parallelism, tensor parallelism, and pipeline parallelism, creating distinct communication groups whose exchanges may overlap in time. In a node-local tensor-parallel example, layer reductions use NVLink, pipeline stages exchange activations and their gradients point-to-point across nodes, and data-parallel groups reduce matching parameter shards over InfiniBand. Other placements change those physical paths while retaining the logical communication requirements.

Each primitive operates on a different process group, a subset of the total GPU population that participates in that particular collective. Classical Message Passing Interface (MPI) uses a communicator as the object that names such a participating set; its communicator size is the number of ranks in that set. MPI libraries already selected collective algorithms based on communicator size and message size (Thakur et al. 2005). GPU communication libraries inherit that algorithm-selection

[4] **Zero-copy communication**: GPUDirect RDMA lets the NIC read gradients directly from accelerator memory, so a 140 GB gradient never passes through host DRAM, whereas a staged path writes and then rereads it there (280 GB of host-memory traffic per send).

[5] **DLRM (Deep Learning Recommendation Model)**: Meta's 2019 architecture for click-through rate prediction uses sharded embedding tables and exchanges the resulting sparse lookups across workers, an AllToAll whose limiting term section 5.8 develops.

↩ The three lighthouse archetypes and the C^3 regimes each one stresses are established in section 1.6.1.

problem and add the further challenge of coordinating overlapping process groups without creating contention between concurrent collectives.

Each parallelism strategy fixes the data it must move, the collective primitive that moves it, and the term most likely to bind (table 5.1), and with them which participants must exchange data. The collective primitives that follow make each exchange's contract precise, the pricing model then charges it per round, and the collective algorithms provide its execution schedule.

Table 5.1: Parallelism-to-Collective Mapping: How each parallelism strategy becomes a traffic pattern. Pipeline parallelism alone relies on point-to-point transfers rather than a collective.

Parallelism strategy	What must move	Primary primitive	Primary constraint
Data Parallelism	Full gradient, averaged across replicas	AllReduce	Bandwidth (large payloads)
FSDP/ZeRO-3	Parameter shards in, gradient shards out	AllGather + ReduceScatter	Bandwidth, high frequency
Tensor Parallelism	Partial layer activations within the node	AllReduce, AllGather	Critical path (NVLink bandwidth and latency)
Sequence Parallelism	Activations sharded along the sequence	AllGather + ReduceScatter	Bandwidth (activation exchange)
Pipeline Parallelism	Activations to the next stage	Point-to-Point (Send/Recv)	Latency (microbatch dependencies)
Expert Parallelism (MoE)	Tokens to the ranks hosting their experts	AllToAll	Startup, injection/bisection, or skew
Embedding Sharding (DLRM)	Embedding lookups to and from shard owners	AllToAll	Granularity, fabric capacity, or skew

In this table, expert parallelism refers to the mixture-of-experts architecture pattern, in which each token activates only a few experts. Data parallelism and fully sharded data parallel (FSDP), which divides each replica's parameters, gradients, and optimizer state across the data-parallel ranks, generate large reductions and gathers that reward byte-efficient rings and hierarchical schedules. Tensor and pipeline parallelism, by contrast, generate smaller, more frequent messages directly on the critical path, so low software overhead and fast node-local links dominate their cost. Expert parallelism and sharded embedding tables, in contrast, produce destination-specific traffic whose bottleneck shifts among message granularity, endpoint injection and reception, fabric bisection, oversubscription, routing, and skew.

The table's rows describe data center parallelism, so they leave out the federated Archetype C. Across all three lighthouse archetypes, the dominant exchange and its bottleneck differ.

Lighthouse 5.1: Communication archetype patterns

A gradient's communication pattern depends on the system's objective function and constraint regime. Each lighthouse archetype faces a distinct communication challenge, and the techniques developed in this chapter map to those challenges differently, as table 5.2 summarizes.

Table 5.2: Archetype-to-Collective Mapping: Each lighthouse archetype produces a characteristic traffic pattern, but the limiting term depends on message shape, placement, and the physical fabric.

Archetype	Primary collective	Candidate limiter	Optimization strategy
Archetype A (GPT-4/Llama-3)	AllReduce	Bandwidth (β)	Hierarchical AllReduce; rail-optimized placement
Archetype B (DLRM at Scale)	AllToAll	Granularity, fabric capacity, or skew	Message coalescing; topology-aware routing; shard balancing
Archetype C (Federated MobileNet)	Client uploads to an aggregator (asynchronous)	Uplink bandwidth and availability	Aggressive quantization; error feedback

The table separates traffic pattern from limiting resource. A dense reduction, a destination-specific exchange, and an intermittent device update require different interventions even though all three serve a training workload. Hierarchical AllReduce, AllToAll schedule selection, and compression with error feedback each receive their own treatment later in the chapter.

A traffic map names which pattern a workload generates, but it does not specify what each rank must hold when the call completes. Before any of those interventions can be priced, each exchange needs a precise contract that states which ranks contribute and what each holds afterward.

5.4 Collective Operation Primitives

Sending a gradient tensor to a peer does not specify which workers must contribute or where the final result belongs. Collective operations supply that group-level contract, using a vocabulary standardized by MPI and inherited by modern ML communication libraries (Message Passing Interface Forum 2015). The four contracts sketched at the start of the chapter differ in what each rank holds afterward (figure 5.2). AllReduce leaves an identical sum (Σ) on every rank. AllGather leaves every rank with the concatenation of all shards. ReduceScatter sums across ranks but leaves each rank one reduced shard (Σ_i). AllToAll performs a distributed matrix transpose, routing each rank's j-th chunk to rank j. Two further primitives complete the set and serve as building blocks for these four: Broadcast, in which rank 0 sends its data to all ranks, and Reduce, in which all ranks aggregate into rank 0.

↪ The bandwidth and latency cost terms of AllReduce, AllGather, ReduceScatter, AllToAll, and Broadcast, under ring, tree, and pairwise-exchange algorithms, are developed in section D.2.

Definition 5.2: Collective operation

Collective operation is a distributed communication pattern in which every rank in a process group invokes a matching operation to aggregate, broadcast, or redistribute data. The operation's contract specifies the output at each rank; it does not require simultaneous entry and does not, by itself, impose a general-purpose barrier before or after the call (Message Passing Interface Forum 2015).

1. **Significance**: Because the contract names only each rank's result, the schedule that carries it decides how communication demand spreads as the group grows. A schedule that funnels every contribution through one endpoint makes the communication term $T_{\text{comm}}(N)$ of the Fleet Law (equation 1.3) grow with N, while a balanced schedule keeps each rank's bytes nearly constant; section 5.6.1 quantifies the gap.
2. **Distinction**: Unlike point-to-point communication, a collective defines one operation over a process group. Ranks may enter at different times, and some algorithms allow one rank to complete before another has entered; correctness depends on matching the operation sequence and argument contract across ranks, not on barrier semantics.
3. **Common pitfall**: Treating a non-blocking collective as complete when its initiation call returns. The returned request or stream event represents work in flight. A dependent consumer must wait for completion, and a late rank can extend that dependency even though the collective is not a barrier.

The primitive choice is the first scaling decision because it fixes which ranks must coordinate and which result each must obtain. Once that contract is chosen, the algorithm and placement determine how the resulting traffic crosses the fabric.

5.4.1 The six core primitives

Calling a full AllReduce when each rank's optimizer updates only a $1/N$ parameter shard moves twice as many bytes as the step needs, because half the work goes into assembling full tensors that every rank immediately discards. Choosing the right primitive therefore means matching the contract in table 5.3 to the exact slice the next computation consumes. The table's rows run from the root-centered patterns (Broadcast and Reduce), through the three in which every rank contributes to and receives part or all of one shared tensor (AllReduce, AllGather, and ReduceScatter), to AllToAll, in which every pair of ranks exchanges distinct data. That order describes routing rather than cost: ReduceScatter and AllGather each move half of AllReduce's bytes because each is one phase of it. The cost column previews the algorithms derived in section 5.6, using N for the participating rank count, M_{coll} for the full tensor, and M for the per-rank AllToAll input payload. For AllReduce, the full tensor has the same byte size as each rank's input payload, the convention used in the following algorithm models. Two schedules appear there: a ring

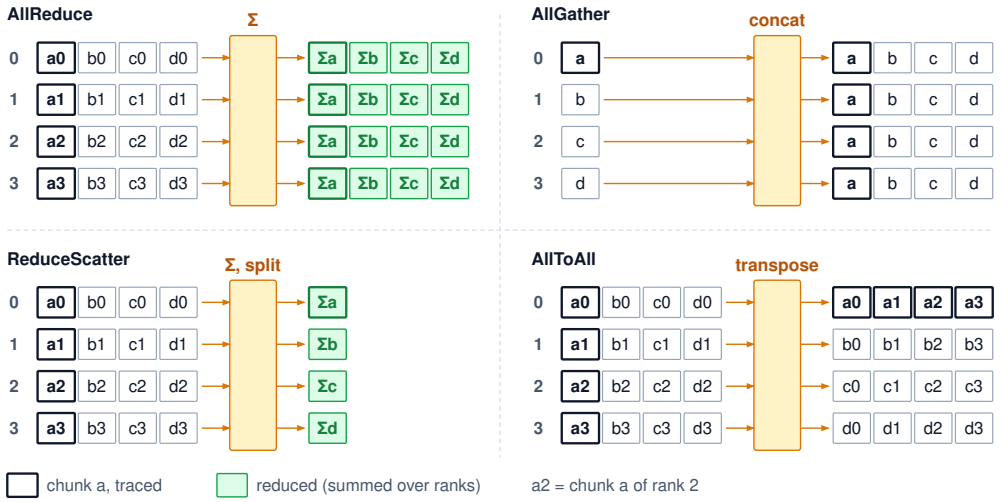

Figure 5.2: Four Central Collective Primitives: Standardized patterns for group communication in distributed systems. In each panel the four rows are ranks 0 to 3, read left to right from each rank's input, through the collective, to what each rank holds afterward. (1) AllReduce: all aggregate and all receive the result. (2) AllGather: all send to all and concatenate. (3) ReduceScatter: all aggregate and results are distributed in shards. (4) AllToAll: every process sends unique data to every other process. The two foundational primitives Broadcast (rank 0 sends to all) and Reduce (all aggregate to rank 0) compose the patterns shown here and are defined in the surrounding prose.

passes chunks between neighbors, whereas a simple full-message tree reduces up a binary tree and broadcasts back down it, forwarding the whole tensor at each of its $2\log_2 N$ levels. For Broadcast and Reduce, the table counts startup rounds and bytes per tree edge separately. Each traverses one tree depth, so the elapsed transfer cost accumulates across its levels. The Tree AllReduce derivation combines those two traversals.

Table 5.3: The Six Collective Primitives: What each primitive computes, its primary use, and its communication cost, ordered from root-centered patterns (Broadcast, Reduce) to the fully destination-specific AllToAll. The order describes routing, not cost.

Primitive	What it does	Primary use case	Communication cost
Broadcast	One sender transmits data to all receivers.	Distribute initial model weights from rank 0 at startup, across all parallelism strategies.	$\mathcal{O}(\log N)$ startup rounds; $\mathcal{O}(M_{\text{coll}})$ bytes per tree edge. Elapsed byte-transfer time also grows with tree depth.
Reduce	Aggregate data from all workers (sum, min, max) to a single root.	Aggregate validation metrics such as loss and accuracy to a logging process.	$\mathcal{O}(\log N)$ startup rounds; $\mathcal{O}(M_{\text{coll}})$ bytes per tree edge. Elapsed byte-transfer time also grows with tree depth.

Primitive	What it does	Primary use case	Communication cost
AllReduce	Aggregate from all workers, then distribute the result to all ($y_i = \sum_{j=0}^{N-1} x_j$ for all i).	Data parallelism: synchronize gradients so every GPU computes the same update.	Ring is bandwidth-optimal at $2\frac{N-1}{N}\frac{M_{\text{coll}}}{\beta}$ but $\mathcal{O}(N)$ latency; the simple full-message Tree model gives $\mathcal{O}(\log N)$ latency with more byte-transfer work.
AllGather	Each worker's data goes to all; the result concatenates every input ($x_i \to [x_0, \ldots, x_{N-1}]$).	Sharded data parallelism (FSDP/ZeRO): collect sharded parameters before a forward or backward pass.	Ring $\frac{N-1}{N}\frac{M_{\text{coll}}}{\beta}$; resident data grows from an M_{coll}/N shard to the full M_{coll}.
ReduceScatter	Reduce across workers, but scatter so each keeps a distinct chunk (worker i receives the i-th block of $\sum x_j$).	Sharded data parallelism: reduce gradients while keeping them sharded to save memory.	Ring $\frac{N-1}{N}\frac{M_{\text{coll}}}{\beta}$; the same ring byte-transfer term as AllGather, with reduction.
AllToAll	The most general pattern: worker i sends a distinct chunk to each worker j, a distributed matrix transpose.	MoE routing tokens to experts; DLRM exchanging embedding lookups across workers.	Per-worker payload $\frac{N-1}{N}M$; the limiter can arise from startup, injection/reception, bisection, oversubscription, routing, granularity, or skew.

Ring achieves AllReduce's bandwidth-optimal cost while the simple full-message Tree model trades bandwidth for logarithmic latency (Patarasuk and Yuan 2009; Thakur et al. 2005). AllReduce itself also decomposes into ReduceScatter followed by AllGather. The decomposition is operational as well as mathematical, since Ring AllReduce's first phase is a ReduceScatter and its second phase is an AllGather. ReduceScatter performs arithmetic, so it does not invert AllGather despite reversing the direction of shard expansion. Full ZeRO-style sharding and PyTorch FSDP use the pair the same way, gathering parameter shards with AllGather before a module needs them and reducing gradients with ReduceScatter after backward so each rank retains only its shard for the optimizer step (Rajbhandari et al. 2020). Sharding parameters, gradients, and optimizer state across workers reduces persistent model-state memory roughly by $N\times$, while temporary full-parameter buffers and prefetching determine peak memory. That memory saving is developed in section 6.3.3; the communication it adds is priced in section 5.4.2.

The same AllGather/ReduceScatter pair also appears in sequence parallelism, where an AllGather reconstructs the activation view needed for a local operation and a later ReduceScatter redistributes the result along the sequence dimension.

A primitive's semantics stay fixed even when the tensor dimension being sharded changes, so every schedule developed for the pair applies to both uses.

Beyond defining data-movement dependencies, collective operations carry explicit interface and numerical contracts. At the interface level, every rank in a process group must issue collectives in a compatible sequence; mismatched operation orders can deadlock or pair unrelated buffers. Operations also enforce shape and type contracts. AllReduce requires matching element counts and datatypes across all ranks, whereas variable-size exchanges require explicit per-destination counts and displacements. These invariants form the contract between the parallel decomposition and the communication runtime: the model decides which tensor slices each rank owns, and the collective contract guarantees that those slices can be recombined deterministically.

Reduction order introduces a second, numerical contract. Floating-point addition is not associative, so ring, tree, and switch-assisted reductions may accumulate the same values in different orders and produce different low-order bits (Goldberg 1991). A correct AllReduce therefore guarantees the specified reduction over all contributions, not bitwise identity across algorithms, rank counts, or hardware. Reproducibility-sensitive workloads must fix the algorithm and process-group configuration or use a reproducible accumulation scheme; ordinary training should treat small order-dependent differences as numerical behavior while still checking for larger rank disagreement.

AllToAll scales differently from AllReduce with cluster size, and section 5.8 develops the bound that governs it. With the six contracts defined, every row of table 5.1 now names a primitive whose output and traffic pattern are precise. The sharded data-parallel row repays closer study, because sharding changes how often those primitives run rather than which ones run.

5.4.2 FSDP communication patterns

Sharding every parameter, gradient, and optimizer-state tensor across N data-parallel ranks saves memory, but it replaces one end-of-step reduction with a stream of collective calls inside the forward and backward passes. Under fully sharded data parallelism (Rajbhandari et al. 2020), each rank holds only $1/N$ of a layer's weights. It must call AllGather before the layer's forward pass to assemble the full weights. After the backward pass, it calls ReduceScatter to leave each rank the gradient for its own shard, and then frees the temporary full weights.

Trading resident memory for on-demand assembly multiplies the collective call count. With one communication group per layer, a schedule that holds each layer's gathered weights until its backward pass finishes issues $2N_L$ collective calls per step (one forward AllGather and one backward ReduceScatter per layer) where unbucketed data parallelism issues one AllReduce. To save peak activation memory, full-resharding FSDP instead frees the full weights right after each layer's forward pass and runs a second AllGather before that layer's backward pass, raising the count to about $3N_L$ calls per step. The byte volume changes far less. Because each AllGather and ReduceScatter over a large group moves nearly M_{coll} bytes per rank across all layers combined, where M_{coll} is the model-sized payload

without optimizer state, the $2N_L$-call schedule sends roughly the AllReduce's $2M_{\text{coll}}$ per rank and the resharded $3N_L$-call schedule sends about $3M_{\text{coll}}$ ($1.5\times$) when parameters and gradients travel at the same width. Different parameter and reduction datatypes shift that ratio. The call count carries its own price, because every call pays a startup cost. An effective startup cost α_{eff} contributes approximately $2N_L\alpha_{\text{eff}}$ per step before overlap, or $3N_L\alpha_{\text{eff}}$ with resharding. FSDP is therefore more sensitive to α_{eff} than an unbucketed data-parallel reduction even though its bytes barely change. The counts describe one grouping policy, since FSDP units need not coincide with layers and bucketed data parallelism also splits its reduction to enable overlap. FSDP implementations mitigate the startup cost through prefetching and communication-stream pipelining, but the relevant α_{eff} must come from a matched collective benchmark rather than a wire-latency specification.

↪ The ZeRO stages and the reshard-after-forward FSDP schedule, with the memory each saves and the communication each adds, are developed in section 6.3.3.

Selecting the right collective algorithm at each invocation requires distinguishing transfer cost from dependency exposure. An FSDP AllGather is latency-sensitive in the scheduling sense, because a layer cannot compute until its full parameters arrive. Its transfer can nevertheless be bandwidth-bound when the parameter tensor is large. Prefetching can hide part of that gather, while a ReduceScatter can overlap with the remaining backward computation. Neither dependency alone selects Ring or Tree; message size, group size, topology, and the available overlap window jointly determine the useful schedule.

The primitives specify what must be communicated, and sharding shows how often a training step invokes them. Choosing a schedule for each invocation first requires a price for every round of an exchange.

5.5 Pricing Collectives by Rounds and Chunks

A gradient bucket of tens of megabytes is large enough to saturate a single network link. Yet when a thousand-GPU ring divides that bucket into a thousand shards, each hop moves only tens of kilobytes and can spend more time starting the transfer than sending its bytes. Pricing a collective therefore requires separating the fixed time to initiate each message from the rate at which bytes move once in transit.

The α-β model $T(n) = \alpha + n/\beta$ prices a transfer over a single link (principle 5), separating a fixed startup cost (α) from a per-byte transfer cost (n/β) (Hockney 1994). A collective pays that price at every step of its schedule, so the two terms, multiplied by the schedule's round count and traffic factor, determine algorithm selection across the fleet.

↩ The α-β model for a single link and its latency-dominated and bandwidth-dominated regimes are established in section 3.4.4.

For collectives, the parameters must describe the effective path. Latency (α) is the startup cost paid at every step of a schedule, so it includes recurring software overhead, PCIe traversal, and network switching time; one-time communicator initialization is a separate setup cost. Bandwidth (β) is the sustained per-direction transfer rate. The critical message size $n^* = \alpha \cdot \beta$, where the two terms are equal, carries over unchanged. It must, however, be compared against each step's chunk (M/N in an N-rank ring) rather than the whole tensor M. That is why a large

↪ Worked message-size regimes and crossover calculations for this model are developed in section D.1.

bucket can still fall below the inter-node crossovers in table 5.4. Below n^*, a step is latency-bound; above it, bandwidth-bound.

The crossover explains two recurring optimizations. For InfiniBand NDR at $\alpha \approx 1.5$ µs and $\beta \approx 50$ GB/s, the knee sits at $n^* \approx 75$ KB, the value section 3.4.4 computed for a single transfer. A 4 KB routing message is far below n^*, so the startup cost dominates. If 100 ready messages have compatible destinations and can share one transfer, fusing them into a 400 KB message reduces the modeled cost from approximately $100\alpha = 150$ µs to $\alpha + n/\beta \approx 9.5$ µs. That is roughly a 16× improvement before packing costs. More generally, N_{msg} serialized messages of size n/N_{msg} can cost up to $N_{\text{msg}}\times$ as much as one message of size n when $n/N_{\text{msg}} \ll n^*$. Fusion is the first optimization, and it motivates framework gradient buckets and destination-aware token coalescing.

Compression is the second, and the crossover tells where it pays. A 140 GB gradient tensor sits far above n^*, so shrinking its bytes shrinks the dominant n/β term directly, provided encoding and aggregation costs are counted. Even keeping only the largest 1 percent of values (Top-k sparsification, developed in section 5.9) leaves 1.4 GB of values before their indices are added, still far above n^*, so the saving remains a byte saving. Compressing a 4 KB routing message, by contrast, offers little, because its unchanged α term already dominates.

Across the typical data center interconnects tabulated in table 5.4, the critical-size column carries the load-bearing pattern: intra-node NVLink stays latency-bound up to several hundred kilobytes, whereas the inter-node fabrics cross over below roughly 100 KB. A message between those crossover sizes can therefore be latency-bound inside a node but bandwidth-bound once it travels between nodes.

Table 5.4: Interconnect Performance Parameters: Effective per-message launch latency (α, including the software stack), per-direction link bandwidth (β, the one-way deliverable rate that enters $T(n) = \alpha + n/\beta$; NVLink's datasheet 900 GB/s is the bidirectional total, so its β is the 450 GB/s one-way rate), and the computed crossover size $n^* = \alpha \cdot \beta$ at each row's α midpoint (for InfiniBand NDR, at the representative 1.5 µs used throughout this chapter), where communication transitions from latency-bound to bandwidth-bound.

Interconnect	Latency (α)	Bandwidth (β)	Critical size (n^*)
NVLink 4.0 (intra-node)	1–2 µs	450 GB/s	~0.7 MB
InfiniBand NDR 400 Gbps	1–3 µs	50 GB/s (per port)	~75 KB
InfiniBand HDR 200 Gbps	2–5 µs	25 GB/s	~87.5 KB
PCIe Gen5 (GPU↔CPU)	2–5 µs	64 GB/s	~224 KB
Ethernet 100 Gbps (RoCE)	5–10 µs	12.5 GB/s	~93.7 KB

The NVLink and NDR rows show the roughly ninefold per-direction cliff of section 2.5.1, which section 3.1 traces across a decade of interconnect generations. Even on the lower-crossover inter-node fabric, a bucket far above n^* can still travel

in chunks below it because a ring divides the bucket among its N ranks. Pricing one bucket at two group sizes shows when that happens and what it costs.

Napkin Math 5.1: The critical message size

Problem: A data-parallel job reduces a 25 MB gradient bucket with Ring AllReduce over InfiniBand NDR, with $\alpha = 1.5$ µs and $\beta = 50$ GB/s. The bucket is hundreds of times larger than the single-transfer knee. Does each step of the ring run in the bandwidth-bound regime on 64 GPUs, and on the 1,024-GPU reference cluster?

Math:

1. **Knee**: $n^* = \alpha \cdot \beta = 1.5 \times 10^{-6}$ s $\times\ 5 \times 10^{10}$ B/s $= 75$ KB.
2. **Chunk per step**: A ring sends M/N per step, 390.6 KB on 64 ranks (above the knee) but only 24.4 KB on 1,024 ranks (below it).
3. **Ring time** $2(N-1)\left(\alpha + \frac{M}{N\beta}\right)$: about 1.2 ms on 64 ranks, of which the byte term is 1.0 ms; about 4.1 ms on 1,024 ranks, where the byte term is still only 1.0 ms.

Systems insight: The regime belongs to the chunk, not to the tensor. The byte term barely moves as the group grows, but at 1,024 ranks each step carries a chunk below n^*, so startup dominates and the same bucket takes several times longer. Large language model (LLM) gradients are bandwidth-bound as tensors, yet a flat ring over a large group can still carry them in latency-bound steps. The levers then shift to larger buckets, fewer rounds, and hierarchy, which is why the algorithms of section 5.6 compete on round count as well as bytes.

For collectives, the two regimes map onto different levers. In the latency-bound regime $(n < n^*)$, where MoE routing tokens, scalar reductions, and the small chunks of a large-group schedule sit, the levers are fusion, fewer schedule rounds, fewer hops, and a leaner software stack. In the bandwidth-bound regime $(n \gg n^*)$, where LLM gradients and optimizer states sit, they are compression, a byte-efficient algorithm, and link aggregation across multiple network interface cards (NICs). Classifying each exchange, and each chunk within it, into one regime is the diagnostic skill the rest of the chapter applies.

Checkpoint 5.1: Per-chunk pricing diagnostics

Verify your understanding of per-chunk pricing regimes:

- ☐ **Chunk regime**: classify each ring step of a 25 MB gradient bucket reduced over 1,024 ranks, on links with $\alpha = 5$ µs and $\beta = 50$ GB/s, as latency-bound or bandwidth-bound.

- ☐ **Software overhead**: determine which type of parallelism benefits more when software overhead (α) is reduced by half, data parallelism or tensor parallelism.
- ☐ **Chunks under an upgrade**: explain why upgrading links from 100 Gbps to 400 Gbps at constant software latency can move a large ring's per-step chunks from the bandwidth-bound to the latency-bound side of $n^* = \alpha \cdot \beta$.
- ☐ **NIC scaling**: assess the True or False claim that, in the bandwidth-bound regime, doubling the number of NICs per node effectively doubles the transmission speed for large tensors.

The pricing model charges a schedule per round and per chunk, but it does not choose the schedule. AllReduce, the most performance-critical primitive, admits several schedules whose round counts and byte volumes differ sharply, and for a large gradient the choice can decide whether gradient synchronization can be hidden at all.

5.6 AllReduce Algorithms and Topologies

A correct AllReduce must give each of 1,000 GPUs the reduced sum of all 1,000 gradient contributions, subject to the floating-point reduction contract, and the algorithm that delivers it sets the cluster's scaling ceiling. The naive answer, in which every GPU sends to one central server whose single network link must carry every worker's gradient, fails first, which makes it the right place to start.

5.6.1 Naive approaches vs. the bandwidth bottleneck

Consider a naive implementation using a parameter server (a star topology), with a dedicated server in addition to the workers. All N workers send their gradients to that server; it sums them and sends the result back. The server must receive $N \times M$ bytes and send $N \times M$ bytes, so its bandwidth budget grows as $T_{\text{comm}} \propto N \times M/\beta$. At 1,000 GPUs, concentrating those transfers at one server creates a scaling bottleneck even if the arithmetic is fast.

This naive approach captures the pressure that early distributed ML frameworks had to manage. Parameter-server systems receive, aggregate, and redistribute model updates through a server tier, and practical implementations shard the parameter space to spread that load (Dean et al. 2012; Li et al. 2014). Sharding reduces the per-server traffic from $N \times M$ to $N \times M/K_{\text{srv}}$ (where K_{srv} is the number of servers). The server tier still grows as workers and model state grow, and it introduces additional complexity in parameter partitioning and consistency management.

The bottleneck comes from concentration, not from total traffic. Every AllReduce algorithm moves more total data as workers are added, because every worker's contribution must be combined and every worker must receive the result. A star, however, routes all of that traffic through one endpoint, so the server's time grows as $N \times M/\beta$. A ring spreads the same work so that each rank sends about $2M$ and

its time stays near $2M/\beta$ however large N becomes. The ratio of the two is about $N/2$, so at 1,024 workers the server's byte time is roughly 500× the ring's, before startup, arithmetic, or contention are counted. Bandwidth optimality makes that comparison precise by measuring an algorithm's required byte movement against a lower bound under a stated communication model, which the next derivation supplies for AllReduce.

War Story 5.1: When the parameter server became the bottleneck (2017)

Context: In 2017, Alexander Sergeev and Mike Del Balso's team at Uber open-sourced Horovod as part of Uber's Michelangelo ML platform, where TensorFlow training jobs needed to scale across many GPUs without forcing every model author to rewrite large portions of training code (Sergeev and Balso 2018).

Mechanism: TensorFlow's stock distributed training relied on a parameter-server pattern that concentrated gradient traffic through a central tier. As worker count N grew, the central server link saturated, degrading scaling efficiency.

Impact: Scaling training beyond a single node resulted in severe throughput bottlenecks and required complex, model-specific parameter partitioning.

Fix: Uber adopted Baidu's ring AllReduce algorithm (Gibiansky 2017), wrapping bandwidth-optimal collective reduction behind a lightweight API that replaced parameter servers with ring communication.

Systems lesson: A collective algorithm is also a developer interface. Scaling improves when the communication primitive is both bandwidth efficient and easy enough that teams actually use it correctly.

5.6.2 The bandwidth-optimal lower bound

Before choosing a schedule to replace the parameter server, we need to know the minimum byte volume any point-to-point AllReduce must move when N ranks each start with an M-byte gradient and neither compression nor in-network switch reduction is used. Reducing one independent data item across N ranks and distributing its result requires at least $2(N-1)$ item transfers in aggregate (Patarasuk and Yuan 2009). The count has two halves. Combining N contributions that start on N different ranks takes at least $N-1$ transfers, because each transfer combines at most two partial sums and so reduces the number of separate partial sums by at most one. Delivering the finished value to the other $N-1$ ranks then takes at least one transfer each. For an M-byte tensor, the minimum aggregate sent volume is therefore $2(N-1)M$ bytes. At least one rank must send the average share, $2(N-1)M/N$ bytes; a balanced algorithm assigns that share to every rank.

Take β as each rank's available send bandwidth, with equal receive bandwidth that can operate simultaneously. Dividing the required sent volume by β gives the full-duplex bandwidth lower bound:

$$T^{\min}_{\text{bandwidth}} = \frac{2(N-1)}{N} \cdot \frac{M}{\beta}$$

As N grows large, the bandwidth lower bound approaches $2M/\beta$, independent of N (principle 11). Ring AllReduce matches the required byte volume under this model; startup and local reduction still add time (Patarasuk and Yuan 2009; Thakur et al. 2005). On a 64-GPU cluster synchronizing the chapter's 1 GB reference buffer over 50 GB/s links, the ring's byte term is about 39.4 ms, establishing the physical floor against which every concrete AllReduce schedule that follows must be judged.

5.6.3 Ring AllReduce

To hit that $2(N-1)M/N$ byte floor without funneling traffic through a central server, Ring AllReduce arranges nodes in a logical loop ($0 \to 1 \to \ldots \to N-1 \to 0$) where each node sends to its successor while receiving from its predecessor at the same time. That even chunk schedule spreads the required byte volume across every rank and reaches the bandwidth lower bound in the ideal endpoint model (Patarasuk and Yuan 2009).

The algorithm splits the vector of size M into N chunks and then alternates communication and local reduction in two phases, a ReduceScatter phase (often called scatter-reduce) followed by an AllGather phase. Algorithm 5.1 states the mechanics before the figure and trace make the same dataflow concrete.

Algorithm 5.1 Ring AllReduce

Require: N ranks in a logical ring; each rank i starts with tensor $\mathbf{g}_i$ of M bytes, split into N chunks
Ensure: every rank holds $\mathbf{g} = \sum_{i=0}^{N-1} \mathbf{g}_i$
1: assign the ring order $0 \to 1 \to \ldots \to N-1 \to 0$
2: **for** $N-1$ ReduceScatter steps **do**
3: each rank sends one chunk (or partial sum) right, receives one from the left, and adds it into the matching local sum
4: **end for**
5: each rank now owns one fully reduced chunk of $\mathbf{g}$
6: **for** $N-1$ AllGather steps **do**
7: each rank forwards a reduced chunk around the ring and stores the chunks it receives
8: **end for**
9: **return** the complete reduced tensor $\mathbf{g}$, held on every rank

Across the $2(N-1)$ send/receive rounds each rank moves M/N bytes per round, for $2(N-1)M/N$ bytes sent and the same received. The bandwidth term therefore reaches the information-theoretic lower bound, while the latency term grows as $2(N-1)\alpha$. On a four-GPU ring with wrap-around links, the state progresses in two phases (figure 5.3). In row (a), $N-1=3$ ReduceScatter steps circulate gradient chunks A through D until each GPU holds exactly one fully

reduced partition (green ΣA through ΣD). In row (b), $N-1=3$ subsequent AllGather steps forward those finished shards around the ring until every device holds the complete sum.

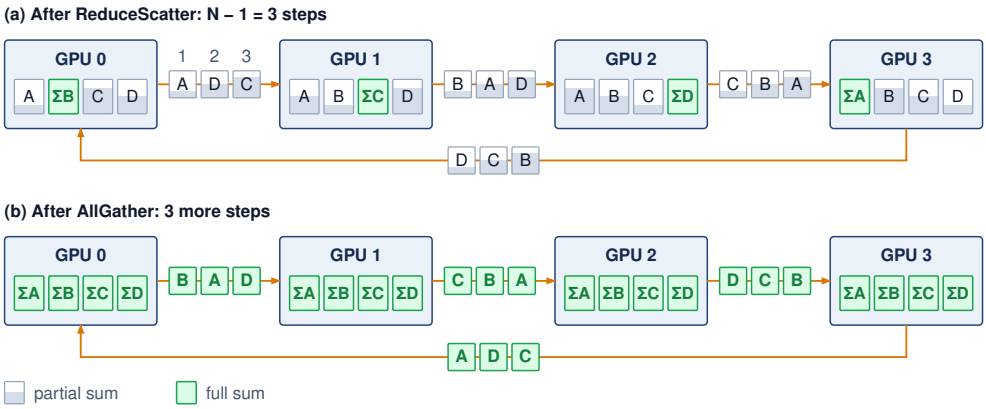

Figure 5.3: Ring AllReduce Data Flow: Four GPUs in a logical ring, each gradient split into chunks A to D; the wrap-around link closes the ring from GPU 3 back to GPU 0. (a) After the $N-1$ ReduceScatter steps, in which every GPU sends one chunk to its neighbor and adds the chunk it receives, each GPU holds one fully reduced chunk. (b) After $N-1$ AllGather steps that forward those finished chunks around the same ring, every GPU holds the full sum. Every link carries data in every step, so each GPU sends $2\frac{N-1}{N}M$ bytes in total, while the $2(N-1)$ steps each pay one startup latency α.

Logical ring edges may share physical links, and startup, local reduction, or contention can leave transfer capacity unused, so byte optimality does not guarantee peak physical-link utilization. To see how the logical schedule itself reaches that byte lower bound, consider 4 GPUs reducing a vector of 4 elements by summation. Each GPU i starts with a local gradient vector $\mathbf{g}_i = [a_i, b_i, c_i, d_i]$ split into 4 chunks (one per GPU), and the algorithm proceeds through two phases.

Example 5.1: Ring AllReduce: Two-phase example (4 GPUs)

Scenario: Four GPUs ($0 \to 1 \to 2 \to 3 \to 0$) perform a Ring AllReduce on local vectors $[1,5,3,7]$, $[2,6,4,8]$, $[3,7,5,9]$, and $[4,8,6,10]$ to compute the element-wise sum $[10,26,18,34]$.

Diagnosis: The trace has to show three properties of the schedule, namely that it takes $2(N-1)=6$ steps, that every GPU sends and receives in every step, and that each step moves only one chunk. Ring AllReduce splits each vector into $N=4$ chunks a, b, c, d. In ReduceScatter step s ($s=1,2,3$), GPU i sends its running copy of chunk $(i-s+1) \bmod 4$ to GPU $(i+1) \bmod 4$, which adds it to its own copy. After the third step, each GPU owns one fully reduced chunk. In AllGather step s, GPU i forwards the finished chunk it completed or received most recently to GPU $(i+1) \bmod 4$, which stores it without arithmetic. In each of the six steps, every GPU receives one chunk and updates the value it holds (table 5.5).

Table 5.5: Ring AllReduce Trace: The chunk each of four GPUs receives in each of the six steps. In the three ReduceScatter steps the GPU adds the incoming chunk to its running partial sum; in the three AllGather steps it stores an already finished sum.

Step	GPU 0	GPU 1	GPU 2	GPU 3
ReduceScatter 1	d: 17	a: 3	b: 13	c: 11
ReduceScatter 2	c: 14	d: 25	a: 6	b: 21
ReduceScatter 3	b: 26	c: 18	d: 34	a: 10
AllGather 1	a: 10	b: 26	c: 18	d: 34
AllGather 2	d: 34	a: 10	b: 26	c: 18
AllGather 3	c: 18	d: 34	a: 10	b: 26

Every cell in every row is filled, so every GPU receives (and, symmetrically, sends) one chunk in every step, and after the sixth step every GPU holds [10, 26, 18, 34].

Systems lesson: Ring AllReduce achieves the optimal byte volume under the stated model: each GPU sends $2\frac{N-1}{N}M$ total bytes, approaching $2M$ as N grows, while the startup-round count continues to grow. Physical-link utilization also depends on placement and runtime overhead.

Checkpoint 5.2: Ring AllReduce mechanics

Verify your understanding of bandwidth-optimal reduction:

- ☐ **Step count**: calculate the number of sequential steps required for a ring of N GPUs to complete the full AllReduce.
- ☐ **Bandwidth optimality**: explain why Ring AllReduce is bandwidth-optimal, including how many times each byte of the total message M traverses the network per GPU.
- ☐ **Straggler impact**: determine the impact on total collective completion time when one GPU in the ring is 50 percent slower than the others.
- ☐ **Send/receive duality**: assess the True or False claim that every GPU is both a sender and a receiver in every step of Ring AllReduce.

Generalizing the six-step trace of example 5.1 to N ranks yields the closed-form cost model for those checkpoint questions: each node sends and receives $\frac{M}{N}$ bytes in each of the $2(N-1)$ steps.

$$T_{\text{ring}} = \underbrace{2(N-1)\alpha}_{\text{Latency Term}} + \underbrace{2\frac{N-1}{N}\frac{M}{\beta}}_{\text{Bandwidth Term}}$$

The bandwidth term approaches $2M/\beta$ as $N \to \infty$, reaching the full-duplex lower bound: each rank sends nearly $2M$ bytes across the two phases and receives the same amount concurrently. In contrast, the latency term scales linearly with N. Across 10,000 nodes, 19,998 sequential startup rounds accumulate substantial latency, which explains why Ring AllReduce becomes uncompetitive for small payloads. For a multi-gigabyte gradient buffer at moderate rank count, however, the bandwidth term dominates completely, as the 70B calculation in notebook 5.2 confirms.

Napkin Math 5.2: AllReduce cost for a 70B model

Problem: Consider a communication-only baseline for a 70B parameter model across 64 GPUs connected by InfiniBand NDR (50 GB/s per port). The bandwidth term barely depends on rank count, so this smaller group reproduces the bandwidth-only estimate from the opening definition while keeping the latency term visible. Each rank contributes a complete logical gradient buffer communicated in BF16 (2 bytes per parameter). This calculation isolates collective cost without establishing that the training state fits on each GPU. How long does one AllReduce take?

Step 1: Size the gradient payload. Each rank in this baseline contributes the complete logical gradient tensor of $7 \times 10^{10} \times 2$ bytes $= 140$ GB. A hybrid layout that partitions the model would instead reduce corresponding gradient shards within smaller groups and requires its own calculation.

Step 2: Apply the Ring AllReduce bandwidth formula.

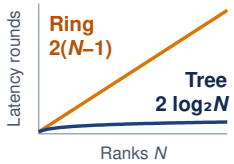
$$T_{\text{bandwidth}} = 2 \cdot \frac{N-1}{N} \cdot \frac{M}{\beta}$$

Substituting: $T_{\text{bandwidth}}$ = 1.96875 $\times$ 140 GB / 50 GB/s $\approx$ 5,512.5 ms.

Step 3: Add the latency term.

$$T_{\text{latency}} = 2(N-1) \cdot \alpha$$

Substituting: $T_{\text{latency}} = 126 \times 1.5$ µs = 0.2 ms.



Step 4: Total communication time. Total: $T_{\text{ring}} \approx$ 5,512.5 ms + 0.2 ms $\approx$ 5,512.7 ms.

Systems insight: The modeled full-buffer AllReduce takes over five seconds under the stated link and rank assumptions, and almost all of it is the bandwidth term. Its effect on step time depends on how much remains exposed

relative to useful computation. When it is fully exposed, halving it saves about 2.8 s per step; across a 100,000-step campaign on these 64 GPUs, that is roughly 4,900 GPU-hours of reserved accelerator time. Large-scale training systems can launch reductions for output-side gradients while input-side layers are still computing. Partitioned training also changes each rank's payload and participating group, so this complete-gradient budget must be recomputed for the actual layout.

5.6.4 Tree AllReduce

Ring AllReduce's byte efficiency comes with many startup rounds. As the group grows, the $2(N-1)\alpha$ term can exceed the byte-transfer term for a fixed payload; the crossover depends on the measured path parameters. Tree AllReduce reduces the number of dependent rounds. In the simple reduce phase, pairs combine contributions and forward partial sums toward a root, taking $\log_2 N$ steps for a balanced power-of-two group. The broadcast phase distributes the result in another $\log_2 N$ steps. This shorter dependency chain motivates the comparison before bandwidth costs are counted.

Ring latency grows with N; tree stays logarithmic.

The simple full-message tree loses parallel activity as contributions converge. A ring activates all N logical edges in each round. In a pairwise tree reduction, the first round has $N/2$ senders and $N/2$ receivers; receiving is useful work, not idleness. The next round has $N/4$ senders and $N/4$ receivers, and the final reduction exchange involves two ranks while the remaining $(N-2)$ have completed their upstream contribution. Sending the full message through successive levels adds byte-transfer time along the dependency path. This is a limitation of the illustrated schedule, not every tree-based implementation or every physical link mapping.

The resulting time complexity depends on the specific tree variant. A simple reduce-then-broadcast tree has logarithmic latency but nonuniform traffic and root/interior bottlenecks. Recursive doubling, in which partners at doubling distances exchange the entire tensor in each of $\log_2 N$ rounds, has the same logarithmic round count and incurs $\mathcal{O}(\log N)$ full-message bandwidth per rank. The following simplified model captures the latency advantage and the potential bandwidth penalty of tree-like collectives:

$$T_{\text{tree-like}} \approx \underbrace{2\log_2 N \cdot \alpha}_{\text{Latency}} + \underbrace{2\log_2 N \frac{M}{\beta}}_{\text{Bandwidth penalty in full-message exchange variants}}$$

The latency term is logarithmic ($\mathcal{O}(\log N)$). For 1,024 nodes, Ring needs 2,046 steps while Tree needs only 20. That roughly 100× reduction in steps makes Tree attractive for small, frequent collectives across large process groups, such as scalar reductions, control messages, or small-batch activation reductions. The bandwidth term carries the penalty, because tree-like algorithms can underutilize links or concentrate traffic on interior links, and recursive-doubling-style full-message exchanges add a $\log_2 N$ bandwidth factor. These penalties make naive

tree variants a poor choice for data parallelism's large gradient AllReduce, where bandwidth efficiency determines whether the network is saturated or partially idle.

For large-scale data parallelism, this bandwidth penalty decides the comparison whenever the implementation repeatedly exchanges full messages or creates root/interior bottlenecks. On the 64-GPU cluster of section 5.6.2, the simple tree forwards the whole tensor once per level on the way up and once per level on the way down, $2\log_2 64 = 12$ full-message transfers. Its byte time is about 240 ms against the ring's 39.4 ms, or 6.1× the ring's byte time. The difference of roughly 200 ms per step would accumulate to about 5.6 hours over a 100,000-step run if fully exposed, although actual wall-clock savings also depend on startup, placement, and overlap. For a 70B-parameter model's 140 GB gradient AllReduce across 1,000 GPUs, a bandwidth-inefficient tree-like variant can erase the latency advantage that motivated it. Optimized double-tree algorithms exist precisely to keep logarithmic latency without imposing that naive bandwidth penalty.

Small activation reductions provide a useful case for fewer startup rounds. For an eight-GPU group communicating a 1 MB tensor, the simple model reduces Ring's $2(8-1)\alpha = 14\alpha$ to Tree's $2\log_2(8)\alpha = 6\alpha$, but Tree's byte term remains about 3.4× Ring's. Whether the saved startups outweigh those extra byte transfers depends on the measured latency and bandwidth. Tensor-parallel collectives also have a scheduling constraint independent of this comparison: a layer that needs the reduced activation must wait for it. A critical-path dependency does not by itself imply a latency-dominated transfer or select a tree algorithm.

5.6.5 Recursive halving-doubling (butterfly)

The simple full-message Tree reduces startup rounds but repeats more byte-transfer work than Ring. Recursive halving-doubling, sometimes called the Butterfly algorithm, combines logarithmic rounds with the optimal byte volume under the flat-network model. It pairs ranks exactly as recursive doubling does, but where recursive doubling exchanges the whole tensor in every round, halving-doubling halves the exchanged region in each ReduceScatter round and doubles it in each AllGather round. That difference removes the $\log_2 N$ byte penalty. For a power-of-two group, it uses $2\log_2 N$ rounds: $\log_2 N$ ReduceScatter rounds followed by $\log_2 N$ AllGather rounds. A partner-bit index k selects the XOR pairing with mask 2^k. The ReduceScatter trace below visits those bits in increasing order as messages shrink; the matching AllGather reverses that order as the assembled result grows.

In the ReduceScatter phase (first $\log_2 N$ rounds), GPU i partners with GPU $i \oplus 2^k$ (XOR of indices). Because the two partners made identical retention choices in all earlier rounds, both enter round k holding partial sums for the exact same $M/2^k$-byte region of the tensor. They split that active region in half, retain complementary halves of size $M/2^{k+1}$, and send the other half to each other to add into the half each retained. Across the $\log_2 N$ rounds, the bytes each GPU sends form a geometric series $M/2 + M/4 + \cdots + M/N = \frac{N-1}{N}M$, leaving each GPU with a distinct M/N-byte slice of the fully reduced result. AllGather traverses the partner bits in reverse,

exchanging completed regions of doubling size $M/N, 2M/N, \ldots, M/2$ until every rank holds the full result.

Summing the $2\log_2 N$ startups and the two symmetric geometric byte series gives the recursive halving-doubling cost:

$$T_{\text{butterfly}} = 2\log_2 N \cdot \alpha + 2\frac{N-1}{N} \cdot \frac{M}{\beta}$$

The schedule combines logarithmic latency ($\mathcal{O}(\log N)$, like Tree) with bandwidth-optimal data movement ($2(N-1)/N \cdot M/\beta$, like Ring). The catch is that it requires nonneighbor communication (GPU i must communicate with GPU $i \oplus 2^k$, which may be physically distant), and it requires N to be a power of two. For clusters where N is not a power of two, additional complexity is needed to handle the irregular cases.

Recursive halving-doubling is used in MPI-style collective implementations and is useful as a theoretical point in the latency-bandwidth trade-off (Thakur et al. 2005). NVIDIA's GPU collective backend, the NVIDIA Collective Communications Library (NCCL), offers implementation families that include ring, tree-derived, hierarchical, NVLink/NVSwitch-aware, and pattern-aware choices, with exact names and availability changing by version and topology (Jeaugey 2017; NVIDIA 2026c). Whatever a particular release calls them, practical communication libraries select algorithms through a topology-aware cost model because nonlocal communication patterns can create contention on shared network links that erodes theoretical advantages.

The partner distance is where topology enters. Consider the ReduceScatter phase for 8 GPUs placed four per node on two nodes, GPUs 0–3 on the first and GPUs 4–7 on the second, which proceeds in $\log_2(8) = 3$ rounds. In round $k = 0$, each GPU i partners with GPU $i \oplus 1$, pairing neighbors: (0,1), (2,3), (4,5), (6,7). They exchange half their data and reduce. In round $k = 1$, the distance doubles: GPU i partners with GPU $i \oplus 2$, creating pairs (0,2), (1,3), (4,6), (5,7). In round $k = 2$, the distance doubles again: GPU i partners with GPU $i \oplus 4$, creating pairs (0,4), (1,5), (2,6), (3,7).

Physical placement determines the cost of these logical pairings (figure 5.4). Rounds $k = 0$ and $k = 1$ pair GPUs within a node, but in round $k = 2$ every GPU on the first node exchanges with one on the second, so that round crosses the node boundary. On eight-GPU nodes the same crossing would appear one round later, at $k = 3$ in a 16-rank group. In a separate 1,024-rank example, the final ReduceScatter round pairs GPU i with GPU $i \oplus 512$. If the two rank halves occupy different racks, those exchanges share the inter-rack fabric. The algorithm's logarithmic rounds and optimal byte volume therefore do not establish its runtime advantage; placement, shared paths, and the changing chunk size in each round must enter the comparison.

5.6.6 Double binary tree

Where recursive halving-doubling requires power-of-two groups and long-distance XOR pairings across fabric cuts, a tree schedule can follow physical topology more

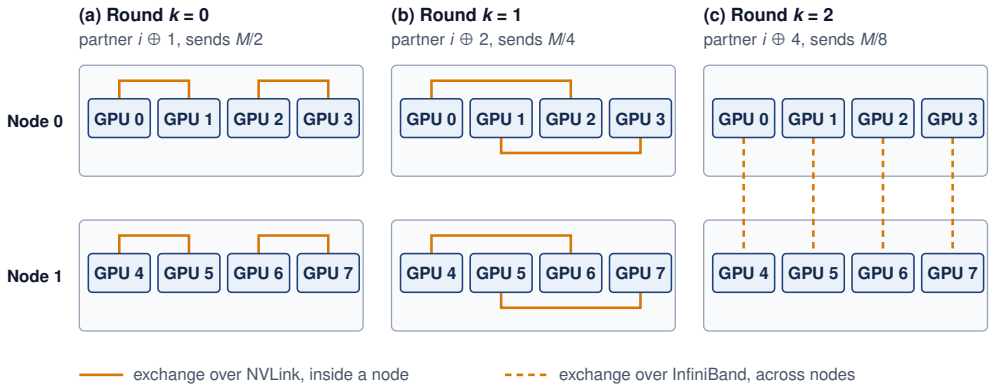


Figure 5.4: Halving-Doubling Partners across a Node Boundary: The ReduceScatter phase of recursive halving-doubling on 8 GPUs placed four per node. In round k, GPU i exchanges with GPU $i \oplus 2^k$ and sends half of the region it still holds, so the exchanged volume halves each round. (a) and (b) The first two rounds pair GPUs inside a node and use NVLink. (c) The last round pairs every GPU with one on the other node, so the round with the smallest message is the only one that crosses the slower fabric. Which round crosses depends on how many ranks each node holds.

flexibly, provided it overcomes the single-tree bandwidth bottleneck. In a single binary tree, half the ranks sit at the leaves and only send (during reduction) or only receive (during broadcast), leaving half of each leaf's bidirectional link capacity idle while interior nodes do double duty. NCCL resolves this imbalance with a double binary tree (Jeaugey 2017; NVIDIA 2026c), constructing two independent binary trees with complementary interior-node roles and running both simultaneously so each carries half the payload.

The complementary-tree construction balances endpoint work by making ranks that act as interior nodes in one tree act as leaves in the other. With eight ranks, build the first tree by labeling the nodes of a binary tree in the order of an in-order traversal (left subtree, then node, then right subtree). In a balanced seven-node tree labeled from 0, in-order traversal puts the leaves at the even ranks 0, 2, 4, and 6 and the interior nodes at 1, 3, and 5. In one simple construction, the eighth rank, 7, joins as one more interior node above that tree. The odd ranks 1, 3, 5, and 7 thus form the first tree's interior and the even ranks are its leaves. The second tree shifts every rank by one position, so the even ranks become its interior and the odd ranks its leaves (figure 5.5). Each tree carries half the tensor, $M/2$, and the two halves never meet.

Two further steps bring the byte term down from the simple tree's $2\log_2 N \cdot M/\beta$ to about $2M/\beta$. First, each tree pipelines its half in small chunks, so while one chunk moves up from the leaves, the next is already leaving them and every level works at once. Tree depth then adds startup rounds and a short pipeline fill, not repeated full-message transfers. Second, count what one rank sends during the reduce phase. As an interior node of one tree it combines the inputs of its (at most two) children and forwards one $M/2$ stream to its parent. As a leaf of the other tree it sends its own $M/2$ contribution. It therefore sends about M in total. The broadcast phase mirrors that traffic, for about $2M$ per rank across both phases, the same per-rank volume as the ring. This logical balance does not guarantee that

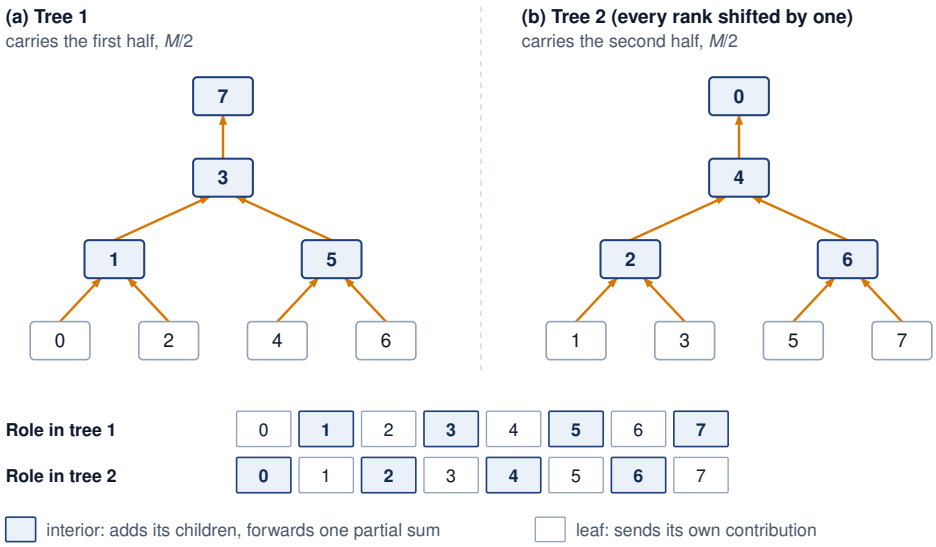

Figure 5.5: Complementary Roles in a Double Binary Tree: Two reduction trees over eight ranks, each carrying half of the tensor toward its root. (a) The first tree places the odd ranks at its interior and the even ranks at its leaves. (b) The second tree shifts every rank by one, which swaps the roles. The strip below shows the result: every rank is an interior node in exactly one tree and a leaf in the other, so it forwards one combined half and sends one half of its own, about M in the reduce phase. The broadcast phase runs the same trees in the opposite direction.

every physical link stays busy or that both trees avoid shared fabric bottlenecks; rank placement and routing still matter.

The combined performance is approximately:

$$T_{\text{double-tree}} \approx 2\log_2 N \cdot \alpha + \frac{2M}{\beta}$$

The ideal bandwidth term approaches $2M/\beta$ while the startup-round count remains logarithmic. This combination makes the double binary tree a useful candidate across message sizes that penalize either the ring's many rounds or the simple tree's repeated full-message transfers. Complementary endpoint roles do not ensure disjoint physical paths, so topology-aware tree construction seeks a good placement, and measurements must establish the achieved rate under contention.

5.6.7 The algorithm crossover point

Plotting the three cost models for a 256-GPU group on a 200 Gbps fabric, over message sizes from 1 KB to 10 GB, shows the simple Tree and Ring curves intersecting near 1 MB (figure 5.6). At small sizes, fewer startup rounds favor the tree schedules; at large sizes, the simple full-message Tree pays more byte-transfer time. The Double Binary Tree curve includes illustrative overhead factors, so it approaches a comparable bandwidth-dominated regime without representing a measured library result. The candidate schedules differ in their latency and bandwidth terms, in whether they reach the bandwidth lower bound, and in the constraint each one places on the group (table 5.6).

Table 5.6: AllReduce Algorithm Comparison: Each algorithm occupies a different point in the latency-bandwidth trade-off space. Ring and Butterfly achieve bandwidth optimality with different latency characteristics, while Double Binary Tree combines logarithmic depth with a near-optimal byte term. The Tree row refers to the simple full-message model, not every tree implementation.

Algorithm	Latency	Bandwidth	Bandwidth optimal?	Constraint
Ring	$\mathcal{O}(N)\alpha$	$2\frac{N-1}{N}\frac{M}{\beta}$	Yes	None
Simple Tree	$\mathcal{O}(\log N)\alpha$	$\mathcal{O}(\log N)\frac{M}{\beta}$	No	None
Butterfly	$\mathcal{O}(\log N)\alpha$	$2\frac{N-1}{N}\frac{M}{\beta}$	Yes	$N = 2^m$
Double Tree	$\mathcal{O}(\log N)\alpha$	$\approx \frac{2M}{\beta}$	Near-optimal	Complementary tree construction

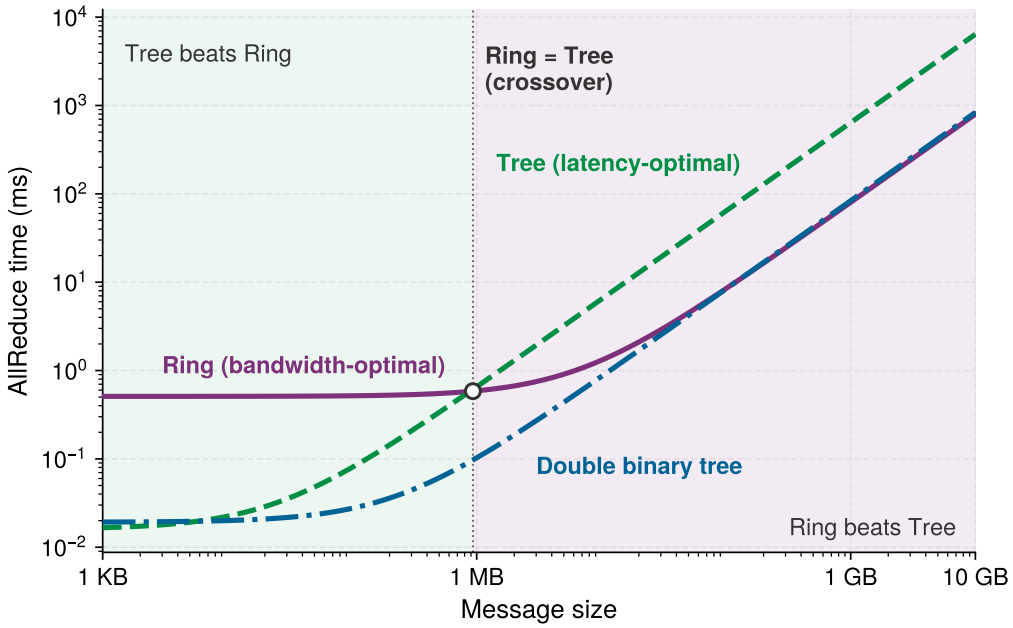

Figure 5.6: Algorithm Crossover in Collective Communication: Below about 1 MB the simple tree's fewer startup rounds make it faster than the ring; above that size the ring's smaller byte volume wins, and the double binary tree tracks the faster of the two across most sizes. The curves are modeled AllReduce times for a 256-GPU group on a 200 Gbps interconnect with $\alpha = 1$ µs, over messages from 1 KB to 10 GB. The double binary tree curve applies modest latency and bandwidth overhead factors (1.2× and 1.05×) to its ideal cost, so it illustrates the model rather than a measured library result.

The intersection near 1 MB in figure 5.6 marks where the modeled Ring and simple Tree have equal total cost. It is an algorithm crossover, distinct from the startup-versus-transfer crossover for one message. Setting $T_{\text{ring}} = T_{\text{tree}}$ and solving for payload M identifies the point where Ring's lower byte cost compensates for its additional startup rounds:

$$T_{\text{ring}} = 2(N-1)\alpha + 2\frac{N-1}{N}\frac{M}{\beta}$$

$$T_{\text{tree}} = 2\log_2 N \cdot \alpha + 2\log_2 N \cdot \frac{M}{\beta}$$

For large N, $(N-1) \approx N$ and $\frac{N-1}{N} \approx 1$, so the ring pays a latency term proportional to N while moving each byte close to the bandwidth limit:

$$T_{\text{ring}} \approx 2N\alpha + \frac{2M}{\beta}, \quad T_{\text{tree}} \approx 2\log_2 N \cdot \alpha + \frac{2\log_2 N \cdot M}{\beta}$$

The tree has the opposite shape: logarithmic startup cost, but each message byte moves through more stages. Setting the estimates equal isolates the message size where the cheaper latency path stops compensating for the extra bandwidth work:

$$2N\alpha + \frac{2M}{\beta} = 2\log_2 N \cdot \alpha + \frac{2\log_2 N \cdot M}{\beta}$$

$$\frac{2M}{\beta} - \frac{2\log_2 N \cdot M}{\beta} = 2\log_2 N \cdot \alpha - 2N\alpha$$

$$\frac{2M}{\beta}(1 - \log_2 N) = 2\alpha(\log_2 N - N)$$

Since $N \gg \log_2 N$ for large clusters, $(\log_2 N - N) \approx -N$ and $(1 - \log_2 N) \approx -\log_2 N$, yielding:

$$\frac{2M}{\beta}(-\log_2 N) \approx 2\alpha(-N)$$

$$\boxed{M_{\text{crossover}} \approx \frac{N \cdot \alpha \cdot \beta}{\log_2 N}}$$

The log-aware crossover formula is the large-N approximation to the exact crossover $M_{\text{crossover}}(N)$ derived in section D.3.1. Within this two-algorithm model, Ring wins above the crossover because its byte savings exceed its extra startup cost; the simple Tree wins below it because the startup saving is larger. Optimized trees and topology-dependent rates require separate comparisons.

On the reference cluster, with the chapter's effective NDR $\alpha = 1.5$ µs and $\beta = 50$ GB/s across all 1,024 GPUs, the estimate gives $M_{\text{crossover}} \approx \frac{1{,}024 \times 1.5\ \mu\text{s} \times 50\ \text{GB/s}}{\log_2 1{,}024} = \frac{1{,}024 \times 1.5\ \mu\text{s} \times 50\ \text{GB/s}}{10} \approx 7.7$ MB. A gradient bucket of tens of megabytes or the full model gradient therefore sits on the ring side of the crossover, while a reduction of a few hundred kilobytes sits on the tree side. The two other configurations in this section depart from that anchor in stated ways. A smaller 256-GPU group on a slower 200 Gbps fabric with $\alpha = 1$ µs moves the curves' intersection down to about 1 MB (figure 5.6). A 64-GPU group on a still slower, higher-latency fabric places a 1 MB buffer almost exactly on the crossover (notebook 5.3).

NCCL's algorithm selection is more nuanced than a two-way split. The double binary tree offers logarithmic latency with near-optimal bandwidth, so it competes with both Ring and Tree across a broad range of message sizes. The library also weighs the number of channels (parallel communication streams), the network topology, and whether a hop is inter-node or intra-node. The effective selection logic resembles a multi-way decision indexed by message size, GPU count, and topology type rather than a single crossover point. The crossover formula nevertheless explains the shape of those choices, because every candidate trades startup rounds against bytes moved. The model therefore names a candidate worth benchmarking rather than proving the library wrong, and an override is retained only after measured collective duration and exposed training-step time confirm it.

Training frameworks decide which payloads reach that analysis. PyTorch DistributedDataParallel (DDP) groups gradient tensors into buckets (section 5.10.3), while FSDP groups parameter gathers and gradient reductions according to its sharding units. A bucket size alone does not locate a crossover, because rank count, effective startup cost, and available bandwidth also enter the comparison. NCCL's algorithm selection must therefore be evaluated for the actual invocation and topology rather than inferred from a nominal bucket-size range. A single 1 MB buffer on a slower fabric shows how close to the crossover a real bucket can sit.

Napkin Math 5.3: The ring vs. tree crossover

Problem: A cluster synchronizes a 1 MB buffer across 64 GPUs. The network has latency $\alpha = 10\,\mu s$ and bandwidth $\beta = 10\,GB/s$. Which algorithm performs better: Ring or Tree?

Math:

Latency:

1. **Ring Latency**: $2(N-1)\alpha = 2 \times 63 \times 10\,\mu s = 1260\,\mu s$.
2. **Tree Latency**: $2(\log_2 N)\alpha = 2 \times 6 \times 10\,\mu s = 120\,\mu s$.

Bandwidth (note the difference):

3. **Ring Bandwidth**: $2\frac{N-1}{N}\frac{M}{\beta} \approx 2 \times \frac{1\,MB}{10\,GB/s} = 196.9\,\mu s$ (optimal: each rank sends about $2M$ in total, the lower bound).
4. **Tree Bandwidth**: $2\log_2 N \cdot \frac{M}{\beta} = 12 \times \frac{1\,MB}{10\,GB/s} = 1200\,\mu s$ (each level sends full message).

Summing the latency and bandwidth terms gives each algorithm's total time (table 5.7).

Table 5.7: Ring vs. Tree AllReduce Timing for a 1 MB Buffer on 64 GPUs: Latency, bandwidth, and total-time terms with $\alpha = 10$ µs and $\beta = 10$ GB/s.

Algorithm	Latency	Bandwidth	Total
Ring	1260 µs	196.9 µs	1456.9 µs
Tree	120 µs	1200 µs	1320 µs

Tree wins, but only by 9 percent. For this 1 MB message, the payload is near the crossover point.

Systems insight: Ring's latency term (10.5× Tree's) nearly balances Tree's bandwidth term (6.1× Ring's). The log-aware crossover estimate predicts $M_{\text{crossover}} \approx N\alpha\beta/\log_2 N = 64 \times 10\ \text{µs} \times 10\ \text{GB/s}/6 \approx 1.1$ MB. At 1 MB, the payload is just below crossover, so Tree wins. At 10 MB, Ring would dominate.

The crossover point sits inside the range that gradient reductions can traverse as bucket sizes change. In this example, the 1 MB AllReduce lies near crossover, whereas a 10 MB DDP bucket is already above it. A fused bucket of 50–300 MB or the full 140 GB BF16 gradient of a 70B parameters model favors Ring over the simple Tree model even more strongly. These conclusions apply to the stated AllReduce configuration. An MoE token-routing payload of the same size still requires an AllToAll schedule, and optimized tree or hierarchical implementations require their own cost comparison.

Checkpoint 5.3: AllReduce algorithm selection

Verify your understanding of Ring vs. Tree AllReduce trade-offs:

- ☐ **Ring vs. Tree**: explain why Ring AllReduce achieves bandwidth-optimal communication (approaching $2M/\beta$) while the simple full-message Tree model incurs $\mathcal{O}(\log N)$ bandwidth overhead.
- ☐ **Crossover point**: calculate $M_{\text{crossover}}$ for a 256-GPU cluster with $\alpha = 5$ µs and $\beta = 50$ GB/s, then determine whether a 10 MB gradient buffer should use Ring or Tree.
- ☐ **ReduceScatter trace**: trace through the ReduceScatter phase of Ring AllReduce for 3 GPUs with a 3-element vector and verify that each GPU ends with the correct partial sum.
- ☐ **Latency limit**: explain why Ring AllReduce's $\mathcal{O}(N)$ latency hurts small, frequent collectives across a large process group, and why that penalty is modest inside an eight-GPU tensor-parallel group.

5.7 Hierarchical Communication

The AllReduce cost models in section 5.6 assume a flat network with uniform endpoint bandwidth, whereas real clusters expose the tiered bandwidth hierarchy of

section 2.5.1. Because intra-node links are abundant and fast while inter-node links are scarce and expensive, hierarchical communication shrinks payloads locally before they cross the scarce tier (decomposing AllReduce into a local ReduceScatter, a cross-node reduction, and a local AllGather) and aligns traffic with the physical fabric, whether switches aggregate packets in the network, rail-optimized trees separate GPU lanes, or direct-connect pods wire accelerators into multidimensional tori.

5.7.1 Hierarchical AllReduce

On a DGX H100 node, each GPU's local NVLink capacity is 450 GB/s per direction (the 900 GB/s datasheet figure is the bidirectional total), while its one inter-node port provides 50 GB/s over InfiniBand. These are endpoint capacity budgets, not a promise of uniform achieved rate to every peer. Intra-node connectivity and simultaneous traffic still matter. That hierarchical network motivates a schedule that assigns work to each tier according to its usable capacity.

A flat ring whose ordering repeatedly crosses node boundaries can leave local NVLink capacity unused while loading scarce inter-node links. Hierarchical AllReduce explicitly partitions the global operation into three stages that align communication volume with the fabric tiers (figure 5.7).

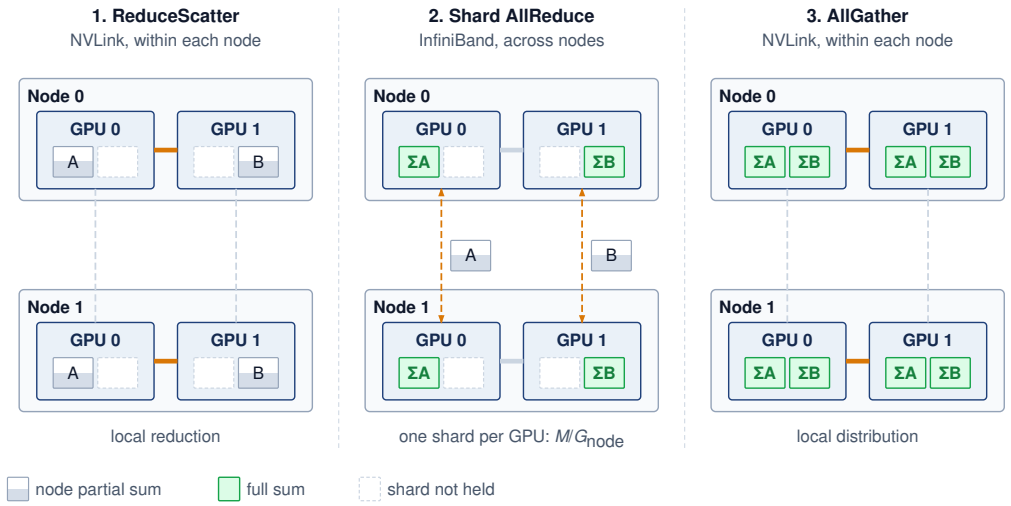

Figure 5.7: Hierarchical AllReduce: Three-phase decomposition that exploits the intra-node/inter-node bandwidth gap. Phase 1 performs intra-node aggregation over NVLink (an NVLink ring acting as a ReduceScatter that leaves each GPU holding a node-shard partial sum), leaving a payload of M/G_{node} on each of the G_{node} GPUs per node. Phase 2 runs an AllReduce across corresponding GPUs using InfiniBand. Phase 3 completes intra-node distribution over NVLink (the AllGather that returns each GPU to the full result). The schematic shows two representative ranks per node; the same decomposition applies to G_{node} ranks.

With G_{node} GPUs in each of N_{nodes} nodes, the three phases form a single causal pipeline. First, an intra-node ReduceScatter over NVLink performs a local reduction among the G_{node} GPUs in each node, leaving each GPU with a $1/G_{\text{node}}$ shard of partially reduced data while consuming only abundant intra-node bandwidth. Next, each corresponding-rank group applies an inter-node AllReduce over InfiniBand to its M/G_{node}-byte input shard, where the chosen collective algorithm

dictates the bytes transmitted across the network fabric. Finally, an intra-node AllGather over NVLink redistributes the globally reduced shards within each node, completing the collective without consuming additional inter-node bandwidth.

Only Phase 2 (Shard AllReduce) loads the slower inter-node InfiniBand links (figure 5.7). In this middle phase, each corresponding-rank group reduces an M/G_{node}-byte shard across N_{nodes} nodes. A ring in that group sends $2(N_{\text{nodes}} - 1)M/(N_{\text{nodes}}G_{\text{node}})$ bytes per participating GPU and receives the same amount. Summing across the node's G_{node} GPUs gives $2(N_{\text{nodes}} - 1)M/N_{\text{nodes}}$ bytes sent per node. Smaller per-port payloads improve elapsed time when the node has independent ports and sufficient fabric capacity; sharding does not create bandwidth on a shared uplink. An 8-node budget quantifies the bandwidth multiplier this decomposition provides when those ports operate in parallel.

Napkin Math 5.4: The hierarchical bandwidth multiplier

Problem: A cluster has 8 nodes, each with 8 GPUs (64 total). The system must AllReduce the chapter's 1 GB reference buffer. Assume each GPU has its own full-rate inter-node port, one rail per GPU as on a DGX H100 (rails are the subject of section 5.7.4.1), with no oversubscription. The flat baseline is a single ring over all 64 ranks. How much faster is Hierarchical AllReduce than that flat ring?

Flat ring AllReduce (ignoring hierarchy):

- Each GPU sends ~2 GB total (the bandwidth-optimal Ring AllReduce formula).
- Every edge of a ring carries the same traffic in every step, so the whole ring advances at the rate of its slowest edge. Every ordering puts at least one fabric-crossing edge on each node, even the node-contiguous ordering that crosses the fabric only once per node.
- **Effective Bandwidth**: Limited by the slowest link = 50 GB/s (InfiniBand).
- **Time**: $\approx 2 \times 1$ GB/50 GB/s = 40 ms (bandwidth term dominates).

Hierarchical AllReduce (3-step decomposition):

1. **Intra-node ReduceScatter**: Each GPU sends 875 MB at 450 GB/s per direction $\rightarrow$ ~1.94 ms
2. **Inter-Node AllReduce**: Each GPU AllReduces a 1 GB/8 = 125 MB shard over InfiniBand; Ring moves roughly $2(N_{\text{nodes}} - 1)/N_{\text{nodes}}$ times that payload, and after adding the small latency term the phase takes ~4.40 ms at 50 GB/s

   (The eight shard groups run concurrently, each on its own GPU's port, so the node's eight ports together carry the full payload in parallel.)
3. **Intra-node AllGather**: Each GPU receives 875 MB at 450 GB/s per direction $\rightarrow$ ~1.94 ms

4. **Total time**: $\approx$ 1.94 ms + 4.40 ms + 1.94 ms = 8.3 ms

Systems insight: Hierarchical AllReduce achieves a 4.8× speedup by reducing the inter-node payload from 1 GB to 125 MB per GPU before the Ring traffic multiplier. The flat ring used one port's worth of fabric bandwidth because a single ring runs at its slowest edge; the hierarchical schedule uses all eight ports at once. That is also its precondition, since a node whose GPUs shared one uplink would carry the eight shard streams one after another and lose most of the speedup. This is why NVIDIA's NCCL and similar libraries often select hierarchical algorithms on multi-node clusters when the topology supports them.

This book's running instance makes the same comparison on the cluster it was defined for. Archetype A's 175B-parameter model produces a 350 GB BF16 gradient, and the reference cluster holds 1,024 GPUs as 128 nodes of 8. A single flat ring over every GPU would spend about 14.0 s per full-gradient reduction. The hierarchical schedule sends one-eighth of the gradient through each GPU's port in a shard ring that spans every node and completes in about 3.1 s, a 4.5× improvement. The cross-node phase still accounts for about 1.7 s of that time. Seconds per step remain a large exposed cost even after hierarchy. That is why the production layout for this instance shards the model so that each data-parallel group reduces a fraction of this payload. It is also why the overlap and compression techniques later in the chapter still matter at this scale.

These three phases also generalize to additional fabric tiers. For example, 4 racks of 4 nodes with 8 GPUs per node contain 128 GPUs. A rack-local ReduceScatter over 32 GPUs can leave each GPU with $1/32$ of the original payload for the cross-rack phase. The total elapsed time still includes both local phases, the cross-rack collective's traffic factor, startup, and contention. A cross-rack oversubscription ratio alone cannot determine a speedup over a flat ring.

5.7.2 Multidimensional reduction on a torus

Hierarchy fits a fabric whose tiers differ in speed. A torus, the direct-connect topology of Google's Tensor Processing Unit (TPU) pods, has uniform links instead, and its collectives reduce along one dimension at a time. TPU v4 pods support a 3D torus topology, unlike the 2D torus used by TPU v2 and v3. In the regular 3D torus model, each chip links directly to six neighbors $(\pm X, \pm Y, \pm Z)$ with equal per-link bandwidth. For collectives, the torus invites dimension-ordered reduction, which decomposes the AllReduce into sequential Ring AllReduces along axis-aligned torus rings. For a pod with $X \times Y \times Z$ chips, ranks first execute independent X-dimension rings for each fixed (Y, Z) coordinate, producing partial sums along each X line. A second phase runs Y-dimension rings to combine those partials across the $X \times Y$ plane. A third phase executes Z-dimension rings across fixed (X, Y) coordinates to complete the global reduction.

On a 4×4 2D torus grid of 16 ranks, the dimension-ordered schedule runs in two phases (figure 5.8). In Phase 1 (orange solid paths), each row executes an

↩ The torus topology and its bisection and path-length trade-offs against the fat-tree are established in section 3.5.4.

independent 4-rank Ring AllReduce across the horizontal X dimension using dashed wrap-around boundary links to close the ring ($2(X-1)=6$ steps). Once row partial sums are established, Phase 2 (slate solid paths) executes orthogonal 4-rank vertical Ring AllReduces down the Y dimension ($2(Y-1)=6$ steps). These phases use direct nearest-neighbor links without multi-hop routing within a logical ring edge. They reduce the startup count from $2(N-1)=30$ rounds on a flat 16-rank ring to $2(X-1)+2(Y-1)=12$ rounds, a 2.5× reduction in the modeled startup term. In this simple form each axis still processes the full message, so the round-count saving comes at a byte cost that the partitioned dimension-wise schedule removes.

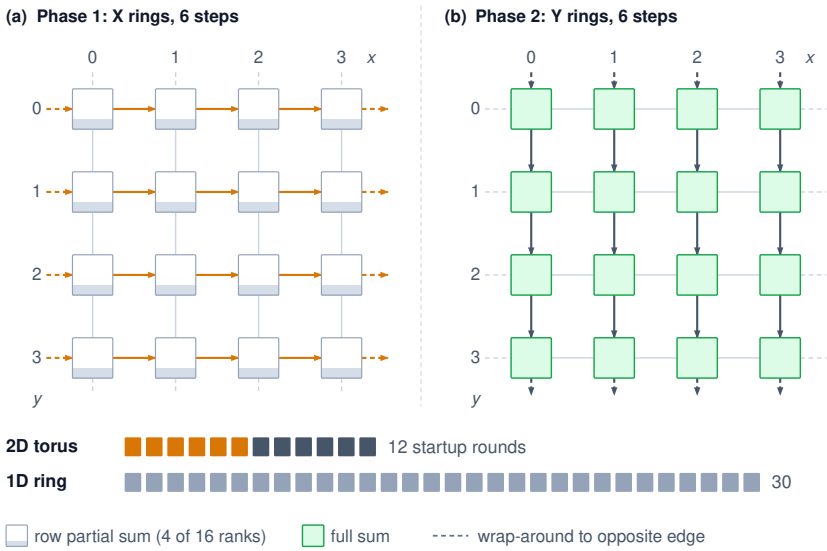

Figure 5.8: Dimension-Ordered Reduction on a Torus Topology: In a 2D torus mesh (4×4 node grid representing a simplified TPU pod slice), AllReduce proceeds sequentially along orthogonal dimensions. Phase 1 (orange) executes four parallel horizontal rings across the X dimension ($2(X-1)=6$ steps). Phase 2 (slate) then executes four parallel vertical rings across the Y dimension ($2(Y-1)=6$ steps) on the row-aggregated partial sums. Dashed stubs mark the torus wrap-around links, each leaving one edge of the grid and re-entering at the opposite edge. This dimension-ordered decomposition needs 12 startup rounds against 30 for a 16-rank 1D global ring, a $2.5\times$ reduction, but each axis processes the full message, so its bandwidth time is $3M/\beta$ for this grid.

The byte term does not shrink with the rings. Because every axis processes the full M-byte tensor, the bandwidth time is $2M[(X-1)/X+(Y-1)/Y+(Z-1)/Z]/\beta$ for equal per-axis bandwidth β. The startup term is $2[(X-1)+(Y-1)+(Z-1)]\alpha$. Shorter rings reduce startup cost, but these sequential full-message AllReduces do not retain the bandwidth cost of one global ring. A bandwidth-efficient multidimensional implementation instead partitions the work with dimension-wise ReduceScatter followed by reverse-order AllGather. The X-dimension ReduceScatter sends $M(X-1)/X$ bytes per rank and leaves each rank at a given X coordinate holding the row-reduced sum for the same M/X shard. Because all ranks in a Y-column share that X coordinate, they hold matching shards and can run a Y-dimension ReduceScatter on that M/X slice alone, sending $(M/X)(Y-1)/Y$ bytes per rank and subdividing the slice to $M/(XY)$. The

Z-dimension ReduceScatter repeats the subdivision across ranks that share both X and Y coordinates, leaving each of the $N = XYZ$ chips with a distinct M/N shard of the global sum after sending $M(N-1)/N$ bytes in total. The mirrored AllGather along Z, Y, and X doubles that volume to $2(N-1)M/N$, the ring's optimal byte term, while keeping the short rings' startup count. The torus thus teaches the same lesson as hierarchy, which is to shrink the payload before each successive stage rather than send the full tensor through every one.

Dimension-ordered reduction follows direct neighbor links and separates axis traffic in time; it does not change the network diameter or eliminate contention with other workloads. The torus topology also provides natural fault tolerance through alternate routing paths. If one link in the X-dimension fails, traffic can detour through the Y or Z dimensions (at the cost of increased latency). The compiler and collective runtime must choose a schedule for the actual topology, message size, and available links.

5.7.3 In-network reduction with SHARP

Hierarchical and dimension-ordered schedules redistribute work across links, but their software reduction stages still require endpoint GPUs to receive and combine contributions. NVIDIA's Scalable Hierarchical Aggregation and Reduction Protocol (SHARP)[6] moves that intermediate aggregation into the network. Instead of routing each partial sum through a GPU for arithmetic, an aggregation-capable InfiniBand switch combines contributions as packets pass through it.

A centralized endpoint reduction and in-switch aggregation send different data up the switch tree (figure 5.9). In the endpoint tree of panel (a), intermediate switches merely forward raw packets, forcing all four full gradient tensors ($\mathbf{g}_0$ through $\mathbf{g}_3$) across the upper links into a single Reducer GPU that executes every addition. In panel (b), SHARP offloads arithmetic to aggregation-capable switch application-specific integrated circuits (ASICs): each intermediate switch computes partial sums ($\mathbf{g}_0 + \mathbf{g}_1$ and $\mathbf{g}_2 + \mathbf{g}_3$) in-flight, leaving only the combined shards for the root switch to finalize. Moving reduction into the network fabric halves the upper link traffic and relieves accelerator endpoints from coordinating arithmetic steps.

SHARP changes both terms of the cost model. On the startup side, it shortens the dependency chain. In a software-based tree reduction, each level waits for an intermediate GPU to receive, reduce, and forward its inputs. With SHARP, the switch performs that step in the packet path, so no GPU execution stage or extra endpoint round trip sits between levels. On the byte side, each upper-tier link carries one partial sum rather than every contribution beneath it (figure 5.9). In the idealized aggregation tree, each GPU sends its contribution up once and receives the result once, whereas a ring rank sends nearly $2M$. Endpoint memory traffic falls for the same reason. Switch processing and contention for aggregation resources add costs of their own, so moving arithmetic into the network changes the α-β terms rather than eliminating them.

Which benefit matters follows the regimes of section 5.5. For small and medium messages, where startup rounds dominate, the shorter dependency chain is the

[6] **SHARP (Scalable Hierarchical Aggregation and Reduction Protocol)**: In-network computing on Quantum InfiniBand switches that performs reduction operations (such as sum, min, and max) as packets traverse an aggregation tree (Graham et al. 2020). The same work reports substantially higher reduction bandwidth than host-based algorithms and describes switch-resource limits on outstanding aggregation groups and trees, which can create contention when many collectives compete for the same in-network resources.

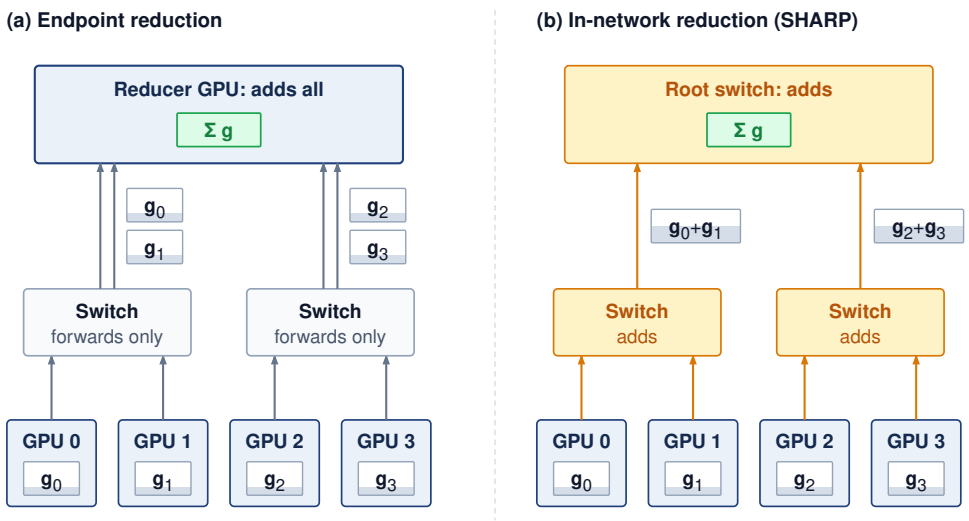

Figure 5.9: Endpoint and In-Network Reduction: The upstream half of a reduction over four GPUs. (a) Switches only forward packets, so every full gradient tensor crosses the upper links and converges on one reducer GPU, which does all the arithmetic. (b) Aggregation-capable switches add their inputs, so each upper link carries one partial sum and the root switch finishes the reduction; the result then travels back down the same tree. A software reduction tree also aggregates along its path, but performs arithmetic at endpoints rather than switches. The diagram compares where arithmetic happens, not measured speedup.

main gain, although for very small messages fixed switch-processing overhead can limit it. For large messages the startup saving becomes proportionally small, and what remains is the byte saving at the endpoints and on the upper tier, which shortens the collective only when those links are the binding resource. Graham et al. (2020) report multi-fold reduction-bandwidth improvements and smaller application-level gains for PyTorch workloads when SHARP Streaming-Aggregation is enabled on HDR/Quantum InfiniBand switches.

Strong scaling campaigns (training a fixed model across more accelerators without proportionally growing batch size) expose the importance of this distinction between collective speed and step time. As the per-accelerator batch shrinks, each gradient tensor stays large (proportional to model size) but the backward pass per accelerator shortens, exposing more of the communication budget. The limiting term can still be bandwidth; strong scaling alone does not establish that startup latency dominates. In-switch aggregation helps when its reduction in endpoint work or fabric traffic shortens the exposed critical path.

In-switch reduction also brings hardware and capacity constraints of its own. The switch ASIC must support the exact reduction operator and numerical format the job uses, such as FP16 or BF16 gradients, which vary across switch generations. Its finite internal memory limits how many aggregation trees can remain active at once. A large cluster running many concurrent jobs or process groups can therefore exhaust switch-tree capacity and fall back to host-based reductions. Moreover, the HDR and Quantum SHARP implementations examined here depend on InfiniBand switch support, so their gains do not carry over to Ethernet fabrics unless an equivalent in-network aggregation path is present.

5.7.4 Topology-aware routing

Two runs of the same 64-GPU Ring AllReduce on identical hardware can differ by a multiple in throughput depending on whether consecutive logical ranks sit on the same NVLink domain or across shared inter-node uplinks. Hierarchy and in-network aggregation change where bytes move and where sums are computed, but their benefit still depends on mapping the logical communication pattern onto physical links.

Communication libraries like NCCL perform topology detection at initialization and use graph search to choose paths through the hardware topology available to them (NVIDIA 2026c). For each pair of ranks, the library must determine whether the peer sits behind a local NVLink switch or 100 meters away across an InfiniBand fabric, because that mapping decides which physical links each logical hop occupies. Local GPU, NVLink, PCIe, and NIC connectivity informs those choices, but local discovery does not reveal every remote switch, route, or competing flow. Fabric configuration and placement information must complement the library's view when diagnosing cross-node contention.

The topology detection process begins with hardware enumeration. NCCL queries the PCIe bus to discover GPU placement, NVLink connectivity between GPUs, and NIC-to-PCIe-switch affinity. From this information, it constructs an internal graph where nodes represent GPUs and edges represent physical links with annotated bandwidth and latency. A graph search algorithm then finds communication paths that maximize aggregate bandwidth while minimizing the number of cross-domain hops (transitions between NVLink, PCIe, and InfiniBand domains). This topology-aware path selection is what allows NCCL to approach theoretical peak bandwidth on well-configured systems, while topology-unaware implementations can leave a large fraction of bandwidth unused.

5.7.4.1 Rail-optimized routing (NVIDIA DGX)

In the eight-GPU DGX layout considered here, each GPU has a dedicated inter-node NIC, and the fabric connects matching NIC positions to rail switches. Rail-optimized routing fits the corresponding-shard phase of hierarchical AllReduce: GPU 0 on Node A exchanges its shard with GPU 0 on Nodes B and C, GPU 1 exchanges with peer GPU 1s, and so on. The eight rails can carry these groups concurrently (table 5.8), subject to their physical capacity and competing traffic. Other collectives may require cross-rail paths.

↩ Rail-optimized cabling, which connects each GPU slot position to its own rail switch, is established in section 3.5.3.

Table 5.8: Rail-Optimized Traffic Distribution: Each rail carries 1/8 of the total traffic independently.

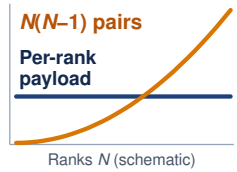
Rail	Participants	Traffic
Rail 0	Node0-GPU0 ↔ Node1-GPU0 ↔ Node2-GPU0 ↔ …	$M/8$ each
Rail 1	Node0-GPU1 ↔ Node1-GPU1 ↔ Node2-GPU1 ↔ …	$M/8$ each
…	…	…
Rail 7	Node0-GPU7 ↔ Node1-GPU7 ↔ Node2-GPU7 ↔ …	$M/8$ each

If all eight shard streams converge on one remote NIC, that endpoint faces 8× the balanced receive demand. In the equal-shard layout, matching each shard group to its intended rail distributes one-eighth of the payload to each NIC. This removes that particular concentration; achieving the predicted rate still requires sufficient switch, uplink, and bisection capacity for concurrent traffic.

NVIDIA designed the DGX node and rail layout together so that Step 2 of hierarchical AllReduce (section 5.7.1) maps each corresponding-rank shard group onto its own rail. NCCL exploits that structure whenever its topology detection finds aligned ranks. When the job scheduler assigns process ranks without topology awareness, however, logical shards and physical rails drift apart. Cross-node traffic is then routed through the wrong NICs or across spine switches, cutting a node's usable injection bandwidth to as little as one-eighth of the rail-aligned value when all eight shard exchanges converge on one NIC. Large deployments therefore enforce topology-aware rank assignment through device ordering (`CUDA_VISIBLE_DEVICES`), NIC binding, and scheduler placement policies so that logical rank i on every node stays bound to rail i.

↪ How the scheduler places a job's gangs on the topology hierarchy so that its collectives stay on fast links is developed in section 8.6.

Hierarchical execution and topology-aware routing connect the cost model to a physical placement. The α-β terms estimate the service required by each scheduled exchange; hierarchy redistributes work across fabric tiers, and rail alignment can balance corresponding-shard traffic across independent ports. None removes shared-capacity limits. Measured collective duration must confirm that the intended placement shortens the dependency path before the design is accepted.



5.8 AllToAll Exchanges at Scale

Hierarchy, in-network reduction, and rail alignment were all developed for AllReduce, whose uniform payload lets every rank follow the same schedule. In a mixture-of-experts model with 64 experts distributed across 8 GPUs (8 experts per GPU), or in the sharded embedding tables of table 5.1, a gating network or lookup table assigns each input to a specific destination rank. Tokens assigned to remote GPUs must physically cross the fabric before expert computation can proceed and return afterward, breaking AllReduce's symmetry so the exchange finishes only when its slowest path completes.

> **Systems Perspective 5.1: AllToAll vs. AllReduce: Why scale differs**
>
> Ring AllReduce can pipeline a uniform payload through neighbor exchanges. AllToAll presents a different scaling problem because every rank has destination-specific traffic, but the logical peer count alone does not determine its cost.
>
> An AllToAll over N ranks creates $N(N-1)$ logical source-destination transfers, yet each rank's aggregate payload can remain fixed under weak scaling. Its lower bound is governed by the largest of four terms: source injection time, destination reception time, traffic crossing the fabric bisection, and per-message startup or scheduling overhead. Oversubscription and routing

determine how much physical capacity those flows share. Message granularity determines how often they pay α. Routing skew determines whether one destination or link becomes the critical path. A full-bisection network carrying balanced, coarse-grained traffic can therefore scale well despite the quadratic logical connection count, whereas an oversubscribed fabric or skewed expert assignment can stall at much smaller N.

Expert parallelism and large-scale recommendation systems can reach a communication wall earlier than standard data parallelism when their traffic exhausts injection, reception, or bisection capacity, or when routing and destination skew create hotspots. The primitive determines the traffic matrix; the physical fabric and routing distribution determine the scaling ceiling.

Logical pairs grow quadratically while per-rank payload can stay flat.

Pricing that 64-expert, 8-GPU MoE layer under uniform routing establishes the baseline transfer volume and injection bound before dynamic skew enters.

Napkin Math 5.5: AllToAll for MoE token routing

Problem: An MoE model processes a batch of 4096 tokens across 8 GPUs (512 tokens per GPU). Each token is a 2048-dimensional hidden state in BF16 (4.096 KB per token). The gating network assigns each token to exactly 1 of 64 experts (8 experts per GPU). Assuming uniform routing (each expert receives 64 tokens), how much data does each GPU send and receive?

Math:

Each GPU holds 512 tokens that need to reach 64 different experts across 8 GPUs. With uniform routing, each GPU sends 64 tokens to each of the other 7 GPUs (keeping 64 tokens local).

- Data per GPU-to-GPU transfer: 64 tokens $\times$ 4.096 KB/token = 262.144 KB
- Total data sent per GPU: 7 $\times$ 262.144 KB = 1.84 MB
- Total data received per GPU: 1.84 MB (symmetric)

Latency Analysis (InfiniBand NDR, $\alpha = 1.5$ µs, $\beta = 50$ GB/s):

Each of the 7 transfers is a 262.144 KB message. From the α-β model: T_{transfer} = 1.5 µs + 5 µs = 6.5 µs per transfer.

If serialized: 7 $\times$ 6.5 µs = 45.5 µs. If all 7 transfers are issued concurrently, they still share the GPU's 50 GB/s injection port. The aggregate injection lower bound is therefore $\alpha +$ total bytes sent$/\beta = 38.2$ µs, before contention and additional collective overhead. Full duplex permits simultaneous sending and receiving; it does not provide one full-bandwidth outgoing port per peer.

Systems insight: The injection result is only a lower bound. If the topology's usable bisection bandwidth is $\text{BW}_{\text{bisect}}$ and V_{cut} bytes must cross its minimum cut, the exchange also obeys $T \geq V_{\text{cut}}/\text{BW}_{\text{bisect}}$. Oversubscription reduces $\text{BW}_{\text{bisect}}$, fine-grained peer messages add startup cost, and expert skew raises

the maximum receive volume above the uniform estimate. The forward pass runs the AllToAll twice per layer, once for token dispatch and once for result collection; training also communicates gradients during backward.

5.8.1 Dynamic routing and expert imbalance in MoE AllToAll

The worked trace in notebook 5.5 assumes uniform token routing, in which every expert receives an identical share of tokens. In production MoE models, routing decisions are dynamic and data-dependent. The exchange keeps its two-phase shape, but its buffer sizes, its slowest receiver, and its load on the fabric all become functions of the routing distribution. The hierarchy just developed for AllReduce reappears as one of the schedules that can contain them.

Each MoE layer performs two exchanges. In an MoE transformer layer with N_{experts} experts distributed across N ranks (N_{experts}/N experts per rank), each rank holds a local batch of B_{tok} tokens. A gating router computes top-k_{experts} routing probabilities over all N_{experts} experts for each token, inducing two collective communication phases separated by expert computation. During token dispatch, each rank partitions its B_{tok} local token activation vectors ($\mathbf{x} \in \mathbb{R}^d$, where d is the model's hidden dimension) according to the destination ranks hosting the selected experts. The rank then executes an AllToAll collective (or variable-size `AllToAllv`) to route tokens across the fabric according to the routing matrix. After each rank computes forward passes through its assigned local expert feed-forward networks (FFNs), the token combine phase executes a second AllToAll collective to route output vectors back to their originating ranks. Each rank then computes the weighted combination of expert outputs:

$$\mathbf{y}_i = \sum_{j \in \text{top-}k_{\text{experts}}} p_{\text{gate}_{i,j}} \cdot \text{Expert}_j(\mathbf{x}_i)$$

Because routing is data-dependent, so are the required buffer sizes, even when the input tensor shape is fixed. One simplified model treats assignments of different tokens independently: the count for expert e is then $B_e \sim \text{Binomial}(NB_{\text{tok}}, p_e)$, where p_e is the fixed probability that a token selects expert e. Correlated tokens or changing router probabilities require a different count model. To avoid reallocating buffers for every routing decision, a capacity-limited implementation can reserve space using an expert capacity factor $C_{\text{cap}} \geq 1.0$, a multiplier on each expert's average share of token assignments (Lepikhin et al. 2021; Fedus et al. 2022):

$$\text{Capacity}_e = \left\lceil \frac{N \times B_{\text{tok}} \times k_{\text{experts}}}{N_{\text{experts}}} \times C_{\text{cap}} \right\rceil$$

The capacity factor exposes a trade-off between reserved space and retained expert assignments. At uniform expected capacity ($C_{\text{cap}} = 1.0$), some experts can still overflow while others have unused slots. A dropping implementation bypasses excess assignments through the residual connection, changing the computation and potentially harming training quality. Increasing headroom ($C_{\text{cap}} > 1.0$, for

example 1.25–1.5) can reduce overflow. If the implementation transmits every reserved slot, its padded payload grows by approximately a factor of C_{cap} relative to the uniform capacity-one budget; kernels that skip unused slots need not perform the corresponding dummy computation. A dropless implementation retains every assignment and can use variable-size `AllToAllv` to avoid sending unused slots. It still needs enough memory for the realized counts and remains exposed to routing skew.

Skew turns the most heavily loaded rank into a straggler. Because token routing is determined by input semantics, some experts inevitably receive disproportionate token volumes. An expert that receives several times the average load raises its host GPU's receive traffic by the same excess. The host's total receive volume depends on the combined load of all experts assigned to it, which is the rank-level quantity in the bound that follows.

Routing skew can create stragglers in both communication and expert computation. An inbound reception bottleneck bounds dispatch completion by the most heavily loaded receiver. Other ranks may finish their transfers earlier, but work that needs the delayed expert outputs must wait. The receive budget gives a lower bound before expert computation and the return exchange are counted:

$$T_{\text{dispatch}} \geq \frac{B_{\text{max}} \times d \times s_{\text{elem}}}{\text{BW}_{\text{rx}}}$$

where $B_{\text{max}} = \max_i \sum_{e \in \text{rank } i} B_e$ counts the largest remotely received token batch at any rank i, restricting B_e in this sum to assignments arriving from other ranks. Here s_{elem} is the bytes per activation element, and BW_{rx} is that rank's receive bandwidth. Bisection capacity provides a separate limit. Ring AllReduce exchanges data with logical ring neighbors, whereas AllToAll permits a complete bipartite exchange. Under uniform destination assignment, a fraction $(N-1)/N \approx 1$ of tokens leaves its source rank; the fraction crossing nodes or a particular fabric cut depends on placement. In the simplified symmetric fabric model with oversubscription ratio $R:1$, usable bisection bandwidth $\text{BW}_{\text{bisect}} = (N \cdot \text{BW}_{\text{inject}})/(2R)$ bounds the time needed to carry traffic across that cut:

$$T_{\text{dispatch}} \geq \frac{V_{\text{cut}}}{\text{BW}_{\text{bisect}}}$$

Napkin Math 5.6: The cost of a hot expert rank

Problem: Return to the uniform routing of notebook 5.5: 8 GPUs, 64 experts, 4.096 KB per token, and one 50 GB/s port per GPU. Suppose skew sends one rank's experts 1.5 times the average remote load. This is an assumed realized routing skew; the per-expert capacity factor reserves total-assignment headroom and does not determine remote arrivals. How does the receive bound on dispatch change?

Math:

1. **Uniform receiver**: Each GPU receives 448 remote tokens, or 1.84 MB, so $T_{\text{dispatch}} \geq 1.84\text{ MB} / 50\text{ GB/s} \approx 36.7\ \mu\text{s}$.
2. **Hot receiver**: $B_{\max}$ rises to 672 remote tokens, or 2.75 MB, so $T_{\text{dispatch}} \geq 2.75\text{ MB} / 50\text{ GB/s} \approx 55.1\ \mu\text{s}$.

Systems insight: The exchange cannot finish before its hottest receiver, so a 1.5× load on one rank raises the dispatch bound for the whole layer by the same factor. Transmitting unused capacity slots can add padding bytes; the amount depends on the packing layout rather than on this receive-skew factor alone. A variable-size exchange removes unused-slot traffic but not the receive bound. Expert computation processes local as well as remote assignments, so its work grows by the same factor only if the hot rank's total local-plus-remote assignment count also grows by that factor, with unchanged work per assignment.

Scale compounds both problems. To amortize small-message overhead across thousands of GPUs, hierarchical MoE runtimes decompose the flat AllToAll into a two-level collective (Hwang et al. 2023). Intra-node NVLink first coalesces tokens destined for experts on the same remote server node. Participating nodes then exchange aggregated payloads over InfiniBand or RoCE, and receiving GPUs use NVLink to distribute tokens to the GPUs hosting the targeted experts. At the logical level, this replaces $N(N-1)$ directed rank pairs with $N_{\text{nodes}}(N_{\text{nodes}}-1)$ directed node pairs; actual transport connections depend on the implementation. Coalescing can improve link utilization and reduce startup overhead, but the token bytes still have to cross the required fabric cuts, and skew can still overload a destination.

5.8.2 AllToAll schedule selection

A flat, fixed-size AllToAll schedule that works well for balanced, megabyte-scale peer transfers on eight GPUs can stall across thousands of GPUs when per-peer chunks shrink to a few kilobytes or when expert skew forces every rank to pad its buffers to the hottest receiver's count. Because `AllToAll` names only the destination-specific contract, the runtime must match its schedule to the traffic matrix and physical hierarchy rather than treating every exchange as one flat pattern. Three schedules cover the common regimes (table 5.9). Direct pairwise exchange suits balanced, coarse per-peer chunks. Hierarchical exchange coalesces many small remote chunks before they cross scarce inter-node links. Variable-size exchange avoids padding when token or embedding counts differ by destination. Hierarchical designs such as Tutel's two-dimensional exchange demonstrate why the best schedule changes with message size, scale, and topology (Hwang et al. 2023).

Table 5.9: AllToAll Schedule Selection: The right schedule minimizes the active bound rather than the logical peer count. Direct exchange preserves simplicity, hierarchy coalesces traffic before scarce links, and variable-size exchange removes padding without removing skew.

Schedule	When it fits	Cost exposed
Direct pairwise exchange	Balanced, coarse per-peer chunks on a small or full-bisection process group	Each rank injects directly to its peers; fine granularity repeats startup and scheduling cost, while oversubscription can bind the bisection
Hierarchical/coalesced exchange	Many small remote chunks across multi-GPU nodes or rails; pack by remote node, exchange aggregates, then redistribute locally	Coalescing amortizes inter-node startups and respects fast local links, but adds packing, local copies, synchronization, and temporary buffers
Variable-size exchange	Token or embedding counts differ by destination and padding to the maximum count would waste substantial bandwidth	Explicit counts and displacements avoid padding, but count exchange and irregular transfers add control overhead; the hottest receiver still sets completion time

The selection test follows the four-term lower bound from perspective 5.1 and section 5.8.1. When per-peer chunks are already coarse and source injection or fabric bisection dominates, coalescing cannot shrink the byte term and only adds local copies. When each remote destination receives a small chunk so that $N\alpha$ dominates instead, a hierarchical schedule replaces those many inter-node startups with a single aggregated exchange per remote node. Under routing skew, a variable-size interface keeps padding from inflating V_{cut}, though the runtime must still provision memory and time for the hottest receiver's load. Because these bounds depend on live routing behavior, a runtime must benchmark candidate schedules under the observed token-count distribution, rank placement, and fabric topology rather than relying on a balanced, fixed-size microbenchmark. Even the best schedule, however, must still transmit the full activation or gradient payload unless the system reduces the bytes themselves.

5.9 Gradient Compression Under Bandwidth Scarcity

Training across data centers over wide-area links or on cloud instances with commodity Ethernet can leave each worker with 10–100$\times$ less network bandwidth than the reference InfiniBand fabric. Federated training on phone-class devices, the Archetype C (Federated MobileNet) regime, faces cellular or Wi-Fi uplinks that are both slower and intermittently available. Even after hierarchical routing and schedule tuning extract all usable capacity from such links, moving a full-precision gradient or a multi-step client update can still dominate step time. Gradient compression attacks the payload size directly by trading numerical representation fidelity for fewer transmitted bits, offering nominal value-payload reductions of 4–1000$\times$ before metadata and aggregation costs reduce the realized

savings. Because noisy or biased updates can slow or stall optimization, the central engineering question is how much communication volume a compressor can remove while preserving progress toward the training quality target.

5.9.1 Precision reduction via quantization

↪ The per-round uplink budget of federated training, and the update compression that fits it to cellular and Wi-Fi links, are developed in section 11.7.2.

Quantization is the least disruptive compression lever when bandwidth is binding because it keeps every gradient element but reduces the bits used to represent it. Most gradients are computed in FP32 (32-bit floating point) or BF16 (16-bit brain float), so reducing bit-width directly reduces communication volume. The useful question is how much gradient fidelity the optimizer can absorb across the progression from mild to aggressive quantization. The compression ratios discussed in this section follow the compression literature and are quoted against FP32 values. The chapter's 70B payload is already BF16, so against it every ratio halves; INT8 saves 2× rather than 4×, and 1-bit encoding 16× rather than 32×.

FP16 halves FP32's value bytes when its range supports the workload, and INT8 stores each quantized value in one byte, a $4\times$ reduction relative to FP32 before scale metadata. A symmetric INT8 scheme uses 255 levels from negative 127 through positive 127. For a nonzero gradient vector, it computes a tensor-wide scaling factor $s = \max(|\mathbf{g}|)/127$, quantizes via $\mathbf{g}_{\text{int8}} = \text{round}(\mathbf{g}/s)$, and has the receiver reconstruct $\hat{\mathbf{g}} = \mathbf{g}_{\text{int8}} \times s$. An all-zero vector requires a separate zero case. Gradients differ from other quantized tensors in the reduction. Each rank computes its scale from its own gradient, so independently scaled integer vectors cannot be added directly to recover the sum of their reconstructed gradients. The collective must carry every rank's scale through the reduction and use sufficient accumulator precision, or reconstruct values before reducing them. At the extreme, 1-bit SGD transmits only the sign of each gradient element ($+1$ or -1), yielding a $32\times$ reduction in value bits over FP32. The receiver reconstructs values using a learned or adaptive scaling factor, though the substantial noise introduced by 1-bit quantization can severely degrade convergence without error-feedback mechanisms (Seide et al. 2014; Karimireddy et al. 2019).

5.9.1.1 Block quantization for gradient communication

↪ Byte widths for every format named here are collected for reference in section A.6.

Using a single scaling factor for an entire tensor makes every element's quantization resolution depend on the largest magnitude. When magnitudes vary substantially across the tensor, small gradients may round to zero even in regions whose values could be represented accurately with a smaller scale. Block quantization addresses this by dividing the gradient tensor into blocks of b_{block} elements (for example, $b_{\text{block}} = 64$ or 128) and computing an independent scaling factor per block. Each block's scaling factor adapts to its local range, improving resolution where that range is smaller at the cost of transmitting $d_{\text{grad}}/b_{\text{block}}$ additional scaling factors for evenly divided blocks.

For a gradient vector of dimension d_{grad} quantized to INT8 with block size b_{block}, the message size is $d_{\text{grad}} \times 1$ byte for the quantized values plus $(d_{\text{grad}}/b_{\text{block}}) \times 4$ bytes for the FP32 scaling factors, or $d_{\text{grad}} + 4d_{\text{grad}}/b_{\text{block}}$ bytes in total. The effective compression is therefore $4d_{\text{grad}}/(d_{\text{grad}} + 4d_{\text{grad}}/b_{\text{block}}) = 4b_{\text{block}}/(b_{\text{block}} +$

4), which for $b_{\text{block}} = 128$ reaches 3.88×, close to the theoretical 4×. For rounding to the nearest level without clipping, the absolute error bound changes from $s \cdot 0.5$, where s is the global scaling factor, to $s_b \cdot 0.5$, where s_b is the block-local scaling factor. Blocks with smaller ranges obtain tighter bounds; the improvement depends on how magnitudes are distributed among blocks.

Interfaces that fuse quantization and reduction must preserve the meaning of each block's scale throughout aggregation. They must also control the resulting numerical error. Deterministic rounding generally introduces bias, whereas suitable randomized quantizers preserve the input in expectation while adding variance. Error feedback addresses accumulated compression error, but the need for it depends on the compressor and optimizer rather than on bit-width alone. Quantization should therefore move only as far down the precision ladder as the convergence budget permits.

5.9.2 Gradient sparsification methods

Even 1-bit quantization must send at least one bit per coordinate, capping its value-payload reduction at 16× relative to BF16 (32× relative to FP32) before scale metadata. Pushing compression to 100× or beyond requires an orthogonal lever, sparsification, which keeps full or half precision for selected coordinates and transmits only a small subset of gradient elements while setting the rest to zero.

5.9.2.1 Top-k sparsification

Top-k compression selects that subset by magnitude: for a gradient vector $\mathbf{g} \in \mathbb{R}^{d_{\text{grad}}}$, it transmits only the K_{top} elements with the largest absolute magnitude, setting the rest to zero (Aji and Heafield 2017; Lin et al. 2018):

$$\text{TopK}(\mathbf{g}) = \mathbf{g} \odot \mathbf{1}_{|\mathbf{g}| \geq |\mathbf{g}|_{(K_{\text{top}})}}$$

where $|\mathbf{g}|_{(K_{\text{top}})}$ is the K_{top}-th largest element by magnitude. The threshold expression retains all ties; an implementation targeting an exact count must break ties at the boundary. With $K_{\text{top}} = 0.001 \times d_{\text{grad}}$ (keeping only 0.1 percent of elements), the retained values occupy 1000× less space before index overhead.

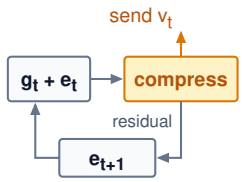
The compression headline must be discounted by the cost of encoding the sparse representation. Transmitting a sparse gradient requires sending both the nonzero values and their indices. For a gradient vector of dimension d_{grad} with K_{top} nonzero elements, the encoded message contains K_{top} values (each in FP32 or FP16) plus K_{top} indices (typically INT32). The total message size is $K_{\text{top}} \times (4 + 4) = 8K_{\text{top}}$ bytes for FP32 values with INT32 indices. The effective compression ratio is therefore $4d_{\text{grad}}/(8K_{\text{top}}) = d_{\text{grad}}/(2K_{\text{top}})$.

For $K_{\text{top}} = 0.001 d_{\text{grad}}$, the encoded message yields a compression ratio of 500×, not the 1000× suggested by the kept-element fraction alone, because the index overhead is significant. Using a 16-bit unsigned index representation (for $d_{\text{grad}} < 65536$) or run-length encoding for suitable sparsity patterns can improve the effective ratio. Aggregation imposes a separate cost. Workers may retain different coordinates, so summing their packed value arrays would combine unrelated

parameters. A sparse collective must match indices and sum contributions to each coordinate; the union of selected coordinates can be much larger than any one worker's selection. Local compression ratios therefore do not directly specify collective traffic or runtime.

Top-k is not the only sparsification rule. Random-k sparsification selects K_{rand} elements uniformly at random and scales them by $d_{\text{grad}}/K_{\text{rand}}$ to maintain an unbiased gradient estimate. Random-k has the advantage of being an unbiased compressor even without error feedback, because $\mathbb{E}[\text{RandomK}(\mathbf{g})] = \mathbf{g}$. Its random selection can discard large components, and rescaling the retained values introduces variance. Top-k retains the largest components but introduces bias. Their convergence behavior therefore depends on the optimizer, residual correction, and gradient distribution; unbiasedness alone does not determine which reaches a quality target sooner.

5.9.2.2 The convergence problem



Naively discarding small gradients with Top-k creates a systematic bias. If a parameter's gradient remains below the selection threshold, even a consistent contribution of 0.01 per step is repeatedly omitted. Over thousands of steps, those omissions can materially change the optimization trajectory. The problem is persistent exclusion, which can occur even when each discarded component looks negligible in isolation.

The bias of uncorrected Top-k means that the usual argument for SGD with an unbiased gradient estimate no longer applies directly. Biased compression can cause convergence failure even when the uncompressed method converges. Deterministic quantization can also repeatedly omit small contributions; randomized quantization and rescaled Random-k instead require accounting for their added variance. Error feedback addresses accumulated compression error for quantized gradients (Seide et al. 2014) and for sparsified gradients (Stich et al. 2018; Karimireddy et al. 2019).

5.9.3 Error feedback and residual accumulation

Error feedback prevents that 0.01 sub-threshold component from being lost forever. Rather than discarding unselected or rounded-away gradient coordinates, each worker retains a local residual accumulator $\mathbf{e}_t$. At step t, the system adds $\mathbf{e}_t$ to the new gradient $\mathbf{g}_t$, compresses the corrected vector, transmits $\mathbf{v}_t$, and stores the untransmitted difference as $\mathbf{e}_{t+1}$, allowing persistent small contributions to accumulate until they cross the transmission threshold.

> **Definition 5.3: Error feedback mechanism**
>
> ***Error feedback*** is a distributed-training technique for gradient compression that maintains a per-worker residual accumulator $\mathbf{e}_t$, re-injecting the compression error back into the next gradient update so that information omitted from the transmitted update remains in the residual. A finite run can end with an untransmitted residual.

Error feedback carries the residual into the next compressed step.

1. **Significance**: Top-k sparsification at 1 percent keeps only the largest 1 percent of gradient values by magnitude, reducing each worker's retained value payload from 140 GB to 1.4 GB for a full 70B gradient, a 100× reduction before sparse-index and aggregation overhead. Without error feedback, the discarded 99 percent of gradient values create a biased update that can harm convergence. With error feedback, omitted information remains in the residual and can influence later selections, supporting the convergence guarantees analyzed for memory/error-feedback variants under their assumptions (Stich et al. 2018; Karimireddy et al. 2019).
2. **Distinction**: Unlike plain lossy compression, which permanently discards sub-threshold gradient components, error feedback delays their transmission. A component too small to send in one step stays in the residual and can influence later transmitted updates as it accumulates; a finite run may still end with an untransmitted residual.
3. **Common pitfall**: A frequent misconception is that error feedback is automatic whenever a compressor is used. It is not: the training system must explicitly preserve and reinject the residual. Without that residual path, Top-k and 1-bit quantization introduce systematic bias that can accumulate across steps (Karimireddy et al. 2019).

Error feedback preserves cumulative gradient information over time. Consider what happens over K steps:

$$\sum_{t=1}^{K} \mathbf{v}_t = \sum_{t=1}^{K} [(\mathbf{g}_t + \mathbf{e}_t) - \mathbf{e}_{t+1}] = \sum_{t=1}^{K} \mathbf{g}_t + \mathbf{e}_1 - \mathbf{e}_{K+1}$$

If the error accumulator remains bounded under the chosen compressor and training assumptions, then as $K \to \infty$:

$$\frac{1}{K} \sum_{t=1}^{K} \mathbf{v}_t \to \frac{1}{K} \sum_{t=1}^{K} \mathbf{g}_t$$

Under that bounded-residual condition, the difference between the two averages vanishes. At a finite stopping point, untransmitted information remains in the residual. Repeated small gradients can accumulate in $\mathbf{e}_t$ until they exceed the compression threshold, as the worked trace illustrates.

The telescoping property of compression error across time is why error feedback can transform a biased compressor into a convergent training method. Theoretical analyses show convergence guarantees for sparsified SGD with memory and for EF-SGD with broad compression operators under their stated assumptions (Stich et al. 2018; Karimireddy et al. 2019). A rounding compressor with no residual path shows what is lost without that memory (table 5.10). It transmits each value rounded to the nearest whole unit, so any value below 0.5 is sent as zero.

Table 5.10: Naive Compression Trace (No Error Feedback): Five-step worked trace showing how a rounding compressor transmits zero whenever an individual gradient falls below 0.5.

Step	True gradient g_t	Transmitted v_t	Cumulative transmitted	Cumulative true
1	0.4	0	0	0.4
2	0.3	0	0	0.7
3	0.2	0	0	0.9
4	0.4	0	0	1.3
5	0.3	0	0	1.6

A residual accumulator $\mathbf{e}_t$ that re-injects the discarded remainder into the next step changes the outcome of the same sequence (table 5.11). Instead of vanishing at each rounding step, the fractional updates accumulate locally until they cross the transmission threshold.

Table 5.11: Error-Feedback Compression Trace: Same five-step sequence under error-feedback compression.

Step	g_t	e_t	$g_t + e_t$	v_t	$e_{t+1} = (g_t + e_t) - v_t$	Cumulative v
1	0.4	0	0.4	0	0.4	0
2	0.3	0.4	0.7	1	–0.3	1
3	0.2	–0.3	–0.1	0	–0.1	1
4	0.4	–0.1	0.3	0	0.3	1
5	0.3	0.3	0.6	1	–0.4	2

Example 5.2: Error feedback mechanism

Scenario: A gradient compression pipeline rounds each gradient value to the nearest whole unit before transmission, so values below 0.5 are sent as zero, over 5 training steps of distributed data-parallel training.

Diagnosis: Naive rounding (table 5.10) discards every value below 0.5, transmitting 0 when the true cumulative gradient is 1.6 (100 percent gradient loss). With error feedback (table 5.11), the residual grows until it crosses 0.5 and is sent, so the run transmits 2 and ends holding –0.4 in the residual. Transmitted plus residual, 2 + (–0.4), equals the true total of 1.6.

Systems lesson: The trace illustrates how error feedback carries omitted information into later updates. By storing untransmitted residual vectors in local accelerator memory ($\mathbf{e}_{t+1} = \mathbf{g}_t + \mathbf{e}_t - \mathbf{v}_t$), repeated small contributions can accumulate until they cross the transmission threshold. The trace demonstrates the residual mechanism; convergence still depends on the compressor and optimizer assumptions.

5.9.4 1-bit Adam compression-aware optimization

Compressing raw gradients works cleanly for stochastic gradient descent, where the parameter update is linear in the gradient. Adaptive optimizers such as Adaptive Moment Estimation (Adam) divide the first moment (momentum) by the square root of a running second-moment (variance) estimate, so compression noise in the raw gradient distorts that nonlinear denominator and can destabilize training. Microsoft's DeepSpeed team observed that Adam's second-moment estimate stabilizes early in training even while momentum continues to evolve (Tang et al. 2021). Rather than compressing raw gradients on every step, 1-bit Adam runs standard full-precision Adam during an initial warmup phase until the variance estimate settles. It then freezes that variance tensor as a fixed adaptive preconditioner and switches to a communication-efficient phase. In this phase, workers communicate only the momentum using 1-bit compression (sign plus a scaling factor) while retaining each compression residual locally for the next step.

Because the frozen preconditioner is no longer perturbed by quantization noise and the local residual feeds omitted momentum back into subsequent messages, the method controls accumulated compression error and preserves Adam's convergence trajectory without requiring each 1-bit message to be an unbiased estimator. Across experiments up to 256 GPUs, Tang et al. (2021) report up to 5× end-to-end communication-volume reduction. That is smaller than the raw 32× ratio of 1-bit values to FP32 momentum, because the uncompressed warmup and other communication costs are included. The same work reports convergence speed that matches uncompressed Adam, with up to 3.3× higher throughput for BERT-Large pretraining and up to 2.9× higher throughput for Stanford Question Answering Dataset (SQuAD) fine-tuning. Designing the compressor around the optimizer's internal state thus succeeds where replacing every raw gradient with its sign would fail, provided the compression overhead remains small compared with the communication time saved.

5.9.5 Bandwidth versus convergence trade-offs in compression

Across quantization, sparsification, error feedback, and 1-bit Adam, greater byte reduction demands stronger residual or preconditioner safeguards to protect convergence. Placing these methods side by side against both FP32 and BF16 baselines (table 5.12) maps each compression ratio to the convergence control and link regime it requires (Seide et al. 2014; Aji and Heafield 2017; Lin et al. 2018; Stich et al. 2018; Karimireddy et al. 2019; Tang et al. 2021).

Table 5.12: Gradient Compression Methods: Encoded-payload ratios relative to an FP32 payload, as the literature quotes them, and relative to the BF16 payload this chapter's examples use. Top-k assumes FP32 values and 32-bit indices in both columns; quantization scales and other metadata reduce the stated upper bounds. No method has a fixed convergence penalty across workloads. The right choice depends on whether bandwidth or convergence speed is the binding constraint; evaluate the complete time to the same quality target, including encoding and any additional training steps.

Method	Ratio vs. FP32	Ratio vs. BF16	Convergence impact	Best use case
FP16	2×	1× (none)	Check range and numerical stability	Common accelerator baseline
INT8 + Error FB	At most 4×	At most 2×	Workload- and scaling-dependent	Bandwidth-constrained clusters
Top-k (1%) + Error FB	At most 50×	At most 25×	Depends on sparsity and residual control	Cross-data-center training
1-bit + Error FB	At most 32×	At most 16×	Requires compression-aware optimization	Extreme bandwidth constraints

5.9.5.1 Decision criteria for gradient compression

The decision rule is not the compression ratio alone. Compression is worthwhile only when the wall-clock time it saves across the run exceeds its encoding overhead plus the cost of any extra steps that slower convergence requires, so the comparison must be made in time to the same quality target. A high communication-computation ratio $\rho = T_{\text{comm}}(N)/(T_{\text{compute}}/N)$ creates an opportunity when that communication is exposed on the critical path. The ratio compares communication time with ideally partitioned compute time and separates compute-bound from communication-bound clusters (section C.3.3). The compressor and optimizer analysis must establish how bias or variance is controlled, including whether error feedback is required; convergence tests then check that the chosen configuration reaches the target.

The first test is per synchronization. Compression shrinks only the byte term, so it helps a payload above n^*, such as a full gradient or a large bucket, and does little for one below it, whose startup term remains (section 5.5). Even above n^*, encoding must cost less than the transfer time it removes.

Napkin Math 5.7: The payback of compression

Problem: A training job takes 40 ms to synchronize a gradient buffer. A compression scheme shrinks the payload, but after scale factors, metadata, and protocol overhead its assumed effective throughput gain is 8×, and encoding and decoding add 2 ms of accelerator time per synchronization. Does compression shorten the synchronization, and by how much?

Math:

1. **Compressed communication time**: 40 ms divided by the effective factor 8 = 5 ms.

2. **Total new time**: 5 ms (comm) + 2 ms (overhead) = 7 ms.
3. **Effective speedup**: 40 ms divided by 7 ms $\approx$ 5.7×.

Systems insight: Compression is a trade of compute for bandwidth. With compression ratio r_{comp} and encoding cost T_{overhead}, it pays off only when $T_{\text{overhead}} < T_{\text{comm}}(N) \times (1 - 1/r_{\text{comp}})$, that is, when encoding costs less than the communication time it removes. In this case, spending 2 ms to save 35 ms of network time is a clear win. On a high-speed NVLink network where $T_{\text{comm}}(N)$ is only 1 ms, the same compression logic would cost more than it saves and slow down training. Always profile the network before adding compression.

The second test spans the full training run, because a compressor that passes the per-step test can still lose once slower convergence adds iterations. Comparing total wall-clock time to the same quality target on a slow and a fast network shows how a modest step-count penalty can reverse the verdict.

Suppose a training run requires 100,000 steps to reach its quality target without compression, with each step taking 500 ms (300 ms compute and 200 ms communication), for a total of 50,000 s. INT8 compression with error feedback of an FP32 payload reduces communication by 4× (from 200 ms to 50 ms per step), but suppose it raises the required steps by 10 percent, to 110,000. The new total is 110,000 steps at 350 ms each, or 38,500 s, a 23 percent improvement. Compression wins here because the per-step saving of 150 ms outweighs the additional steps.

The same model on a faster network, where communication takes only 30 ms per step, reverses the verdict. Compression cuts that to 7.5 ms, saving 22.5 ms per step, but still adds 10,000 steps at 307.5 ms each. The run now takes 33,825 s instead of 33,000 s, 2.5 percent longer. In this serial compute-plus-communication model, the break-even value of ρ depends on the assumed compression ratio and extra steps, with no separate encoding cost included. A training schedule with overlap must instead compare the exposed time saved against encoding and convergence costs. Scheduling transfers during independent computation offers another way to reduce that exposed time.

Checkpoint 5.4: Gradient compression decisions

Verify your understanding of when and how to apply gradient compression:

- ☐ **Error feedback**: explain why uncorrected 1-bit SGD can fail to converge and why 1-bit Adam introduces warmup and residual correction, comparing how each method handles information loss.
- ☐ **Compression payoff**: determine whether applying 4× gradient compression improves total step time when the backward pass takes 800 ms and AllReduce takes either 200 ms or 2,000 ms.

- ☐ **Error accumulator**: derive the steady-state behavior of the error accumulator e_t when the true gradient is constant at $g = 0.3$ and the compression threshold is 0.5.
- ☐ **Top-k vs. quantization**: choose between Top-k sparsification and quantization for a workload, accounting for compression ratio and sparse-index encoding overhead.

5.10 Communication-Computation Overlap

Even with hierarchical routing and gradient compression, waiting until the entire backward pass finishes before launching AllReduce leaves every GPU idle across the full transfer window before the optimizer can update the weights. **Communication-computation overlap** hides that stall by running transfers concurrently with independent backward-pass computation, attacking the communication time that algorithm selection and compression leave exposed. How much of a transfer can be hidden depends on which parts of that transfer occupy the processor and which occupy only the network.

5.10.1 The LogP model of what overlap can hide

The α-β model estimates transfer duration without specifying how much independent computation can proceed during that transfer. Adding the entire estimate to compute time therefore overstates step time when overlap is possible. The **LogP model** (Culler et al. 1993) separates network transit from processor involvement with four parameters:

- L_{LogGP} **(latency)**: The time for a message to traverse the network (similar to α).
- o **(overhead)**: The processor time spent initiating or completing a transfer. During this work, the same execution resource cannot compute, making o the nonoverlappable cost. In a distributed training context, dispatch, device-kernel launch, memory registration, and runtime progress can all contribute. The value is an effective parameter of a particular software and hardware path, so it must be measured with the same collective, process group, and topology used by the workload.
- g **(gap)**: The minimum spacing between consecutive sends or consecutive receives at a processor. It limits endpoint message rate but does not describe every source of link contention in a routed fabric.
- N **(rank count)**: The number of ranks in the communication group. The original model names this processor count with its final letter, P; this chapter writes it N to match its other collective cost formulas.

LogP distinguishes network latency (L_{LogGP}, which can be hidden) from processor overhead (o, which cannot). Independent computation can overlap the network transit interval, while initiation and completion overhead remain exposed on the execution resource that performs them.

Napkin Math 5.8: Hiding communication behind computation

Problem: A training pipeline attempts to overlap gradient AllReduce with the next layer's backward pass. The backward pass takes 500 µs. Represent the complete transfer by a toy budget with network time 100 µs, processor overhead $o = 50$ µs to initiate, and $o = 50$ µs to receive. Assume both overhead intervals occupy the same execution resource as backward computation, with independent network progress and no contention. Can the communication be hidden under these assumptions?

Math:

1. **Overlappable portion**: Network latency L_{LogGP} = 100 µs (data in flight while GPU computes).
2. **Non-overlappable portion**: $2o$ = 100 µs (GPU busy initiating/receiving).
3. **Compute available**: 500 µs.
4. **Hidden**: All 100 µs of L_{LogGP} can overlap with compute.
5. **Exposed**: The 100 µs of $2o$ overhead cannot overlap.

Result: Effective time is 100 µs + max(500 µs, 100 µs) = 600 µs. The network latency is hidden, but the processor overhead remains exposed. Applied to every layer of a backward pass, the same split determines which gradient transfers a training step can hide.

Systems insight: The α-β model captures the total communication time. The LogP model reveals how much of it can be hidden. When designing pipelined training, optimize for low o (kernel bypass, GPUDirect) rather than high β alone.

The α-β model estimates transfer duration from latency and bandwidth measurements. LogP adds the processor/network distinction needed to estimate exposed delay in pipelined execution. Choosing a communication schedule therefore requires both a transfer budget and the independent computation available to overlap it.

When messages are large and pipelined across the network, the LogGP model (Alexandrov et al. 1995) extends LogP with a gap-per-byte parameter G, modeling the streaming cost of long messages. These models describe multiprocessor communication with endpoint rate and capacity limits; they are not restricted to one flow on one link. Their compact parameters do not explicitly represent every shared path, oversubscribed cut, or routing hotspot. For congestion-sensitive workloads, particularly AllToAll for MoE, measurements on the target placement must test whether the model captures the active bottleneck.

↪ The LogGP long-message cost model and its gap parameters are developed in section D.1.2.

5.10.2 Layer-by-layer overlap

Gradient computation during the backward pass proceeds layer by layer, from the output layer back to the input layer. The gradient for layer ℓ is available as soon as that layer's backward pass completes, even while layers $\ell-1, \ell-2, \ldots$ are

still computing. That ordering lets the gradient for layer ℓ start communicating immediately while the GPU computes the gradient for layer $\ell - 1$. Over a four-layer backward pass, the transfers for layers 4 through 2 run beneath later backward work, and only the transfer for layer 1, which becomes ready last, is left exposed before the optimizer step (figure 5.10).

In PyTorch's `DistributedDataParallel`, this overlap is implemented through gradient hooks. Each parameter registers a hook that marks its gradient ready. Once all required gradients in a bucket are ready, the reducer can launch an asynchronous AllReduce, preserving the same collective order across ranks. Meanwhile, the backward pass continues computing gradients for earlier layers. A transfer is hidden only if it completes before its result is needed; queued communication can consume part of that window, and the last bucket's transfer remains exposed (section 5.10.4).

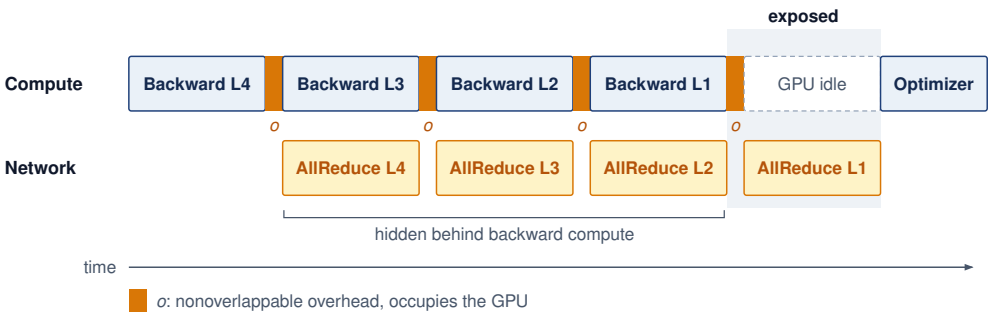


Figure 5.10: Communication-Computation Overlap: The backward pass runs from the last layer to the first, and each layer's gradient AllReduce launches as soon as that layer finishes, so it runs on the network while the GPU computes the next layer's gradients. The first layer finishes last and has no computation left to hide behind, so its AllReduce is exposed before the optimizer step. Overlap succeeds only when the nonoverlappable overhead (o) is small, leaving the bulk transfer free to proceed concurrently. Durations are schematic.

The effectiveness of this overlap depends on the relative sizes of computation and communication at each layer. For transformer models, the largest gradient tensors belong to the attention and feed-forward weight matrices, which are also the most computationally expensive layers. That computation cannot hide the same layer's gradient transfer, because the gradient is ready only afterward. It can hide a previously launched transfer; the ordering and cost of the remaining layers determine each gradient's overlap window.

The overlap strategy interacts with algorithm choice from section 5.6 and section 5.7. An isolated-collective crossover need not predict the best training-step schedule, because the dependency schedule determines how much of each candidate's transfer time is exposed. Overlap with the backward pass can reduce Ring's exposed latency penalty, but the benefit must be measured with the actual gradient-ready times and runtime progress behavior. The optimizer step still cannot begin until every required reduction completes, so the transfers of the last layers processed, those closest to the input, stay exposed.

5.10.3 Bucket fusion

The layer-by-layer overlap described in section 5.10.2 assumes that each layer's gradient is communicated as a single message. In reality, a transformer layer contains dozens of individual parameter tensors (query, key, value projection matrices, output projection, layer norm parameters, feed-forward weights, and biases). Launching a separate AllReduce for every individual parameter would create thousands of small-message collectives, each paying the full α_{eff} overhead. To avoid this, DDP uses bucket fusion to group parameters into buckets (often configured around tens of megabytes, with 25 MB a common PyTorch reference point) and launches one AllReduce per bucket. The bucket size represents a trade-off: larger buckets amortize α_{eff} overhead but delay the start of communication (because the bucket cannot be sent until all its parameters have computed gradients). Smaller buckets start communication earlier but pay more α_{eff} overhead.

The optimal bucket size depends on gradient-ready times, tensor sizes, and network characteristics. Smaller buckets can start communication sooner when waiting for more gradients would consume the overlap window. Larger buckets can amortize startup when repeated small transfers dominate. Neither choice follows from the model family alone; the useful measure is the resulting training-step time, including the exposed final transfer. PyTorch's `bucket_cap_mb` parameter in DDP allows tuning this trade-off.

Bucket membership also determines how early communication can begin. A bucket containing one late gradient must wait even if its other gradients are ready. DDP can use reverse parameter registration order as an approximation to backward readiness and, depending on configuration, rebuild buckets from the observed backward order. Registration order need not match forward execution order, especially in models with branches or reused parameters. Grouping gradients that become ready together helps preserve the overlap window while maintaining a consistent collective sequence across ranks.

5.10.4 Overlap limits and exposed communication

Even well-tuned bucket fusion cannot hide all communication behind backward compute. Three structural limits (processor launch and completion overhead, pipeline boundary stalls at the start and end of backpropagation, and the HBM footprint of in-flight buffers) cap how much transfer time can disappear. First, the LogP model's overhead parameter o represents processor time consumed by initiating or completing transfers; in the simplified LogP budget, initiation and completion consume $2o$ per operation on the participating execution resource, so when backward compute intervals are short relative to that overhead, hiding network transit still leaves processor overhead exposed.

The pipeline also has boundary effects. During the first backward computation, no gradient from this pass is ready to communicate. Once the output-side gradient is ready, however, its communication can overlap with the remaining backward work. At the other end, the input-side gradient has no subsequent backward computation to hide its transfer. More layers create a longer overlap window, but

depth alone does not guarantee high coverage: if communication takes longer than each compute interval, a backlog remains even in a deep model.

A third limitation arises from memory pressure. Buffers used by an in-flight transfer must remain valid while independent computation produces or consumes other tensors. Their overlapping lifetimes can increase peak GPU memory use, although views and buffer reuse can avoid separate copies. For FSDP workloads, prefetching parameters can keep multiple materialized groups resident at once, trading memory savings for communication overlap. The engineering challenge is to hide transfers within the available memory budget, and FSDP's prefetch and resharding policies are the controls that set this trade-off.

Together, processor overhead, boundary stalls, and per-layer transfer time determine how much of a collective schedule can hide behind backward computation. Pricing a realistic 32-layer transformer backward pass shows how much communication remains exposed when each layer's reduction outlasts its compute window.

Napkin Math 5.9: Overlap budget for a 7B transformer

Problem: A 32-layer transformer model (7B parameters) is trained on 64 GPUs. Assume the data-parallel reducer communicates FP32 gradients, about 875 MB per layer, in 100 MB buckets, four times the common 25 MB default. Each layer's backward pass takes 15 ms. Assume the cluster achieves 3 ms per bucket under its contention and protocol overheads, so each layer's gradients take 27 ms, and assume equal layers and the same charge for the final partial bucket. What is the backward-plus-communication time with and without overlap?

Without overlap (sequential):

$T_{\text{sequential}} = T_{\text{backward}} + T_{\text{comm}}(N)$ = 480 ms + 32 $\times$ 27 ms = 1344 ms.

With overlap (pipelined):

Each layer's AllReduce (27 ms) runs in parallel with the next layer's backward pass (15 ms). Since 27 ms > 15 ms, there is 12 ms of exposed communication per layer that cannot be hidden.

Communication runs back to back from the moment the output layer's gradients are ready. Each later reduction overruns its backward window by the exposed amount, so the backlog grows by that much per layer, and the last reduction adds its full duration after the backward pass ends:

$T_{\text{pipelined}} = T_{\text{backward}} + T_{\text{layer comm}} + (N_L - 1) \times T_{\text{exposed}}$ = 879 ms.

Systems insight: Overlap reduces backward-plus-communication time by 34.6 percent. The remaining exposed communication comes from the AllReduce being slower than the per-layer backward pass. To reduce the backlog, either lengthen the independent compute window (for example, with a larger batch) or reduce AllReduce time. The final gradient still has an exposed transfer tail, and any change must preserve the intended training workload and

quality target. The overlap is most effective when per-layer backward compute exceeds the reduction time ($T_{\text{layer backward}} > T_{\text{layer comm}}$).

The verdict turns on the assumed per-bucket charge. The hierarchical model of notebook 5.4 prices one uncontended 100 MB bucket on these eight nodes at about 0.85 ms, or 7.6 ms per layer, inside the 15 ms backward window, so at that rate every transfer except the last would hide. An overlap budget is therefore only as good as its achieved per-bucket time, which the calibration of section 5.11.2 measures rather than assumes.

An overlap budget joins the collective's transfer cost to the model's dependency schedule. Realizing that budget requires a runtime whose asynchronous progress and device-memory path preserve the independent work available between gradient production and consumption.

5.11 Communication Libraries and Runtimes

An overlap schedule only works if the communication backend can move the required tensors while independent computation proceeds. Production libraries realize the same algorithms and schedules, so the engineering decision is which one preserves the chapter's model, topology, and overlap assumptions on the target hardware.

5.11.1 Backend selection

A collective runtime that bounces GPU tensors through host DRAM over PCIe or ignores NVLink and rail topology can cut effective reduction bandwidth by an order of magnitude even when it implements the right ring or tree schedule. Four properties therefore separate communication backends in practice: the device memory path, topology awareness, portability, and observability. NCCL leads on the first two for NVIDIA GPUs because it executes the collective algorithms of section 5.6 and section 5.7 directly on GPU-resident buffers (Jeaugey 2017; NVIDIA 2026c). Its kernel fusion combines reduction arithmetic with data movement so intermediate results do not bounce back to HBM. GPUDirect RDMA lets the network card read and write GPU memory directly over PCIe without staging payloads through host DRAM. To keep multiple links busy at once, channel pipelining splits each collective across parallel communication channels, though realized throughput still depends on NIC placement, routing, and contention because extra channels cannot create port capacity. Documented environment variables then expose these choices for observability, with `NCCL_ALGO` and `NCCL_PROTO` inspecting or overriding the selected algorithm and protocol and `NCCL_DEBUG` reporting the active topology, channels, and schedule (NVIDIA 2026c).

MPI matters when portability, CPU-side coordination, or HPC integration is the binding requirement (Message Passing Interface Forum 2015), and two of its features bear directly on overlap. Non-blocking collectives such as `MPI_Iallreduce` return a request handle that the application tests or waits on, a completion model different from NCCL's ordering on CUDA streams. Persistent collectives, intro-

duced in MPI 4.0, initialize an operation once and activate it at every step, amortizing setup for a training loop that repeats the same AllReduce shape. Either model hides a transfer only when independent work exists and the runtime makes progress. MPI's one-sided communication (`MPI_Put`, `MPI_Get`, `MPI_Accumulate`) maps onto RDMA hardware and suits asynchronous designs in which one process writes another's memory without its participation. CUDA-aware MPI implementations accept GPU pointers, but the selected transport decides whether data still passes through host memory, so that path must be benchmarked against NCCL.

Portability is the strength of Gloo, a PyTorch backend for CPU tensors, development, and testing whose TCP transport exercises collective semantics on one machine before a job reaches an accelerator cluster. Whether a faster shared-memory transport is active must be measured rather than assumed. Other accelerators have their own backends, AMD's RCCL for the ROCm stack and Intel's oneCCL, because the same algorithm has different effective α, β, and topology constraints on each platform. PyTorch's `torch.distributed` routes each call to the backend its process group names, so teams often mix them, with NCCL reducing gradients in a GPU group while a CPU group uses Gloo for barriers, scalar broadcasts, or sampler state. Applied to common scenarios, the four properties select a library, or a pairing of libraries, for each (table 5.13).

Table 5.13: Communication Library Selection: Choose based on hardware and workload requirements. Many NVIDIA GPU training deployments use NCCL; Gloo serves as a portable fallback.

Scenario	Recommended library	Rationale
Multi-GPU training (NVIDIA)	NCCL	GPUDirect, kernel fusion, NVLink-aware
CPU-only distributed training	Gloo or MPI	Mature CPU optimizations
Development/debugging	Gloo	Cross-platform, no CUDA dependency
Mixed vendor GPUs	Vendor-specific groups; validate cross-group path	NCCL, RCCL, and oneCCL are vendor-specific
HPC integration	MPI + NCCL	MPI for job launch, NCCL for GPU collectives

The table follows from the chapter's cost model. A backend's memory path and topology choices determine how it uses the fabric, and its diagnostic signals help identify whether α, β, or processor overhead limits the job. The resulting performance must still be measured with the workload's collective and placement.

5.11.2 Calibrating collective communication models

When an engineer runs `nccl-tests` on a new cluster and compares the reported `AllReduce` time against the naive point-to-point expression $\alpha + M/\beta$, the achieved bandwidth appears to be roughly half of the link specification even on a healthy

fabric. The bandwidth-latency trade-off (principle 5) provides accurate first-order predictions only when it models the same collective that the benchmark executes: for a ring AllReduce over N ranks and an M-byte tensor, the first-order cost is $2(N-1)\alpha + 2(N-1)M/(N\beta)$, whereas a tree, a hierarchical schedule, and a switch-assisted reduction each carry their own step counts and traffic factors. NCCL also selects protocols, channels, and algorithms according to message size and detected topology, making those runtime choices part of the experimental condition (Jeaugey 2017; NVIDIA 2026c).

A calibrated collective model therefore records the operation, reduction datatype, rank count, tensor size, algorithm and protocol, topology, rank placement, and achieved bus bandwidth. It then fits effective α and β to measurements from that same configuration, as section 3.4.4 does for one measured NCCL AllReduce. Comparing predicted and observed time under this contract reveals software overhead or topology loss without mistaking a collective's algorithmic traffic factor for library inefficiency. The resulting parameters apply only to the measured regime; changing the collective, process group, topology, or library version requires recalibration. A calibrated model selects a collective schedule and sizes its overlap window. Attributing an observed training-step regression to kernels, memory, communication, or contention is a broader measurement task, which the program goodput analysis of section 9.6 develops.

Communication diagnosis begins by comparing the workload against a matched bare-collective baseline and recording the selected algorithm, protocol, rank placement, and achieved bandwidth. A healthy baseline with a slow training step points to invocation granularity, contention, stragglers, or insufficient overlap rather than the fabric alone. Profiler traces and the attribution workflow separate those causes; the output needed here is the calibrated α, β, and overlap window that select a collective schedule.

The backend must satisfy both the collective contract and the measured execution budget. A fast isolated collective is insufficient when its placement, invocation order, or progress behavior leaves the training step waiting.

5.12 Fallacies and Pitfalls

Communication optimization attracts persistent misconceptions because the interaction between latency, bandwidth, topology, and compression creates nonobvious failure modes that simple mental models miss. Each of the following pitfalls traces a common rule of thumb to the physical or algorithmic boundary where it breaks down.

Fallacy: *Bandwidth is the only metric that matters.*

For small control messages or sufficiently small token exchanges, latency (α) dominates, and buying 400G networking will not help a message that takes 5 µs to serialize in software. Section 3.4.4 draws that point-to-point split at the critical message size $n^* = \alpha \cdot \beta$. A collective hides a less obvious case. The regime belongs to each schedule step's chunk rather than to the tensor, so a gradient bucket far

above n^* can still travel in latency-bound steps on a large ring, where fewer rounds or larger buckets help and added bandwidth helps little.

Pitfall: *Assuming AllReduce works for everything.*

AllReduce computes one reduction over compatible element counts and datatypes; it does not implement destination-specific routing. In expert parallelism and recommendation systems, each worker instead sends distinct data to different peers. These workloads require AllToAll or its variable-count form, whose performance depends on injection bandwidth, bisection bandwidth, oversubscription, message granularity, routing, and skew rather than logical connection count alone.

Fallacy: *Pipeline parallelism eliminates communication overhead.*

Pipeline parallelism exchanges activations and their backward gradients between adjacent stages. It can coexist with data-parallel AllReduce, and transfer cost still depends on tensor size and placement. Each stage boundary is a point-to-point dependency on the critical path, so a stage cannot start a microbatch until its activations arrive. The pipeline bubble, the time stages sit idle while the pipeline fills and drains, adds to whatever transfer time remains exposed. The bubble analysis of section 6.5.2 shows that shrinking it requires many more microbatches than stages, a constraint on batch size and activation memory that no faster link removes. Parallelism choices must therefore account for both communication dependencies and schedule-induced idleness.

Pitfall: *Using Ring AllReduce by default without checking message size and topology.*

Ring achieves the bandwidth-optimal term $2\frac{N-1}{N}\frac{M}{\beta}$ in the endpoint model but pays $\mathcal{O}(N)$ latency. For a 1 MB gradient across 64 GPUs with $\alpha = 10$ µs and $\beta =$ 10 GB/s, the simple Tree model wins because Ring's extra startup cost (about 1140 µs beyond Tree's) exceeds Tree's extra byte-transfer cost (about 1000 µs beyond Ring's). The log-aware crossover estimate $M_{\text{crossover}} \approx N\alpha\beta/\log_2 N$ guides this two-model comparison. Runtime selection should be evaluated with the actual algorithm variants and placement.

Fallacy: *Gradient compression is safe without error feedback.*

Top-k sparsification can achieve 99 percent compression, but naively discarding small gradients can prevent convergence. Without error feedback ($\mathbf{e}_{t+1} = (\mathbf{g}_t + \mathbf{e}_t) - \mathbf{v}_t$), gradients below the threshold are lost forever, accumulating systematic bias that can destabilize training or leave a persistent optimization error.

Pitfall: *Evaluating gradient compression by communication speedup alone.*

Even a 100× communication speedup must be evaluated against the complete training budget when reaching the target quality requires 2× more iterations. It helps only if the reduction in total step time outweighs the extra iterations. The right metric is time to target quality, not time per iteration. Communication microbenchmarks measure collective time, while the engineering decision depends on time to target quality, and the two diverge whenever compression introduces gradient bias or variance that slows convergence. Validate compression on the

target convergence benchmark with the deployment training schedule, not on a synthetic AllReduce microbenchmark alone.

Fallacy: *Async collectives always hide latency.*

Python's `dist.all_reduce(..., async_op=True)` only returns control to the CPU. The LogP model distinguishes network latency L_{LogGP} (overlappable) from processor overhead o (nonoverlappable). The condition $T_{\text{compute}} > o$ alone does not guarantee that a transfer is hidden. The remaining independent work must cover the transfer interval, the runtime must make progress, and dependent consumers must wait for completion.

Pitfall: *Silent data corruption in the network.*

Networks are not perfect. A bad cable, faulty NIC, or firmware bug can corrupt data below the level where the training framework sees an explicit error. At 10,000 nodes running 24/7, even rare bit errors can appear often enough to matter. The communication-specific lesson is that bandwidth tuning is incomplete without end-to-end validation: checksums, collective result checks, gradient-norm sanity tests, and the fault-tolerance mechanisms of chapter 7 must catch silent data corruption before corrupted gradients become model updates.

Fallacy: *Flat AllReduce is good enough for multi-node training.*

A single flat Ring AllReduce runs at the rate of its slowest edge. On a multi-node cluster, that edge is one cross-node port at 50 GB/s over InfiniBand rather than the 450 GB/s per direction available within the node, however carefully the ranks are ordered. For an 8-node cluster with 8 GPUs per node, the worked hierarchical schedule assigns one-eighth of the payload to each inter-node shard group and runs the eight groups on eight ports at once. The result is an $8\times$ reduction per group rather than a reduction in aggregate cross-node bytes. The modeled gain of about 4.8× in section 5.7.1 therefore depends on independent port capacity. A multichannel flat schedule that also occupies several ports at once requires its own traffic accounting.

Pitfall: *Assuming one cost formula fits every intra-node algorithm.*

NVSwitch provides high-radix, nonblocking connectivity within supported DGX generations, but it does not turn an arbitrary AllReduce into a one-step reduction. Unless the switch generation and software path provide in-network reduction, endpoints still execute a ring, tree, or other scheduled algorithm over NVLink paths. Newer switch-assisted designs require their own documented cost model. Capacity planning should therefore use the algorithm and hardware generation that the runtime actually selects. Apply the corresponding intra-node traffic factor, the inter-node ring or tree factor, and their hierarchical composition rather than substituting a generic crossbar hop for reduction work.

Fallacy: *Rank-to-GPU mapping does not affect collective performance.*

If the job scheduler assigns ranks to GPUs without considering the physical topology, hierarchical AllReduce and rail-optimized routing may route traffic suboptimally. A common symptom is that `nccl-tests` reaches full bandwidth on the

cluster while the training job achieves only a fraction of it, because the job's ranks were placed so that corresponding shards cannot stay on one rail. Message sizes, overlap, and competing traffic can produce a similar gap. Before benchmarking, record each rank's GPU, NIC binding, node, and rail and confirm the intended layout (for example, ranks 0–7 on node 0 and ranks 8–15 on node 1, with local rank i on each node bound to rail i). Contiguous rank numbers on a node alone do not establish that corresponding shards use the intended physical rails. A benchmark that omits this record and the NCCL topology configuration is not reusable evidence, because a placement difference then reads as a library or hardware regression.

5.13 Summary

Every mechanism in this chapter works on the communication term $T_{\text{comm}}(N)$ of the Fleet Law (equation 1.3), either shrinking it through better schedules, placement, and smaller payloads or enlarging T_{overlap} so that less of it is exposed. Each spends effort on the Communication axis of C^3 so that added compute does not sit waiting. The mechanisms compose into one ordered judgment that starts with the collective contract. The primitive whose output the next computation consumes fixes which ranks exchange data and what each holds afterward, and no faster schedule can recover bytes spent delivering a broader result than the model needs. Once the contract is fixed, the α-β model, the critical size $n^* = \alpha \cdot \beta$, and the ring-tree crossover $M_{\text{crossover}}$ price each candidate schedule round by round on its per-step chunk rather than on the whole tensor.

A schedule priced on a flat network realizes that cost only when hierarchy, rail alignment, and rank order map the logical exchange onto the physical links. Compression and overlap then determine how much of the remaining transfer reaches the critical path. LogP separates the network transit time that overlap can hide from the processor overhead it cannot, and every candidate is judged by time to the same quality target rather than isolated collective speed. A model calibrated against the same collective, process group, and topology closes the loop by separating a schedule's inherent traffic from library or placement loss.

Key Takeaways: Every byte has a travel cost

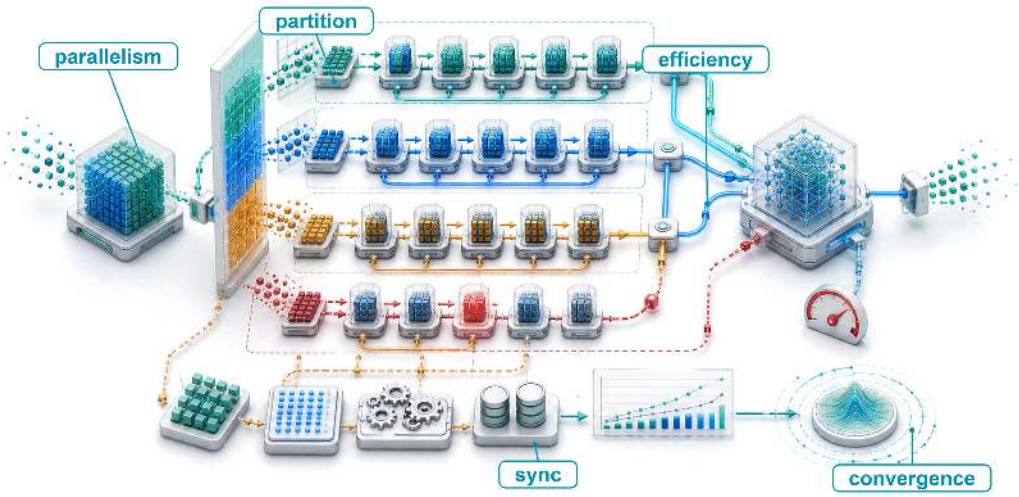
- **Contract first, then price per round**: Choose the narrowest primitive whose output the next computation consumes, then price its schedule round by round. Each round pays the startup cost on a chunk, so the critical size $n^* = \alpha \cdot \beta$ (principle 5) classifies the chunk rather than the tensor. Collective duration also depends on round count and traffic volume; fit parameters with a benchmark that matches the workload's collective and topology.
- **Algorithm choice is scale-dependent**: Ring AllReduce is bandwidth-optimal but pays $\mathcal{O}(N)$ latency; the simple full-message Tree model uses fewer rounds ($\mathcal{O}(\log N)$) but more bandwidth work. Use the log-aware

crossover estimate $M_{\text{crossover}} \approx N\alpha\beta/\log_2 N$ to reason about the switch point.

- **Hierarchy exposes parallel network capacity**: Local reductions over fast NVLink leave smaller shards for the slow InfiniBand tier. The effective bandwidth gain requires independent port capacity for concurrent shard exchanges; splitting a payload cannot multiply the capacity of a shared uplink.
- **AllToAll schedule selection follows the active bound**: Direct exchange preserves simplicity for balanced coarse chunks, hierarchy amortizes startup across scarce inter-node links, and variable-size exchange removes padding under skew. Injection bandwidth, bisection capacity, oversubscription, message granularity, and the hottest receiver determine which schedule wins.
- **Error feedback controls lossy compression error**: Sparsification can discard 99 percent of each transmitted update while accumulating the compression residual locally and adding it before the next compression step. Under the analyzed assumptions, this bounds accumulated compression error and restores convergence guarantees even though individual compressed updates can remain biased.
- **Overlap is limited by remaining independent work**: Gradient hooks and bucket fusion let communication run during later backward computations, but the final transfer and any communication backlog remain exposed. Evaluate the resulting step time, not model depth alone (principle 10).
- **Placement determines usable bandwidth**: Logical collective schedules share physical links according to rank placement and routing (principle 6). A matched benchmark must record that placement; changing the mapping can change the bottleneck even when the algorithm and hardware stay fixed.

If parallelism decides what must be communicated, collective communication measures what that communication costs. Every collective, whatever its contract, is priced first by the same two terms, a startup latency paid once per round and a transfer time paid per byte. The useful optimization is the one that shortens the training dependency path while preserving the required result.

What's Next: From traffic to partitioning



The fleet now has its traffic patterns and a price for each of them: a startup latency per round, a transfer time per byte, and a placement that decides which links carry the load. Which exchanges a training step actually issues, how large they are, and how often they run all follow from how the model and its data are divided among accelerators. The next chapter makes that

division explicit. It partitions training across data, tensor, pipeline, and expert dimensions and uses the costs derived here to judge when each partition repays the communication it creates.

↪ Data, tensor, pipeline, and expert parallelism, and the hybrid configurations that combine them, are developed in chapter 6.

Purpose

Why can adding accelerators make training slower?

Splitting a training job across machines creates more compute capacity, but it also requires those machines to exchange state and agree on updates. Each accelerator may finish its local work sooner while spending more of the step waiting for other workers. Once communication and waiting consume the time saved by parallel execution, adding accelerators raises the bill without shortening the run. Single-node optimization remains necessary, yet faster local arithmetic cannot remove a dependency on data that another machine has not delivered. Memory pressure complicates the decision, because a model may require distribution simply to fit, even when the resulting exchanges are expensive. Dividing its state across more devices can relieve that limit while exposing another in network bandwidth or scheduling. Conversely, replicating a model can process more examples at once without reducing the memory needed for each copy. Neither improvement alone establishes that training will finish sooner. Changing how examples are grouped or when updates become available can change the work required to reach the target quality. Engineers must therefore compare complete training configurations, accounting for memory, communication, update behavior, and

elapsed time together. The practical question is where additional hardware buys useful progress and where it merely creates more coordination. That judgment determines which models and experiments fit the available schedule and budget. In C^3 terms, each partitioning strategy trades parallelized compute against network-bound communication and coordination across workers.

Learning Objectives

- Apply the Fleet Law to diagnose compute-, memory-, communication-, or coordination-bound distributed training regimes
- Calculate scaling efficiency, estimate useful batch size, and budget synchronization overhead for data-parallel training
- Design memory-sharding plans that trade accelerator capacity for additional communication
- Map tensor, pipeline, sequence, expert, and data parallelism onto hardware bandwidth tiers and model structure
- Analyze microbatch pipeline schedules for bubble overhead, activation residency, and synchronous update ordering
- Evaluate synchronization and low-precision policies under staleness, straggler, and numerical-stability constraints
- Synthesize hybrid parallelism configurations for frontier, recommendation, and alignment training constraints

6.1 Why Distribution Is Necessary

A 175B-parameter reference model cannot load onto a single accelerator, because its FP16 weights alone exceed the memory of the device that must hold them (chapter 4). The empirical scaling law (principle 9) keeps pushing frontier models further past what one machine can store or finish in calendar time. The accelerator hierarchy, network fabric, and storage pipeline form the physical foundation of the fleet, and chapter 5 priced the collective operations that move state across it. The remaining challenge is deciding how to partition the training job: which intermediate results and gradients must cross that fabric, and when workers must synchronize, while preserving the optimization process a single device would have followed.

In the fleet stack (figure 1.4), distributed training occupies the Distributed Execution row of the Distribution band, the logic that partitions the *mathematical* workload across the *physical* fleet. Data, tensor, pipeline, and hybrid parallelism create different traffic patterns for the interconnect to carry, and selecting among them requires evaluating the reference workload against finite high-bandwidth memory (HBM) capacity, compute throughput, and input bandwidth.

↩ The power-law relationship between quality and compute, data, and parameters, and the compute-optimal allocation it implies, are established in section 1.3.

Three distinct limits push a training workload past a single accelerator. Memory exhaustion hits first when model parameters, optimizer states, and activation storage exceed single-device capacity. For full mixed-precision training with Adaptive Moment Estimation (Adam), the convention of 16 bytes per parameter can exceed an 80 GB accelerator at roughly 5 billion parameters before activations. Larger 10–20B models therefore need sharding, offload, or another memory-saving approach (Rajbhandari et al. 2020). The failed allocation establishes a capacity problem without by itself choosing the remedy.

↪ Accelerator HBM capacity, the ceiling these per-parameter budgets are measured against, is developed in section A.4.

Even when a model fits in memory, unacceptable training duration can still force distribution because a single device may require weeks or months to converge, turning wall-clock time itself into a systems constraint. GPT-3's 175B-parameter training run used a cluster of V100 GPUs (Brown et al. 2020), illustrating why the calendar, alongside HBM capacity, drives scale-out.

Input demand at dataset scale adds a third pressure: dataset bytes govern storage capacity, whereas the training schedule governs the required delivery rate. As section 4.4 showed, either can motivate distributed data services, although a large dataset alone does not require distributing model computation. Together, capacity, calendar, and input delivery define the constraints a training configuration must satisfy.

The first signal, memory exhaustion, has a long history, traced in figure 6.1. Over the plotted span, single-accelerator memory grew about 15× from the K80 to the B200, while the memory needed to train a state-of-the-art model grew by roughly 4 orders of magnitude. Among the plotted models, the curves cross in 2020 at GPT-3, whose training state exceeded the largest accelerator then available by about 35×. GPT-3 marks where the gap passed an order of magnitude, and every later plotted frontier model also sits far above the capacity curve. For those models, spreading state beyond one device's memory is a precondition for training at all rather than a way to train faster.

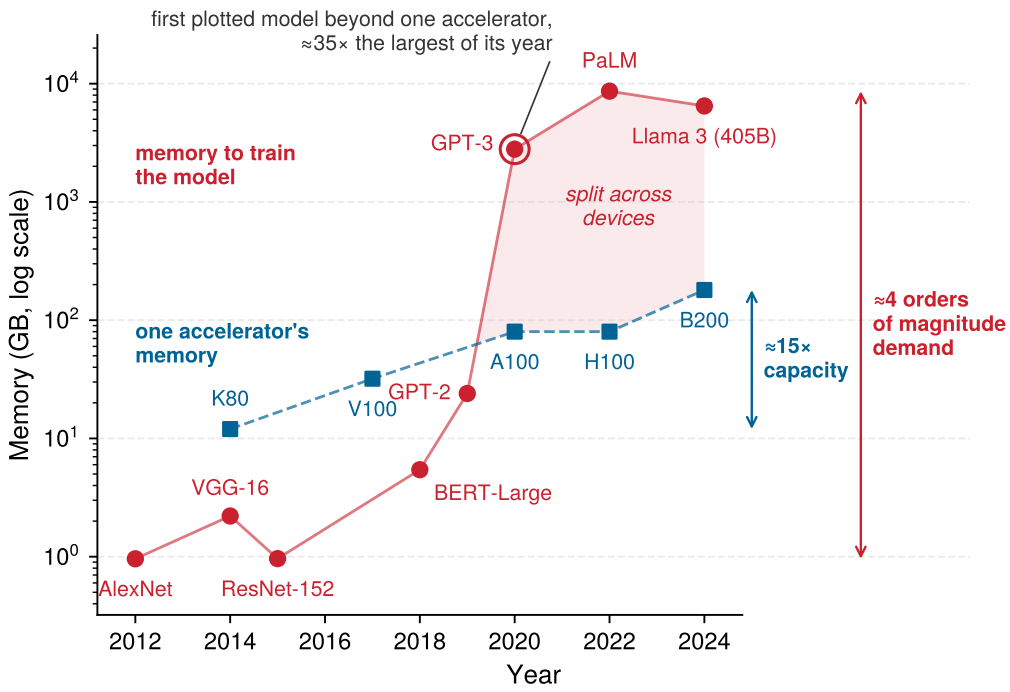

Figure 6.1: The Memory Wall: Accelerator memory capacity plotted against the memory a state-of-the-art model needs to train. Capacity climbs steadily while demand climbs faster, and the widening gap is why weights, gradients, and optimizer state must be split across devices rather than merely compressed. Training memory assumes 16 bytes per parameter for mixed-precision Adam state; parameter counts are from Epoch AI (2026c) and capacities are vendor specifications.

Whichever signal motivates distribution, the system must state which optimization update it implements. The synchronous baseline is developed first. In it, the 1,024 GPUs of the volume's Archetype A (GPT-4/Llama-3) reference cluster combine their contributions before advancing to the next parameter version. The running instance in this chapter is a GPT-3-class 175B-parameter dense transformer. Matching the global batch, loss normalization, and optimizer state preserves the corresponding single-device update mathematically. Later synchronization models deliberately relax that update ordering and must be evaluated under their own convergence assumptions.

↩ The three systems archetypes and their binding constraints are established in section 1.6.1.

Definition 6.1: Distributed training

Distributed training partitions the optimization loop across multiple compute nodes, distributing data or model computation and coordinating contributions according to a specified update protocol.

1. **Significance**: Partitioning training state across devices can meet a memory budget that exceeds one accelerator. GPT-3 (175B parameters) requires approximately 350 GB in BF16 (FP16 also stores 2 bytes per value, so the chapter's byte counts hold for either format), more than 4× the 80 GB capacity of a single H100. If weights remain entirely in HBM, their aggregate capacity lower bound is 5 H100s. Adding BF16 gradients plus FP32 Adam master weights and moments gives about 2.8 TB, or at least 35 H100s before activations. These lower bounds do not establish a runnable placement; offload changes the capacity calculation, and the time budget can require more accelerators than memory alone.
2. **Distinction**: CPU threads can share a coherent address space, while accelerators generally hold separate training-state allocations even within one node. Distributed training extends coordination across those devices and node boundaries through collectives or point-to-point transfers governed by the chosen update protocol.
3. **Common pitfall**: A frequent misconception is that distributed training scales linearly with node count. In practice, communication overhead grows with cluster size and the serial fraction of each step (Amdahl's Law): a fixed serial fraction of the single-device baseline bounds strong-scaling speedup.

Distribution expands three costs that determine whether a partition is viable. Communication overhead includes gradient aggregation through AllReduce, which returns the same reduced tensor to each participant, or rank. For P parameters across N devices, a ring AllReduce, in which each worker passes gradient chunks only to its neighbor in a logical ring, sends approximately $2(N-1)/N \times M_{\text{grad}}$ bytes per worker per step. Here the gradient payload M_{grad} is the P gradient values times their storage width. That payload is not total fleet traffic.

↩ The ring schedule and the derivation of its $2(N-1)/N$ volume are established in chapter 5.

Fault tolerance becomes more demanding as the number of failure sources grows. Under independent constant-rate failures, 1,024 GPUs that each have a mean time to failure (MTTF) of 50,000 hours produce a GPU failure about every 49 hours, the cluster's mean time between failures (MTBF). Whether each event interrupts training depends on recovery and redundancy; section E.1.3 develops the assumptions.

Algorithmic stability adds a separate constraint when the partition changes global batch size or update ordering. Learning-rate scaling and warmup are candidate responses to large-batch behavior (Goyal et al. 2017), not requirements unique to multiple machines. A viable design must satisfy all three budgets.

Communication and coordination costs enter every step through the Fleet Law (principle 10), which decomposes the per-step time:

$$T_{\text{step}}(N) = \frac{T_{\text{compute}}}{N} + T_{\text{comm}}(N) + T_{\text{sync}}(N) - T_{\text{overlap}}$$

↩ The Fleet Law and its compute, communication, and coordination terms are established in section 1.5.4.

The **communication-computation ratio**, $\rho = T_{\text{comm}}(N)/(T_{\text{compute}}/N)$, compares communication time with ideally partitioned compute time for fixed global work. It is the time consequence of communication intensity CI (equation 1.1), the bytes moved per operation of the workload. When transfers run at link bandwidth β and each device computes at sustained rate $R_{\text{peak}}\eta_{\text{hw}}$, $\rho \approx \text{CI} \times R_{\text{peak}}\eta_{\text{hw}}/\beta$, so the same workload becomes more communication-bound on faster accelerators or slower links. This ratio identifies the pressure to overlap communication; the complete step time also depends on how much exchange is hidden and how much coordination remains exposed.

↩ The α-β message model, with startup latency α and sustained bandwidth β, is established in section 3.4.4.

↪ The communication-computation ratio, evaluated for representative data-parallel and point-to-point transfers and related to communication intensity, is developed in section C.3.3.

Two regimes follow from this ratio. When $T_{\text{compute}}/N \gg T_{\text{comm}}(N)$, the cluster is compute-bound, and communication is small relative to useful computation, provided coordination and input delivery do not introduce another limit. Large-batch training of a dense convolutional model such as ResNet commonly sits here. When $\rho \gtrsim 1$, $T_{\text{comm}}(N)$ matches or exceeds T_{compute}/N and the cluster is communication-bound. Insufficient overlap then leaves substantial time waiting for gradients or activations. Large language models (LLMs) with billions of parameters to synchronize, and Deep Learning Recommendation Model (DLRM)-style workloads whose embedding exchanges saturate the network, frequently land in this regime. These are typical operating points rather than fixed labels. Batch size, partitioning, and placement can move the same workload across the boundary, so the ratio must be measured for the configuration at hand. Where a workload lands also depends on how its training loop is cut across devices, the choice each parallelism strategy makes.

↪ The optimizations that help, and the ones that are wasted, for a compute-bound, communication-bound, or coordination-bound fleet are collected for reference in section B.5.2.

6.2 The Parallelism Design Space

Once a model or its training time outgrows a single GPU, the training loop offers three nested axes to split across devices: the examples in a batch, the layers of the model, and the matrix operations inside each layer. Data parallelism assigns different examples to model replicas; pipeline parallelism assigns successive

layer groups to different devices; tensor parallelism splits the operations inside a layer. Because every split adds inter-device communication and synchronization overhead on top of single-machine compute and memory limits (Appendix A), profiling and design must treat these three strategies as *loop transformations* applied by a cluster-level compiler.

In compiler terms, data parallelism acts like a parallel for-loop that assigns different batch indices to devices running the same model. Tensor parallelism resembles vectorization, or single instruction, multiple data (SIMD), by partitioning the work inside matrix operations. This is an analogy for the work split rather than for a shared instruction stream or register file, since the devices still exchange tensor shards over an interconnect. Pipeline parallelism instead resembles instruction pipelining, assigning successive layer groups to stages so that overlapping microbatches keep those stages active, subject to dependency delays and load balance.

Whichever loop a strategy unrolls, distributed training[1] spreads the workload across machines that must coordinate to train a single model. Coordination here means keeping every model shard or replica on a compatible training step. Basic barriers can keep a small research run ordered, but long-running training jobs also need timeout, checkpoint, and recovery mechanisms so one failed worker does not waste days of compute.

Mapping those three loop transformations onto hardware follows the cluster's interconnect hierarchy. Within a single node, multiple GPUs coordinate across separate device memories over high-bandwidth NVLink or PCIe links,[2] with collective libraries such as NCCL scheduling the transfers.

Crossing node boundaries adds slower inter-node network links, fault-tolerance exposure, and cluster orchestration, so single-GPU kernel and memory efficiency must be tuned first rather than multiplied as waste across the fleet. Matching the three loop splits to these intra-node and inter-node tiers decomposes the design space onto a three-dimensional grid, $N = N_{\text{DP}} \times N_{\text{PP}} \times N_{\text{TP}}$, that partitions cluster execution across tensor parallelism (N_{TP}, intra-layer sharding), pipeline parallelism (N_{PP}, sequential stage partitioning), and data parallelism (N_{DP}, batch replication). Each cell of the grid is one accelerator coordinate (figure 6.2).

Under the three-dimensional partitioning of figure 6.2, called **3D parallelism**, the total accelerator allocation scales as the product $N = N_{\text{DP}} \times N_{\text{PP}} \times N_{\text{TP}}$. The axes represent distinct mathematical partitions, but they are not independent configuration knobs. Tensor and pipeline degrees must divide the model structure, the data-parallel degree and microbatch schedule must produce a viable global batch, every partition must fit memory, and each communication group must map onto an adequate topology and acceptable failure domain. Training systems therefore select a jointly feasible coordinate rather than tuning N_{DP}, N_{PP}, and N_{TP} in isolation.

6.2.1 Parallelism strategy selection and engineering trade-offs

A parallelism strategy that places frequent, high-volume exchanges on a slow link fails before it leaves the whiteboard, because communication stalls the accelerators

[1] **Distributed training**: Google's DistBelief (2012) was an early framework for training neural networks across thousands of machines, but its parameter server architecture created bandwidth bottlenecks at central nodes. This limitation drove the shift to decentralized AllReduce patterns in successors such as Horovod and PyTorch DistributedDataParallel (DDP), where each data-parallel worker sends and receives about $2(N-1)/N$ times the gradient size per step rather than concentrating traffic at a single server (Dean et al. 2012; Sergeev and Balso 2018; S. Li et al. 2020; Patarasuk and Yuan 2009).

↪ Checkpointing and recovery for long-running training jobs are developed in chapter 7.

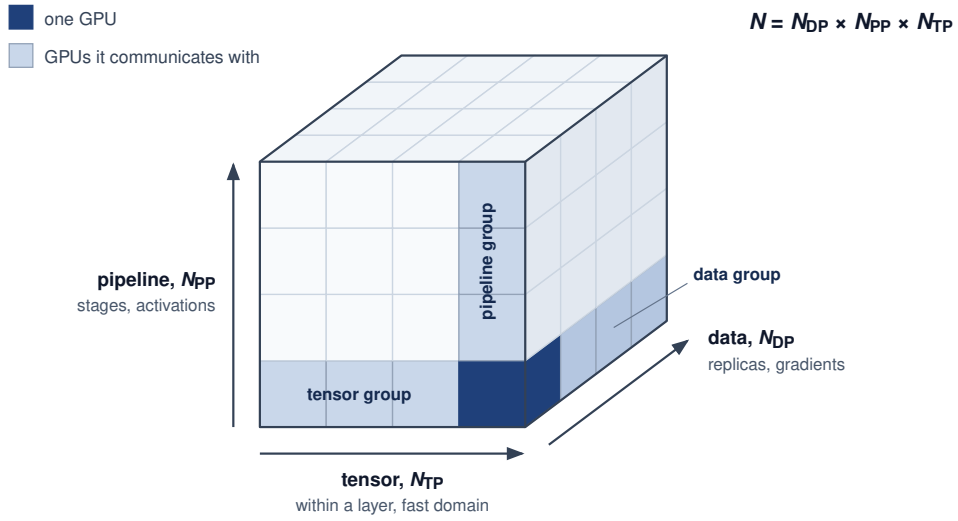

Figure 6.2: The 3D Parallelism Cube: The configuration space decomposes cluster training across three orthogonal axes: tensor parallelism (N_{TP}, intra-layer sharding), pipeline parallelism (N_{PP}, sequential stage partitioning), and data parallelism (N_{DP}, batch replication). Each cell is one accelerator, identified by its $(N_{\text{DP}}, N_{\text{PP}}, N_{\text{TP}})$ coordinate, so the cube holds $N = N_{\text{DP}} \times N_{\text{PP}} \times N_{\text{TP}}$ devices. A feasible point must jointly satisfy model divisibility, per-device memory limits, and the network hierarchy that carries each axis's traffic.

it was meant to feed. Choosing a strategy is therefore a constraint satisfaction problem governed by parameter count (P), batch size (B), and interconnect bandwidth. A first feasibility screen compares the traffic each strategy creates against the hardware topology (table 6.1). In that screen, N_L denotes layer count, S sequence length, and d hidden width. The table identifies traffic sources rather than complete byte budgets; datatype width, partition degree, and communication frequency enter the worked mechanisms below.

[2] **NVLink**: NVIDIA's point-to-point GPU interconnect delivers 300 GB/s–450 GB/s per-direction bandwidth, roughly 12×–18× InfiniBand HDR per port. This bandwidth gap is why tensor parallelism, which requires AllReduce on every layer, favors the fast NVLink domain, while pipeline and data parallelism can tolerate slower links when their traffic budgets fit. NVLink Switch systems can extend that fast domain beyond one server.

Table 6.1: Parallelism Communication Costs: Tensor parallelism exchanges partial layer results frequently and favors a fast communication domain, which can span servers. Pipeline parallelism transfers boundary activations; its bandwidth need depends on tensor shape and microbatch schedule. Data parallelism synchronizes gradient bytes, whose exposed cost depends on overlap and topology. Memory sharding addresses capacity but does not automatically reduce communication.

Strategy	Communication pattern	Comm. volume	Hardware constraint
Data Parallel (DP)	AllReduce Gradients	$\propto M_{\text{grad}}$ (gradient bytes)	Requires high bisection BW
Tensor Parallel (TP)	AllReduce Activations	$\propto B \times S \times d \times N_L$ (per-layer activations)	Fast domain matched to layer traffic
Pipeline Parallel (PP)	Point-to-Point (P2P)	$\propto B \times S \times d$ (Activations)	Link must sustain stage activations

Those bandwidth requirements impose a hard constraint on hardware placement: each parallelism axis must map onto an interconnect tier that can sustain its traffic within the compute budget. A quick back-of-envelope bandwidth feasibility check catches a mismatch before any code is written.

↩ The communication domains and bandwidth hierarchy used to evaluate placement are established in section 2.5.1.

Systems Perspective 6.1: Bandwidth feasibility check

Frequent tensor-parallel collectives must fit the layer-time budget. The test compares the time one layer's local share of computation takes with the time its collectives take on each candidate link. For the forward pass of one GPT-3 layer split 8 ways, processing one 2,048-token sequence at half of an H100's dense FP16 peak:

- Local compute per layer: about 1.9 ms
- Tensor-parallel transfer per layer over NVLink: about 0.4 ms
- The same transfer over one NDR InfiniBand port: about 3.5 ms

On NVLink the exchange is a fraction of the layer's compute; across InfiniBand it would take longer than the compute it serves. The amount hidden depends on independent work available in the execution schedule. NVLink is one suitable fast domain, but the test uses message bytes, exposed latency, and sustained link rate rather than an interconnect brand or chassis boundary. Cross-rack placement may favor pipeline or data parallelism when the available fabric cannot meet the tensor-parallel budget; their activation and gradient traffic must also be checked.

The communication costs in table 6.1 already narrow the choice before any mechanism has been developed, because a strategy is viable only when its traffic fits the tier that must carry it. What each formula implies in practice depends on the mechanics of data, tensor, and pipeline parallelism developed over the rest of the chapter, and section 6.8 turns the same constraints into a decision procedure once those mechanics are in place.

6.3 Data Parallelism

When a model fits on one accelerator but training takes weeks, replicating its computation lets several workers process examples concurrently. The initial data-parallel baseline gives each worker the same model state and a local portion of one global minibatch. Combining those local contributions before the optimizer update preserves the intended global-batch estimator; the sampling and weighting conditions below explain when that equivalence holds.

Definition 6.2: Data parallelism

Data parallelism distributes training examples across workers that execute the model and combine their contributions to its optimization updates.

1. **Significance**: With N workers each processing a local batch of B_{local} examples once per update, the global batch size is $N \times B_{\text{local}}$. At fixed local work, 1,024 workers offer an ideal 1,024$\times$ throughput increase before exposed overhead. A 1B-parameter model with BF16 gradients contributes a 2 GB gradient payload; ring AllReduce moves $2(N-1)/N$ times that payload per worker. Realized speedup depends on local compute, collective service, overlap, and load balance.
2. **Distinction**: The replicated synchronous baseline keeps a full model copy on each worker and aggregates gradients before each optimizer update. Model parallelism instead partitions the model's computation.

Sharded data parallelism, developed below, retains data-parallel computation while distributing training-state storage.

3. **Common pitfall**: Data parallelism does not scale indefinitely with worker count. Holding the local batch B_{local} fixed while adding workers grows the global batch. Beyond the workload-dependent critical batch size, additional examples yield diminishing reductions in the steps needed to reach target quality (Shallue et al. 2019). The crossover developed in section 6.4.6 therefore limits the statistical benefit even when gradient variance continues to decrease.

Data parallelism applies when examples can be processed independently, as in training a ResNet model (He et al. 2016) on ImageNet. Each replica computes its local loss gradient, and the workers combine those contributions to reproduce the intended global-batch gradient. The averaging rule makes the sampling and weighting assumptions explicit.

Consider a model with parameters θ training on a dataset D. The loss function for a single data point x_i is $\mathcal{L}(\theta, x_i)$. In standard stochastic gradient descent (SGD) with batch size B, the gradient update for a minibatch is:

$$\mathbf{g} = \frac{1}{B} \sum_{i=1}^{B} \nabla_\theta \mathcal{L}(\theta, x_i)$$

In data parallelism with N devices, each device k computes gradients on its own minibatch $\mathcal{B}_k$:

$$\mathbf{g}_k = \frac{1}{|\mathcal{B}_k|} \sum_{x_i \in \mathcal{B}_k} \nabla_\theta \mathcal{L}(\theta, x_i)$$

When all workers use the same local batch size, the global update averages these local gradients:

$$\mathbf{g}_{\text{global}} = \frac{1}{N} \sum_{k=1}^{N} \mathbf{g}_k$$

Under that equal-batch assumption, the averaging is mathematically equivalent to computing the gradient on the combined batch $B_{\text{total}} = \bigcup_{k=1}^{N} \mathcal{B}_k$:

$$\mathbf{g}_{\text{global}} = \frac{1}{|B_{\text{total}}|} \sum_{x_i \in B_{\text{total}}} \nabla_\theta \mathcal{L}(\theta, x_i)$$

For unequal local batch sizes, the combined-batch gradient is the weighted average $\mathbf{g}_{\text{global}} = (1/|B_{\text{total}}|) \sum_k |\mathcal{B}_k| \mathbf{g}_k$. Data parallelism therefore maintains the statistical properties of SGD training, because sampling the intended global batch across devices, computing local gradient sums independently, and normalizing by the aggregate denominator reproduces its estimator. The reduction step uses an AllReduce over local gradient sums and valid-item counts.

Three batch quantities recur from here on, and the chapter keeps them apart. A worker's local batch B_{local} is the set of examples it processes for one update, playing the role of $\mathcal{B}_k$ above. The global batch $B_{\text{global}} = N \times B_{\text{local}}$ is the set the update averages over. Pipeline parallelism later splits a batch into m microbatches of size B_{micro} that flow through stages one after another; the word microbatch is reserved for those pipeline slices.

↪ The ring and tree AllReduce cost models that set the price of this synchronization are developed in section D.2.1.

Checkpoint 6.1: Data parallelism mechanics

Verify your understanding of how data parallelism distributes work:

- ☐ **State placement**: determine whether data parallelism shards or replicates the model state (weights) across GPUs.
- ☐ **Global batch size**: calculate the effective global batch size for 8 GPUs with a per-GPU batch size of 32.
- ☐ **Single-device equivalence**: explain why data parallelism is mathematically equivalent to single-device training with a larger batch size.
- ☐ **Binding constraint**: identify the primary hardware resource that constrains data parallelism as more nodes are added: GPU TFLOP/s or network bandwidth.

The method parallels gradient accumulation, where a device accumulates contributions from multiple forward and backward passes before one optimizer update. Both techniques use gradient addition and the intended loss denominator to process a larger effective batch. Distribution adds communication, partial failures, and coordination to that arithmetic. The implementation must preserve the update while accounting for those costs.

6.3.1 Data parallelism implementation

The implementation details matter because the SGD equivalence only holds when each phase preserves the intended aggregate sampling and weighting, complete local gradient contributions, and a single synchronized update. The concrete workflow follows the dataflow from assigning local batches to synchronizing the computed gradients. The five-stage execution pipeline in figure 6.3 follows four GPU swimlanes. Identical model replicas ingest disjoint batch shards and compute local gradients ($\mathbf{g}_0$–$\mathbf{g}_3$). They then synchronize through a ring AllReduce collective before applying uniform parameter updates.

The gradient synchronization stage of figure 6.3 (stage 4) creates a dependency, because each rank must receive the completed reduction before applying its optimizer update. The exposed wait can reflect bandwidth, collective startup, or a late contribution. Measuring that wait determines whether synchronization limits scaling; the dependency alone does not identify the binding resource.

6.3.1.1 Dataset splitting

Data splitting is the first place where the SGD equivalence can fail, but uniqueness and equal-sized shards are sufficient conditions rather than the invariant itself.

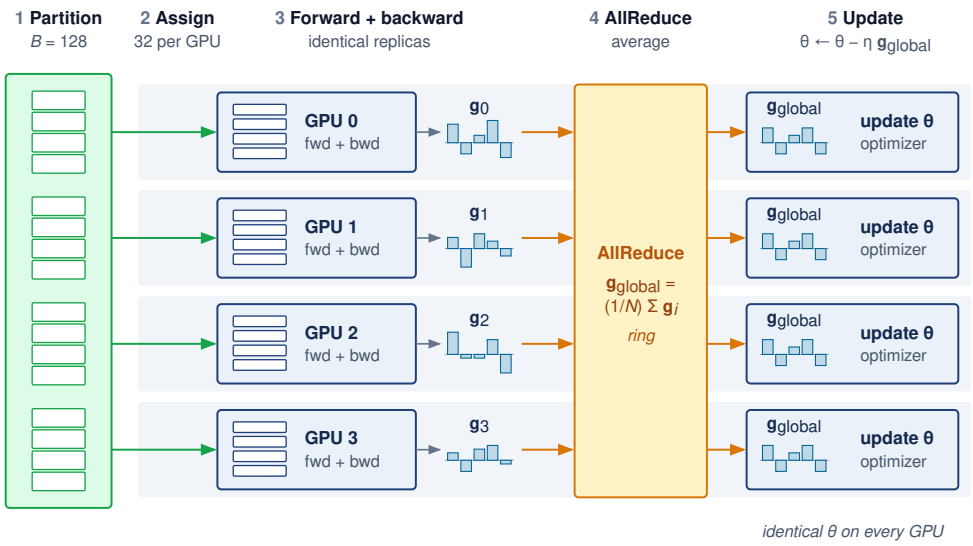

Figure 6.3: Data Parallelism Implementation Pipeline: The five-stage workflow for data-parallel training: (1) partition the global batch, (2) assign sharded mini-batches to individual GPUs, (3) compute independent forward and backward passes to produce local gradients $\mathbf{g}_i$, (4) execute an AllReduce collective across the cluster to obtain the average gradient $\mathbf{g}_{\text{global}}$, and (5) update parameters identically across all devices. This strategy preserves the mathematical semantics of single-device SGD while distributing the compute burden.

The aggregate examples or tokens, their sampling probabilities, and their gradient weights must reproduce the intended global-batch estimator. Uniform sampling without replacement can assign disjoint shards. Sampling with replacement can legitimately repeat examples. Variable-length batches can assign unequal token counts if the reduction weights each worker by its valid-example or valid-token denominator. An unweighted mean of unequal local means instead overweights workers with smaller denominators.

The sampler is therefore an integral component of the distributed training system rather than merely an input-loader convenience. A distributed sampler coordinates workers by rank and can deterministically partition or draw indices from a seeded sampling stream. The 1.28 million training images of ImageNet-1k do not divide evenly across 32 GPUs. A sampler that pads by repeating examples gives each GPU 40,037 examples per epoch and adds 17 repeats across the job. The loss normalization or sample weights must account for those repeats when exact epoch-level weighting matters. A recorded seed and deterministic index stream make sample assignment repeatable. Bitwise run reproducibility additionally depends on kernel determinism, collective reduction order, numerical precision, and checkpointed random-number-generator state.

6.3.1.2 Compute-phase forward and backward passes

For a replicated model whose local forward and backward operations require no cross-worker state, the computation phase is *embarrassingly parallel*. Each GPU executes the model on its local batch; synchronized normalization or additional

model partitioning can introduce communication within that phase. To isolate the activation term, consider an unpartitioned 175B reference model at a local batch of 4 sequences and sequence length 2048. This is a hypothetical memory budget, not a feasible one-GPU training configuration, because weights and optimizer state must fit as well. Without optimization, storing these activations for backpropagation would consume roughly 1.1 TB of HBM, an order of magnitude beyond the capacity of even an H100 GPU. Activation checkpointing recomputes selected activations during the backward pass rather than retaining them, reducing this example's footprint to ~19.3 GB at the cost of extra computation.

The capacity test must include activations rather than stopping at bytes per parameter. Section A.6 tabulates the 16-byte-per-parameter training state from which this test starts. At the point of peak residency,

$$M_{\text{total}} = M_{\text{weights}} + M_{\text{gradients}} + M_{\text{optimizer}} + M_{\text{activations}},$$

with communication buffers and temporary workspaces consuming additional headroom. Sharding reduces the first three terms according to its stage, whereas sequence length, local batch size, and pipeline scheduling govern $M_{\text{activations}}$. Activation checkpointing reduces that last term by retaining only selected boundaries and recomputing the omitted forward operators during backpropagation (Narayanan et al. 2021). Full recomputation re-executes about one extra forward pass per step. Because a backward pass costs roughly two forward passes, a step that needed three forward-pass equivalents of arithmetic now needs four, about a third more (Chen et al. 2016). Selective recomputation re-executes only operators whose activations are large but cheap to produce, such as the attention softmax and dropout, and keeps most of the memory saving for a few percent of extra arithmetic (Korthikanti et al. 2023). Recomputed operations raise hardware FLOPs utilization (HFU) but not model FLOPs utilization (MFU), which credits only the model's own forward and backward work. A plan that buys feasibility with full recomputation therefore pays for it in useful throughput. The memory saved is purchased with additional FLOPs and a longer critical path. A feasible parallelism plan must budget both effects.

As the backward pass traverses the computation graph in reverse, it produces gradients for the parameters held by each replica or shard. Under pure data parallelism, a full 175B FP16 replica would imply a 350 GB gradient tensor per worker, which exceeds single-accelerator memory budgets. Large runs therefore combine data parallelism with sharding, tensor parallelism, or pipeline parallelism. Each local gradient contributes to the intended global-batch estimator. Aggregation can begin as gradient tensors become ready, overlapping later backward computation, but the optimizer must wait for the completed contributions it consumes. This readiness schedule connects local computation to collective communication.

6.3.1.3 Gradient synchronization

Gradient synchronization combines local contributions into the synchronous update. Each replica must receive the aggregate before applying that update. In a centralized parameter-server design with fixed per-worker payload and update

frequency, the server receives $\mathcal{O}(N)$ incoming traffic. That concentration becomes a bottleneck when demand exceeds the server tier's service capacity; sharding the server state or changing the communication pattern can relieve it.

The replicated synchronous baseline distributes aggregation through collective communication. AllReduce lets each worker contribute its local gradient tensor and receive the same reduced result, which the training loop normalizes to obtain the global average. In sharded variants such as ZeRO and FSDP, ReduceScatter and AllGather change which result each worker retains, leaving each worker only its own shard of the reduced gradient and reconstructing full parameters on demand. Small messages emphasize startup latency; large messages emphasize sustained bandwidth. Centralized aggregation remains another design choice, particularly for the sparse workloads developed later.

At the Distributed Execution row of the fleet stack, the loop specifies an AllReduce contract while its implementation determines the cost. For a large worker group, ring AllReduce transfers approximately $2M_{\text{grad}}$ bytes per worker for an M_{grad}-byte gradient payload. Chapter 5 derived this approximate $2M_{\text{grad}}$ volume and compared algorithms whose startup costs, topology, and contention differ. That chapter also examined how libraries such as NCCL schedule exchanges within and across communication domains.

↩ The result contracts of AllReduce, ReduceScatter, and AllGather, and the decomposition of AllReduce into a ReduceScatter followed by an AllGather, are established in section 5.4.1.

When a measured collective deviates from these estimates, the diagnosis compares the trace against what each candidate algorithm predicts on the same hardware. A typical comparison sets a flat ring against a hierarchical AllReduce, which reduces within each NVLink node before crossing the inter-node fabric. A hypothetical trace on an A100 cluster with HDR InfiniBand shows the comparison at work. An AllReduce of a 3 GB gradient tensor across 128 nodes (1,024 GPUs) takes 100 ms, against a flat-ring estimate of 239.8 ms and an idealized hierarchical estimate of 48.5 ms. The observation rules out the flat schedule, and the residual above the hierarchical ideal must come from lower achieved rates, startup, or a late participant. Switch counters showing inter-node links at 60 percent utilization do not settle the question, because an aggregate can hide one saturated port during the exposed interval. Per-port and per-channel traces must locate the bottleneck before any topology change.

Across the wider design space, figure 6.4 compares three synchronization topologies. The bandwidth-optimal ring AllReduce circulates chunks along neighbor links ($2(N-1)/N$ volume). The centralized parameter server is constrained by network interface card (NIC) saturation at the server node. The dense mesh of logical AllToAll peer traffic requires $N(N-1)$ messages. In dense synchronous data-parallel settings, ring AllReduce avoids a single reducer bottleneck by distributing traffic evenly across participating links, as Baidu's implementation illustrates (Gibiansky 2017).

↩ Hierarchical AllReduce and its cost relative to a flat ring are established in section 5.7.1.

The panels separate an aggregation algorithm, a centralized architecture, and a collective traffic pattern. They do not provide interchangeable implementations of the same operation. Only the first two aggregate gradients; the AllToAll panel previews the exchange that sparse embedding tables and mixture-of-experts

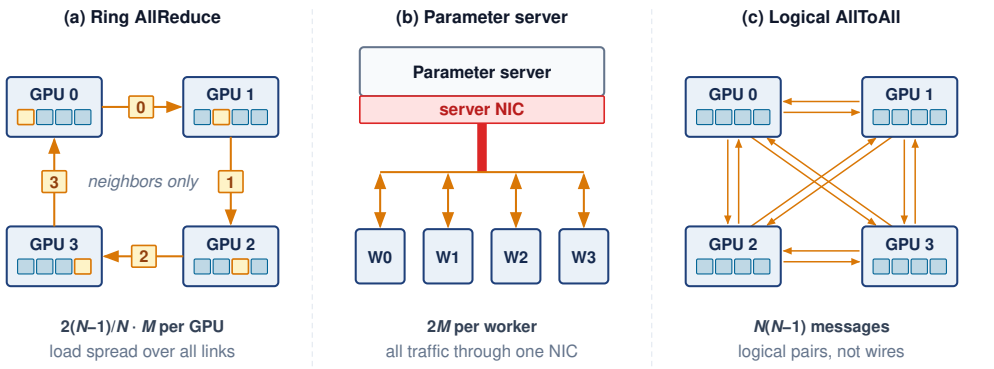

Figure 6.4: Communication Patterns and Their Costs: Ring AllReduce and a parameter server illustrate two ways to aggregate updates. AllToAll instead routes distinct data to each peer; the complete graph shows logical destinations, not a requirement for dedicated physical links. A switched fabric can carry this traffic, with cost determined by message size, routes, and contention.

layers need, in which every worker sends different data to every other worker (section 6.5.5). Libraries choose algorithms and routes for the requested collective on the available fabric; a logical complete graph does not guarantee one-round physical delivery.

6.3.1.4 Parameter updating

Parameter updating closes the replicated synchronous contract. After the gradient AllReduce (Patarasuk and Yuan 2009), every worker holds the same global gradient and applies it to its own replica with SGD, momentum, or Adam, so the update stays decentralized without losing equivalence to single-device training. Identical gradients alone are insufficient, because optimizer moments, learning rates, and step counts must also match across replicas. Frameworks automate the cycle of splitting data, computing gradients, synchronizing, and updating, but they cannot remove the ordering constraint that keeps the replicas coherent: every worker must finish aggregating the current step's gradient before any replica computes from the updated weights.

6.3.1.5 Synchronization models

Whether every worker must wait for that barrier on every step defines the job's synchronization model. The baseline is bulk synchronous parallel (BSP), the superstep-and-barrier model just described, in which workers compute from one parameter version, combine their gradient contributions, and complete the update before computing from the next version. This is a dependency order, not a requirement that every device update at the same wall-clock instant. Relaxing it changes the optimization process as well as the waiting time.

↩ Bulk synchronous parallel execution and its barrier cost are established in section 3.2.

BSP provides synchronous update semantics, in which every worker computes from the same parameter version and reaches the next update boundary together. With the same global batch and reduction, this matches the corresponding synchronous single-device update mathematically. It does not by itself guarantee bitwise reproducibility. Floating-point reduction order, nondeterministic kernels,

data-order state, and failure recovery can still change the result. The synchronization cost is that the slowest worker determines iteration time. A worker that keeps producing correct results but runs markedly slower than its peers is a **straggler**, and under BSP every straggler delays the entire step.

Stale synchronous parallel (SSP) relaxes this constraint by allowing workers to proceed up to s iterations ahead of the slowest worker before blocking. This bounds staleness while reducing synchronization delays. SSP requires careful learning rate tuning since workers compute gradients on slightly different parameter versions. The bounded staleness guarantee provides a middle ground between BSP's strong consistency and fully asynchronous approaches (Ho et al. 2013).

Asynchronous parallel (ASP) execution removes the global update barrier, allowing a worker's contribution to be applied while others continue computing; asynchronous SGD is the optimizer run under that protocol. Less barrier waiting can improve update throughput, but communication and shared-state contention remain. Gradients computed from older parameter versions introduce staleness that can affect convergence. Section 6.4.4 develops the objective and delay assumptions needed to evaluate that trade-off. The three models lie on one spectrum, from the strong consistency of BSP to the barrier-free updates of ASP (table 6.2).

Table 6.2: Synchronization Model Trade-Offs: BSP, SSP, and ASP trade consistency for throughput along a spectrum. BSP preserves synchronous update boundaries but pays for the slowest worker; SSP permits bounded progress ahead of slower workers; ASP removes the global update barrier without a finite protocol-wide staleness bound. Throughput and time to target quality depend on the workload and implementation. Reproducibility requires a separate deterministic-execution contract.

Model	Consistency	Throughput	Convergence	Use case
BSP	Strong	Bounded by slowest worker	Same synchronous update semantics	Controlled final training runs
SSP	Bounded staleness	Less global-barrier waiting	Depends on delay and tuning	Hyperparameter search
ASP	Weak	No global update barrier	Depends on staleness and objective	Large heterogeneous clusters

Execution traces for four workers with one straggler make the differences visible (figure 6.5). Under BSP, global barriers force the faster workers into idle wait blocks while straggler W3 completes. Under SSP, bounded slack ($s = 1$) lets them run ahead and throttles the drift with brief pauses. Under ASP, asynchronous updates remove the global barrier without imposing a finite staleness bound, although communication and resource contention can still leave workers waiting.

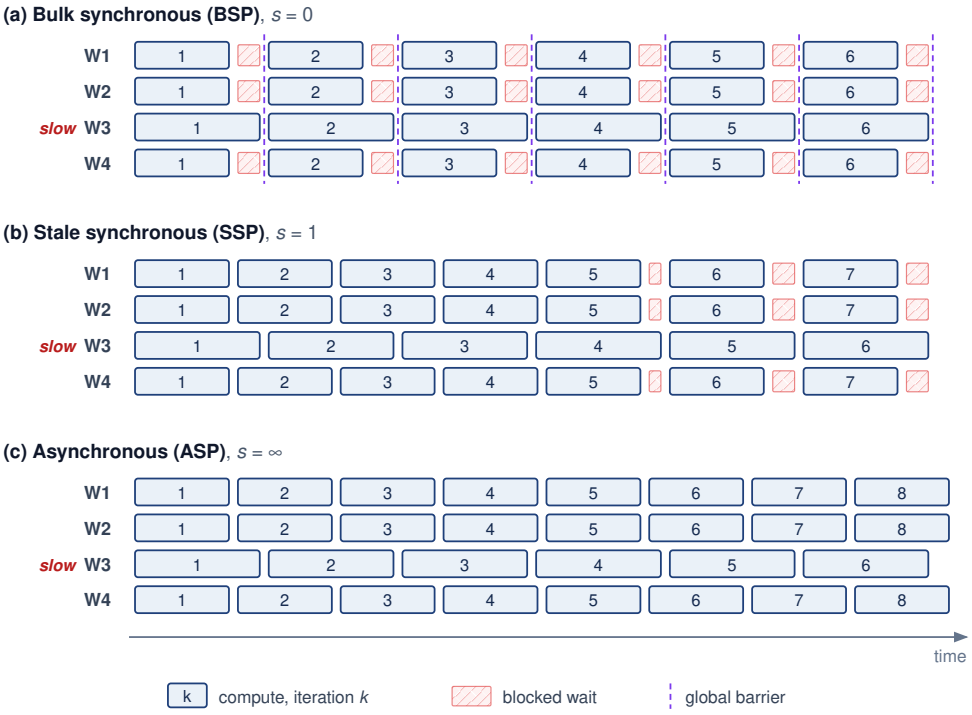

Figure 6.5: Distributed Synchronization Models: The timelines compare three synchronization strategies. Top: bulk synchronous parallel (BSP) forces all workers to wait at a global barrier every step. Middle: stale synchronous parallel (SSP) allows workers to proceed up to s steps ahead of the slowest worker. Bottom: asynchronous parallel (ASP) execution removes the global update barrier while allowing gradient staleness; communication and resource contention can still delay progress.

6.3.1.6 Barrier semantics and failure modes

An optimizer update that consumes an AllReduce result must wait for every required contribution. Workers can execute independent computation while a collective is in flight, but they must issue compatible collectives in the same group order and wait for completion before consuming the result. This coupling creates failure modes absent from single-device training.

One missing worker stalls the entire AllReduce barrier.

A worker failure can leave peers waiting for a contribution that will never arrive. The runtime may report a communication error, or the operation may remain blocked until a timeout detects the failure. Watchdogs bound that wait so the job can enter recovery rather than retain an unusable allocation indefinitely.

Collective mismatches occur when workers issue incompatible operations, tensor shapes, or ordering within a communication group. Conditional computation

can create such a mismatch if some workers omit an expected reduction. Variable sequence lengths or different expert routes do not inherently violate the protocol; the runtime must construct a compatible communication schedule for those varying local computations.

Stragglers extend an iteration when their late work lies on its critical path. Thermal throttling, network congestion, or OS jitter can delay a required contribution even when other workers are ready. At 1,000 GPUs with a 1 percent straggler probability per GPU per step, the expected count is 10 stragglers per step, but the number that matters under BSP is the chance of a step with none at all. That chance is the per-GPU on-time probability raised to the GPU count, about 0.004 percent. Almost every step therefore waits for at least one slow worker, which is why the slowest worker, not the typical one, sets step time. The resulting exposed wait depends on how late that contribution arrives and what independent work remains. Deployed systems bound these waits with timeouts and heartbeat monitoring, and elastic training lets a job continue with a resized worker group after a failure.

↪ Heartbeat and collective-timeout failure detection, and the trade-off between restarting healthy workers and leaving peers blocked, are developed in section 7.9.1.

6.3.2 Data parallelism trade-offs

Data parallelism is the simplest way to add accelerators because it leaves each replica's model computation intact, but adding workers eventually hits either a communication wall or a statistical wall (Ben-Nun and Hoefler 2019). Near-linear throughput scaling requires local compute efficiency, balanced input delivery, and small exposed synchronization costs. Which wall arrives first depends on whether the global batch stays fixed or grows as workers are added. Holding the global batch fixed while adding workers is **strong scaling**: each worker's local batch shrinks, so communication must hide behind less computation. Holding the local batch fixed so that the global batch grows with N is **weak scaling**: per-worker computation stays constant, but each update averages more examples, which eventually stops reducing the number of updates needed. The rest of the chapter refers to the two regimes by these names.

Weak scaling pays off when the larger global batch still reaches the target accuracy. Goyal et al. (2017) trained ResNet-50 on ImageNet in about one hour on 256 GPUs at a global batch of 8,192 images; the learning-rate rules that let that batch reach the target accuracy are developed in section 6.4.5. Replicated data parallelism retains the model's local operators, and frameworks can trigger gradient reductions as backward computation produces them. Each replica executes a complete forward and backward pass, avoiding the layer-stage fill and drain bubbles of pipeline parallelism. Input stalls, imbalance, and exposed reductions can still leave devices idle.

These advantages hold only until replication runs into memory capacity, communication bandwidth, or statistical diminishing returns. The memory wall binds first on large models because a replicated worker holds every parameter, gradient, and optimizer state, demanding more than 1 TB per replica for the 175B-parameter example before activations. Even when the state fits, communication limits useful scaling once its exposed cost grows relative to local work. As N increases, the

ideal ring bandwidth term $\frac{2(N-1)}{N}\frac{M_{\text{grad}}}{\beta}$ approaches a constant for a fixed gradient payload M_{grad} and link bandwidth β, while startup latency, topology, and shrinking local computation worsen the balance. Statistical efficiency then sets the ceiling under weak scaling, because growing $B_{\text{global}} = N \times B_{\text{local}}$ with N eventually yields diminishing reductions in update count. Strong scaling avoids that batch-size ceiling only by shrinking each worker's local batch, which exposes the communication trade-off sooner.

Napkin Math 6.1: GPT-2 data parallel scaling: Single node

A GPT-2 scaling scenario makes the efficiency loss concrete by holding the model fixed and changing only the communication domain. GPT-2 stands in for the 175B reference here because it fits on one GPU, so pure replicated data parallelism applies and communication is the only variable. The first case keeps all eight GPUs inside a single NVLink node.

Single-GPU baseline

- Batch size: 16 (with gradient checkpointing, fits in 32 GB)
- Time per step: 1.8 s
- Baseline time for 50K single-GPU steps: 25 hours

The following durations hold the total sample budget fixed, so larger global batches require fewer optimizer updates. They assume those samples attain the same quality; the calculation establishes throughput scaling, not convergence equivalence.

8 GPUs: single node with NVLink

- Per-GPU batch: 16, global batch: 128
- Gradient synchronization: 5.2 GB @ 450 GB/s (NVLink, per direction) $\approx$ 11.7 ms

Performance results:

- Compute: 1800 ms per step
- Communication: 11.7 ms per step
- Total: 1811.7 ms per step
- Speedup (throughput): 8×
- Parallel efficiency: 99.4 percent

Training time: 25 hours ÷ 8 = 3.1 hours

Inside the node, NVLink keeps gradient exchange small relative to compute, so efficiency stays near 99.4 percent. The picture inverts once the same model must synchronize across nodes over a commodity network.

Napkin Math 6.2: GPT-2 data parallel scaling: Commodity scale-out

The second case scales the same GPT-2 run across multiple nodes, replacing the intra-node NVLink hop with inter-node Ethernet for the bulk of the AllReduce. The 10 Gb Ethernet link models a commodity cloud tier without a dedicated training fabric, far slower than the InfiniBand of the reference cluster, which makes the cost of leaving the node easy to see.

Commodity network configuration: 32 GPUs across 4 nodes

- Per-GPU batch: 16, global batch: 512
- Intra-node communication: 11.7 ms (NVLink)
- Inter-node communication: 5.8 GB @ 1.25 GB/s (10GbE) $\approx$ 4650 ms

Performance results:

- Compute: 1800 ms (27.9 percent of time)
- Communication: 4661.7 ms (72.1 percent of time), so communication dominates and becomes the bottleneck.
- Total: 6461.7 ms per step
- Speedup (throughput): 8.9× faster $\rightarrow$ 2.8 hours
- Parallel efficiency: 27.9 percent

The scale-out run bought its larger global batch with four nodes on a slow network. A single node can reach the same global batch another way, by running several local microsteps and accumulating their gradients before one AllReduce. The comparison below is therefore between two placements, one node with accumulation against four nodes without it. Accumulation's job is to keep the global batch equal, while the saving comes from never leaving the NVLink domain.

Napkin Math 6.3: Gradient accumulation speedup

Problem: A GPT-2 run on a commodity 10G network is communication-bound at 32 GPUs across 4 nodes, costing $359 for a fixed number of samples. Can a single 8-GPU node that uses gradient accumulation to match that global batch process the same samples for less?

Math:

1. **Effective batch size**: 8 GPUs $\times$ batch 16 $\times$ 4 accumulation steps = 512.
2. **Communication overhead**: With 4-step accumulation, the job AllReduces once every 4 steps (overhead = 11.7 ms / (4 $\times$ 1800 ms) $\approx 0.162\%$).
3. **Training duration**: Total time is 3.1 hours.
4. **Scale-out baseline cost**: 4 nodes $\times$ 2.8 hours $\times$ $32/hr = $359.
5. **Accumulation cost**: 3.1 hours $\times$ $32/hr = $100.

Systems insight: The one-node plan saves $259 (72.1 percent). Almost all of that saving comes from placement, because the four-node run spent most of each step on the slow inter-node link and the single node never uses it. Gradient accumulation is what makes the single node a fair substitute, because it reproduces the four-node global batch. Its own contribution to speed is small, since the same node already ran at 99.4 percent parallel efficiency without accumulation. Accumulation on a multi-node job still requires inter-node synchronization once per window.

In this GPT-2 scenario, changing the communication domain drops efficiency from 99.4 percent to 27.9 percent. Accumulation can preserve the effective batch while avoiding the slow scale-out link, at the cost of additional local computation between updates. It leaves each worker's replicated model state unchanged, however; reducing that memory burden requires sharding.

6.3.3 Memory-efficient data parallelism with ZeRO and FSDP

Replicated data parallelism stores an identical copy of weights, gradients, and optimizer state on every GPU, so a 7B-parameter model demands 112 GB on each device and overflows an 80 GB accelerator before a single activation is allocated. The Zero Redundancy Optimizer (ZeRO) (Rajbhandari et al. 2020) and PyTorch's Fully Sharded Data Parallel (FSDP) (Zhao et al. 2023) remove that duplication by sharding training state across workers while keeping each worker's full forward and backward computation.[3] Sharding can make a model fit in memory without splitting its layer computations across devices.

[3] **ZeRO (Zero Redundancy Optimizer)**: Introduced by Microsoft researchers in 2019 and released in the DeepSpeed library (Rasley et al. 2020), ZeRO's stages progressively partition optimizer states, gradients, and parameters. FSDP draws on the fully sharded approach associated with ZeRO's deepest stage; the shared partitioning principle does not imply identical implementations or communication schedules.

Definition 6.3: Sharded data parallelism

Sharded data parallelism partitions optimizer state, gradients, and at the deepest stage the parameters themselves across data-parallel workers. Each worker processes its own minibatch shard and uses collectives to obtain the parameters and reduced gradients it needs. Full sharding reduces each worker's persistent state toward $1/N$ of the replicated training state; activations and temporary buffers still contribute to peak memory.

1. **Significance**: Under the mixed-precision Adam convention used here, 16 bytes of state per parameter gives a 7B-parameter model 112 GB of training state, exceeding a 80 GB accelerator before activations. ZeRO Stage 3 across 64 workers reduces persistent state per device to 1.75 GB (0.25 bytes per parameter). The resulting AllGather and ReduceScatter traffic trades memory capacity for communication whose exposed cost depends on the interconnect and available overlap.
2. **Distinction**: Unlike vanilla data parallelism, which replicates training state, sharded data parallelism partitions its storage. Unlike model parallelism, it retains each worker's full forward and backward computation.

Fully sharded execution gathers parameters for the current computation; the resharding schedule determines when it releases them.

3. **Common pitfall**: A frequent misconception is that sharding is free memory. The on-demand AllGathers place parameter traffic on the critical path of every layer in every step. On slower interconnects or at small per-worker batch sizes, the exposed communication erodes throughput faster than the memory savings help. Capacity is purchased with bandwidth.

The scale of the savings is clearest on a model whose replicated training state only modestly overflows one accelerator, so that the effect of each sharding stage stays visible. The 175B reference returns after this trace when the question becomes whether sharding alone is enough.

Napkin Math 6.4: ZeRO memory savings

Problem: Training a 7B parameter Llama-2 model in mixed precision requires 16 bytes per parameter for weights, gradients, and optimizer state. Does the full training state fit on a single A100-80 GB, and how does ZeRO Stage 3 with 64 GPUs change the per-device memory requirement?

Baseline: Standard DDP (replicated state) Per-Parameter Memory Cost:

- **Weights (FP16)**: 2 bytes
- **Gradients (FP16)**: 2 bytes
- **Optimizer state (FP32)**: 12 bytes (4 master weight + 4 momentum + 4 variance)
- **Total**: 16 bytes/parameter

Total Memory for 7B Model:

$$C_{\text{state,total}} = 7 \times 10^9 \times 16 \text{ bytes} \approx 112 \text{ GB}$$

Baseline outcome: Out-of-memory (OOM) on A100-80 GB.

Optimization: ZeRO-3 (fully sharded) With $N = 64$ GPUs, state is partitioned:

- **Weights**: $2/N$ bytes
- **Gradients**: $2/N$ bytes
- **Optimizer**: $12/N$ bytes
- **Total**: $16/N = 0.25$ bytes/parameter effective storage

Per-GPU Memory:

$$C_{\text{state,ZeRO3}} = \frac{112 \text{ GB}}{64} \approx 1.75 \text{ GB}$$

Result: The persistent state fits, leaving ~78 GB for activations, gathered parameters, temporary buffers, and runtime allocations. Their simultaneous peak determines whether the chosen batch size fits.

ZeRO reaches that result in stages, and the intermediate stages matter because each one buys memory with a different communication pattern. Optimizer sharding alone (ZeRO-1) already brings the replicated footprint of the same model under the accelerator ceiling, because optimizer state is three-quarters of it. Gradient sharding (ZeRO-2) and parameter sharding (ZeRO-3/FSDP) continue toward the fully sharded figure (figure 6.6). Each stage also changes which collectives the update uses (table 6.3).

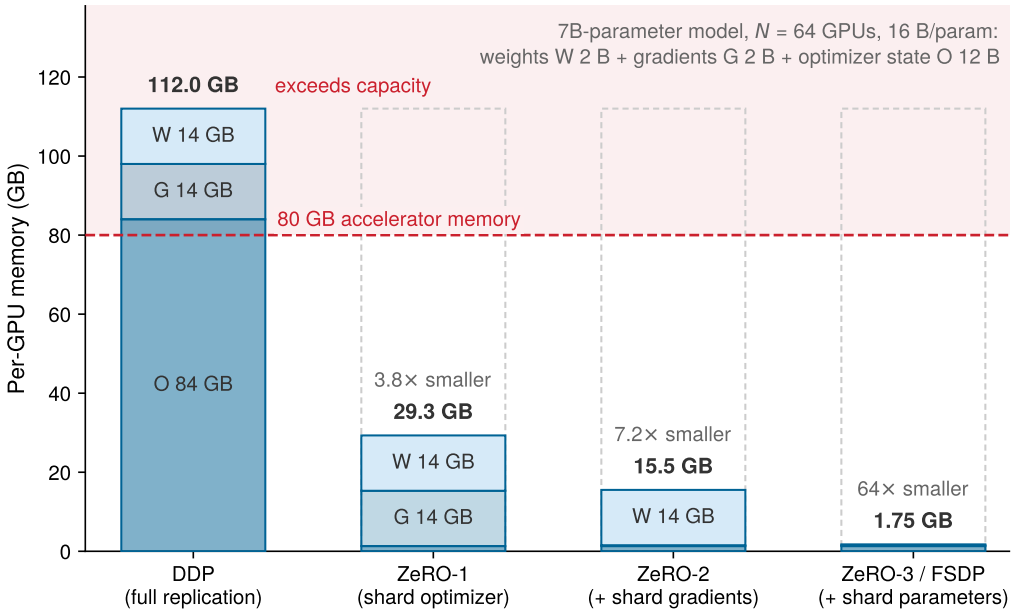

Figure 6.6: ZeRO Memory Reduction: Standard data parallelism (DDP) replicates all model states across every GPU. ZeRO progressively partitions these states: ZeRO-1 shards optimizer states, ZeRO-2 adds gradient sharding, and ZeRO-3 shards the parameters themselves; each dashed outline marks the replicated stack a stage no longer holds. ZeRO-3 achieves linear memory scaling, enabling models with 100B+ parameters to fit on accelerators that could not hold the replicated state.

Table 6.3: ZeRO Sharding Stages: Each stage shards a different layer of training state and trades a different communication primitive. ZeRO-1 and ZeRO-2 both replace the gradient AllReduce with a reduction to each shard's owner and a parameter AllGather, matching DDP volume, and differ only in whether each worker keeps a full-size gradient buffer; ZeRO-3 (FSDP) adds per-layer AllGathers during forward and backward passes, unlocking near-linear memory scaling at $1.5\times$ communication.

Stage	What is sharded	Memory reduction	Communication overhead
ZeRO-1	Optimizer states only	~4×	Reduce to owner + AllGather (1× DDP volume)
ZeRO-2	+ Gradients	~8×	ReduceScatter + AllGather (1× DDP volume)

Stage	What is sharded	Memory reduction	Communication overhead
ZeRO-3/FSDP	+ Parameters	$\sim N$ (linear in workers)	AllGather before each layer ($1.5\times$ DDP volume)

The first step, ZeRO-1, shards optimizer states across GPUs so each GPU stores only $1/N$ of the Adam optimizer-related state. During backpropagation, each worker still materializes the full 2 bytes/param gradient buffer locally, which is why gradient memory remains unsharded in table 6.3. Once gradients are ready, however, they need only be reduced to the worker responsible for each parameter shard via a ReduceScatter, and after each worker updates its owned shard, an AllGather broadcasts the updated parameters to restore the full replicas. This two-phase schedule (one gradient ReduceScatter plus one parameter AllGather) matches the table's $1\times$ baseline communication volume, whereas running a full gradient AllReduce followed by a parameter AllGather would add 50 percent more traffic. Under the 12-byte convention that counts FP32 master weights, momentum, and variance, sharding the optimizer state reduces cluster-wide storage from $12N$ bytes/param to 12 bytes/param in total.

Building on that owner-update contract, ZeRO-2 eliminates persistent full-model gradient buffers by streaming the ReduceScatter during the backward pass. As each layer or communication bucket finishes its backward computation, workers immediately ReduceScatter that bucket's gradients and free the slices owned by other ranks, leaving each GPU with only its $1/N$ persistent shard of reduced gradients. Each worker then updates its $1/N$ parameter partition using the corresponding optimizer state, and an AllGather restores the updated parameter replicas. In the ideal ring accounting, the gradient ReduceScatter and the parameter AllGather each transfer $P(N-1)/N$ elements per worker, for $2P(N-1)/N$ across both phases, matching DDP's byte volume ($1\times$) when gradient and parameter communication widths match. Replicated parameters avoid forward parameter gathers, although model operations may still communicate. Under the FP16-gradient convention, persistent gradient storage falls from $2N$ bytes per parameter across N workers to 2 bytes per parameter in total, or $2/N$ per GPU, apart from transient bucket buffers.

At the deepest stage, ZeRO-3 and FSDP partition the parameters as well, leaving each GPU with a $1/N$ persistent slice of all three training states. Because workers no longer hold full parameter replicas between steps, the post-update parameter AllGather disappears and is replaced by two on-demand parameter AllGathers during computation. Each sharded unit gathers its parameters before the forward pass and immediately releases the non-local slices, then gathers them a second time before the backward pass and releases them again once local gradients are computed, and finally runs a ReduceScatter to deliver the completed gradients to each shard's owner for the local optimizer update. Across four ranks (figure 6.7) and under matching communication widths, ZeRO-1 ($M_{\text{optimizer}}/4$) and ZeRO-2 ($M_{\text{optimizer}}/4, M_{\text{gradients}}/4$) each execute two collective

phases per step and retain the baseline $1\times$ communication volume. ZeRO-3 ($M_{\text{weights}}/4, M_{\text{gradients}}/4, M_{\text{optimizer}}/4$) executes three collective phases of one parameter-equivalent payload each (forward AllGather, backward AllGather, and gradient ReduceScatter), which yields $3/2 = 1.5\times$ the baseline two-phase volume in this accounting.

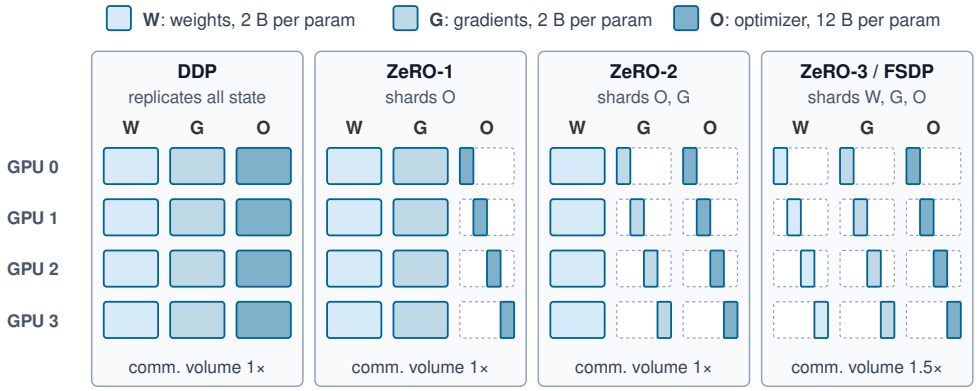

Figure 6.7: ZeRO State Partitioning across GPU Ranks: Which copy of each training state every GPU holds, for 4 workers. A filled full-width tile is a replicated copy; a quarter-width segment inside a dashed outline is that GPU's shard, stepping one quarter per rank. ZeRO-1 shards optimizer state ($M_{\text{optimizer}}/4$), ZeRO-2 adds gradients ($M_{\text{gradients}}/4$), and ZeRO-3 shards parameters too ($M_{\text{weights}}/4$). The footers give per-worker communication volume relative to DDP: only ZeRO-3 pays more, for the parameter AllGathers.

Full sharding adds parameter-readiness dependencies that replicated DDP avoids. With one sharding unit per layer, the forward pass needs an AllGather to reconstruct parameters (M_{layer} bytes). Resharding after forward requires another gather before backward (M_{layer} bytes), followed by a ReduceScatter for gradients (M_{layer} bytes under equal communication precision). For a model with N_L layers, this schedule performs about $3N_L$ collective operations per step. DDP instead AllReduces gradient buckets as they become ready. At large worker counts, the ideal per-worker transfer volumes approach $3M_{\text{param}}$ bytes versus $2M_{\text{param}}$ for DDP. Here M_{param} is the model's parameter bytes at the communication precision, not full training state, and it equals M_{grad} when parameters and gradients travel at the same width. These volumes do not determine elapsed time alone. While layer ℓ computes, layer $\ell + 1$ can prefetch parameters, subject to memory headroom and fabric contention.

The allocation lifetimes in figure 6.8 separate persistent ownership from the temporary buffers needed to execute one sharding unit.

A model fits only when all simultaneously live allocations fit. The persistent shards therefore establish a floor, while gathered units, saved activations, and prefetch determine how far the execution peak rises above it.

The choice between FSDP and DDP begins with peak memory. If replicated state, activations, and working buffers fit, DDP avoids repeated parameter gathers. When optimizer and gradient storage are the obstacle, ZeRO-2 offers savings while leaving parameters replicated. If parameters themselves do not fit, ZeRO-3/FSDP,

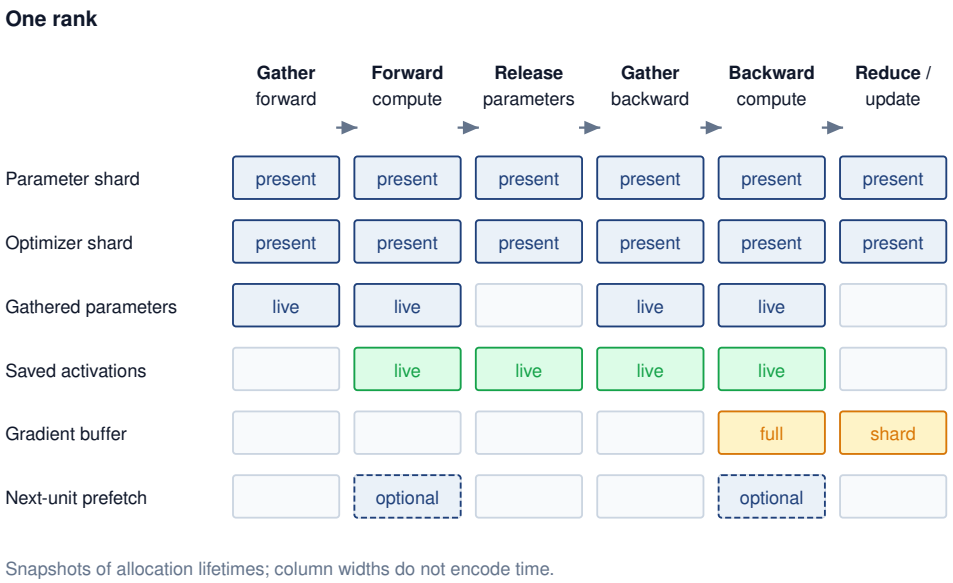

Figure 6.8: FSDP Parameter Lifetimes: One rank executes a sharding unit under a policy that reshards parameters after forward computation. Gathered parameters disappear between forward and backward, while saved activations remain until backward consumes them. Dashed cells show optional prefetch of another unit; these allocations can coexist with the current unit. The cells describe logical lifetimes, not byte totals or operation durations. Implementations may alias shard storage or reuse buffers.

offload, or partitioned computation must address that remaining constraint. For a 70B+ model on 80 GB devices, the need for tensor parallelism depends on the gathered layer size, activation budget, and throughput target; parameter count alone does not decide it.

Memory-efficient data parallelism requires careful tuning of sharding strategy (by layer, by transformer block, or flat) and mixed precision settings. Finer sharding reduces per-GPU memory but increases communication frequency, because more AllGather and ReduceScatter operations must execute per training step. Replicated or sharded, a data-parallel design earns its added workers only when they turn into faster progress toward target quality, and scaling efficiency measures that conversion.

6.4 Scaling Efficiency and Convergence

Data parallelism and ZeRO sharding show how communication and synchronization enter every training step, yet raw step throughput alone cannot judge a distributed run. When doubling the number of GPUs yields only 1.5× speedup for the same work, scaling efficiency is 75 percent, and if the larger global batch also requires more optimizer updates to reach the same loss, wall-clock time to quality degrades further. Evaluating a distributed configuration therefore requires separating two questions: how efficiently added devices execute each step, and how batch growth or stale updates affect the number of steps to convergence. The hardware scaling metrics below apply to every parallelism strategy; the convergence

analysis that follows concerns data-parallel batch growth and synchronization slack, establishing a batch-size constraint that tensor and pipeline configurations must also respect when combined with data parallelism.

6.4.1 The mathematics of scaling efficiency

That first question is answered by scaling efficiency, the fleet-level ratio introduced with the Fleet Law in section 1.5.4. If a model trains in time T_1 on one device, ideal (linear) scaling would train it in time T_1/N on N devices; communication overhead, pipeline bubbles, and load imbalance widen the gap between that ideal and the realized time T_N. Equation 6.1 formalizes the ratio:

$$\eta_{\text{scaling}} = \frac{T_1}{N \times T_N} \tag{6.1}$$

where T_N is the training time on N devices. Measured per step of the same work, T_1 is the quantity the Fleet Law writes as T_{compute}, the single-device compute time that its compute term divides by N. An efficiency of 1.0 means perfect linear scaling; an efficiency of 0.5 means the run achieves only half the ideal speedup.

Definition 6.4: Scaling efficiency

Scaling efficiency (η_{scaling}) is the ratio of actual training throughput to ideal linear throughput when increasing the number of ML compute devices (N).

1. **Significance**: The ratio in equation 6.1 measures added devices against the specified baseline. At 0.50 efficiency, a 10,000-GPU run delivers the throughput that 5,000 perfectly scaled devices would, so half of the accelerator-hours buy no progress relative to ideal scaling. The equivalence is to an idealized baseline. A real 5,000-GPU run would have its own, typically higher, efficiency, and the loss is spread across every device as waiting rather than concentrated in idle ones.
2. **Distinction**: Unlike single-node efficiency, which captures local bottlenecks like BW, scaling efficiency measures how performance changes with device count. Communication time $(T_{\text{comm}}(N))$ and synchronization contribute, but changing local kernel shapes or input delivery can also affect the ratio.
3. **Common pitfall**: A frequent misconception is that scaling efficiency is constant. In reality, it depends on both device count and problem size. For a fixed model, the communication-to-compute ratio typically worsens as N increases (Amdahl's Law). At a fixed N, a smaller model or local batch leaves less computation per device to hide startup latency and coordination, so its efficiency falls sooner.

The Fleet Law leads to the scaling efficiency metric for fixed global work. Substituting its step time (principle 10) for T_N in equation 6.1, with T_{compute} standing for T_1 per step as noted there, gives equation 6.2:

$$\eta_{\text{scaling}} = \frac{T_{\text{compute}}}{N \times T_{\text{step}}(N)} = \frac{1}{1 + \frac{N(T_{\text{comm}}(N) + T_{\text{sync}}(N) - T_{\text{overlap}})}{T_{\text{compute}}}} \tag{6.2}$$

This form states the scaling efficiency bound (principle 12), under which perfect linear scaling ($\eta_{\text{scaling}} = 1.0$) is a *theoretical limit*, not a *practical target*. Real systems fall short of it by an amount that depends on the configuration and grows with N. The 175B data-parallel example below reaches only 15 percent, and the hybrid layouts later in the chapter recover much of that loss without reaching 1.0. The gap between $\eta_{\text{scaling}} = 1.0$ and the achieved efficiency is the price of distributed execution, paid in communication and coordination.

The equation also exposes the **scaling wall**. As N increases, the compute term (T_{compute}/N) shrinks, but the communication and synchronization terms can remain constant or grow. A ring AllReduce's bandwidth term, for example, stays near its bound however many workers join (principle 11). Eventually, the denominator is dominated by overhead, driving efficiency toward zero.

For data-parallel training of the 175B reference model, the per-step communication cost is dominated by the AllReduce of 350 GB of gradients, and how much of that exchange hides behind computation decides the efficiency. The scaling efficiency depends on computation per communicated byte. At fixed tokens per update, increasing parameter count raises both transformer computation and gradient bytes roughly proportionally, so model size alone does not guarantee better scaling. Larger batches raise computation per optimizer step without changing gradient size. The catch is that large batches can harm convergence and so require learning-rate tuning and warmup schedules. Network bandwidth enters directly because doubling InfiniBand bandwidth halves the bandwidth term, but efficiency changes according to the full step-time denominator rather than in direct proportion. The network fabric is therefore a first-order determinant of cluster productivity, not a secondary concern. Every point of scaling efficiency it recovers is returned across the much larger accelerator investment, which is why fabric spending is judged by the efficiency it buys rather than by its own price.

These factors interact, so efficiency cannot be inferred from model size or GPU count alone. The following worked model fixes the parameter count, tokens per update, accelerator count, effective bandwidth, local compute efficiency before communication, and overlap before calculating one efficiency point. Changing any of those inputs requires recomputing the full step-time model.

Napkin Math 6.5: Scaling efficiency for a 175B model

Setup: A communication-only model for training a 175B model on a DGX H100 cluster with 400 Gb/s InfiniBand per GPU. Pure replicated data parallelism is a counterfactual baseline here: the calculation isolates gradient exchange but does not establish that the full training state fits on each device.

- **Compute per step** (assuming batch size 2M tokens, 6 FLOPs per parameter per token): $O_{\text{step}} = 6 \times 175 \times 10^9 \times 2 \times 10^6 \approx 2.1 \times 10^{18}$ FLOPs
- **Per-GPU compute time** on 1,024 GPUs, each at 1,979 TFLOP/s peak in the 8-bit floating-point (FP8) format developed in section 6.4.8 (50 percent local compute efficiency before communication). The general matrix multiplications (GEMMs) run in FP8 while the gradients below still cross the wire in FP16, because the collective's data type is chosen independently of the arithmetic's: $T_{\text{compute}}/N \approx 2.1$ seconds
- **AllReduce time** (for 350 GB of gradients using ring-AllReduce with overlap): $T_{\text{comm,exposed}}(N) \approx 11.9$ seconds (raw ring transfer takes $2 \times (N-1)/N \times 350/50$, about 14 seconds; the schedule could hide 75 percent of that transfer, but the available compute window caps hidden communication at 15 percent of raw transfer time)
- **Scaling efficiency**: $\eta_{\text{scaling}} = T_{\text{compute,local}}/(T_{\text{compute,local}} + T_{\text{comm,exposed}})$, which is equation 6.2 with the per-device compute window $T_{\text{compute,local}} = T_{\text{compute}}/N$ and the exposed term standing for $T_{\text{comm}}(N) + T_{\text{sync}}(N) - T_{\text{overlap}}$. Here the numerator is 2.1 s and the complete denominator is 14 s, giving 15 percent. The exposed communication term already subtracts the hidden portion from the raw transfer time and includes collective synchronization; subtracting overlap again would double-count the same saving.

Systems insight: The low efficiency (15 percent) shows why naive data parallelism at this scale is insufficient. It is one operating point, fixed by 2M per update, 1,024 GPUs, and 15 percent overlap, not a universal threshold. Another cluster size requires recomputing per-device compute time, collective cost, overlap, and topology. Hierarchy-aware systems recover much of the lost efficiency by combining data parallelism with tensor parallelism, which communicates over NVLink, and pipeline parallelism, which overlaps computation with communication.

↩ The compute window that bounds how much of a collective can hide is established in section 5.10.4.

6.4.1.1 Parallelism-infrastructure interaction

The scaling efficiency of a run is set by the *interaction* between the model's communication requirements and the infrastructure's bandwidth hierarchy, not by the *model architecture alone*. Recovering the efficiency that pure data parallelism lost above means mapping each parallelism dimension onto the bandwidth tier that can carry its traffic. Section 6.6 works through three concrete configurations once tensor and pipeline parallelism have been developed.

↩ The message size at which ring AllReduce overtakes tree AllReduce, derived from the latency and bandwidth terms of each algorithm, is established in section 5.6.7.

The collective algorithm adds its own dependence on message size. Tree-based AllReduce reaches every rank in $\mathcal{O}(\log N)$ steps and suits small, latency-bound messages, whereas large gradient buffers favor the bandwidth-optimal ring; message size, topology, and contention decide between them.

Even for pre-frontier transformers, those algorithm choices translate into substantial link-bandwidth requirements. BERT-Base (110M parameters) requires approximately 440 MB of gradient synchronization per iteration in FP32, while BERT-Large (340M parameters) requires approximately 1.4 GB. Because a ring AllReduce across 64 GPUs moves nearly twice the gradient bytes through each GPU's link, finishing BERT-Large synchronization within 50 ms demands roughly 54 GB/s of sustained per-GPU bandwidth, and BERT-Base about a third of that. At 175B parameters, meeting the step budget requires combining 3D parallelism, gradient accumulation, and overlap rather than relying on a single flat collective, and whatever communication remains unhidden acts as the unscalable residual that Amdahl's Law prices next.

6.4.2 Scaling physics and Amdahl's Law with communication

Even a small unscalable cost in a single-device step eventually dominates distributed execution, because adding N devices shrinks the parallelizable compute share (T_1/N) while leaving the fixed residual untouched. An Amdahl-style model separates that scalable work from the fixed residual fraction r of the single-device baseline (section C.3.2).

That baseline fraction is not the synchronization share a profiler reports for a distributed step (the distributed Amdahl pitfall of section 1.5.4), because the compute share has been divided by N while the residual has not. A residual of 1 percent of the single-device step occupies about 84 percent of each step on 512 GPUs. Reading the observed share as r would therefore overstate the residual many times over and predict a far lower speedup ceiling than the model implies.

Plotted on log-log axes up to 512 GPUs, the same fixed-residual model shows how much speedup each residual fraction gives up (figure 6.9), complementing the scaling efficiency bound (principle 12). In this illustrative model, a small baseline fraction ($r = 0.1\%$) stays closer to ideal scaling than a larger fraction ($r = 1\%$). A residual equal to a tenth of baseline time ($r = 0.10$) limits asymptotic speedup to $1/r = 10\times$. Actual collective and coordination costs can change with worker count, so predicting a training run requires the full step-time accounting of equation 6.2.

Published benchmark runs show the same shortfall in practice. MLPerf Training times complete runs to a fixed quality target, and several submitters report the same system at several sizes within one round (Mattson et al. 2020; MLCommons 2025b). Each of 5 such series for the GPT-3 and Llama 3.1 405B benchmarks falls below the ideal line drawn through its smallest configuration (figure 6.10). On NVIDIA's Eos cluster, GPT-3 trained in about 58 minutes on 512 H100 GPUs and 3.9 minutes on 10,752. A 21× increase in accelerators therefore cut the time 14.9×, a scaling efficiency (equation 6.1, measured relative to the smallest configuration rather than one device) of 71 percent. Across the series, the largest configuration keeps 71–84 percent of ideal. Two effects compound in these numbers. Communication and coordination grow with worker count, and the larger configurations also train with larger global batches, which can require more samples to reach the target (section 6.4.6). Separating the two requires the step-level accounting of equation 6.2.

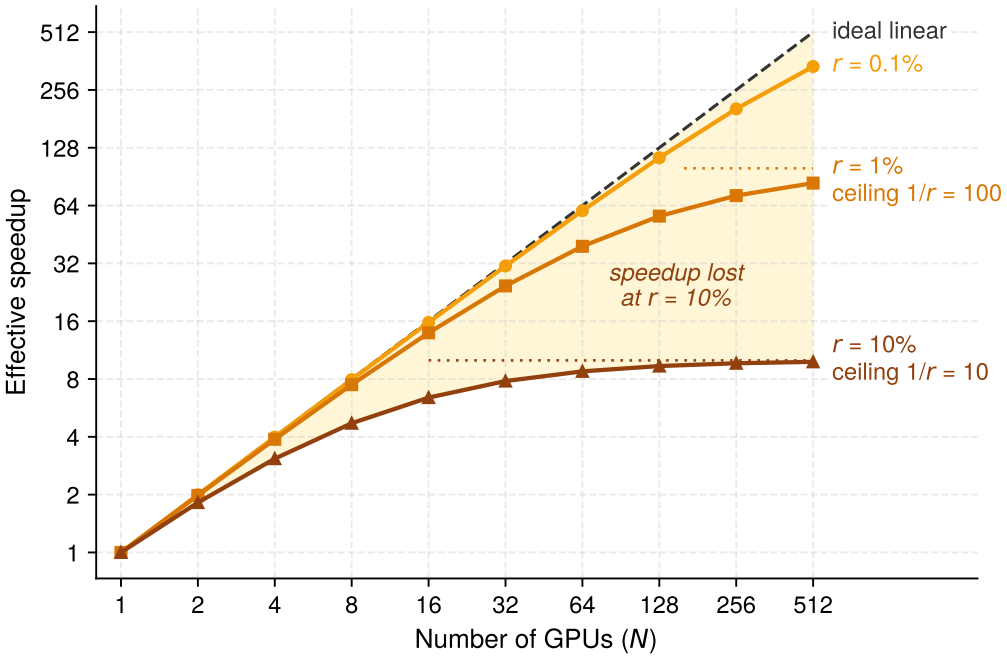

Figure 6.9: Speedup under a Fixed Residual: Effective speedup $N/(1+(N-1)r)$ against GPU count on log-log axes, for illustrative fixed residual fractions r of baseline step time. Ideal scaling (dashed) is linear. Each curve bends away from it and flattens near $1/r$: at 512 GPUs, $r = 0.1$ percent still delivers about two-thirds of ideal speedup, 1 percent about one-sixth, and 10 percent under $10\times$ in total. Darker curves carry larger r.

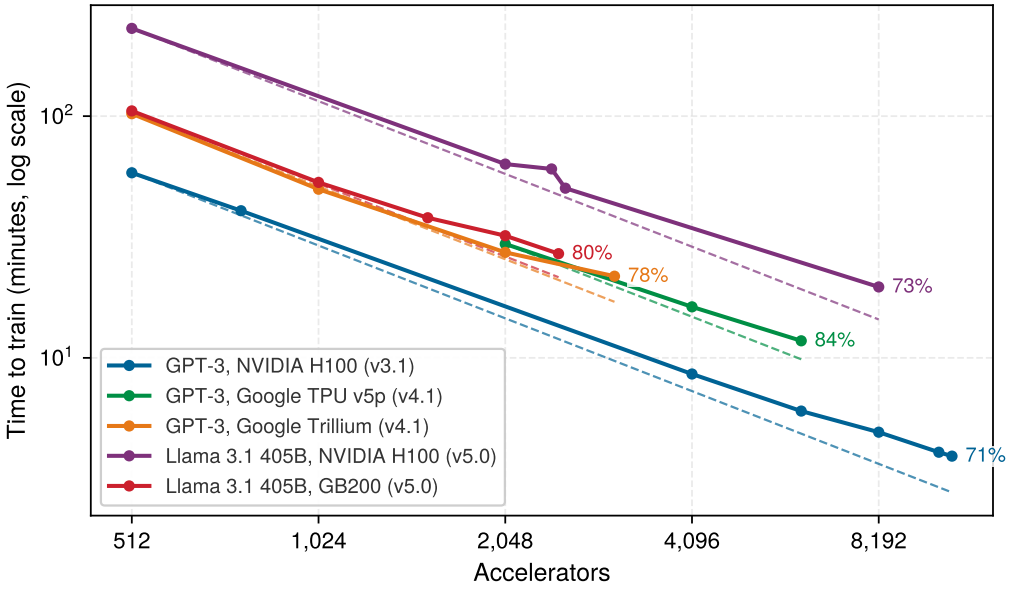
Predicting a run means pricing each term of equation 6.2 for the configuration at hand. For a large-message ring AllReduce, the communication term's bandwidth contribution is $\frac{2(N-1)}{N}\frac{D_{\text{vol}}}{\beta}$. This is the fleet counterpart of the single-machine iron law's data-movement ratio D_{vol}/BW. Here D_{vol} is the payload being reduced (the gradient bytes M_{grad} under data parallelism, or a shard of model state under sharding), and β is sustained per-link bandwidth. The expression omits per-message startup latency. Each wait must enter the accounting once.

↪ The single-machine iron law and its data-movement term are developed in section A.2.

This communication overhead costs energy as well as wall-clock time, and the energy cost of communication grows with the physical distance between devices. At the scale of 10,000 GPUs, moving data is itself a power load. A full H100 NVLink envelope of roughly 9 PB/s at 7.5 pJ/bit represents about 540 kW before cooling and switch overhead. The smaller NDR InfiniBand envelope (500 TB/s at 35 pJ/bit) still represents about 140 kW. The per-boundary accounting behind these per-bit costs is developed in section 5.2. Overlap hides communication time but not its energy, so avoiding unnecessary movement is the direct way to reduce the power term.

Communication energy climbs from HBM out to the network.

As the device count grows for a fixed workload, the balance can move from a linear scaling regime toward a communication-bound regime. The transition has no universal GPU count, because it depends on compute per device, message sizes, topology, and overlap. Coordination overhead becomes consequential when its



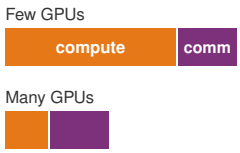


Figure 6.10: Measured Scaling in MLPerf Training: Time to train against accelerator count on logarithmic axes for five same-round series of the GPT-3 175B and Llama 3.1 405B benchmarks. Each dashed line is ideal scaling from that series' smallest configuration, and the label gives the scaling efficiency of its largest configuration relative to its smallest. Global batch size grows with scale in several series, so the gap from ideal includes batch-dependent convergence as well as communication and coordination. Times are recomputed from the published run logs and can differ slightly from official scores. Data from MLCommons (2025b).

exposed time is no longer small relative to useful computation. Measurements at the intended workload and placement must establish the efficiency curve.

The efficiency metrics directly influence the choice of parallelism strategy. Data parallelism works well in the linear scaling regime but becomes communication bound at scale. The model-parallel strategies developed after this section replace part of that gradient traffic with other costs, which the same efficiency equation prices once each mechanism is in place. Hardware efficiency metrics govern throughput, yet convergence theory determines whether distributed training reaches the same solution quality as single-device training. Parallelism affects optimization convergence in three ways: convergence rate changes with batch size, adding workers yields diminishing returns beyond the critical batch size, and learning-rate schedules must be revalidated when the global batch changes.

More GPUs shrink each step's compute, not its communication.

6.4.3 Convergence rate for synchronous data parallel SGD

Averaging gradients across N workers processes N times as many examples per step, but only reduces the number of steps to convergence when gradient noise—rather than loss curvature—is what holds back a larger step size. Formally, let $\mathcal{L}$ be lower bounded by $\mathcal{L}_{\text{inf}}$ and have L_s-Lipschitz gradients, so the smoothness constant limits how sharply the gradient can change as parameters move. Each worker computes gradients from B_{local} independent samples. At update t, the aggregated estimator $\mathbf{g}_t$, the average of the N workers' local gradients, is unbiased, and its conditional variance satisfies $\mathbb{E}[\|\mathbf{g}_t - \nabla\mathcal{L}(\theta_t)\|^2 \mid \theta_t] \leq \sigma^2/(NB_{\text{local}})$. When

averaging reduces that noise, synchronous SGD makes steady progress toward parameters where the gradient is small. These assumptions bound progress toward a small gradient norm, not convergence to a global minimizer or a particular validation accuracy.

Theorem 6.1: Convergence rate for distributed SGD

For the update $\theta_{t+1} = \theta_t - \eta \mathbf{g}_t$ with constant step size $0 < \eta \leq 1/L_s$, after T synchronized updates,

$$\frac{1}{T}\sum_{t=0}^{T-1} \mathbb{E}\left[\|\nabla \mathcal{L}(\theta_t)\|^2\right] \leq \underbrace{\frac{2(\mathcal{L}(\theta_0) - \mathcal{L}_{\text{inf}})}{\eta T}}_{\text{optimization term}} + \underbrace{\frac{\eta L_s \sigma^2}{N B_{\text{local}}}}_{\text{stochastic-variance term}}.$$

Choosing $\eta = \min\left\{1/L_s, \sqrt{2(\mathcal{L}(\theta_0) - \mathcal{L}_{\text{inf}}) N B_{\text{local}} / (L_s \sigma^2 T)}\right\}$ balances the two terms. Before the smoothness cap becomes active, the stochastic contribution scales as $\mathcal{O}(1/\sqrt{N B_{\text{local}} T})$.

The theorem isolates the benefit that follows from the assumptions. With equal local batch size B_{local}, synchronous data-parallel SGD computes the same mini-batch estimator as one worker using batch size $N \times B_{\text{local}}$ for that update, and the estimator variance decreases as $1/(N \times B_{\text{local}})$. It does not say that every increase in batch size proportionally reduces time to a target loss; learning-rate limits and critical-batch-size effects still apply. This distinction is the statistical efficiency of distributed training, separate from hardware efficiency. Because the theorem assumes perfect synchronization (BSP), convergence guarantees degrade as staleness increases whenever workers proceed at different rates or apply stale gradients.

6.4.4 Staleness impact across synchronization models

When a slow worker applies a gradient computed on an older parameter version, the update pushes the model along a direction that the current parameters may have already outgrown. The staleness parameter τ_{stale} counts how many updates occur between computing and applying a gradient, tying the barrier savings of BSP, SSP, and ASP (section 6.3.1.5) to solution quality (Ho et al. 2013; Dutta et al. 2018). Because the damage from stale gradients depends on the objective, step-size schedule, worker count, and delay distribution, no single additive penalty applies across all runs.

Definition 6.5: Gradient staleness

Gradient staleness (τ_{stale}) is the number of parameter updates that occur between the time a gradient is computed and the time it is applied to the global model state.

1. **Significance**: It represents the synchronization error in distributed optimization. Increasing τ_{stale} can improve throughput by reducing barrier

waits ($T_{\text{sync}}(N)$), but it typically degrades the rate of convergence, requiring more optimizer steps, and therefore more FLOPs, to reach the same accuracy.

2. **Distinction**: Unlike network latency, which is a physical delay, staleness is an algorithmic offset that arises from the choice of synchronization protocol (e.g., ASP, SSP).
3. **Common pitfall**: A frequent misconception is that staleness is "always bad." In reality, it is a throughput-convergence trade-off: for some large-scale workloads, allowing bounded staleness is one practical way to keep thousands of GPUs in use.

The convergence behavior differs across these models in ways that directly affect training cost and solution quality. In BSP ($\tau_{\text{stale}} = 0$), all workers compute on the same parameter version and aggregate before updating. Under the assumptions of theorem 6.1, the synchronized estimator inherits the $N \times B_{\text{local}}$ minibatch guarantee.

SSP ($\tau_{\text{stale}} \leq s$) allows workers to proceed up to s iterations ahead of the slowest worker. Ho et al. (2013) bound the average regret of their SSP update sequence at $\mathcal{O}(\sqrt{(s+1)N/T})$ for N workers and T updates. Average regret is the per-update gap between the loss its iterates incur and the loss of the best fixed parameters chosen in hindsight. The bound assumes convex Lipschitz component functions, a bounded domain, and a decreasing step size. It makes the staleness dependence explicit, since the bound grows with s. It measures a different quantity from the gradient-norm bound of theorem 6.1, which covers nonconvex objectives, so the two rates cannot be compared directly.

Asynchronous SGD imposes no protocol-wide finite delay bound. Removing the barrier can improve update throughput, but a convergence rate requires additional assumptions about realized delays, the objective, and the step-size schedule. Dutta et al. (2018) analyze this as an error-runtime trade-off in which worker speed and gradient staleness jointly determine whether accepting a delayed update helps. Therefore neither a fixed square-of-average-delay penalty nor the complete loss of N-worker variance reduction follows from asynchronous execution alone. The protocol fixes each model's delay control, but the strength of its convergence guarantee depends on further assumptions (table 6.4).

Table 6.4: Convergence Properties by Synchronization Model: The synchronization protocol determines the delay model; the convergence rate follows only after the objective, gradient, delay, and step-size assumptions are fixed.

Model	Delay control	Scoped guarantee	Systems effect
BSP	$\tau_{\text{stale}} = 0$	Synchronous $N \times B_{\text{local}}$-minibatch theorem 6.1	Waits for the slowest worker
SSP	$\tau_{\text{stale}} \leq s$	$\mathcal{O}(\sqrt{(s+1)N/T})$ average regret under convex assumptions (Ho et al. 2013)	Bounds delay while reducing some waits

Model	Delay control	Scoped guarantee	Systems effect
ASP	No protocol-wide finite bound	No universal rate without additional delay and objective assumptions	Removes the global barrier but applies stale updates

6.4.5 Learning rate scaling rules

Even under zero-staleness BSP ($\tau_{\text{stale}} = 0$ in table 6.4), scaling out across N workers changes the optimization trajectory whenever the global batch grows with the cluster. Multiplying the global batch by k cuts the number of optimizer updates per epoch by the same factor, so keeping the single-GPU learning rate leaves the model under-trained, while jumping straight to a k-fold larger step size can destabilize early epochs. Whenever data parallelism changes the effective batch size, the learning-rate schedule must be revalidated against the target quality; two scaling rules provide starting points for that adjustment.

The linear scaling rule (Goyal et al. 2017) proposes that when batch size is multiplied by k, learning rate also increases by k:

$$\eta_{\text{new}} = k \cdot \eta_{\text{base}}$$

The approximation compares one large-batch step at learning rate $k\eta$ with k consecutive small-batch steps at learning rate η. At batch size $k \times B$, independent gradient contributions reduce estimator variance by factor k, but lower variance alone does not establish stability. The approximation also requires gradients to change little over the corresponding k small-batch steps. Goyal et al. (2017) validated the recipe for ResNet-50/ImageNet at global batch size 8,192 with gradual warmup. Layer-wise adaptive rate scaling (LARS) and layer-wise adaptive moments based optimizer (LAMB) provide related large-batch approaches for ImageNet and BERT-style pretraining (You et al. 2017; You et al. 2020). A warmup period increases the learning rate from η_{base} to $k \cdot \eta_{\text{base}}$ over the first W iterations to reduce early instability; the schedule still requires validation:

$$\eta_t = \eta_{\text{base}} + \frac{t}{W}(k \cdot \eta_{\text{base}} - \eta_{\text{base}}) \quad \text{for } t < W$$

The rule and the warmup were introduced together, and the run that introduced them shows why the scaled learning rate needs the warmup. A learning-rate schedule tuned for an eight-GPU run need not reach the same accuracy at 256 GPUs once the global batch grows with the worker count.

War Story 6.1: The one-hour ImageNet run (2017)

Context: Facebook AI Research set out to train ResNet-50 on ImageNet in one hour using 256 GPUs, pushing data parallelism far beyond the batch sizes that earlier practice treated as safe (Goyal et al. 2017).

Mechanism: Scaling the global batch to 8,192 cut the number of optimizer updates per epoch by the same factor. Keeping the small-batch learning rate left too few effective updates to reach the target accuracy, while scaling the learning rate up by the same factor destabilized optimization in the first epochs, when the loss surface changes fastest.

Impact: Without the gradual warmup recipe, the large-batch runs reported higher training and validation error than the small-batch baseline. Higher hardware throughput alone did not preserve the quality target.

Fix: The team introduced the linear learning-rate scaling rule paired with a 5-epoch gradual warmup schedule, stabilizing optimization at batch size 8,192.

Systems lesson: Distributed training demands more than parallel hardware alone. Scaling changes the optimization regime, so the cluster, communication schedule, batch size, and learning-rate schedule must be tuned as one system.

The square root scaling rule is an alternative learning-rate heuristic to test when increasing batch size:

$$\eta_{\text{new}} = \sqrt{k} \cdot \eta_{\text{base}}$$

This rule increases the learning rate more slowly than linear scaling. Its suitability depends on the optimizer, schedule, and training regime; exceeding a critical-batch estimate does not make it mandatory or guarantee convergence. The learning rate must be validated against the same target quality.

LARS (You et al. 2017) scales each layer's update relative to its weight norm. The simplified LARS expression below illustrates the ratio of weight norm to gradient norm with weight decay. LAMB (You et al. 2020) applies a related layer-wise adaptation to an Adam-based update rather than using this raw-gradient denominator:

$$\eta_\ell = \eta_{\text{global}} \cdot \frac{\|\mathbf{w}_\ell\|}{\|\mathbf{g}_\ell\| + \lambda_{\text{reg}} \|\mathbf{w}_\ell\|}$$

Here λ_{reg} is the weight-decay coefficient in the illustrated LARS expression, distinct from the failure-rate parameter used in reliability analysis. Layer-wise scaling controls update magnitude relative to parameter magnitude, but does not guarantee convergence for arbitrary batches. Its systems role is to extend the range of validated batch sizes over which added data-parallel workers can reduce time to quality.

6.4.6 Critical batch size and diminishing returns

Increasing the global batch eventually yields diminishing reductions in the optimization steps needed to reach a fixed target quality. The critical batch size B^* marks the transition point beyond which increasing batch size yields diminishing returns in convergence per sample seen.

Definition 6.6: Critical batch size

Critical batch size (B^*) is a workload-dependent crossover batch size beyond which further batch growth yields diminishing reductions in optimization steps per added sample (McCandlish et al. 2018; Shallue et al. 2019).

1. **Significance**: It characterizes statistical scaling, separately from hardware throughput. In the gradient-noise model, batches well below B^* can reduce step count approximately in proportion to batch growth; above it, additional samples buy progressively smaller step-count reductions.
2. **Distinction**: Unlike the memory-limited batch size (determined by memory capacity and activation footprint), the critical batch size depends on the model, data, optimizer, training phase, and target quality.
3. **Common pitfall**: A frequent misconception is that training can be sped up indefinitely by adding GPUs. In reality, B^* is a guide to diminishing statistical returns, not a hard physical ceiling or a universal optimum in wall-clock time.

The gradient-noise-scale proxy for the critical batch size can be estimated as:

$$B^* \approx \frac{\text{tr}(\Sigma)}{\|\nabla \mathcal{L}(\theta)\|^2}$$

where $\text{tr}(\Sigma)$ is the trace of the gradient covariance matrix (total gradient variance) and $\|\nabla \mathcal{L}(\theta)\|^2$ is the squared gradient norm (signal strength). Intuitively, B^* is the batch size at which averaging reduces gradient variance to the level of the true gradient magnitude.

Published large-batch regimes illustrate the scale rather than providing fixed thresholds. On ImageNet, Goyal et al. (2017) stabilized ResNet-50 at global batch 8,192 with warmup, and LARS extends ImageNet large-batch training further in some settings (You et al. 2017). For BERT-Large pretraining, LAMB reports training at 32K–64K batch sizes with layer-wise adaptive updates (You et al. 2020). Across other domains, McCandlish et al. (2018) show useful batch-size limits ranging from tens of thousands in ImageNet-like settings to millions in reinforcement-learning workloads, so new frontier-language-model thresholds should be measured rather than copied.

The gradient-noise model separates statistical efficiency from hardware efficiency. Well below B^*, increasing batch size can reduce optimization steps almost proportionally while preserving similar total sample use. Near B^*, the trade-off between fewer updates and more samples becomes material. Above it, step count approaches a lower limit while sample use continues to increase. Neither maximum samples per second nor minimum training time necessarily occurs at B^*: those objectives also depend on device utilization, communication, and the validated learning-rate schedule.

On log-log axes, the gradient-noise trade-off appears as a divergence between optimization step count and total sample consumption (figure 6.11). Below the critical threshold ($B/B^* < 1$), increasing batch size yields near-linear reductions in optimization steps with negligible sample waste. Past the crossover point at $B/B^* = 1$ (where both normalized costs equal 2), the step count curve asymptotically flattens toward 1 while total examples processed climb steeply along the $1 + B/B^*$ trajectory.

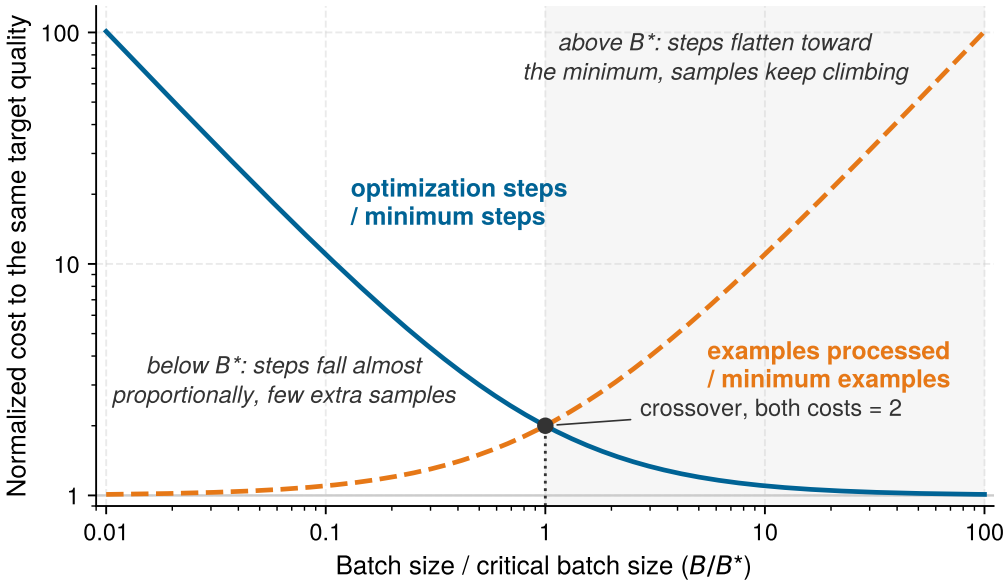

Figure 6.11: Statistical Cost of Larger Batches: A normalized illustration of the gradient-noise trade-off model, with batch size divided by the fitted critical batch. Optimization steps approach a lower limit as batches grow, while total examples processed increase. The crossover is not a hardware-throughput optimum or a measured threshold for a particular model (McCandlish et al. 2018).

Dividing the critical batch by the per-worker batch B_{local} estimates where worker growth leaves the near-proportional statistical scaling regime. With one local batch per update and its size held fixed, the crossover occurs around $N \approx B^*/B_{\text{local}}$ workers. Past that point, additional workers mainly raise sample throughput that the optimizer cannot convert into proportionally fewer steps. Gradient accumulation increases each worker's contribution per update and lowers the corresponding worker count. Shrinking B_{local} moves the crossover outward but leaves less computation per worker to hide communication, coupling statistical and hardware efficiency.

That crossover informs a cost-time trade-off rather than setting a mandatory worker count. Larger batches may still reduce time to target even as they consume more examples. That benefit must be established with measured step time and a validated learning-rate schedule at the same target quality. Changing synchronization or compression also changes the optimization process, so its communication savings must be weighed against any additional steps required.

Checkpoint 6.2: Scaling decisions

Given a 7B-parameter model distributed across a cluster of 64 A100 GPUs (80 GB HBM2e each), estimate the critical-batch crossover. Use a pilot trace with $\text{tr}(\Sigma) = 1.6 \times 10^6$, $\|\nabla \mathcal{L}(\theta)\|^2 = 100$, per-GPU batch $B_{\text{local}} = 4$, and a proposed gradient-accumulation depth of 32 steps, giving $B_{\text{global}} = 64 \times 4 \times 32 = 8{,}192$ samples.

- ☐ **Critical batch size**: calculate the critical batch size (B^*), where the gradient noise scale equals the batch size.
- ☐ **Proposed batch**: use the critical batch size proxy $B^* \approx \frac{\text{tr}(\Sigma)}{\|\nabla \mathcal{L}(\theta)\|^2}$ to evaluate the proposed batch size.
- ☐ **Efficiency distinction**: explain why the gradient-noise estimate can assess statistical scaling but cannot establish hardware scaling efficiency without compute and communication timings.

6.4.7 Communication cost versus convergence speed

Communication savings matter only through the resulting time and cost to reach target model quality. Scaling a transformer language model from 8 to 64 workers, with a per-worker batch of $B_{\text{local}} = 32$, shows how shorter steps and extra iterations to the same target combine into that cost.

Napkin Math 6.6: Scaling from 8 to 64 workers

Setup: This illustrative comparison assumes the iteration counts needed to reach one fixed target quality. They are scenario inputs, not measured convergence results or predictions from GPU count. The baseline is 100K iterations on single GPU with $B_{\text{local}} = 32$.

8 workers (BSP)

- Effective batch size: $B = 8 \times 32 = 256$
- Learning rate: $\eta = 8 \times \eta_{\text{base}}$ (illustrative candidate with warmup; validate for the workload)
- Expected iterations: 100K / 8 = 12.5K iterations
- Assumed iterations to the same target: 12.8K iterations (98 percent efficiency)
- Communication overhead: 15 percent (NVLink intra-node)
- Wall-clock speedup: 100K × 1 / (12.8K × 1.15×) = 6.8×

64 workers (BSP)

- Effective batch size: $B = 64 \times 32 = 2{,}048$
- Learning rate ($N = 64$ workers): $\eta = N \times \eta_{\text{base}}$ is the scenario's assumed candidate schedule, not a prescription determined by B^* alone
- Assuming $B^* \approx 4{,}000$ (below critical): the useful-worker bound is $B^*/B_{\text{local}} \approx 4{,}000 \ / \ 32 \approx 125$ workers, so 64 workers stay inside the near-proportional regime; this estimate does not validate a learning-rate schedule
- Expected iterations: 100K / 64 = 1.56K iterations
- Assumed iterations to the same target: 1.72K iterations (91 percent efficiency)
- Communication overhead: 45 percent (InfiniBand inter-node, 8 nodes)
- Wall-clock speedup: 100K × 1 / (1.72K × 1.45×) = 40.1×

SSP workers: 64 workers ($s = 4$)

- Same effective batch size: $B = 2{,}048$
- Illustrative learning-rate reduction, not a staleness theorem: $\eta' = \eta_{\text{BSP}}/\sqrt{1+s}$ with $s = 4$, giving $\eta' \approx 0.45 \times \eta_{\text{BSP}}$
- Expected iterations: Higher due to staleness penalty
- Assumed iterations to the same target: 2.1K iterations (74 percent efficiency)
- Communication overhead: 25 percent (reduced synchronization)
- Wall-clock speedup: 100K × 1 / (2.1K × 1.25×) = 38.1×

Analysis (table 6.5)

Table 6.5: Illustrative Scaling Comparison: Assumed iteration counts to one target quality, communication increments relative to local compute time, and the resulting speedup and sample efficiency. These are scenario calculations, not empirical optimizer benchmarks.

Configuration	Iterations	Comm. overhead	Wall-clock speedup	Sample efficiency
1 GPU (baseline)	100,000	0%	1×	100%
8 GPU BSP	12,800	15%	6.8×	98%
64 GPU BSP	1,720	45%	40.1×	91%
64 GPU SSP	2,100	25%	38.1×	74%

The 64-GPU BSP configuration achieves 40× speedup despite only 91 percent sample efficiency because the communication overhead (45 percent) is offset by the larger worker count. SSP at 64 workers comes close in wall-clock time with lower per-iteration communication (25 percent), but the extra iterations its stale updates require hold it to 38.1× against BSP's 40.1×. In this scenario it therefore finishes slightly later and costs slightly more than 64-worker BSP.

Cost Analysis (assuming \$2/GPU-hour):

- 8: 12.8K iters × 0.46 s/iter × 8/3600 × \$2/GPU-hour = \$26
- 64 BSP: 1.72K iters × 0.58 s/iter × 64/3600 × \$2/GPU-hour = \$35
- 64 SSP: 2.1K iters × 0.50 s/iter × 64/3600 × \$2/GPU-hour = \$37

Despite higher parallelism, 64-GPU training costs more per run due to communication overhead and reduced sample efficiency. The 8-GPU configuration is more cost-efficient, but its 6.8× speedup against the 64-GPU run's 40.1× leaves it several times slower in wall-clock time. The choice depends on whether minimizing cost or minimizing time-to-result is the priority.

On the cost-time plane of figure 6.12, 64-worker BSP dominates 64-worker SSP on both axes. SSP saves communication per iteration, but its stale updates need enough extra iterations to cost more and finish later, while 8-worker BSP remains the cheaper and slower option.

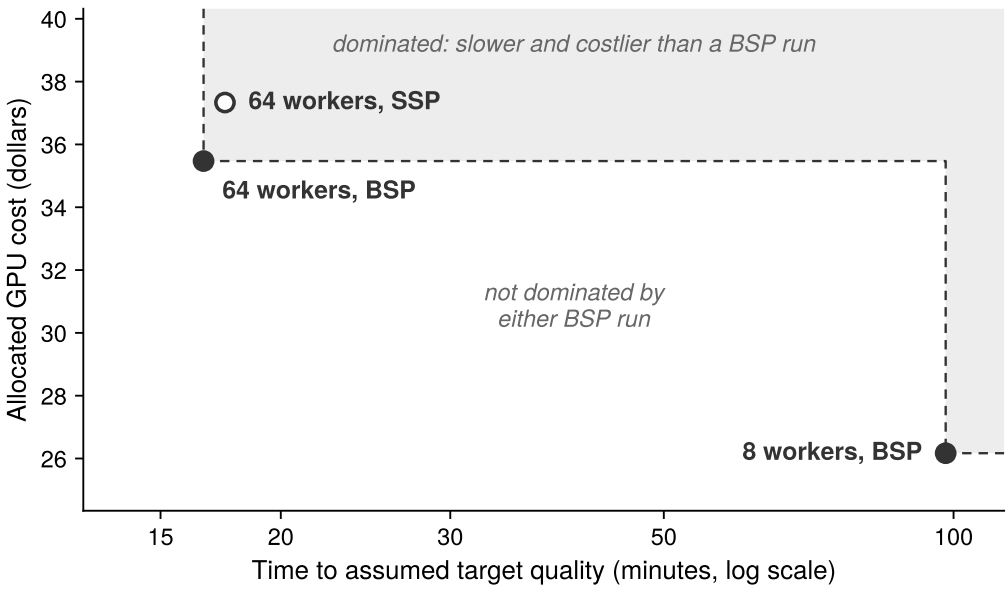

Figure 6.12: Cost and Time in the Illustrative Scaling Scenario: Points reuse the assumed convergence counts and step times in the preceding notebook. The eight-worker configuration costs less but finishes later; the assumed sixty-four-worker SSP configuration is dominated by BSP in both cost and time. This is not a universal ranking of synchronization methods.

Moving a job along this cost-time frontier requires shrinking each message, synchronizing less often, or relaxing the global reduction topology. Gradient

compression shrinks the payload directly by transmitting quantized, sparsified, or low-rank approximations. Examples include sign-based updates (Bernstein et al. 2018), Deep Gradient Compression (Lin et al. 2018), PowerSGD (Vogels et al. 2019), quantized SGD with convergence analysis (Alistarh et al. 2017), and empirical sparse gradient dropping for neural machine translation (Aji and Heafield 2017).

↩ Quantized, sparsified, and low-rank gradient compression, the error feedback that keeps them convergent, and the criteria for when they pay, are established in section 5.9.

Instead of shrinking each payload, Local SGD lowers synchronization frequency by letting workers perform H_{local} local updates before averaging, which cuts collective calls per local update by a factor of H_{local}. Results for smooth, strongly convex objectives can recover synchronous SGD's asymptotic rate under specified learning-rate and local-update-interval conditions (Stich 2019), so the synchronization interval remains part of the convergence contract rather than an unrestricted communication saving.

Where Local SGD keeps a global AllReduce at wider intervals, Decentralized SGD replaces the global collective with sparse neighbor exchanges along a communication graph. Immediate bandwidth demand drops, at the cost of taking additional rounds to spread information across the group. Graph connectivity, link service time, and the optimization effect of delayed mixing determine whether that trade-off helps a geographically distributed workload.

Choosing among these three levers depends on which bottleneck binds and how many extra iterations the altered update costs. Each candidate must be judged by measured time to the same target quality. A narrower numeric format offers one more way to shrink the payload without changing the collective schedule, under conditions that FP8 makes precise.

6.4.8 FP8 for distributed training

Running matrix multiplications in 8-bit floating point (FP8) accelerates local compute, which can make a distributed job *more* communication-bound if gradients still cross the network in 16-bit precision. Compute precision and communication precision are separate choices: casting GEMM operands to half as many bytes reduces operand storage and local memory traffic, but it halves a collective payload only when the communication path explicitly transmits that narrower representation.

↩ The throughput that narrower precisions buy on current accelerators is established in section 2.8.1.

FP8 matters to distributed training only after four dtypes are distinguished: the stored parameter dtype, the GEMM operand dtype, the accumulator or master-state dtype, and the collective wire dtype. Traditional mixed-precision training commonly retains FP32 optimizer or master state while using FP16/BF16 operands. FP8-capable accelerators add E4M3 (four exponent bits and three mantissa bits) and E5M2 (five exponent bits and two mantissa bits) operand formats optimized for different tensor distributions (Micikevicius et al. 2022).

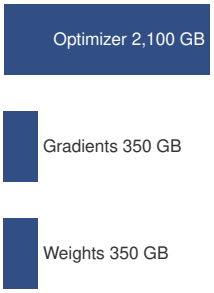
The two FP8 formats trade precision against range. E4M3 keeps an extra mantissa bit for scaled *weights and activations*, which cluster within a predictable range, while E5M2 keeps an extra exponent bit for scaled *gradients*, which can span many orders of magnitude during backpropagation. Because tensor magnitudes drift during training, each tensor is multiplied before conversion by a scale, commonly derived from its recent maximum absolute value, a policy called *dynamic scaling*. Neither

the format nor the scaling policy guarantees that every value survives conversion, so training quality must be validated for each workload.

An FP8 training contract pairs FP32 master or optimizer state and FP8 GEMM operands with higher-precision accumulation, and it can approach FP16 training quality on suitable workloads (Micikevicius et al. 2022). FP8 halves bytes only for tensors actually stored or transmitted in FP8, so a collective that reduces FP16 gradients still moves FP16 bytes even when every preceding GEMM ran in FP8. FP8 therefore earns its place in distributed training when lower-precision compute shortens the local critical path, or when an explicit communication cast shrinks payloads while the accumulation and scaling policy protects convergence. It changes representation, not the parallelization axis. Compression, local updates, and narrower formats all make each data-parallel step cheaper, yet none of them partitions an individual layer or its activations; that remaining capacity constraint motivates model parallelism.

↪ Per-parameter training memory under each of these formats is collected for reference in section A.6.

6.5 Model Parallelism



Sharded data parallelism distributes stored state but still asks each worker to execute every layer on its local examples. If one layer's gathered parameters and working memory exceed device capacity, or its execution is too slow for the target schedule, splitting that computation becomes a candidate. Model parallelism addresses this form of the memory capacity gap (principle 2) by assigning different computations to different devices. Its value must be compared with offload, recomputation, and smaller local batches under the same throughput and quality requirements.

Definition 6.7: Model parallelism

Model parallelism is a distributed training strategy that partitions a single neural network's parameters or operations across multiple devices so each device computes a distinct portion of the model.

1. **Significance**: If a model with parameter state M_{weights} is split across $N_{\text{TP}}N_{\text{PP}}$ model-parallel devices, the ideal per-device parameter footprint falls toward $M_{\text{weights}}/(N_{\text{TP}}N_{\text{PP}})$, enabling training of models that exceed single-device memory. The cost is extra communication for activations and gradients plus idle time from sequential dependencies, so the memory gain must exceed the transfer and pipeline-bubble overhead introduced by the partition.
2. **Distinction**: Unlike data parallelism, which replicates the full model on every worker and shards the minibatch, model parallelism shards the model itself. Pipeline parallelism and tensor parallelism are implementation forms of model parallelism: one partitions layers into stages, while the other partitions individual tensor operations.

3. **Common pitfall**: A frequent misconception is that model parallelism automatically speeds up training. Its primary benefit is capacity, not throughput; without careful scheduling and overlap, downstream devices wait for upstream activations and utilization can fall below a single-device baseline.

Weights are only a small slice of the full Adam training state.

Memory fit alone does not settle whether a model needs this kind of partition. For a 175B-parameter model, weights alone occupy 350 GB, or about 5.5 GB per GPU across a 64-GPU group, one-sixteenth of the 1,024-GPU reference cluster. Full mixed-precision Adam training state is much larger, 2,800 GB globally, yet ZeRO-3 across the same 64 GPUs reduces it to roughly 43.8 GB per GPU before activations, which fits an 80 GB accelerator. ZeRO-3 can therefore make the static state fit, as the notebook below confirms. It pays for that fit in traffic, because every step regathers every layer's parameters across the data-parallel fabric, roughly three times the model's parameter bytes per worker (section 6.3.3). It also cannot split an individual layer's computation or activations across devices. Tensor parallelism addresses both limits by partitioning individual weight matrices across devices, using the column-then-row pairing of figure 6.16, detailed in section 6.5.3, which confines collective communication to block boundaries. Pipeline parallelism instead stages sequential layers across devices (section 6.5.2).

Activations add a separate memory requirement. Under the earlier unchecked-storage assumptions, a 2048-token sequence through 175B parameters produces roughly 1.1 TB at a local batch of 4 sequences; optimizer sharding does not reduce that storage. Recomputation trades memory for extra FLOPs, partitioning distributes activations, and offload moves them to another memory tier. Kernel and batch-size choices also change the budget. Full activation checkpointing brings the same modeled case down to ~19.3 GB. The following notebook, which uses a single-sequence local batch, checks whether ZeRO-3 plus checkpointing fits the model without partitioning its computation.

Napkin Math 6.7: The memory wall of scale

Problem: Training a 175B-parameter model (like GPT-3) on a 64-GPU group of NVIDIA A100s (80 GB), smaller than the 1,024-GPU reference cluster. The A100 carries the same 80 GB of HBM as the reference H100, so the capacity verdict carries over, and a small group is the harder test of whether sharding alone suffices. Can data parallelism with ZeRO-3 handle this?

Math:

1. **Parameter storage**: 175B params $\times$ 2 bytes (FP16) = 350 GB.
2. **Gradients and optimizer state**: Gradients add 175B params $\times$ 2 bytes = 350 GB, while Adam FP32 master weights, momentum, and variance add 175B params $\times$ 12 bytes = 2,100 GB.
3. **Total static memory**: 2,800 GB.

4. **ZeRO-3 sharding**: With 64 GPUs, per-GPU static memory = 2,800 GB/64 GPUs ≈ 43.8 GB.
5. **Activation memory**: For sequence length 2048 and batch size 1, the canonical full-checkpointing strategy stores ≈ 4.8 GB of activations per GPU.

Systems insight: 43.8 GB (static) + 4.8 GB (dynamic) = 48.6 GB. Under this simplified accounting, ZeRO-3 plus full activation checkpointing fits within the 80 GB A100 capacity, leaving material headroom for framework buffers and transient layer gathers. If those additional allocations exceed the remaining HBM, the design can reduce the local batch, offload state, increase the sharding degree, or add tensor or pipeline parallelism; tensor parallelism is not the only recourse.

In this example, sharding and checkpointing make the modeled state fit, leaving two distinct reasons to partition the model itself. One is regather traffic: on the 1,024-GPU reference cluster, ZeRO-3 moves about 1.1 TB per worker per step for this model, which on one NDR InfiniBand port takes about 10× as long as the step's computation. The other is layer execution, since full sharding gathers parameters on demand without ever splitting a single layer's computation or activations across devices. Model parallelism instead cuts the computation graph directly, either between sequential layer groups (such as layers 1–4 and layers 5–8) or inside a layer across channels and attention heads. Layer cuts introduce pipeline dependencies that leave downstream devices idle while an upstream stage computes, creating the pipeline bubble that governs utilization for this partition. Channel and head cuts instead expose concurrent work within a layer at the price of intra-layer exchanges. Other workloads still need these cuts to fit peak memory capacity.

These cuts enable the large-scale cases that exceed a single device for different reasons. GPT-3, with 175B parameters, was trained with model parallelism within each matrix multiplication and across layers (Brown et al. 2020), avoiding a full-parameter regather on every step. Vision transformers processing high-resolution $16k \times 16k$ pixel images use model parallelism to bound activation memory. Mixture-of-experts (MoE) architectures, whose sparsely activated feed-forward blocks are developed in section 6.5.5, distribute their conditional computation paths across hardware (Shazeer et al. 2017; Lepikhin et al. 2021; Fedus et al. 2022).

Each partitioning strategy trades single-device memory overflow for a different systems cost: layer-wise partitioning pays in idle time, pipeline parallelism pays in scheduling complexity to hide that idle time, and tensor parallelism pays in NVLink bandwidth to split individual layers. Sequence and context parallelism, expert parallelism, and sparse embedding sharding then extend the same trade-off to long-context activations, sparsely activated experts, and sparsely touched embedding tables.

Checkpoint 6.3: Model parallelism foundations

Verify your understanding of model sharding:

- ☐ **Memory relief**: determine whether model parallelism reduces the memory footprint per GPU for a given model.
- ☐ **Sequential dependency**: identify whether sequential dependencies between layer-wise model shards arise in the forward pass, the backward pass, or both.
- ☐ **Pipeline bubble**: explain why unscheduled layer-wise model parallelism can lead to lower GPU utilization than data parallelism through the "pipeline bubble."
- ☐ **Layer vs. tensor split**: distinguish layer-based and tensor-based ways to split a Transformer layer.

6.5.1 Layer-wise partitioning

Where ZeRO-3 met the capacity limit by sharding storage while every worker still executed every layer, layer-wise model parallelism gives each device a *unique* contiguous block of layers to compute. It is the least invasive model cut: with 8-way partitioning, the 175B-parameter model's 350 GB of FP16 weights fall to approximately 44 GB per GPU, though activations, gradients, and optimizer state still need sharding, offload, or pipeline scheduling (section 6.6).

Because consecutive layer blocks remain sequentially dependent, however, a single batch passing through those stages in order leaves every other GPU waiting for its turn. In a 16-layer transformer placed four consecutive layers per GPU (figure 6.13), panel (a) shows each device holding one-quarter of the weights and exchanging only boundary activations and gradients, while panel (b) reveals the utilization penalty: without microbatch pipelining, each GPU computes in only two of the eight schematic time slots and sits idle for the other six.

Partitioning layers changes where an optimizer update runs without necessarily changing the update rule. Each GPU can apply Adam (Kingma and Ba 2015), AdaFactor, or another optimizer to its parameter slice once the required gradients are complete. A device holding transformer layers 1–12 updates those layers; tied parameters, global gradient clipping, or a combined data-parallel group can still require coordination. Preserving synchronous optimization also requires the schedule to use consistent parameter versions. Sequential dependencies introduce pipeline bubbles, and unequal stage service times add waiting. The engineering problem is to overlap microbatches and balance stage work while preserving that update contract (Rasley et al. 2020).

6.5.2 Pipeline parallelism

Without pipelining, a four-stage layer partition leaves three of the four GPUs idle at any moment because downstream stages cannot start until upstream stages finish the entire batch (figure 6.13). Pipeline parallelism breaks that stall by splitting

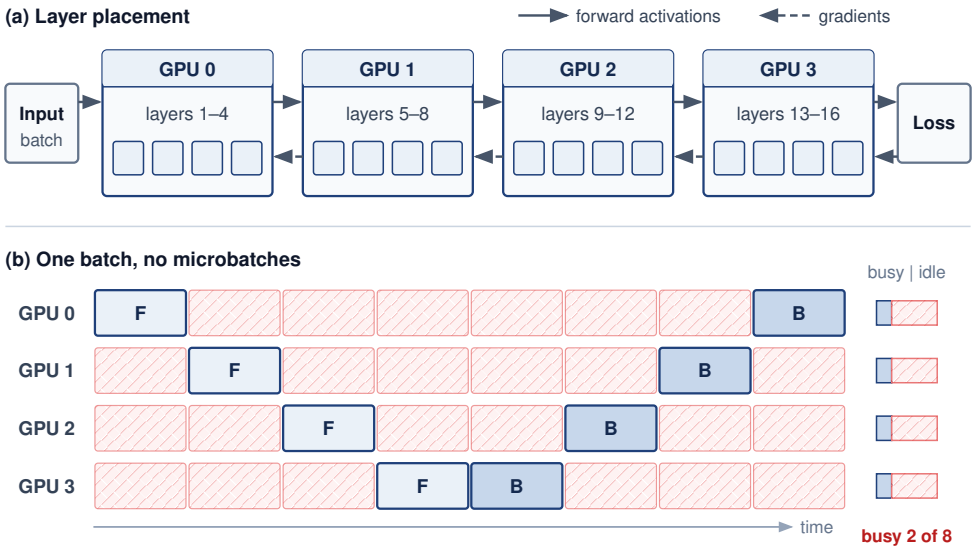


Figure 6.13: Layer-Wise Model Parallelism: (a) A 16-layer transformer placed four consecutive layers per GPU, cutting each GPU's weight footprint to one-quarter of the model. Forward activations cross each stage boundary left to right; gradients return right to left. (b) Without microbatching, one batch visits the stages in turn, forward (F) and then backward (B) in reverse, in equal schematic time slots, so each GPU works in only 2 of 8 slots. The microbatched schedule in figure 6.14 fills much of that idle time.

the batch into smaller microbatches and streaming them through the stages like a relay race. As soon as GPU 1 finishes the initial transformer blocks on microbatch 1, it hands the resulting activation tensor to GPU 2 and immediately starts microbatch 2. For the 175B model with hidden dimension 12,288 and a microbatch of 4 sequences at 2,048 tokens each, that forward handoff carries approximately 201 MB per stage boundary per microbatch. GPU 2 needs that payload before processing the same microbatch, creating a dependency chain through the stages, while other microbatches occupy the remaining stages concurrently. Backward propagates activation gradients in reverse as each stage computes gradients for its own parameters.

Definition 6.8: Pipeline parallelism

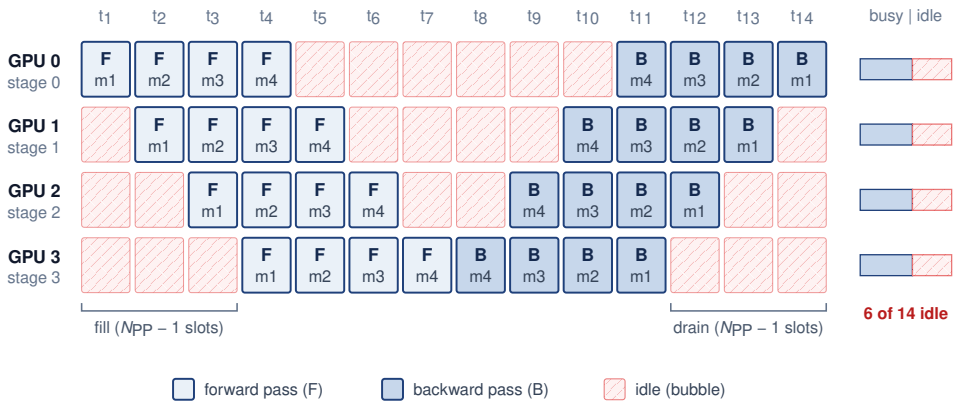
Pipeline parallelism is a model parallelism technique that partitions a neural network's layers into sequential stages assigned to different devices, passing activations forward and gradients backward between stages while overlapping computation across stages using microbatches to maintain throughput.

1. **Significance**: Each boundary transfers forward activations and backward activation gradients. A forward tensor contains $B_{\text{micro}} \times S \times d \times 2$ bytes at BF16, where B_{micro} is the microbatch size. For a hidden dimension of 8,192 with microbatch size 1 and a 2,048-token sequence, the forward payload is approximately 8,192 $\times$ 2,048 $\times$ 2 $\approx$ 34 MB

per microbatch per boundary. Backward traffic and all microbatches must be counted before comparing this with a per-update gradient AllReduce or sizing a 50 GB/s InfiniBand link. In a balanced noninterleaved schedule with ideal transfers, the idle fraction is approximately $(N_{\text{PP}}-1)/(m+N_{\text{PP}}-1)$, where N_{PP} is the stage count and m the microbatch count.

2. **Distinction**: Tensor parallelism partitions operations within a layer and introduces communication among their participants. Pipeline parallelism instead transfers activations and their gradients between sequential stages. This coarser exchange can suit slower links when the transfer fits within the stage schedule; the interconnect name alone does not establish feasibility.
3. **Common pitfall**: A frequent misconception is that adding pipeline stages always improves throughput. Each additional stage increases the pipeline bubble fraction $(N_{\text{PP}}-1)/(m+N_{\text{PP}}-1)$ unless the number of microbatches m scales proportionally, causing hardware to idle and erasing the benefit of deeper partitioning.

In the GPipe schedule of figure 6.14, a four-stage pipeline processes four microbatches ($N_{\text{PP}}=4, m=4$). Dividing the global batch into discrete microbatches allows forward passes to overlap diagonally across stages before backward passes unfold in reverse order. While microbatching raises hardware utilization above naive sequential placement, pipeline fill (t_1–t_3) and drain (t_{12}–t_{14}) bubbles still leave each device idle for 6 of 14 time slots.



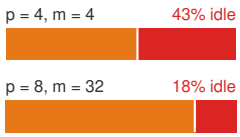


Figure 6.14: Pipeline Parallelism Schedule: A 4-stage pipeline processes 4 microbatches with all forward passes (F) before any backward pass (B), as in GPipe. Rows are pipeline stages and columns are equal time slots. Each backward pass enters a stage only after the next stage has produced that microbatch's gradient, so every stage idles $N_{\text{PP}}-1$ slots in the forward phase and $N_{\text{PP}}-1$ in the backward phase, 6 of 14 slots in all.

Tracing the schedule grid in figure 6.14 column by column reveals how the fill and drain bubbles arise. In the first slot only stage 0 has work, the forward pass

of microbatch 1. In the second, stage 0 starts microbatch 2 while stage 1 receives microbatch 1's activations, and by the fourth slot every stage holds a different microbatch. The last stage then turns microbatch 4 around into its backward pass, and gradients travel upstream in reverse microbatch order, so stage 0 waits until the eleventh slot for its first gradient. Each stage therefore idles 3 slots in the forward phase and 3 more in the backward phase, 6 of the 14 slots in the step. Those idle slots may fall at the start of its row, the middle, or the end. That share, about 43 percent, is the bubble fraction $(N_{\text{PP}}-1)/(m+N_{\text{PP}}-1)$ at $N_{\text{PP}}=m=4$. Adding microbatches lengthens the busy diagonal without lengthening fill and drain in this balanced schedule. Increasing m is therefore one way to reduce the idle fraction; later schedules also change which work can occupy the gaps.

The same bubble term becomes concrete in the following worked example, where an 8-stage pipeline and 32 microbatches still leave a measurable amount of idle time.

Enough microbatches shrink the bubble even as stages double.

↪ The bubble fraction across stage and microbatch counts, and its interleaved-schedule variant, are developed in section D.4.

Napkin Math 6.8: The cost of the pipeline bubble

Problem: A large-model training run uses pipeline parallelism across 8 stages. To hide the sequential delay, the batch is split into 32 microbatches. What fraction of GPU cycles does the pipeline bubble leave idle?

Math: For balanced, noninterleaved synchronous stages under the one-forward-one-backward (1F1B) schedule developed below, with ideal transfers, the bubble fraction follows from the stage and microbatch counts. The time units below each combine one forward and one backward service interval; they are not individual optimizer steps.

1. **Wait time**: At the start and end of each batch, GPUs sit idle for $N_{\text{PP}}-1$ steps.
2. **Productive time**: GPUs compute for m steps.
3. **Bubble fraction**: $(N_{\text{PP}}-1)/(N_{\text{PP}}-1+m) = 7\ /\ (7+32) \approx 17.9$ percent.

Systems insight: Pipeline parallelism is a *utilization-memory trade-off*. With this stage count and schedule fixed, reducing the bubble from 18 percent to 5 percent requires more microbatches (m). In general, holding the bubble under 10 percent requires $m > 9(N_{\text{PP}}-1)$, because $(N_{\text{PP}}-1)/(m+N_{\text{PP}}-1) < 0.1$ rearranges to that bound. The activation memory those microbatches need depends on the schedule. GPipe retains activations across the microbatches, whereas the 1F1B schedule developed next releases them during the steady state. The modeled 17.9 percent idle fraction also motivates interleaved pipelining, which divides each device's work into smaller stages. Interleaving can reduce the original 18 percent bubble, but additional transfers and memory requirements determine the net gain.

GPipe[4] (Huang et al. 2019) introduced synchronous pipeline parallelism with

[4] **GPipe**: Published by Google in 2019, GPipe introduced synchronous microbatch pipelining that trained a 557M-parameter AmoebaNet across 8 Tensor Processing Units (TPUs) with near-linear scaling. Its schedule keeps every microbatch's activations live until the backward pass, the cost that later schedules reduce.

microbatch accumulation, while PipeDream (Narayanan et al. 2019) developed asynchronous approaches with weight stashing. Modern systems use 1F1B (one-forward-one-backward)[5] scheduling to reclaim activation memory earlier. That lower memory pressure makes larger microbatch counts practical, and the larger m is what shrinks the bubble term.

At the schedule level, 1F1B is a warmup, steady-state, and drain loop. In algorithm 6.1, each stage alternates forward work for newer microbatches with backward work for older microbatches once gradients arrive, so activations can be released before the whole batch has completed.

5 | **1F1B (one-forward-one-backward) scheduling**: Unlike GPipe (which processes all forward passes before any backward passes), 1F1B interleaves them. For equal-sized microbatch activations and a non-interleaved schedule, peak retained activations per stage fall from $\mathcal{O}(m)$ under GPipe to at most $\mathcal{O}(N_{\text{PP}})$ under 1F1B, where m is the microbatch count and N_{PP} the pipeline-stage count. Summed across stages, the corresponding bounds are $\mathcal{O}(mN_{\text{PP}})$ and $\mathcal{O}(N_{\text{PP}}^2)$. This memory reclamation is what enables the large microbatch counts ($m \gg N_{\text{PP}}$) required to keep the pipeline bubble small.

Algorithm 6.1 One-forward-one-backward pipeline schedule

Require: N_{PP} ordered pipeline stages; m microbatches; activation links $j \to j{+}1$ and gradient links $j{+}1 \to j$
Ensure: one optimizer update after gradients accumulate across all m microbatches

split the global batch into m microbatches; assign consecutive layers to the N_{PP} stages
warm-up: launch forwards from stage 0, forwarding each activation downstream as produced
for each stage in steady state **do**
    alternate one backward (oldest ready microbatch) with one forward (next microbatch)
    release a microbatch's activation as soon as that stage's backward consumes it
end for
drain: finish the remaining backward passes in reverse stage order
apply the optimizer update once every stage has accumulated gradients for all m microbatches

Run on four stages with eight microbatches, the schedule gives each stage a short warm-up of forward passes, a steady state that alternates one backward with one forward, and a drain of the remaining backward passes (figure 6.15). The warm-up and drain phases still leave a bubble of roughly $(N_{\text{PP}}-1)/(m+N_{\text{PP}}-1)$, 6 of 22 slots here. Interleaving backward work in the steady state, however, frees each activation as soon as its backward consumes it. Stage 0 never holds more than four microbatches' activations where an all-forwards-first schedule would hold all eight, so peak activation memory grows with the stage count rather than the microbatch count. That is the gain over GPipe-style all-forward-then-all-backward scheduling, and it lets the system raise m until activation memory, recomputation, or the global-batch constraint becomes the next limit.

The activation handoff has shape $B_{\text{micro}} \times S \times d$; its completion still constrains the next stage. The 1F1B schedule in algorithm 6.1 reduces activation residency, but fill, drain, communication, and load imbalance leave idle time. Filling those

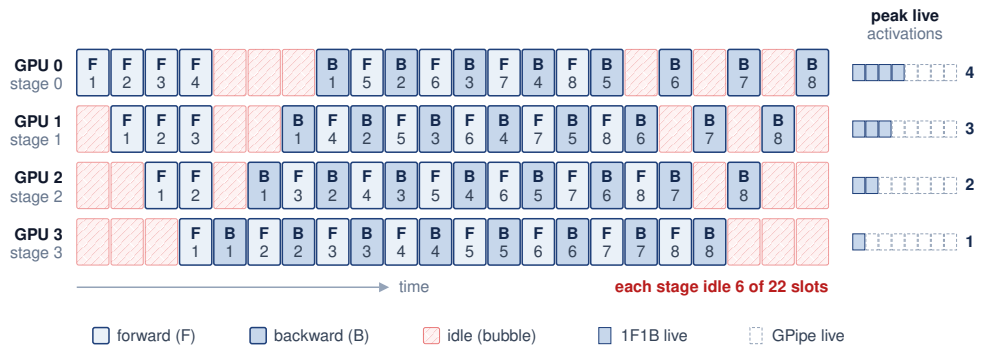

Figure 6.15: One-Forward-One-Backward (1F1B) Pipeline Schedule: Four stages process eight microbatches in equal schematic slots. After a warm-up of forward passes, each stage alternates one backward pass with one forward pass, then drains its remaining backward passes. Fill and drain still idle every stage for 6 of 22 slots, the bubble fraction $(N_{\text{PP}}-1)/(m+N_{\text{PP}}-1)$, but each stage releases a microbatch's activations as soon as that microbatch's backward pass runs. The bars at the right count the most microbatches whose activations a stage holds at once, four at stage 0 and one at the last stage, against the eight an all-forwards-first schedule would hold (dashed).

remaining slots requires separating work that releases an upstream dependency from work that can wait.

Zero-bubble pipeline schedules further reduce idle time by decoupling the two matrix multiplications inside each layer's backward pass. In a standard backward pass, the GPU computes both $\partial\mathcal{L}/\partial\mathbf{X}$ (the activation gradient propagated backward to the preceding stage) and $\partial\mathcal{L}/\partial\mathbf{W}$ (the weight gradient accumulated locally for the optimizer step) back-to-back as a single backward unit. Zero-bubble scheduling splits them into separate kernels. A B kernel multiplies the incoming upstream gradient by the stage's persistent weights $\mathbf{W}^T$ to compute only the activation gradient $\partial\mathcal{L}/\partial\mathbf{X}$ and immediately sends it to the previous stage. A W kernel multiplies the saved forward activation $\mathbf{X}^T$ by the upstream gradient to compute the weight gradient $\partial\mathcal{L}/\partial\mathbf{W}$ locally. Because upstream stages cannot begin their own backward work until they receive $\partial\mathcal{L}/\partial\mathbf{X}$, the B kernel sits on the critical path and must execute promptly, whereas the W kernel has no cross-stage dependency and can be scheduled opportunistically to fill local pipeline bubbles.

The B/W split creates scheduling freedom, although all deferred W kernels must still finish before the corresponding optimizer update. In the balanced four-stage, eight-microbatch schedule of figure 6.15, noninterleaved 1F1B still leaves $3/11 \approx 27$ percent of each stage's time idle, by the bubble fraction derived above. Reordering forward, activation-gradient, and weight-gradient work allows deferred W kernels to soak up those idle slots. Approaching zero bubble time in practice also depends on kernel durations, memory headroom, and optimizer synchronization, so splitting the backward pass alone does not guarantee it.

The trade-off is memory. Because the B kernel needs only the incoming gradient and the persistent weights $\mathbf{W}$, whereas the W kernel requires the saved forward activation $\mathbf{X}$, a stage cannot free a microbatch's forward activation when B finishes. Deferring W to fill a later bubble forces the stage to keep both $\mathbf{X}$ and the incoming gradient resident in device memory until W finally executes, increasing peak

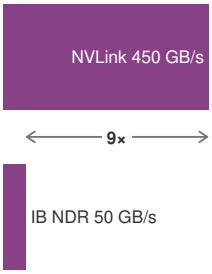
memory usage. Some implementations address this by combining zero-bubble scheduling with activation checkpointing, selectively recomputing certain activations before W rather than storing them across the delay. The interaction between these techniques creates a three-way trade-off among pipeline bubble size, memory consumption, and recomputation overhead, an example of the displacement of overhead (principle 14).

6.5.3 Tensor parallelism

Every pipeline schedule so far keeps whole layers on each device, which is why its traffic is confined to stage boundaries and tolerates moderate interconnect bandwidth. The same property sets its limit. A pipeline cannot help when a single layer's weights or activations exceed one device, and it cannot shorten the time one layer takes, because that layer still runs on one accelerator.

Tensor parallelism splits the weight matrices within each layer instead of assigning complete layers to devices. This operator-level parallelism (also called intra-layer parallelism) enables finer-grained distribution but requires high-bandwidth interconnects for the frequent intra-layer communication it introduces.

Definition 6.9: Tensor parallelism



Tensor parallelism partitions individual tensor operations across devices, commonly through column-parallel or row-parallel weight splits. Communication combines or redistributes the resulting tensor shards as required by the next operation. The Megatron-style forward-pass example below illustrates one such arrangement.

1. **Significance**: The Megatron-LM arrangement developed below uses two AllReduce operations per transformer block in the forward pass, one after attention and one after the MLP. Each reduces a 2-byte activation tensor of $B \times S \times d$ elements, where B counts the sequences in flight through the layer. A ring AllReduce moves roughly $2(N_{\text{TP}} - 1)/N_{\text{TP}}$ times that payload per GPU, and the exchange recurs in every one of the 96 blocks of the GPT-3 shape, with backward adding corresponding exchanges. Whether that traffic hides behind computation depends on the link that carries it, which the arithmetic after the mechanism quantifies. Computing model FLOPs utilization (MFU) requires the complete compute and exposed-communication time, not the bandwidth ratio alone.
2. **Distinction**: Unlike pipeline parallelism, which communicates only at layer boundaries and transfers small activation slices, tensor parallelism synchronizes within every layer via AllReduce. It is therefore sensitive to the per-operation latency of the interconnect and favors a fast communication domain such as NVLink, which can extend beyond one node.

3. **Common pitfall**: Extending tensor parallelism across nodes without checking the transfer budget can erase the compute saving. The reference NVLink specification is approximately 900 GB/s bidirectional, or 450 GB/s per direction; InfiniBand NDR provides 50 GB/s per port, a 9× per-direction gap. These specifications identify a placement risk. Whether the split helps depends on sustained bandwidth, operation size, compute saved, and overlap.

Frequent intra-layer exchanges favor placing tensor-parallel groups within the fastest available communication domain. Pipeline stages communicate at coarser boundaries and can often span slower domains when their transfers fit the schedule. This difference motivates a hybrid that maps each exchange to a suitable fabric tier; it does not impose a universal node boundary for either strategy.

Megatron-style tensor parallelism[6] (Shoeybi et al. 2019) partitions matrix multiplications by alternating column and row splits. In the two-GPU dataflow of figure 6.16, column-parallel splitting partitions the first weight matrix $\mathbf{A} = [\mathbf{A}_1 \mid \mathbf{A}_2]$ to produce local activation slices $\mathbf{Y}_1, \mathbf{Y}_2$ from replicated input $\mathbf{X}$. Row-parallel splitting then partitions the second weight matrix $\mathbf{B} = [\mathbf{B}_1; \mathbf{B}_2]$ so that each GPU computes partial products $\mathbf{Z}_1, \mathbf{Z}_2$ locally. This defers cross-device communication to a single amber AllReduce that reconstructs output $\mathbf{Z}$.

Tensor-parallel exchanges belong on the fast tier, about 9× an NDR port.

Column-parallel linear layers split weights along columns. For input $\mathbf{X}$ and weight matrix $\mathbf{W} = [\mathbf{W}_1 \mid \mathbf{W}_2]$ split across 2 GPUs:

$$\mathbf{Y} = \mathbf{X}\mathbf{W} = \mathbf{X}[\mathbf{W}_1 \mid \mathbf{W}_2] = [\mathbf{X}\mathbf{W}_1 \mid \mathbf{X}\mathbf{W}_2]$$

Each GPU computes its partition independently. The concatenation in the equation is logical, because when the next operation is row-parallel, each output shard remains on its producing device and feeds the matching weight shard without an AllGather. The row-parallel half of the pattern splits weights along rows, $\mathbf{W} = \begin{bmatrix} \mathbf{W}_1 \\ \mathbf{W}_2 \end{bmatrix}$:

$$\mathbf{Y} = \mathbf{X}\mathbf{W} = \mathbf{X}_1\mathbf{W}_1 + \mathbf{X}_2\mathbf{W}_2$$

Each GPU computes a partial sum, and the system pays one AllReduce to combine the partial outputs.

The column-then-row sequence of figure 6.16 embodies the governing architectural invariant. Pairing a column-parallel layer directly with a row-parallel layer allows intermediate activations $(\mathbf{Y}_1, \mathbf{Y}_2)$ to remain strictly local on each GPU, confining inter-device synchronization to a single collective at the end of the block. This locality holds because the intermediate operation between the two projections acts independently on each GPU's column slice without cross-rank data. Megatron applies that pattern twice in each transformer block. In multi-head attention, the QKV projection is column-parallel along the head dimension so that each GPU receives the complete query, key, and value vectors for a disjoint subset of $N_{\text{heads}}/N_{\text{TP}}$

6 | **Megatron-LM**: NVIDIA's 2019 framework that trained an 8.3B-parameter transformer (24× BERT-Large and 5.5× GPT-2 at the time) with only two AllReduce operations per transformer block in the forward pass (one after attention, one after the multilayer perceptron (MLP)). The run reached 76 percent scaling efficiency across 512 GPUs, and its partitioning remains influential in large-scale transformer training.

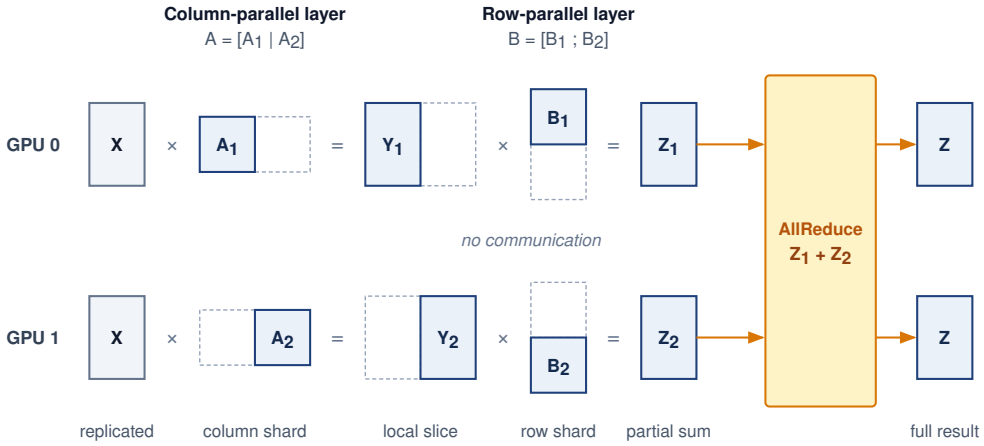


Figure 6.16: Matrix Partitioning under Tensor Parallelism: A Megatron-LM layer pair on two GPUs, read left to right. The first layer (for example, QKV or the first feed-forward layer) is split by columns, $\mathbf{A} = [\mathbf{A}_1 \mid \mathbf{A}_2]$, so each GPU computes its own slice $\mathbf{Y}_i$ of the replicated input's output. The second layer is split by rows, $\mathbf{B} = [\mathbf{B}_1; \mathbf{B}_2]$, so each slice feeds its matching shard on the same GPU without communication. The only collective is the amber AllReduce that sums the partial outputs $\mathbf{Z}_1 + \mathbf{Z}_2$, leaving the full result on both GPUs.

attention heads, computes attention locally for those heads, and feeds the resulting head outputs into the row-parallel attention output projection. In the feed-forward network, the first linear layer is column-parallel, the element-wise nonlinearity applies independently to each coordinate of the local slice, and the second linear layer is row-parallel. The forward pass therefore places one AllReduce after attention and one after the feed-forward network, for two forward AllReduce operations per transformer layer. In the backward pass, the dataflow reverses so that gradients enter each row-parallel output layer without communication, while at the input of each column-parallel layer every GPU computes a partial input gradient from its local weight slice and runs an AllReduce to sum those contributions before the preceding residual connection, adding two symmetric backward AllReduces per layer. Communication volume per transformer layer depends on sequence length S, hidden dimension d, tensor-parallel degree N_{TP}, and batch size B. The batch size is the number of sequences in flight through the layer (the local batch, or the microbatch B_{micro} when the layer also sits in a pipeline). The activation payload is:

$$M_{\text{act}} = B \times S \times d \times s_{\text{elem}}$$

A ring AllReduce transfers approximately $2(N_{\text{TP}} - 1)/N_{\text{TP}} \times M_{\text{act}}$ bytes per GPU, which is close to $2M_{\text{act}}$ for large N_{TP}. For the GPT-3 shape ($S = 2048$, $d = 12{,}288$, 96 layers) with $B = 4$ and FP16, the activation payload is $4 \times 2048 \times 12{,}288 \times 2 \approx 201$ MB.

At $N_{\text{TP}} = 8$ the ring factor is 1.75, giving roughly 352 MB per AllReduce. With two AllReduces in each of the 96 layers, this totals approximately 67.6 GB per forward microbatch. The symmetric backward exchanges bring the total to roughly 135 GB per forward/backward microbatch, before any recomputation. Set against the

computation it serves, that volume is modest on the right link and prohibitive on the wrong one. At the per-layer compute rate of the earlier feasibility check, one such microbatch takes about 2.2 s of forward and backward computation per GPU. Its tensor-parallel traffic takes about 0.3 s on NVLink but about 2.7 s on one InfiniBand port, longer than the computation. The number of microbatches per update and the available overlap then determine the required fabric service rate.

Tensor parallelism eventually reaches a workload-dependent limit because smaller operation shards leave less computation to cover communication. Per-GPU ring AllReduce bytes approach $2\times$ the activation tensor size, while local matrix shapes and collective startup costs change with group size. The useful degree therefore depends on layer shape, microbatch size, and the fast communication domain. Llama 3 405B's TP=8 arrangement within NVLink-connected H100 nodes (Dubey et al. 2024) and node-local groups in other large training systems (Z. Jiang et al. 2024) illustrate a placement choice, not a universal eight-device limit. Tensor parallelism also costs more to adopt than data parallelism. It replaces standard linear layers with column-parallel and row-parallel variants inside the model definition, whereas data parallelism wraps the model externally without modifying its internals.

6.5.4 Sequence and context parallelism

While tensor parallelism partitions weight matrices within linear layers, the memory footprint of large-scale transformer training is increasingly dominated by activations. As models scale their context length from thousands to hundreds of thousands or millions of tokens ($S \geq 32\text{k} \ldots 1\text{M}+$), the activation footprint scales proportionally:

$$M_{\text{activations}} = \mathcal{O}(B \times S \times d \times N_L)$$

for linear, normalization, and residual layers, and $\mathcal{O}(B \times N_{\text{heads}} \times S^2 \times N_L)$ for untiled attention (or $\mathcal{O}(B \times S \times d \times N_L)$ with tiled FlashAttention). At long contexts, activation memory dwarfs parameter storage, exposing the memory capacity gap (principle 2). Two complementary methods address this constraint by sharding along the sequence axis: sequence parallelism (SP) within the tensor-parallel domain, and context parallelism (CP) across dedicated long-sequence process groups.

Definition 6.10: Sequence and context parallelism

Sequence and context parallelism partition the token sequence dimension to reduce per-device activation storage. Sequence parallelism (SP) retains sequence shards during operations such as LayerNorm and Dropout within a tensor-parallel group. Context parallelism (CP) partitions the sequence across a dedicated group and exchanges the information needed for attention, through mechanisms developed below that either pass key/value blocks around a ring or transpose between sequence and head partitions.

1. **Significance**: Long contexts can exhaust activation memory even when sharded model state fits. The relevant limit depends on batch size, layer shapes, attention kernels, and checkpointing. Sequence parallelism divides the targeted activation storage by N_{TP} while preserving the ideal collective payload volume in the decomposition below. Context parallelism distributes sequence-dependent storage; linear context growth ($c \times S_{\text{single}}$, with c denoting the context-parallel degree) is an ideal capacity estimate that still requires communication buffers and computation to fit the budget.
2. **Distinction**: Tensor parallelism partitions weight matrices along hidden dimensions d, whereas context parallelism partitions the sequence axis S. Ring Attention exchanges key/value chunks between devices, while Ulysses uses an AllToAll to transpose between sequence and head dimensions. Both require placement that can service their exchanges within the attention schedule.
3. **Common pitfall**: Assuming context parallelism eliminates the quadratic attention compute complexity. CP distributes the attention computation across devices, reducing *per-device* memory and FLOPs by $1/c$, but the *aggregate* cluster FLOPs for dense self-attention still scale quadratically as $\mathcal{O}(S^2)$.

6.5.4.1 Megatron sequence parallelism

In the Megatron-style arrangement just derived, the column-then-row pairing in figure 6.16 splits the QKV projection and first MLP layer column-wise, and the attention output projection and second MLP layer row-wise. The surrounding LayerNorm, Dropout, and residual operations retain replicated activations across all N_{TP} devices. LayerNorm operates across a token's hidden features, while Dropout and residual addition operate element-wise; none requires another token's features. This token independence permits partitioning the otherwise replicated $B \times S \times d$ activation tensor along its sequence dimension.

Megatron Sequence Parallelism (Korthikanti et al. 2023) eliminates this redundancy by sharding the sequence dimension across the N_{TP} ranks for all non-tensor-parallel operations. Instead of replicating activations, each GPU holds only a $B \times (S/N_{\text{TP}}) \times d$ slice during LayerNorm and Dropout.

This sharding incurs zero additional communication volume. In standard tensor parallelism, the row-parallel matrix multiplication is followed by an AllReduce to sum partial products across ranks. An AllReduce decomposes into a ReduceScatter followed by an AllGather, the identity established among the collective primitives in section 5.4.1:

$$\text{AllReduce}(x) \equiv \text{AllGather}(\text{ReduceScatter}(x))$$

Megatron-SP decouples this collective pair across the transformer block. Following the row-parallel linear layer, a ReduceScatter reduces partial sums while scattering

the resulting activations along the sequence dimension, leaving each GPU with an S/N_{TP} token slice. LayerNorm, residual additions, and Dropout then execute on these local slices with zero cross-device communication. Immediately before the next column-parallel linear layer, an AllGather across the sequence dimension reassembles the complete S tokens required for the weight-partitioned matrix multiplication.

In this ideal payload accounting, standard TP executes two AllReduces per transformer block ($2 \times 2(N_{\text{TP}}-1)/N_{\text{TP}} \times M_{\text{act}}$ bytes), while Megatron-SP executes two ReduceScatter and AllGather pairs ($2 \times [(N_{\text{TP}}-1)/N_{\text{TP}} + (N_{\text{TP}}-1)/N_{\text{TP}}] \times M_{\text{act}} = 2 \times 2(N_{\text{TP}}-1)/N_{\text{TP}} \times M_{\text{act}}$ bytes). The volumes match while the targeted activation storage falls by a factor of N_{TP}. Equal bytes do not imply equal elapsed time, because separating the collectives changes readiness, startup costs, and overlap opportunities.

6.5.4.2 Context parallelism with ring attention versus Ulysses

Megatron-SP shards the S dimension across the N_{TP} devices only outside the attention and MLP blocks; inside self-attention, each tensor-parallel rank still processes the full sequence length S for its local heads, so long-context runs can still exhaust HBM even after sequence parallelism and activation checkpointing. Context parallelism of degree c breaks that ceiling by partitioning the sequence itself across c accelerators throughout the entire block, including attention. Because every query token must still attend to keys and values from other sequence partitions, context parallelism requires cross-partition exchanges, supplied either by ring-based point-to-point transfers, by AllToAll head-sequence transpositions, or by a hierarchical combination of both. The ring method relies on an online softmax that maintains a running maximum and running sum of attention scores as key/value tiles arrive, rescaling earlier partial sums whenever the maximum changes so no device ever materializes the full attention matrix.

Ring Attention (Liu et al. 2023) organizes devices in a logical ring where each GPU holds a query chunk $\mathbf{Q}_i$ of length S/c and an initial key/value chunk $(\mathbf{K}_i, \mathbf{V}_i)$. Computation proceeds in c rounds along the ring. In each round, GPU i computes block attention between its stationary $\mathbf{Q}_i$ and resident $(\mathbf{K}_j, \mathbf{V}_j)$ tiles using an online softmax accumulator. At the same time, it asynchronously transmits $(\mathbf{K}_j, \mathbf{V}_j)$ to ring neighbor $(i+1) \bmod c$ and receives $(\mathbf{K}_{j-1}, \mathbf{V}_{j-1})$ from $(i-1) \bmod c$. After c rounds every query chunk has attended to every key/value tile, yet no device ever stores the full key/value sequence (figure 6.17).

For one sequence with standard multi-head attention, let $n = S/c$ be the tokens per chunk, d the total head width, s_{elem} the bytes per stored element, $R_{\text{peak}}\eta_{\text{hw}}$ the sustained attention FLOP/s, and BW_{link} the one-way transfer rate. Computing both $\mathbf{QK}^T$ and the weighted-value product costs approximately $4n^2d$ FLOPs, while sending $\mathbf{K}$ and $\mathbf{V}$ costs $2nd\,s_{\text{elem}}$ bytes. Ignoring startup, softmax, and overlap interference gives the necessary tile-size estimate:

$$\frac{4n^2d}{R_{\text{peak}}\eta_{\text{hw}}} \geq \frac{2nd\,s_{\text{elem}}}{\text{BW}_{\text{link}}} \iff n \geq \frac{s_{\text{elem}}R_{\text{peak}}\eta_{\text{hw}}}{2\text{BW}_{\text{link}}}$$

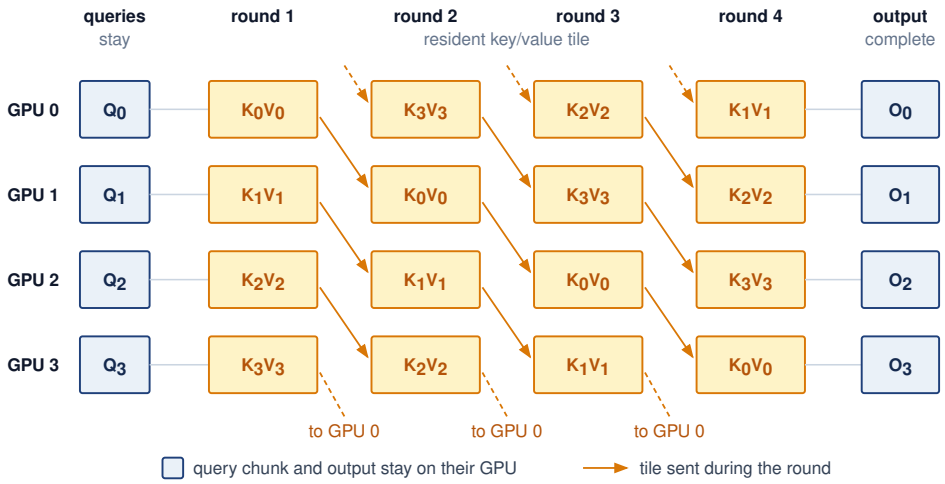

Figure 6.17: Ring Attention Rounds: Context parallelism of degree four on four GPUs. Each GPU keeps its query chunk and, in each round, attends to the key/value tile it currently holds while sending that tile to the next GPU in the ring; dashed arrows close the ring from GPU 3 back to GPU 0. After four rounds every query chunk has seen every tile, so each GPU's attention output for its own queries is complete. The transfer hides behind the block computation only when chunks are long enough, the overlap condition derived next.

This compares computation time with transfer time; HBM bandwidth cannot substitute for $R_{\text{peak}}\eta_{\text{hw}}$. It is an idealized overlap condition, not a guarantee.

For an H100 sustaining half its dense FP16 peak with 2-byte elements, the condition requires chunks of at least about 1,100 tokens per device when KV tiles travel over NVLink, and about 9,900 tokens when they cross one NDR InfiniBand port. A million-token context split across a few dozen devices clears both bounds, whereas splitting a 32K context across many nodes can leave each chunk too short to hide its transfers.

Grouped-query attention changes the transferred KV width, and causal masking changes the tile work. Both require recomputing the two costs. In causal autoregressive attention, a query token can attend only to earlier or current positions, so whenever a rank holding query chunk i receives a key and value chunk from a later sequence position $j > i$, the entire upper-triangular tile is masked out. Under naive contiguous partitioning, rank $i = 0$ holds the earliest tokens and performs useful work only on its own chunk ($j = 0$), sitting idle during the remaining $c - 1$ ring rounds while rank $c - 1$ (holding the final tokens) computes on every round. Because the ring steps synchronously at the pace of the busiest rank, this load imbalance leaves half the cluster's compute cycles idle. Production implementations eliminate this skew with zigzag or striped token partitioning, which splits the sequence into $2c$ sub-chunks and gives each device one early sub-chunk and one complementary late sub-chunk (for example, one chunk from the start of the sequence and one from the end). Every device then holds the same share of unmasked causal tiles in every round of the ring.

DeepSpeed Ulysses (Jacobs et al. 2023) exploits the independence of attention heads rather than circulating tiles along a ring. Each head attends over the whole

sequence without reading any other head's scores, so the attention work can be split by heads instead of by tokens. Outside the attention core, activations are sharded along the sequence dimension (S/c tokens, all N_{heads} attention heads). Before computing self-attention, an AllToAll collective transposes the tensor from sequence-partitioned `[S/c, h, d_head]` to head-partitioned `[S, h/c, d_head]`. Each GPU now holds the full sequence length S, but only a subset N_{heads}/c of attention heads. Each device computes standard local FlashAttention across the full sequence for its heads; each rank owns complete heads, while the kernel handles causal masking locally. A second AllToAll collective transposes the attention output back to `[S/c, h, d_head]`. Ulysses is conceptually clean and reuses single-GPU attention kernels, but requires that the head count be divisible by the context degree ($N_{\text{heads}} \geq c$). Under Grouped Query Attention (GQA), where the key-value head count H_{KV} is smaller, a direct head-sharding implementation requires compatible divisibility and $c \leq H_{\text{KV}}$. Replicating KV heads changes that limit and its communication budget.

The ownership map in figure 6.18 makes this transpose explicit. Unlike the stationary query chunks in figure 6.17, a Ulysses rank receives every token for its assigned heads.

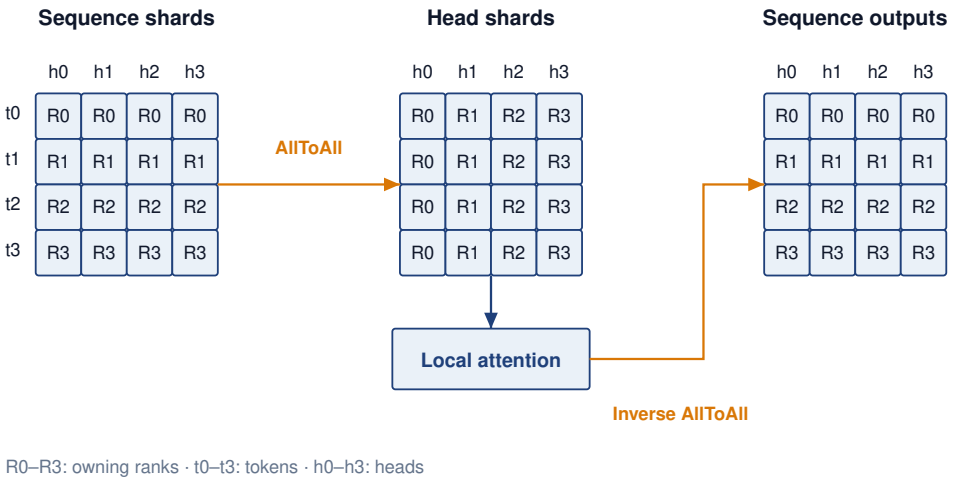

Figure 6.18: Ulysses Ownership Transpose: A schematic with four ranks, four tokens, and four attention heads labels each token–head tile by its owning rank. The first AllToAll changes ownership from token rows to head columns. Each rank computes attention across the full sequence for its head, then the inverse AllToAll restores token ownership for subsequent layers. The head dimension is omitted. This example assumes ordinary multihead attention with compatible divisibility; it does not depict KV-head replication under grouped-query attention.

The exchanged tiles change where attention executes rather than removing its interactions. Head count and KV-head layout constrain this partition even when the activation bytes fit in memory.

A hierarchical configuration can combine head-sequence transposes within a fast domain and ring exchanges between domains. For an eight-device intra-node domain, a Ulysses group satisfies ($c_{\text{intra}} \leq 8$), while a second degree (c_{inter}) determines the ring's inter-node partition. In this example, Ulysses partitions heads

locally and Ring Attention circulates KV blocks across nodes. The arrangement is feasible only if head divisibility, peak memory, link service time, and the overlap condition all hold; hierarchy alone does not prevent fabric saturation.

6.5.5 Expert parallelism (mixture of experts)

Tensor, pipeline, sequence, and context parallelism all partition dense layers that every token traverses, so scaling a dense model's parameter count increases its per-token compute cost in lockstep. MoE architectures (Shazeer et al. 2017) break that lockstep through conditional computation, and expert parallelism distributes the resulting capacity across devices. In an MoE layer, the feed-forward block contains N_{experts} independent feed-forward networks ("experts"), and a gating network selects only a small subset, often top-1 or top-2, for each token. Adding more experts while holding each expert's shape and the selected count fixed expands stored parameters without increasing expert FLOPs per token, trading dense matrix work for routing and all-to-all communication.

In a distributed setting, experts are partitioned across workers, with each rank hosting a disjoint subset of expert networks. One routing cycle across four ranks shows the sequence (figure 6.19). After top-k_{experts} gating selects destination experts, an AllToAll dispatch shuffles tokens across the fabric to the hosting ranks. Expert FFNs then compute locally, and a second AllToAll return routes the processed activations back to the originating ranks to form the gate-weighted sum. The backward pass repeats both exchanges in reverse order, sending output gradients to the ranks hosting the experts and returning input gradients to the ranks that own the tokens. The primary advantage is decoupling model size from per-token compute, which lets parameter count grow within feasible hardware budgets. The primary constraint is the AllToAll communication, which is bandwidth-intensive and sensitive to load imbalance.

Definition 6.11: Expert parallelism

Expert parallelism is the distribution strategy for mixture-of-experts models that places different experts on different devices and routes each token's activations to the devices hosting its selected experts through AllToAll collectives, scaling total parameter count across the cluster without scaling the compute each token consumes.

1. **Significance**: It decouples model capacity from compute budget. For illustration, a trillion-parameter MoE model may activate on the order of 10B parameters per token, so per-token FLOPs remain near those of a 10B dense model while capacity grows roughly 100×. The price is communication structure: every MoE layer requires two AllToAll shuffles per pass (dispatch and combine) whose volume scales with tokens moved times hidden dimension, stressing the cluster's bisection bandwidth rather than any single link.

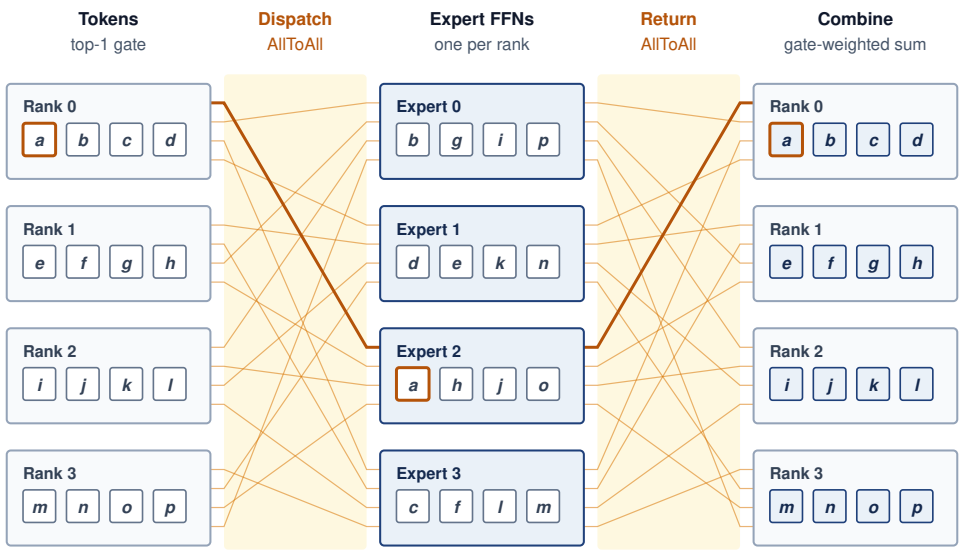

Figure 6.19: Mixture-of-Experts (MoE) AllToAll Routing: Expert parallelism on four ranks, one expert per rank, read left to right and drawn for top-1 routing with one token traced. Each rank's gate picks the top-k_{experts} experts for its tokens; the first AllToAll dispatches every token to the rank that hosts its expert, the experts compute, and a second AllToAll returns the results so each rank can form the gate-weighted sum for its own tokens. In both exchanges every rank may send to every other rank, which is why the pattern stresses the fabric's bisection bandwidth.

2. **Distinction**: Unlike tensor parallelism, which splits dense operations so that every device computes a fraction of every token, expert parallelism is conditional computation. Each device computes only the tokens routed to its experts, which makes both the communication pattern and the load distribution data-dependent rather than fixed by the architecture.
3. **Common pitfall**: A frequent misconception is that experts share work evenly. A hot expert receiving, for example, 3–5× its uniform share can overflow its device's activation buffer while sibling devices idle. Capacity limits and routing penalties are possible responses; a design that retains every assignment must instead accommodate the resulting memory and scheduling demand.

AllToAll dispatch routes token activations to their assigned experts. Consider $N_{\text{experts}} = 64$ experts across 64 GPUs, processing a routing-group batch of $B = 4$ sequences of length $S = 2048$ and hidden dimension $d = 4096$. Under top-1 routing, $B \times S$ tokens each contribute one activation vector. At FP16, the logical dispatch payload is $B \cdot S \cdot d \cdot 2$ bytes, approximately 67 MB; returning expert outputs doubles the forward payload to about 134 MB per block. Local destinations reduce bytes crossing the network, multiple selected experts increase routes, and backward adds gradient transfers. The resulting service time depends on placement and load balance, including in Switch Transformer (Fedus et al. 2022) (up to 2,048 experts) and GShard (Lepikhin et al. 2021).

↩ The terms that set an AllToAll's completion time, from traffic across the fabric bisection to hotspots created by skewed expert loads, are established in section 5.8.

Uniform routing is a useful capacity baseline, not a guarantee. An expert receiving several times its uniform share, the hot expert of the definition above, needs correspondingly more token processing and activation storage. The actual skew depends on the learned router and batch. A hot expert can exhaust its buffer or delay the step while other experts remain underused, coupling memory feasibility to load balance.

One response bounds expert workload with a capacity factor C_{cap}. For top-1 routing, a capacity of roughly $C_{\text{cap}} \cdot (B \times S)/N_{\text{experts}}$ token assignments per expert provides headroom above uniform load. A dropping implementation sends excess tokens past that expert through the residual connection; implementations that retain every assignment instead need memory and scheduling to accommodate the imbalance. An auxiliary load balancing loss can encourage less concentrated routing. Models using more than one expert per token, such as Mixtral 8x7B with top-2 routing (A. Q. Jiang et al. 2024), require a capacity budget that counts all selected assignments rather than reusing the top-1 denominator unchanged.

Sparse routing gives MoE layers the same coordination problem that the embedding tables of Archetype B (DLRM at Scale) pose. In both, which device a token's data must reach depends on the data itself, so load balance cannot be fixed in advance. MoE language models nonetheless remain Archetype A (GPT-4/Llama-3) workloads, because their dense layers still carry the tensor, pipeline, and data-parallel traffic developed above.

6.5.6 Sparse embedding sharding

Expert parallelism places parameters that only some tokens touch. Recommendation models push that sparsity much further. Their parameters are dominated by embedding tables (often 10 TB+) that no single GPU can hold, and their updates are sparse, because a batch of users interacts with only a tiny fraction of the items. Sharding those tables is model parallelism over stored state rather than over computation. The parameter server (PS) architecture, formalized by Li et al. (2014), remains a common way to do it. A parameter server architecture separates workers, which compute gradients, from servers, which store parameters and apply updates.

For dense models such as ResNet or BERT, that separation concentrates traffic, as section 6.3.1.3 noted. With N workers, a server's inbound links must absorb N gradient streams at once. This incast problem is why dense training moved to ring AllReduce, in which every worker sends and receives at its own link rate and the aggregate load spreads across all nodes.

Sparse embedding tables reverse that balance. In a sparse parameter-server design, the tables are sharded across servers, and workers request only rows indexed by their local minibatches. A sparse pull returns those embedding vectors; a sparse push sends updates for the touched rows. This pattern avoids exchanging the complete table, but hot rows, lookup rates, and network contention can still limit throughput. Embedding-sharding frameworks such as TorchRec also support accelerator-based layouts, so sparse partitioning should not be equated with a CPU-only server architecture. Recommendation training at this scale is the volume's

Archetype B (DLRM at Scale) regime, and it differs from the dense running example in which resource binds first.

Whether the shards live on servers or in accelerator memory, each table must be split along some axis. Row-wise sharding partitions embedding tables by row, placing the whole embedding vector of the entity with identifier id on the shard that equation 6.3 selects:

$$s = \text{hash}(\text{id}) \bmod N_{\text{shards}} \tag{6.3}$$

Each shard s contains approximately $N_{\text{entities}}/N_{\text{shards}}$ embeddings, where N_{entities} is the total number of entities and N_{shards} is the shard count. Column-wise sharding instead partitions each embedding vector $\mathbf{e}$ across devices, as equation 6.4 writes it:

$$\mathbf{e} = [\mathbf{e}^{(0)}, \mathbf{e}^{(1)}, \ldots, \mathbf{e}^{(N_{\text{shards}}-1)}] \tag{6.4}$$

Each device stores a slice of every embedding. Hybrid sharding combines both approaches, and the choice among the three depends on lookup patterns and communication overhead (table 6.6).

Table 6.6: Embedding Sharding Strategies: Comparison of row-wise, column-wise, and hybrid embedding placement strategies, balancing lookup locality against network communication collectives and memory load balancing.

Sharding strategy	Lookup pattern	Communication	Best for
Row-wise	Single device per lookup	AllToAll gather	Uniform access patterns
Column-wise	All devices per lookup	AllGather	Hot embeddings
Hybrid	Varies by embedding	Mixed	Production RecSys

The trade-off is locality against load balance. Row-wise sharding keeps each embedding vector whole on one device, while column-wise sharding spreads its dimensions across devices. Both require returning the pieces each consuming computation needs, but placement alone does not prescribe a collective; the runtime can use shard RPCs or collectives according to where inputs and outputs reside. A row-wise layout commonly realizes its lookups as an AllToAll of whole vectors, and a column-wise layout as an AllGather of slices of each vector (figure 6.20). Hybrid placement can replicate or column-partition hot embeddings while row-sharding the cold tail, trading additional storage and communication against concentrated lookup load.

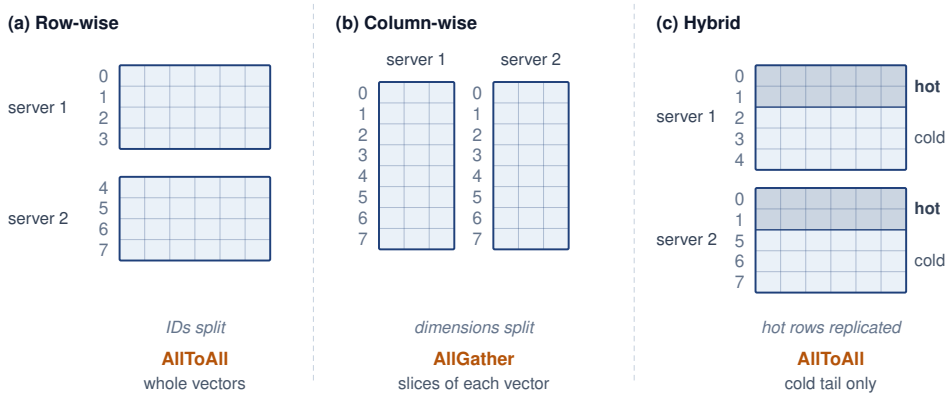

Figure 6.20: Embedding Sharding Strategies: Row-wise sharding places complete embedding vectors on specific servers based on entity ID, requiring a network gather for lookup. Column-wise sharding splits each vector across all servers, allowing parallel local lookups followed by an AllGather, which is efficient for popular "hot" embeddings. Hybrid sharding combines these approaches, using replication or column sharding for hot items and row sharding for the "cold" long tail to balance load and memory.

On accelerators, a row-wise layout turns each training step's lookups into an AllToAll exchange. Every worker sends the indices its minibatch touches to the shards that own them and receives the embedding vectors back, and the backward pass returns gradients for the touched rows along the same routes. The exchange obeys the AllToAll bound of section 5.8, and like MoE dispatch its volume and balance depend on which rows the data touches, so hot rows overload their owners unless the layout replicates or splits them.

Lighthouse 6.1: Archetype B (DLRM at Scale): DLRM vs. LLM scaling

Each workload scales through a distinct mechanism and is bound by a different resource. Dense LLMs scale through data, tensor, and pipeline parallelism, constrained by compute throughput and by the bandwidth that dense gradient and activation collectives need over fabrics such as NVLink and InfiniBand. Sparse recommendation models such as DLRM scale by sharding embedding tables of 10 TB or more across parameter servers or accelerator memory, where aggregate memory capacity, lookup rate, and the latency of many small random accesses dominate. The distinction shapes cluster design, favoring accelerator pods built around high-bandwidth dense fabrics for LLMs and memory-capacity-rich layouts for recommendation systems. This holds whether the embedding shards live in CPU-hosted servers, in accelerator HBM, or in a tiered hybrid that keeps hot rows on accelerators and cold rows in host memory.

6.6 Hybrid Parallelism

The 175B-parameter running example has now exhausted each parallelism family on its own. Data parallelism with ZeRO-3 makes the state fit, but the per-step parameter regather priced in section 6.5 would take about 10× as long as the

computation it serves, while tensor parallelism confined to one 8-GPU node still leaves several hundred gigabytes of training state per device. Because replication and state sharding (section 6.3) distribute examples and storage whereas tensor and pipeline partitioning (section 6.5) distribute layer computation, **hybrid parallelism** composes both families orthogonally: model parallelism splits the architecture so each replica fits available HBM and stays on fast links, while data parallelism scales throughput across multiple model replicas to process 300 billion tokens within calendar limits. This orthogonal composition defines Archetype A training at frontier scale.

Lighthouse 6.2: Archetype A (GPT-4/Llama-3): Physics of 3D parallelism

Archetype A (GPT-4/Llama-3) illustrates the motivation for hybrid parallelism. Parameter count (P) must first be converted to a complete memory budget before comparison with device capacity (M_{device}), while dataset size (D) and the deadline determine the throughput target. Tensor parallelism partitions layer computations within a suitable communication domain; pipeline parallelism assigns consecutive layers to stages; and data parallelism distributes examples from D across replicas. A design combines the dimensions that address its constraints; efficient execution does not require all three in every case.

To see why the combination matters, consider three parallelism configurations for training the 175B model on a 1,024-GPU cluster organized as 128 nodes of 8 GPUs each. The progression from pure data parallelism through tensor and pipeline parallelism makes the efficiency gain concrete.

In Configuration A, pure data parallelism (DP-1024) serves as a communication counterfactual rather than a feasible placement for this model. The FP16 weights alone occupy 350 GB, so an A100 or H100 cannot replicate them; sharding only optimizer states does not change that fact. If replication were possible, all 1,024 ranks would form one data-parallel group, and each rank would participate in an AllReduce of the 350 GB gradient tensor across the InfiniBand fabric. The 15 percent calculation in section 6.4 isolates that communication cost.

Configuration B introduces intra-node tensor parallelism alongside data parallelism (TP-8, DP-128). Within each of 128 model replicas, 8 GPUs use tensor parallelism over NVLink. The corresponding tensor shard from every replica forms one 128-rank data-parallel group, so the layout contains 8 such groups. Each rank AllReduces its 1/8 gradient shard, 43.75 GB rather than 350 GB, and TP communication remains within the fast NVLink domain. This is a communication comparison only. At 16 bytes per parameter each GPU would still hold about 350 GB of training state, so the layout also needs optimizer and gradient sharding across its data-parallel group before it fits. The inter-node AllReduce time drops from 14 seconds to approximately 1.75 seconds. If the compute time is still 2.1 seconds, the unoverlapped efficiency improves to about 54.5 percent. The smaller transfer also fits inside the compute window. The same optimistic

schedule assumed for the data-parallel baseline can therefore now hide its full 75 percent of the transfer behind backward computation, which lifts efficiency to about 83 percent.

Configuration C adds pipeline stages across nodes (TP-8, PP-4, DP-32) so that each of 32 model replicas uses 8-way tensor parallelism within a stage and 4 pipeline stages across nodes. For each of the 8×4 tensor-and-pipeline shard positions, the corresponding ranks from all replicas form one 32-rank data-parallel group. Each rank therefore AllReduces a $350/(8 \times 4) \approx 10.94$ GB gradient shard. Pipeline communication forwards activations between stages and has lower volume than a full-model AllReduce. The trade-off is the pipeline bubble. At the beginning and end of each training step, some pipeline stages are idle while waiting for activations from earlier stages or gradients from later stages. The bubble fraction is approximately $(N_{\text{PP}} - 1)/(m + N_{\text{PP}} - 1)$, so with 4 pipeline stages and 32 microbatches per training step, the bubble wastes roughly 9 percent of compute ($3/35 \approx 8.6\%$). The smaller shard takes about 0.44 seconds to AllReduce, and under the same overlap model as configuration B most of it hides behind backward computation. Charging the bubble against the compute window and adding the remaining exposed transfer gives a predicted efficiency of about 87 percent, a few points above configuration B's 83 percent. The pipeline cuts the data-parallel traffic by another factor of 4, and that saving slightly outweighs the bubble it introduces. Configuration C does not fit memory by itself either. Its training state is about 87.5 GB per GPU, above the 80 GB of an H100. Adding ZeRO-1 across its 32-rank data-parallel group closes that gap. Each GPU then keeps its tensor-and-pipeline slice of weights and gradients but only a $1/32$ share of that slice's optimizer state, about 24 GB in all, which leaves most of the HBM for activations and buffers. ZeRO-1 matches plain DDP's ideal data-parallel byte volume at matching communication widths (table 6.3), but equal bytes do not preserve the overlap schedule. Gradient reduction to owners must precede their optimizer updates, and the updated-parameter AllGather follows those updates. The predicted efficiency remains conditional on that schedule achieving the modeled exposed communication time. TP-8, PP-4, DP-32 with ZeRO-1 passes this simplified persistent-state memory budget; its reduction, update, and parameter-gather readiness must still be priced before accepting the throughput prediction.

Within this comparison's communication model, the configuration that places frequent tensor-parallel exchanges in the fast NVLink domain, pipelines across nodes, and leaves only small data-parallel gradient shards for InfiniBand has the best predicted efficiency. Peak memory, kernel shape, and scheduling still need verification before that prediction becomes a runnable design. The infrastructure hierarchy therefore dictates the parallelism hierarchy. Here, hierarchy-aware parallelism means matching exchange requirements to measured communication domains rather than choosing each degree independently.

Definition 6.12: Hierarchy-aware parallelism

Hierarchy-aware parallelism is the strategy of mapping different parallel execution modes to the physical bandwidth tiers of the cluster.

1. **Significance**: It places high-frequency synchronization (for example, tensor parallelism) on fast links such as NVLink, while assigning lower-frequency exchanges (for example, data parallelism) to slower tiers when their transfers fit the schedule. This alignment can improve scaling efficiency (η_{scaling}) by reducing exposed communication time (T_{comm}) and latency (L_{lat}); the gain depends on readiness, contention, and available overlap.
2. **Distinction**: Unlike uniform parallelism, which treats all node-to-node links as equal, hierarchy-aware strategies respect the bandwidth cliffs between die, node, and rack boundaries.
3. **Common pitfall**: A frequent misconception is that any model can be sharded across any number of nodes. In reality, if the hierarchy mapping is wrong (for example, sharding a large tensor across a slow inter-rack link), the communication time will dwarf the compute time, making the scale-out useless.

The dependence runs both ways, because a parallelism configuration also determines which traffic the fabric must carry. In the TP-8, PP-4, DP-32 layout, tensor reductions stay within each fast local domain, pipeline traffic crosses neighboring stages, and data-parallel groups synchronize corresponding shards across replicas. Rail-optimized and hierarchical fabrics can exploit that structure, but a workload mix that adds expert AllToAll traffic changes the global bandwidth requirement. Infrastructure planning must therefore evaluate the anticipated communication groups together rather than optimizing the fabric for a single layout.

↩ Rail-optimized fabrics, which cable each GPU slot position to its own rail switch, are established in section 3.5.3.

6.6.1 The 3D training loop

A 175B-parameter model trained with 3D parallelism can be traced on a fleet configured with tensor parallelism (TP) of 8 GPUs, pipeline parallelism (PP) of 16, and data parallelism (DP) of 128. The term names the coordinated composition of data, pipeline, and tensor parallelism introduced with figure 6.2. This configuration uses 16,384 GPUs (8 GPUs $\times$ 16 $\times$ 128) organized into a hierarchy of bandwidth domains. That is sixteen times the 1,024-GPU reference cluster, so every level of the hierarchy is exercised even though parameter count alone would not require all three dimensions.

The training step begins at the data-parallel level. Each of the 128 model replicas receives a distinct slice of the global batch. Within each replica, the model is split across 16 pipeline stages (nodes), with microbatches flowing sequentially from the embedding layer on Node 0 to the loss calculation on Node 15. At the finest granularity, within each node, the 8 GPUs fuse into a single "super-accelerator" via TP. The transformer matrix multiplications are split across these devices; column-

and row-parallel pairs retain local intermediate shards and exchange partial results at the reduction points already derived. For a 175B-scale hidden dimension, the activation payload is roughly 201.3 MB. The resulting tensor-parallel traffic is about 4.2 GB per pipeline stage per microbatch in the forward pass, or 8.5 GB including the backward pass. Across the full 96-layer replica, the forward tensor-parallel traffic is about 67.6 GB. This traffic is the highest-intensity in the system, but its exposed latency can remain small relative to compute because the chips communicate over 300 GB/s–450 GB/s of local bandwidth per direction.

The backward pass exposes dependencies between parallelism dimensions. Nodes exchange activation gradients point-to-point, roughly 201.3 MB per microbatch per stage boundary in this example. A smaller payload still stalls a stage if it arrives after the stage needs it. Data-parallel synchronization creates another dependency. Although full-model gradients occupy about 350 GB, each data-parallel group exchanges only the corresponding tensor- and pipeline-parallel parameter shard. Gradient bucketing groups ready gradients as backward computation proceeds. Which exchange limits the step depends on its readiness, service time, and overlap; data parallelism is not necessarily the final bottleneck.

↩ Bucket fusion, which groups gradients that become ready together into larger reductions so communication can begin during backpropagation, is established in section 5.10.3.

The architectural imperative is *bandwidth matching*, in which each exchange's startup and transfer time must fit its available compute or overlap interval. In this mapping, frequent TP exchanges use the NVLink domain (300 GB/s per direction or higher), while PP transfers cross nodes and DP reductions overlap backward computation. Accumulation can enlarge the compute interval between DP synchronizations, subject to the global-batch constraint. An infeasible mapping leaves part or all of the 16,384 GPUs fleet waiting. Comparing service time with the schedule completes the feasibility check introduced in section 6.2.1.

6.6.2 Hybrid-parallelism worked example

Applied to physical infrastructure, bandwidth matching turns cluster design into a placement problem, and memory capacity per device (80 GB–80 GB) bounds every placement. For the 3D training loop's layout on 16,384 GPUs, built from 8-GPU NVLink nodes, this reasoning leads to a concrete placement. Fix tensor parallelism at $N_{\text{TP}} = 8$ so the bandwidth-heavy matrix-multiplication collectives stay within one 8-GPU node. Map pipeline parallelism across nodes in the same high-bandwidth rack or island, here $N_{\text{PP}} = 16$, with $N_{\text{PP}} = 8$ as the alternative when the per-device memory budget allows. Use data parallelism for the remaining scale-out dimension across pods. The result is not a generic rule but a consequence of matching each traffic pattern to the cheapest fabric tier that can carry it. With the placement fixed, the next question is whether the static model state fits inside each accelerator's HBM budget.

The memory budget for a 175B model must include every persistent training component. Under the mixed-precision Adam convention used here, each parameter has FP16 weights and gradients, an FP32 master weight, and two FP32 optimizer moments, totaling 16 bytes before activations and workspaces. With tensor parallelism degree 8 alone, these components occupy 350 GB per device, exceeding H100-class capacity. Adding 16 pipeline stages spreads that state across

the product of the two degrees, yielding 21.9 GB per device under even partitioning. A budget that counts only weights and optimizer moments, about 13.7 GB per device here, understates this total. Activation peaks, layer imbalance, and communication workspaces must fit in the remaining memory before this configuration is feasible.

Once the configuration fits in memory, its traffic still follows the same tiers, and each data-parallel group reduces only its tensor-and-pipeline shard of the 350 GB gradient buffer once per update. Gradient bucketing overlaps that reduction with backward computation, so its exposed cost depends on the computation remaining before the optimizer needs the reduced shard.

The last cost is scheduling rather than bandwidth, because a pipelined model is only efficient when enough microbatches are in flight to keep all stages busy. This remaining cost is the pipeline bubble developed in section 6.5.2. Applying its bubble fraction $\frac{N_{\text{PP}}-1}{m+N_{\text{PP}}-1}$ to this hybrid layout, $N_{\text{PP}} = 16$ stages with $m = 32$ microbatches waste $\frac{15}{47} \approx 31.9\%$ of theoretical compute capacity, nearly one-third. Configuration C's 4 stages at the same microbatch count waste roughly 9 percent. The deeper pipeline is chosen at this scale for two reasons. Its 16 stages spread the full training state to about 21.9 GB per device without optimizer sharding. Filling 16,384 GPUs with configuration C's 32-GPU replicas would instead need 4× as many data-parallel replicas, which multiplies the global batch $N_{\text{DP}} \times m \times B_{\text{micro}}$ by the same factor at the same per-replica schedule. The shallow pipeline spends global batch; the deep one spends bubble. The 1F1B scheduling that reclaims activation memory, and the larger microbatch counts it makes practical, drive the bubble fraction down asymptotically. Every added microbatch also enlarges the global batch, so the bubble target must be reconciled with the critical-batch constraint from section 6.4.6.

The Blackwell reference shows how a wider fast communication domain changes 3D parallelism choices. NVLink 5 provides 1.8 TB/s of bidirectional bandwidth per GPU, twice the Hopper reference's capacity, which shortens the transfer term for a fixed payload but does not reduce message startup latency. Larger tensor-parallel (N_{TP}) groups, such as $N_{\text{TP}} = 16$ or $N_{\text{TP}} = 32$ across nodes, remain subject to topology and local-kernel efficiency. For a 1 trillion-parameter model, one candidate uses $N_{\text{TP}} = 16$ across two 8-GPU nodes joined by NVLink Switch and $N_{\text{PP}} = 8$. Relative to the Hopper layout's $N_{\text{TP}} = 8$ and $N_{\text{PP}} = 16$, this preserves the model-partition product while halving stage count, and the bubble must be recomputed from the new stage and microbatch counts rather than assumed to halve. The 10 TB/s internal link joins Blackwell's two dies behind one logical GPU, so those dies are not separate tensor-parallel ranks. Improving local bandwidth shifts pressure outward. Once intra-node exchanges bind less, the inter-node fabric that carries pipeline and data-parallel traffic, together with any expert AllToAll service, becomes the term to check against the next tier. The same placement constraints can be made operational through design-space search.

Example 6.1: Automated design space search

Scenario: An engineering team schedules a 175B-parameter model across 8,192 H100 GPUs (80 GB HBM each), eight times the 1,024-GPU reference cluster so that the pipeline and data-parallel degrees both have room to vary. The team navigates the multi-dimensional 3D-parallelism search space (TP $\times$ PP $\times$ DP).

Diagnosis: Candidate configurations must fit within 80 GB HBM and satisfy the modeled communication budget. The search evaluates TP $\times$ PP $\times$ DP factorizations and selects TP=8 GPUs, PP=8, and DP=128 as the best predicted MFU among configurations feasible under its assumptions. That result is a candidate for measurement, not proof of the best attainable runtime.

Systems lesson: This search favors TP=8 GPUs within the reference topology's fast domain and PP=8, with 36.4 percent projected MFU. The result balances memory, local computation, transfers, and pipeline idle time within the model. A different topology, microbatch schedule, or kernel efficiency can change the preferred factorization.

Adjusting any one dimension shifts the pressure onto the other two, making the factorization TP $\times$ PP $\times$ DP a tightly coupled system rather than three independent knobs. A projected MFU such as this search's still needs comparison with measured execution, and published runs report MFU well below peak that can fall as the same model moves to more GPUs (figure 9.2 in section 9.2.2).

Checkpoint 6.4: Hybrid 3D parallelism

Verify your understanding of how parallelism strategies combine:

- ☐ **Dimension roles**: identify which dimension in a TP=8, PP=16, DP=128 configuration partitions operations within each layer inside one node.
- ☐ **Bubble vs. depth**: determine how moving from PP=16 to PP=8 changes the pipeline bubble fraction.
- ☐ **DP vs. PP**: explain the trade-off, with the budget fixed at that layout's 16,384 GPUs, between increasing DP (data parallelism) and increasing PP (pipeline parallelism).
- ☐ **Latency sensitivity**: identify which dimension, TP, PP, or DP, is most sensitive to inter-node latency.

The three configurations and the worked layout tell one story. Pure data parallelism moves the full 350 GB gradient over the slowest tier and reaches only 15 percent scaling efficiency. Keeping tensor parallelism inside the NVLink domain cuts each rank's share of that traffic by the tensor-parallel degree, and pipeline stages cut it again at the price of a bubble. Communication alone does not make a layout feasible, however. Each layout must also hold the full training state, which

is why configurations B and C still need optimizer sharding and why the worked layout adds pipeline depth until the persistent state falls to about 21.9 GB per device. Hybrid parallelism is therefore the joint solution of a memory constraint, a bandwidth hierarchy, and a batch-size limit, and every axis added to satisfy one of them tightens another. Alignment training tests that joint solution hardest, because it asks one fleet to host several models with different memory and compute profiles at the same time.

6.7 Multi-Model Training for Alignment and RLHF

A cluster partitioned to train a single model cannot run post-training alignment in place, because reinforcement learning from human feedback (RLHF) coordinates up to four distinct models inside a single training step. In proximal policy optimization (PPO), an active policy generates responses token by token, a preference-trained reward model scores them, a frozen reference copy constrains policy drift, and a learned value model estimates expected returns to guide the gradient update. Those roles carry sharply different memory footprints and alternate between memory-bandwidth-bound autoregressive generation and compute-bound backward passes. Direct preference optimization (DPO) sidesteps online generation and drops the separate reward and value models, trading live exploration for a simpler two-model loop. Designing an alignment cluster therefore starts by tallying which models, states, and execution phases must coexist on the fleet.

6.7.1 The multi-model coordination problem

Holding four models in accelerator memory at once multiplies the static state budget before a single prompt is even decoded, and only two of those models ever run a backward pass. In PPO (Schulman et al. 2017), as used in InstructGPT-style systems (Ouyang et al. 2022), the four roles differ sharply in execution mode and memory burden (table 6.7). In figure 6.21, the policy π_θ generates responses for scoring by the frozen reference and reward models and evaluation by the value model M_{value}. The penalized reward ($r - \beta_{\text{KL}}\,\text{KL}$) subtracts a Kullback–Leibler divergence penalty, weighted by a coefficient β_{KL} unrelated to link bandwidth β, to discourage drift from the reference. Generalized advantage estimation (GAE) combines rewards and value estimates to judge how much better a response was than expected. Those estimates guide policy updates; the value model learns to predict returns, the cumulative discounted reward that follows each generated token. Reference and reward models remain forward-only in this loop, and shared-backbone implementations can combine roles without changing their distinct responsibilities.

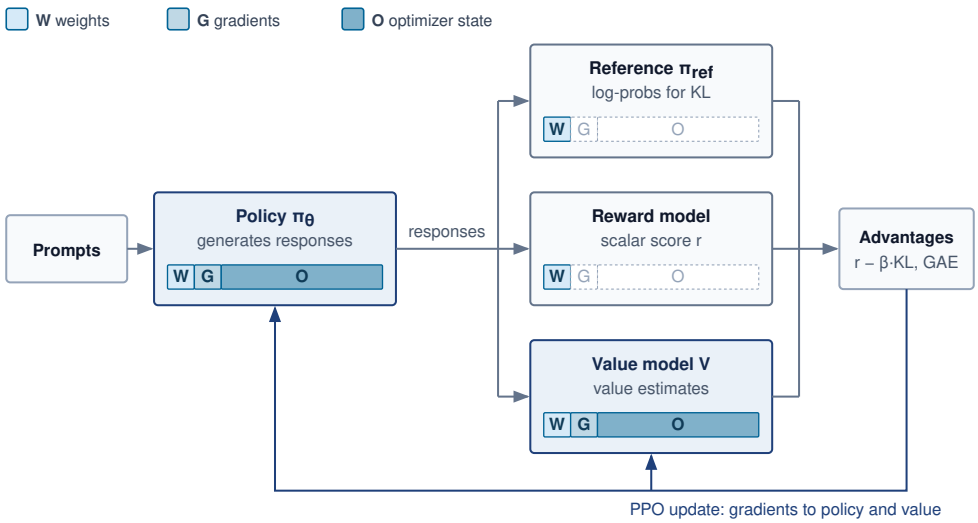

Figure 6.21: One PPO-Style RLHF Step: The policy generates responses to a batch of prompts. The frozen reference model supplies log-probabilities for the KL penalty, the frozen reward model supplies a scalar score, and the trained value model supplies value estimates. The penalized reward and value estimates form advantages, which update the policy and value models. Blue cards carry gradients and optimizer state; slate cards run forward passes only and hold weights alone, as each card's weight, gradient, and optimizer-state strip shows; strip widths follow the 2, 2, and 12 bytes per parameter of mixed-precision Adam, unlike the equal-width columns of figure 6.7. That asymmetry drives placement.

Table 6.7: RLHF Model Coordination Roles: PPO-style RLHF coordinates models with different execution modes and memory footprints, so placement decisions must separate trainable policy and value state from inference-only reference and reward state.

Model	Role in PPO-style RLHF	Execution mode	Memory burden
Policy Model	The model being aligned and optimized.	Training mode with gradients, optimizer moments, and activations.	For a 70B-parameter model in mixed precision with Adam, memory is approximately $70B \times (2 + 2 + 12) = 1{,}120$ GB, the same budget as standard pretraining.
Reference Model	A frozen copy of the pretrained policy that supplies the KL-divergence penalty.	Inference mode only.	FP16/BF16 parameters without gradients or optimizer state; a 70B model needs about $70B \times 2 = 140$ GB, roughly 8× less than the training configuration.
Reward Model	A preference-trained scorer that produces scalar rewards for generated sequences.	Inference mode only.	Often smaller than the policy; a 13B reward model requires approximately 26 GB in FP16, but it must process every generated sequence.
Value Model	The PPO critic that estimates expected future reward.	Training mode, either separate or sharing a policy backbone.	A full-size separate critic can add another 1,120 GB; smaller models or shared-backbone designs reduce this to 200–400 GB.

The aggregate memory demand of the four-model PPO system dwarfs standard pretraining. A naive co-location of a 70B policy, 70B reference, 13B reward, and 13B value model requires approximately 1,494 GB of accelerator memory, before accounting for the KV caches and intermediate activations generated during sequence generation. A key-value (KV) cache stores attention keys and values for previously processed tokens so the policy can generate the next token without recomputing that state. It grows with the number and length of active sequences, creating a temporary memory budget distinct from weights and optimizer state. On H100 GPUs with 80 GB of HBM each, this system requires a minimum of 19 GPUs as an aggregate static-state capacity lower bound, including optimizer state and gradients. This division does not establish a feasible placement, because each phase must also fit its KV or activation peak, workspaces, and uneven shards. Replicated policy groups increase the total state further.

6.7.2 Infrastructure asymmetry between training and inference models

The defining infrastructure challenge of RLHF is not the *total memory footprint* but the *asymmetry* between the models' compute profiles. The policy and value models require full backward passes with gradient computation, activation checkpointing, and optimizer updates, compute-intensive operations that benefit from tensor parallelism and high arithmetic intensity. The reference and reward models, by contrast, perform only forward passes over generated sequences. Their scoring passes do not require optimizer state, and they need not decode token by token. The policy's rollout phase creates the autoregressive generation workload and its KV-cache budget. Separating scoring from generation matters because forward-only execution does not imply a single memory or compute profile.

The asymmetry creates a placement dilemma. Co-location permits devices to serve different phases, but inactive model state can occupy memory needed for the active phase. Dedicated pools allow each role to use a suitable execution configuration, but pools may idle while waiting for another role's output. Separation also adds transfers of generated sequences, scores, and updated policy weights. The design must compare phase utilization and data movement rather than assume that either placement eliminates waste.

The PPO rollout phase introduces autoregressive dependencies absent from the teacher-forced pretraining baseline. The policy generates responses before sequence-level rewards guide its updates. At small active batches, decoding is often memory bandwidth bound because each new token requires another model pass. For a Llama-2-70B-style grouped-query attention policy generating 1,024 tokens for each of 256 active sequences, the per-token cache bytes of equation 10.5 put the generated-token portion at 85.9 GB. That portion alone already exceeds the 80 GB of HBM on one H100, and prompt tokens add KV state as well. This temporary cache must fit alongside the state live during rollout; its lifetime differs from training activations and optimizer state.

↪ The capacity wall this cache imposes on serving systems is developed in section 10.7.1.

RLHF systems address this asymmetry through temporal multiplexing. During the generation phase, the cluster behaves like an inference system: the policy model generates sequences while the reference model computes log-probabilities, and

batching active sequences alongside their KV state determines how much useful work shares each weight read. During the training phase, the same fleet switches back to training mode and computes gradients through the policy and value models using the 3D parallelism configuration of section 6.6, where activation residency and gradient synchronization again govern the schedule. Because PPO alternates between inference-shaped rollout work across four model roles and training-shaped updates, teams often ask how much of that infrastructure overhead can be eliminated by reformulating the alignment objective itself.

6.7.3 Resource requirements for PPO versus DPO

Standard offline DPO (Rafailov et al. 2023) answers that question by removing the separate reward and value models, along with the online rollout phase, from the update loop, reformulating alignment as a supervised loss over offline preference pairs. The policy learns directly from preferred and dispreferred responses using their log-probabilities relative to a frozen reference; because those responses are already in the training data, the update requires neither autoregressive generation nor advantage estimation.

A DPO implementation that retains a resident reference has two model roles, the trainable policy and the frozen reference. For fixed preference pairs and a fixed reference, reference log-probabilities can instead be precomputed, removing that model from the repeated update loop. Offline DPO needs no autoregressive rollout during those updates. Variable lengths still require padding, packing, or length-aware batching, and policy training can use the same partitioning, accumulation, and overlap mechanisms as pretraining.

The infrastructure difference follows from how each method obtains feedback. Offline DPO learns from a fixed preference dataset, so the policy never receives feedback on new responses. PPO-style training scores responses from the evolving policy and can expose behavior the dataset lacks, provided the reward signal is reliable. The generation phase, the reward and value models, and the memory they occupy are the price of that online loop, so the choice is settled by achieved quality per unit of total resource cost.

To make the infrastructure trade-off concrete, consider aligning a 70B policy model using a policy/reference pool of 256 H100 GPUs (80 GB HBM each). PPO's separate reward and value pools sit outside that allocation. The policy is a 70B-class model rather than the 175B reference, a size at which each role's memory budget stays readable while the four PPO roles together still need at least 19 GPUs, more than one node.

Napkin Math 6.9: RLHF infrastructure budget: PPO vs. DPO

Problem: This alignment setup co-locates a 70B policy model with a 70B reference model and, for PPO, uses pools outside the 256-GPU policy/reference allocation for a 13B reward model and a 13B value model. Under 3D parallelism (TP=8 GPUs, PP=4, DP=8), how much memory resides on each

policy GPU, and which separate model pools and generation-phase memory requirements does DPO remove?

PPO memory budget (per-GPU, with TP=8 GPUs, PP=4, DP=8 for policy)

The policy model under 3D parallelism with TP=8 GPUs and PP=4 distributes one replica's 1,120 GB training state across 32 GPUs, yielding 35 GB per GPU. The reference model, requiring only 140 GB for inference, can instead be sharded across an additional 8 GPUs pool outside the policy allocation at 17.5 GB each. It can also be co-located with the policy GPUs at an additional 4.4 GB per GPU (140 GB / 32 GPUs). The 13B reward model adds 26 GB shared across its pool. The 13B value model in training mode adds approximately 208 GB (13B $\times$ 16 bytes/param) across its pool.

Total static memory (one co-located policy + reference replica on 32 GPUs): 35 GB + 4.4 GB $\approx$ 39.4 GB per GPU, leaving $\sim$ 46.5 GB for activations and KV cache. With generation-phase KV caches for a rollout batch containing 256 sequences and 1,024 tokens inside one $TP \times PP$ policy replica, each policy GPU must reserve an additional 85.9 GB/32 GPUs $\approx$ 2.7 GB for its KV cache shard. The remaining $\sim$ 43.8 GB is generation-phase headroom. Once rollout KV state is released, the update phase recovers the 46.5 GB headroom before allocating training activations and other runtime buffers. The phase peaks must be evaluated separately.

DPO memory budget (same parallelism configuration)

The policy model uses the same 35 GB per GPU. The reference model adds 4.4 GB per GPU (co-located). No reward model, no value model, no KV cache for generation.

On the policy GPUs, total static memory is 35 GB + 4.4 GB = 39.4 GB per GPU, identical to PPO's co-located policy/reference footprint. Both have 46.5 GB available before update-phase activations and runtime buffers when PPO releases its rollout KV cache. DPO removes the separate generation peak and the reward/value model pools; the absence of rollout KV state alone does not establish larger update microbatches.

Throughput comparison

PPO alternates generation and parameter updates. If generation consumes 60 percent of an iteration in this illustrative schedule, updates occupy the remaining 40 percent; this time fraction is not MFU. Update-phase MFU must be multiplied by that fraction to report update computation over the whole iteration, using the same allocated hardware denominator. DPO eliminates online generation, but its measured throughput still depends on sequence lengths, reference scoring, parallelism, and memory use. The static-state comparison in table 6.8 is therefore kept separate from these schedule-dependent effects.

Table 6.8: PPO vs. DPO State and Execution Phases: Static-state totals sum one copy of each model across its device pool, including trainable optimizer state and gradients. Data-parallel replication and phase-specific runtime allocations add to these totals; the table does not determine a minimum device count or measured MFU.

Metric	PPO (70B policy)	DPO (70B policy)
Models required	4 (policy, ref, reward, value)	2 (policy, reference)
Static state, one copy of each model	$\sim$ 1,494 GB	$\sim$ 1,260 GB
Device count	Depends on placement and phase peak	Depends on placement and activation peak
Generation phase	Yes (autoregressive)	None
Update throughput	Shares the schedule with generation	No online-generation phase
Data pipeline	Online generation	Static preference pairs

Systems insight: In this 13B reward/value-model scenario, DPO reduces the one-copy static-state budget by 15.7 percent by eliminating the reward and value models. It also removes online generation, but the throughput benefit requires a measured schedule. Infrastructure constraints therefore weigh on the choice between PPO and DPO as much as modeling preferences do. An organization with a limited GPU budget may prefer DPO because it restores the workload to a fixed-data training loop. If the PPO value model is policy-sized rather than 13B, the reduction is larger still, from 2,406 GB to 1,260 GB.

6.7.4 Sequence length variance and batching challenges

The throughput comparison in notebook 6.9 noted that even after DPO removes online generation, realized step time still depends on sequence-length variance. Pretraining often packs documents into fixed-length blocks, such as 2,048 or 4,096 tokens, whereas alignment batches combine prompts and responses whose lengths can span a 10–50$\times$ range within a single minibatch. Those variable lengths directly govern activation residency, padding waste, and load balance across workers.

Length variance creates two interacting problems. Padding every sequence to the longest in a batch can leave most token positions unused. A batch of one 2,048-token sequence and fifteen 128-token sequences, padded to 2,048 tokens, fills only 3,968 of its 32,768 positions. Kernels that execute padded positions therefore spend about 88 percent of their work on padding, while kernels that skip them recover most of that waste. Dynamic batching groups similar lengths to reduce padding, but assignments across workers still need balancing. A worker processing longer sequences can have a larger activation peak and finish later, leaving other workers waiting for the required gradient contributions.

Sequence packing combines short sequences within a fixed-length input, with attention masking that keeps their contexts separate, and adaptive microbatching

sizes each microbatch by token count or predicted memory. Alignment adds a constraint that pretraining lacks. The reduction must keep the objective's own denominator, valid-token counts for a token-mean PPO loss and pair counts for standard DPO (Rafailov et al. 2023), so packing changes layout but not weighting. Balancing token work across workers then remains a performance goal rather than a correctness requirement.

RLHF shows why no single parallelism strategy is sufficient by itself. The policy model may need tensor and pipeline parallelism, the reference and reward models behave like inference services, the value model may require training state, and the rollout data pipeline changes shape from step to step. The procedure that handles this case is the general one, which identifies the binding constraint first and then chooses the parallelism pattern that moves the least data while fitting the required state.

6.8 Parallelism Strategy Comparison

A parallelism strategy is useful only if it moves the binding constraint without creating a larger one. Assembling data, tensor, pipeline, and hybrid partitioning into a coherent decision procedure requires evaluating where each strategy relocates overhead across the cluster's memory and interconnect hierarchy. For a new model, the decisive questions are which memory state fits, how often communication occurs, where the pipeline bubble appears, and which abstraction cost the engineering team can tolerate. Sequence, context, and expert parallelism sit beside the 3D core in table 6.9, and they remain subject to the same batch, memory, and topology constraints.

Table 6.9: Parallel Training Strategies: Data, tensor, and pipeline parallelism form the canonical 3D core. Sequence/context parallelism extends the partition along token positions, while expert parallelism extends it across sparse model capacity. Strategy selection remains an engineering feasibility test: identify the binding constraint, the communication primitive it creates, the placement decision it forces, and the measurement that proves the strategy is helping.

Strategy	Binding constraint	Primary movement	Placement decision	Validation signal
DDP	Model state fits on one accelerator	AllReduce gradients every step	Replicate full model across data-parallel workers	Step time dominated by compute, not synchronization
FSDP/ZeRO	Model state exceeds one accelerator	Gather parameters; ReduceScatter gradients	Size prefetch and reshard windows within peak memory	State plus activations and workspaces fit
Tensor parallelism	One layer or tensor operation exceeds local capacity	Reduce or gather partial layer results	Keep tightly coupled partitions on fast local links	Exposed collective time fits the layer-time budget

Strategy	Binding constraint	Primary movement	Placement decision	Validation signal
Pipeline parallelism	Layer stack fits only when split by stage	Activations and gradients between stages	Balance stages and live microbatch activations	Bubble and peak activation memory meet budget
Sequence/context parallelism	Activations or attention context exceed local capacity	Exchange sequence shards or attention state	Partition long sequences across a low-latency group	Longer context fits without communication dominating
Expert parallelism	Sparse expert capacity exceeds local memory	Route token activations with AllToAll	Balance expert load across a high-bisection group	Expert imbalance and dropped-token rate stay bounded
Hybrid parallelism	More than one constraint binds at once	Multiple collectives on coupled axes	Satisfy divisibility, batch, topology, and failure domains	MFU improves within memory and network budgets

A decision path condenses the table, starting from memory fit and then asking which structure breaks the budget (figure 6.22). Before accepting any branch, check peak memory, global batch, communication service time, and load balance together; bandwidth is a feasibility constraint throughout the decision, not an afterthought.

Identifying the binding constraint comes before choosing an implementation stack, which is why both the strategy comparison and the decision path stay deliberately coarse. Dense large-model training and recommendation-style workloads motivated each of these partitioning strategies. The same constraint logic also reaches the federated edge case (table 6.10), where the bottleneck shifts from accelerator memory and fabric bandwidth to unreliable devices, privacy, and intermittent connectivity. A configuration chosen across these regimes still has to be expressed in software, and the way a framework expresses it decides which of the chapter's budgets the engineer controls directly.

Lighthouse 6.3: Distributed archetype spectrum

Partitioning and coordination choices differ with the system's primary bottleneck:

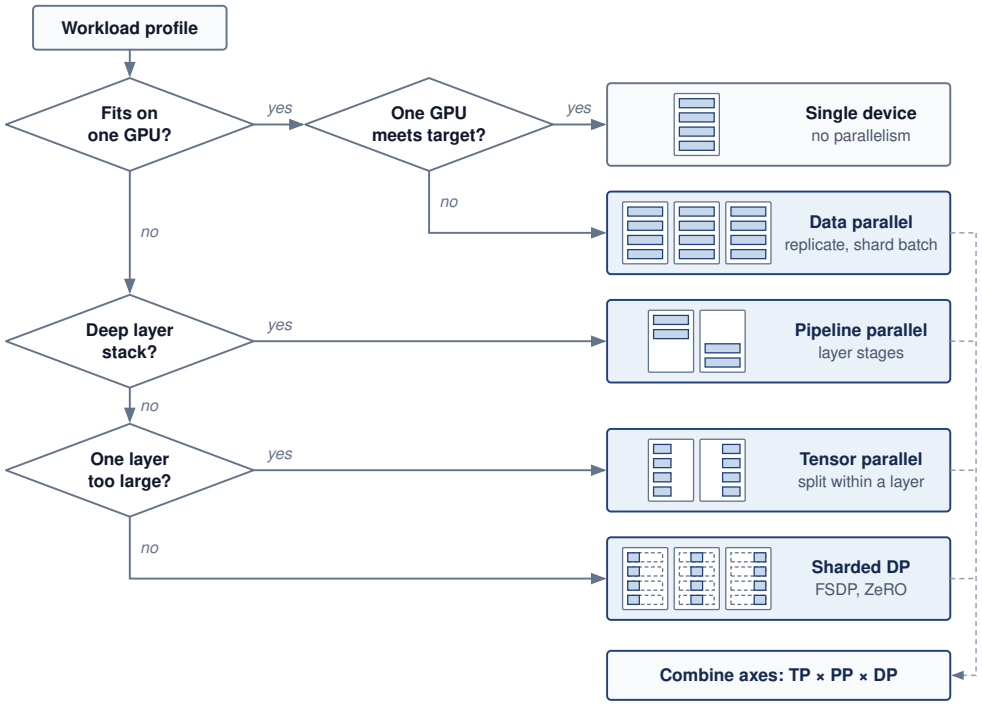

Figure 6.22: Parallelism Strategy Decision Framework: A selection guide that begins with memory fit. For a model that fits on one device, evaluate data parallelism against the throughput target and input-delivery budget; the complete dataset need not fit in accelerator memory. A model that does not fit is routed by the structure that breaks the budget, with sequential depth leading to pipeline parallelism, an oversized single layer to tensor parallelism, and otherwise sharded data parallelism (FSDP/ZeRO). Combine parallelism axes when the workload requires them. Peak memory, global batch, bandwidth, and workload imbalance constrain every candidate.

Table 6.10: Partitioning Strategy by Archetype: Partitioning and coordination choices differ with the dominant bottleneck.

Archetype	Primary partitioning strategy	The logic
Archetype A (GPT-4/Llama-3)	Hybrid 3D parallelism	Combine tensor (width), pipeline (depth), and data (throughput) parallelism to fit roughly 3.5 TB of weights under third-party estimates (OpenAI has not disclosed the parameter count).
Archetype B (DLRM at Scale)	Embedding sharding	Partition massive 10 TB+ tables across parameter servers or accelerator shards; use sparse AllToAll updates.
Archetype C (Federated MobileNet)	Federated learning	The same logic extends to coordinating on-device MobileNet updates across unreliable, privacy-constrained edge devices; section 11.7 develops this regime.

6.9 Frameworks and Runtime Contracts

A TP-8, PP-16, DP-128 layout that passes every feasibility check on paper can still hang at its first collective if two ranks disagree on group membership, or run slowly if gradient buckets become ready in an order the collective runtime cannot overlap. Choosing DDP, FSDP/ZeRO-style sharding, tensor parallelism, or pipeline parallelism is therefore also a decision about which constraints the runtime owns and which constraints the engineer must manage directly. Sparse workloads add a fourth contract, the parameter-server push/pull interface (Li et al. 2014) developed for Archetype B in section 6.5.6.

The training framework defines process groups, gradient buckets, and the point in backpropagation when each reduction becomes ready; the collective runtime maps those reductions onto ring, tree, or hierarchical algorithms. The engineer must choose compatible group membership and bucket order and verify which communication remains exposed on the step's critical path.

Production frameworks expose these same strategies under different names, which makes a translation aid useful when reading their documentation or configuration files. Four widely used stacks name the chapter's strategies differently (table 6.11); the names change between releases, but the partition each one implements does not.

Table 6.11: Framework Names for the Parallelism Strategies: A translation aid, not a ranking. Each entry names the mechanism a framework uses for the partition developed in this chapter; exact class and option names vary across releases.

Strategy	PyTorch	DeepSpeed	Megatron-LM	JAX
Data parallel	DistributedDataParallel (DDP)	DeepSpeed engine, ZeRO stage 0	Data-parallel process groups	Batch axis sharded over a device mesh

Strategy	PyTorch	DeepSpeed	Megatron-LM	JAX
Sharded data parallel	Fully Sharded Data Parallel (FSDP)	ZeRO stages 1–3	Distributed optimizer	Parameter and optimizer state sharded over a mesh axis
Tensor parallel	DTensor tensor-parallel APIs	AutoTP or Megatron integration	Column- and row-parallel linear layers	Sharding annotations on model axes, partitioned by the compiler
Pipeline parallel	`torch.distributed.pipelining`	Pipeline engine	Pipeline schedules (1F1B, interleaved)	User-written stage schedules

The training design therefore determines message size, readiness order, and frequency, while collective algorithms determine how those messages move. No framework abstraction changes those physical costs, so distributed-training efficiency ultimately depends on interconnect bandwidth, memory capacity, synchronization latency, and the useful overlap admitted by the computation graph. Confusing the simplicity of a framework API with exemption from those physical costs produces the recurring engineering mistakes below.

6.10 Fallacies and Pitfalls

↩ Overlap of gradient exchange with backpropagation, the lever that takes communication off a step's critical path, is established in section 5.10.

Even when a framework makes switching from single-node DDP to multi-node execution a one-line configuration change, the underlying physics still governs the step time. In the GPT-2 scale-out of notebook 6.1 and notebook 6.2, moving the same model from one NVLink node to four Ethernet-connected nodes quadrupled the GPU count but cut parallel efficiency from 99.4 percent to 27.9 percent. The following misconceptions generalize that error, each treating one term of the step-time accounting as if it were the whole budget.

Fallacy: *Linear speedup is achievable with sufficient engineering effort.*

Amdahl's Law limits speedup when a fixed serial component remains exposed. Synchronous gradient aggregation creates an update dependency, but some of its work can overlap backward computation. As section 6.4 shows, $\eta_{\text{scaling}} = 1/(1+N(T_{\text{comm}}(N)+T_{\text{sync}}(N)-T_{\text{overlap}})/T_{\text{compute}})$ depends on the exposed overhead relative to useful compute as N changes. A 1,000-GPU allocation therefore does not by itself justify a 1,000$\times$ speedup forecast. Local kernel efficiency, memory feasibility, communication, and convergence must be evaluated against the specified baseline. Linear scaling is a result to demonstrate for an operating range, not a return guaranteed by device count.

Pitfall: *Optimizing MFU without considering scaling efficiency.*

A single-node MFU measurement does not predict fleet throughput by itself. For a fixed workload and hardware peak convention, scaling efficiency compares measured distributed throughput with ideal replication of that single-node baseline.

Multiplying the baseline MFU by this scaling efficiency gives distributed MFU; multiplying an already measured distributed MFU by the same scaling efficiency counts communication and synchronization losses twice. The chapter's own numbers make the difference concrete. A single node running at 50 percent MFU, scaled with the 83 percent scaling efficiency of the overlapped TP-8 layout in section 6.6, delivers about 41 percent MFU across the fleet. A planner who measures that 41 percent on the full cluster and then applies the 83 percent again would budget for about 34 percent and buy capacity the job does not need. Capacity planning must state the device count and measurement window for each metric. Checkpointing, recovery, and replay require additional accounting only when those losses fall outside that window. Useful goodput must count retained model progress rather than repeated work, under the accounting boundaries of section 9.2.3.

Fallacy: *Hyperparameters tuned on small clusters transfer directly to large-scale training.*

Engineers tune hyperparameters on 8-GPU workstations then deploy to 256-GPU clusters expecting identical behavior. At scale, convergence behavior changes. The most sensitive hyperparameter is learning rate. As section 6.3 explains, global batch increases with GPU count when local batch and accumulation depth remain fixed, so the learning-rate schedule must be revalidated. The linear scaling rule of section 6.4.5, which the one-hour ImageNet run established, suggests $\eta_{\text{new}} = \eta_{\text{base}} \times (B_{\text{new}}/B_{\text{base}})$, but this relationship holds only within bounds. As models scale, they eventually encounter the critical batch size of section 6.4.6, where adding more data per step yields diminishing returns in convergence.

Beyond the critical batch size, this relationship breaks down in a model-, data-, and optimizer-dependent way. A team that takes a small-cluster learning rate, multiplies it mechanically with GPU count, and jumps directly to a much larger global batch may see lower final quality or slower sample efficiency even though hardware throughput improved. Warmup schedules, weight decay adjustment, layer-wise optimizers such as LARS/LAMB, and careful momentum tuning can recover accuracy in some regimes, but require systematic experimentation at target scale. Organizations that skip these scaling studies waste thousands of GPU-hours on suboptimal runs.

Pitfall: *Adding GPUs to data-parallel jobs without modeling communication.*

More GPUs improve time to target only if the gain in processing rate outweighs communication overhead and any additional sample use. With fixed local batch size, adding data-parallel workers increases the global batch; fixing the global batch instead reduces local work and can expose more communication. The critical-batch analysis in section 6.4.6 supplies a workload-dependent statistical guide, not universal GPU-count or model-size thresholds. Compare complete learning curves and cost at the same target quality before committing to a larger allocation.

Fallacy: *Memory capacity alone determines the parallelism strategy.*

A model that exceeds device capacity needs a feasible partition, but memory fit does not select the fastest one. Tensor parallelism exchanges partial results within layers, while pipeline parallelism transfers stage-boundary activations and intro-

duces scheduling bubbles. Their relative cost depends on layer shapes, microbatch count, placement, and overlap. Compare complete training-state and activation budgets together with measured time to target; an unsupported throughput percentage or a weights-only fit cannot settle the choice.

Pitfall: *Applying FSDP or ZeRO without measuring efficiency trade-offs.*

Engineers adopt FSDP universally after reading that it "reduces memory and enables larger models." Sharding trades memory capacity for communication overhead: full-shard FSDP gathers parameters before layer execution and reduces gradient shards during backward, with another parameter gather when the forward pass resharded them. The relevant comparison begins with the complete training-state budget. Under the mixed-precision Adam convention established here, the 7B worked example exceeds single-device capacity before activations, so standard DDP cannot fit that state on an A100-80 GB. A weights-only fit does not establish a feasible training baseline. When the complete state, activations, and workspaces fit without sharding, DDP can avoid the repeated gathers; when they exceed the 80 GB capacity, the comparison must include a feasible alternative such as sharding or offload. FSDP provides value when it enables training at all or when the larger local batch it permits offsets its communication cost. ZeRO-Offload extends capacity through CPU memory but adds transfers of its own. The decision therefore requires measuring peak memory and exposed communication for the same workload and optimizer contract.

Fallacy: *Parallelism overhead is roughly constant regardless of model size.*

Engineers benchmark parallelism strategies on convenient small models then apply those conclusions to large-scale training. For dense transformers at fixed tokens per update, computation and gradient bytes both grow roughly proportionally with parameter count, as the earlier scaling analysis established. Larger parameter count alone therefore does not imply a better computation-to-communication ratio. Architecture, sequence length, local batch size, partition degree, and kernel efficiency determine how much useful work each rank performs; gradient representation and process-group membership determine how much it communicates. A larger model can also require a different partition that introduces new layer collectives or pipeline bubbles. Reliable strategy selection holds the workload and target quality explicit, then recomputes memory fit, local compute time, communication volume, and the available overlap window at the target scale. A small-model benchmark becomes transferable evidence only when those governing terms remain comparable.

Pitfall: *Treating scaling efficiency as a property of the hardware alone.*

A vendor benchmark might report 85 percent scaling efficiency at 1,024 GPUs, and procurement teams then plan capacity as if that number were a cluster constant. Scaling efficiency is a joint property of four things: the workload's communication-to-computation ratio, the parallelism strategy (data, pipeline, tensor, hybrid), the network topology (fat-tree vs. torus vs. dragonfly), and the software stack (NCCL version, kernel fusion, overlap quality). Reference numbers from dense large-

language-model benchmarks transfer poorly to other workloads and fabrics. They may overstate scaling for graph neural networks with irregular communication and for embedding-heavy recommendation models, whose AllToAll embedding exchanges and many small random lookups load the fabric differently from dense gradient AllReduce (section 6.5.6). They also say nothing about a commodity-Ethernet placement like the GPT-2 scale-out, which lost most of its parallel efficiency on leaving the node. Capacity planning should use measured scaling on the target workload, not a vendor hero benchmark.

Fallacy: *Gradient accumulation is free.*

Gradient accumulation can reduce synchronization from every microstep to once per window of k microsteps, eliminating $(k-1)/k$ of those synchronization events when the implementation defers reduction. The saving has costs. A resident gradient buffer remains live throughout the accumulation window; for the 7B model, the FP16 buffer occupies 14 GB. Retaining graphs across microsteps or increasing the local batch size can add activation pressure. Accumulating eight microsteps makes updates $8\times$ less frequent per processed microstep, but wall-clock spacing also depends on the communication saved. Larger effective batches can change convergence, and narrow accumulation formats can lose small contributions or overflow. The dtype, loss normalization, and reduction schedule must therefore be validated at the intended batch size. Accumulation trades communication frequency against update spacing, memory residency, and numerical stability.

6.11 Summary

Scaling laws keep pushing frontier training budgets past what one machine can hold or finish in time, and distributed training is how the fleet absorbs that growth. It confronts the scaling wall, the workload-dependent operating point beyond which communication and coordination can consume the compute time saved by adding accelerators. A feasible design must preserve the intended optimization update while satisfying model-state, activation, batch-size, and interconnect constraints. Hardware throughput alone is insufficient; the comparison must also account for time to the target model quality.

Each partition relocates cost along the C^3 axes. Data parallelism divides compute across replicas and pays in communication, the gradient aggregation whose exposed share set the scaling efficiency of the 175B communication example. Tensor parallelism divides work inside a layer and pays in communication on the critical path, which confines it to a fast domain. Pipeline parallelism divides layer depth and pays mostly in coordination, the fill and drain bubble that only more microbatches, better balance, or a smarter schedule can shrink. The 3D parallelism cube in figure 6.2 unites these trade-offs in one coordinate space ($N_{\text{DP}} \times N_{\text{PP}} \times N_{\text{TP}}$). A feasible point must satisfy peak memory and global-batch constraints as well as communication and coordination budgets.

Sharding and model partitioning make different parts of the training state fit, while synchronization and precision policies determine whether the resulting updates remain useful. Hybrid layouts compose these choices within the bandwidth

hierarchy. The alignment workload extends the same reasoning to multiple models and alternating generation and update phases, where peak memory depends on which state is live together.

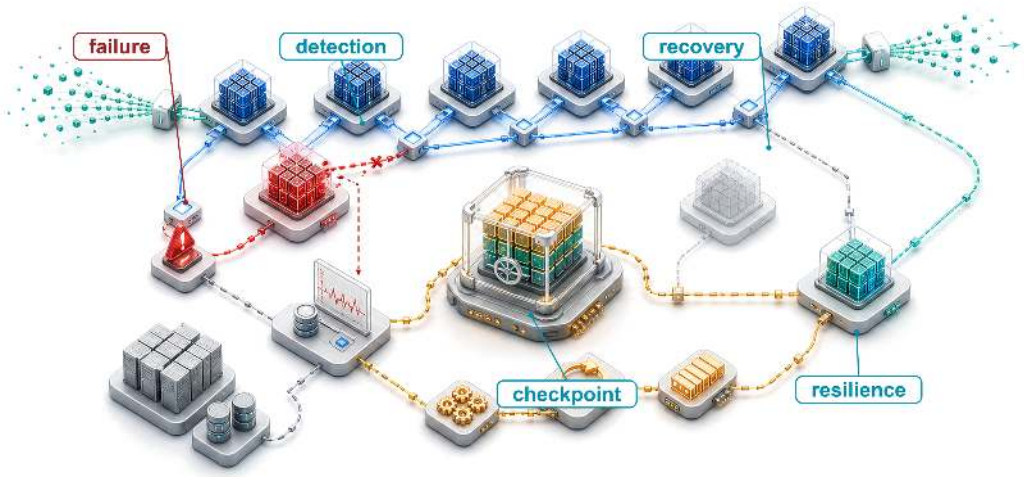
The chapter's strategies are complementary dimensions of one design space rather than alternatives. Systems such as Megatron-LM map tensor, pipeline, data, and expert exchanges to the communication domains that can carry them, and that matching is what delays the communication-bound regime as the fleet grows. The workload archetypes weight those dimensions differently. Archetype A (GPT-4/Llama-3) combines dense-model partitioning with state sharding and, at long contexts, sequence or context partitioning. Archetype B (DLRM at Scale) shards sparse embedding state and pays in lookup traffic rather than layer collectives. Archetype C (Federated MobileNet) moves the coordination problem onto unreliable edge devices. In each case the binding constraint, not the archetype label, selects the configuration.

Key Takeaways: Parallelism relocates overhead

- **Splitting work moves the bottleneck**: Distributed training does not make the underlying computation smaller; it converts memory pressure into communication volume, synchronization delay, or idle pipeline time (principle 12). The winning strategy is the split that sends overhead to the least binding part of the fleet.
- **The slowest worker sets synchronous step time**: Under bulk-synchronous updates every step waits for its last required contribution, so a rare per-worker delay becomes a near-certain per-step delay at thousands of workers. Stale and asynchronous protocols trade that waiting for staleness, which can cost extra steps to the same target quality.
- **Throughput must serve convergence**: Larger global batches can improve hardware efficiency while yielding diminishing progress per sample. Compare time to the same target quality, and treat the critical-batch estimate as a workload-dependent guide for selecting batch size and update schedules.
- **Sharding buys memory with messages**: ZeRO and FSDP partition optimizer state, gradients, and parameters (principle 2), reducing replicated storage. Peak memory must still include activations, temporary gathers, and workspaces; exposed ReduceScatter and AllGather costs determine whether the capacity gain also improves throughput.
- **Tensor parallelism needs a fast domain**: Splitting operations inside layers creates frequent communication on the dependency path. Place those groups on links with sufficient bandwidth and low latency; the relevant boundary is the communication domain, which may span nodes, rather than the server enclosure.

- **Pipeline parallelism trades bytes for bubbles**: Layer staging reduces communication frequency, but fill and drain slots leave accelerators idle (principle 10). Microbatching with $m \gg N_{\text{PP}}$ is the mechanism that turns model depth into throughput rather than pipeline slack.
- **Hybrid layouts are joint decisions**: Combine only the partitioning and sharding strategies needed to satisfy the workload's constraints (principle 14). Model divisibility, batch size, peak memory, communication groups, and failure domains must form one feasible configuration; improving one axis can expose a limit on another.

The displacement of overhead (principle 14) makes a feasible partition the beginning of the design problem. A memory-saving split is useful only if its communication and schedule still meet the run's time-to-quality budget. Every mechanism in this chapter shrinks the per-device compute term T_{compute}/N or the per-device training state, and pays for it in $T_{\text{comm}}(N)$, in $T_{\text{sync}}(N)$ through barriers, stragglers, and pipeline bubbles, or in lost overlap. In C^3 terms, no partition removes the overhead of scale; it only relocates that overhead among compute, communication, and coordination. The engineering judgment is therefore to compare complete configurations, including their exposed dependencies, rather than optimize each parallelism axis independently.



What's Next: From logic to resilience

The fleet now has its traffic patterns (communication) and its logic (parallelism). Every configuration in this chapter, however, assumed that all ranks in each communication group arrive, on time and with correct data. A collective is not a barrier, but each dependent consumer still waits for every contribution, so one crashed node, failed link, or GPU that slows down without failing stalls the whole synchronous group. A contribution corrupted in transit is reduced into every replica's update. Across thousands of accelerators such events stop being rare. Chapter 7 begins by computing how often they arrive, then builds the checkpointing, recovery, and elastic training that keep the computation making progress on imperfect hardware.

7

Fault Tolerance

Purpose

Why does scale transform hardware failure from rare exception to routine condition that systems must absorb continuously?

A single accelerator can run for years between hardware failures. A thousand accelerators turn that same component risk into failures every couple of days, and ten thousand see failures every few hours, while shared power and network faults can interrupt many workers at once. Individual devices need not become less reliable for the fleet to experience failures routinely. A program on one machine can often stop and restart when a component fails; a distributed training job must also recover agreement among surviving workers about which progress remains valid. Restarting quickly is of little value if the restored state silently changes the computation. Preserving more state reduces the work at risk, but consumes storage bandwidth and memory while the job is healthy. Waiting longer between saves reduces that overhead while increasing the progress a failure can erase. Serving imposes a different consequence: users may abandon a request before recovery completes, and replacing a worker may leave the request's context unavailable. A response that arrives on time can still be unacceptable if recovery has discarded information needed to produce it. Engineers must therefore bound lost work and

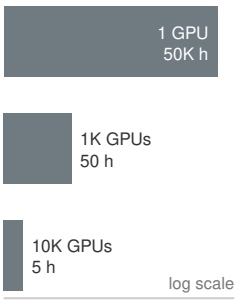
recovery delay while preserving the validity of training and the usefulness of service. The goal is continued useful execution despite repeated failures, with the costs and limits of recovery made explicit. In C^3 terms, fault tolerance spends compute and communication on coordination so that component failures do not routinely become failures of the entire workload.

Learning Objectives

- Calculate mean time between fleet failures from component rates and estimate interruption frequency for large training clusters
- Classify hardware, software, silent-data-corruption, and slow-but-alive failures by detectability, blast radius, and recovery path
- Select checkpoint intervals that balance write overhead against acceptable lost work and recovery delay
- Design distributed checkpointing and elastic recovery plans for multi-terabyte model state across accelerator fleets
- Design serving redundancy, failover, and state-recovery policies under latency budgets and partial failures
- Select graceful degradation strategies that preserve useful service when models, features, regions, or capacity fail
- Evaluate detection timeouts, restart strategies, and fault-injection evidence against a per-failure recovery-time budget

7.1 Failure Analysis at Scale

Imagine a 10,000-GPU cluster midway through a three-month training run for a new foundation model. The parallel training plan and the communication layer beneath it have done their job, and thousands of devices exchange gradients through AllReduce, AllGather, and AllToAll as if they were one machine. Then the arithmetic of scale catches up. A GPU fails every few hours, and if the system cannot absorb that ordinary physical event, synchronized training halts while compute worth about $0.5M a day sits idle. **Fault tolerance** is the system property that lets distributed execution continue making useful progress when components fail, degrade, or disappear. In the fleet stack of figure 1.4, fault tolerance occupies the Reliability & Control row of the Distribution band, where it protects the progress that parallelism and communication produce.



That fragility is the direct consequence of successful synchronization. Every collective in chapter 5 assumed that all ranks in its process group arrive, and each dependent consumer waits for every contribution. One stalled device can therefore stop progress in its synchronous training group, even while unrelated jobs continue elsewhere in the fleet. Fault-tolerant ML systems preserve progress by detecting failure, checkpointing recoverable state, restarting or elastically reshaping jobs, and treating hardware churn as normal execution rather than an exceptional path. That reliability envelope covers both halves of the fleet's work. Training needs recovery that preserves weeks of accumulated progress, while serving needs redundancy, failover, and graceful degradation that preserve a latency contract, and both draw their spare capacity from a shared fleet pool.

↪ How the scheduler holds spare capacity for failed jobs and prepositions replacement nodes while a missed heartbeat is confirmed is developed in section 8.2.2.

Not every failure announces itself. A component can stop outright, slow down while still answering liveness checks, or keep running while it computes wrong values. The quiet cases pair low detection rates with a high blast radius, because the

system keeps running on state it should no longer trust. The recovery target here is therefore trustworthy execution: preserving valid training progress and restoring a service after its infrastructure or software fails. A restored model can still make poor predictions on changed inputs even when every component executes correctly. Evaluating that behavioral robustness requires a separate contract for model quality under distribution shifts and adversarial inputs, developed in chapter 14. The distinction lets us use model-quality signals to diagnose a fault without treating every quality regression as evidence of failed hardware.

Because failures cannot be eliminated at this scale, fault-tolerant systems verify completion rather than assume it, treat failure as a normal code path, exercise recovery continuously, and account for partial failures that naive error handling may not anticipate. These techniques draw on decades of distributed systems research, but ML workloads change the economics. Training checkpoints are large but can be sized from the model and optimizer state, while some optimization algorithms tolerate bounded numerical perturbations without requiring bitwise replay. That tolerance must be established for the training method; stochasticity does not make arbitrary corruption or inconsistent recovery safe. A recovery design can exploit approximate execution only while preserving its declared convergence and quality requirements. Making failure a routine part of operation starts with knowing how often failures arrive, and the mathematics that follows makes the shift from *rare exception* to *routine occurrence* precise.

Fleet mean time between failures (MTBF) collapses from 50,000 h to 5 h as GPUs multiply.

7.2 The Mathematics of Inevitable Failure

A single data-center GPU can run for years without a hardware fault, yet a synchronous job spanning ten thousand of those same GPUs is interrupted every few hours. System reliability engineering explains why individual device longevity erodes so quickly when thousands of components must stay healthy at the same time (Birolini 2017). Each component has a failure rate λ,[1] measured in failures per unit time. When λ is constant, the probability that a single component survives without failure until time t follows an exponential distribution,[2] as in equation 7.1:

$$R_{\text{single}}(t) = e^{-\lambda t} \tag{7.1}$$

The expected time to failure of this component equals $1/\lambda$. In this book's convention, mean time to failure (MTTF) names a single component's expected time to its first failure. MTBF names the repairable system's expected operating time between successive failures, excluding recovery downtime. Under the constant-rate exponential model used here the two coincide numerically, and the fault-tolerance model uses MTTF for per-component constants and MTBF for composed system rates. Data center GPUs often use planning MTTF values in the tens of thousands of hours, with field behavior depending on operating conditions, cooling effectiveness, manufacturing variation, and workload stress.[3] Section E.1.2 catalogs the reference per-component FIT and MTTF values (GPU, high-bandwidth memory (HBM), network interface card (NIC), power supply, PCIe switch, optical cable, ToR switch) that anchor these λ and FIT figures. A reader can substitute the con-

[1] **Failure rate (λ)**: Expressed in FITs (Failures In Time), where 1 FIT equals one failure per billion device-hours. A data center GPU with a 50,000-hour mean time to failure has FIT $= 20{,}000$, corresponding to $\lambda_{\text{hour}} = 2.0 \times 10^{-5}$ failures/hour. That seems negligible for one device but becomes dominant at fleet scale: a cluster with 10,000 GPUs accumulates 200,000,000 FITs from GPUs alone, translating to an expected GPU failure every 5 hours.

stant for any device and reproduce the rates used throughout the fault-tolerance analysis.

When multiple independent components operate in a system where any single failure causes system failure, equation 7.2 formalizes how system reliability becomes the product of individual component reliabilities:

$$R_{\text{system}}(t) = \prod_{i=1}^{N} R_{\text{single}_i}(t) = \prod_{i=1}^{N} e^{-\lambda_i t} \tag{7.2}$$

For N identical components with individual failure rate λ, equation 7.3 gives the identical-component simplification:

$$R_{\text{system}}(t) = e^{-N\lambda t} \tag{7.3}$$

The system failure rate becomes $N\lambda$, and equation 7.4 expresses how the system MTBF scales inversely with component count. This inverse scaling explains why per-device reliability that looks excellent in isolation erodes at cluster scale:

$$\text{MTBF}_{\text{system}} = \frac{1}{N\lambda} = \frac{\text{MTTF}_{\text{component}}}{N} \tag{7.4}$$

The consequence is a gap between failure cadence and job length. At 10,000 GPUs, the GPU-only calculation gives an expected interval of 5 hours, so a training run measured in weeks accumulates dozens of expected failures and one measured in months accumulates hundreds. These are planning averages, not a schedule of incidents; a shorter job can finish without failure even when its expected failure count exceeds one. Once the expected time between failures falls below the length of the job, fault tolerance becomes part of the execution budget for long-running fleet work. Applied to the landmark training runs of section 1.1, whose accelerator counts grew by about four orders of magnitude between 2012 and 2024, the same per-device planning rate puts the largest of them, with more than ten thousand GPUs, below a 10-hour system MTBF. Recovery therefore becomes an active scheduling constraint rather than a reliability feature.

7.2.1 Composing component reliability

The GPU-only calculation of equation 7.4 supplies the scale intuition; a real training system then composes GPUs, HBM, links, power supplies, storage paths, and redundancy into one failure budget. Component rates are usually quoted in the FIT units introduced with the failure rate, so the 50,000-hour GPU contributes 20,000 FIT to whatever system contains it. The new question is how different component rates compose, and the composition rule depends on the redundancy structure and the independence assumptions. For series systems (for example, a node where all 8 GPUs must work), failure of any component fails the whole. With independent constant-rate failures, the reliabilities multiply as in equation 7.2, so the rates add even when the components differ:

$$\text{MTBF}_{\text{system}} = \frac{1}{\sum \lambda_i}$$

[2] **Poisson process**: A statistical model for events occurring independently at a constant average rate. In this model, event counts follow a Poisson distribution and waiting times follow an exponential distribution, giving the survival function $R_{\text{single}}(t) = e^{-\lambda t}$. With independent identical component hazards, the probability of at least one failure in a 10,000-component cluster is $1 - e^{-N\lambda t}$. The aggregate hazard $N\lambda$ scales linearly with component count; the failure probability is nonlinear in both N and t, approaching $N\lambda t$ only when that product is small.

↪ The independence, exponential-lifetime, and Poisson results this failure arithmetic rests on are developed in section E.1.1.

Under this additive failure-rate law, the system failure rate grows linearly with component count while system MTBF falls in inverse proportion. Every unredundanted component on the critical path adds its FIT contribution directly to the denominator.

The same product governs instantaneous availability, a different quantity from the survival function $R_{\text{single}}(t)$. Availability A is the probability that a component is up at a randomly chosen instant, counting repairs, whereas $R_{\text{single}}(t)$ is the probability that it has not yet failed by time t. If each GPU is independently up with probability A_{GPU}, all N are up together with probability $(A_{\text{GPU}})^N$, which is the reliability gap of equation 1.2. For the chapter's 10,000-GPU cluster, a per-GPU availability of 99.99 percent (only 52.6 minutes of downtime per year) leaves about a 37 percent chance that every GPU is up at the same instant. That power erodes even highly reliable hardware once N reaches fleet scale, so software must handle failures automatically.

[3] **GPU MTTF variation**: This chapter uses 50,000 hours as a planning constant for current data center GPUs (A100 and H100 class), not as a guarantee for every deployed GPU. Published fleet studies from Google TPUv4 pods and Meta GPU clusters report that field reliability depends on topology, cooling, workload, and operational practice (Zu et al. 2024; Kokolis et al. 2025; Dubey et al. 2024). The planning constant therefore anchors the arithmetic, while operators should substitute measured fleet rates when they have them.

Systems Perspective 7.1: Scale transforms failure

A cluster of 10,000 GPUs turns a per-GPU MTTF of 50,000 hours into a system MTBF of 5 hours. For a repairable system, steady-state availability is $A = \text{MTBF}/(\text{MTBF} + \text{MTTR})$, where mean time to recovery (MTTR) is the recovery interval. Cutting MTTR from 30 minutes to 5 minutes raises availability from 90.91 percent to 98.36 percent. This stationary two-state model assumes unconstrained repair capacity and complete outage; correlated incidents, repair contention, and degraded operation require direct measurement (Birolini 2017). Systems must engineer recovery, not merely improve components.

Engineering faster recovery is one response to that arithmetic; redundancy is the other. For parallel systems providing redundancy, suppose that any surviving component can satisfy the required service. With independent failures and no repair during the observation interval, the system survives until every component has failed:

$$R_{\text{system}}(t) = 1 - \prod_{i=1}^{N_{\text{red}}} (1 - R_{\text{single}_i}(t))$$

Series composition is the training job's problem, because a synchronous step needs every participant. Parallel composition is the serving fleet's lever, and it returns when interchangeable replicas protect a latency contract. Both rules, however, describe whatever the model calls a component, and the fault rate assigned to that component depends on which protections sit inside it.

Lighthouse 7.1: Archetype A (GPT-4/Llama-3): Memory soft-error scale

Composition makes the distinction between raw faults and job interruptions essential. Memory soft-error rates are quoted per megabit of storage rather than per device, so the exposure grows with memory capacity. As an illus-

trative raw-bit-error budget, assume 250 FIT per megabit across 1,024 GPUs with 80 GB each, the size of the Archetype A reference cluster. The resulting interval between raw memory errors is roughly 20 seconds. This is not a measured job-failure interval. Error-correcting code (ECC) protection can correct covered error patterns before they affect computation, while detected uncorrectable errors and escaped corruption require different recovery paths. At that raw rate, unprotected memory in the reference cluster would corrupt training state many times per hour, so ECC is a precondition for large-scale training rather than an option. A fleet reliability budget therefore needs the residual job-interrupting and silent-corruption rates under its actual protection scheme; raw bit-error rates alone cannot establish whether memory, logic, or interconnect dominates.

These raw bit-error rates justify ECC, but they are not the interruption rates that set checkpoint cadence; the worked cascade that follows uses device MTTF values that already include the effect of that protection. The cascade also treats its GPU, PCIe, power, and network contributions as separate categories, so a measured whole-node rate that already includes those paths cannot be added to them again.

7.2.2 Cluster MTBF calculation

Consider a training cluster designed for large language model development, roughly ten times the 1,024-GPU Archetype A reference cluster, with the following specifications:

- 10,000 NVIDIA H100 GPUs
- Individual GPU MTTF: 50,000 hours
- Each GPU connected to host via PCIe (MTTF: 200,000 hours)
- Each node contains 8 GPUs fed by 6 power supply units (MTTF: 100,000 hours each) in 4+2 redundancy, so the node keeps full performance with any 2 of them failed
- Network infrastructure per node (NIC, cables): MTTF 150,000 hours

Each GPU operates within a failure domain that includes the GPU itself, its PCIe connection, and a proportional share of the node's shared power and network infrastructure. Dividing a node-wide subsystem rate by the 8 GPUs in the node prorates one shared failure source across those GPUs, so that multiplying the per-GPU total by all 10,000 GPUs in the final step counts each node's shared hardware once per node rather than eight times. Power enters the sum only through supplies whose single failure stops the node, counted as n_{psu} in the power equation. With the node's supplies in redundant sets, no single unit qualifies, so the power term below is zero in this first-order calculation. The approximation omits the residual risk that additional independent failures exhaust redundancy before repair. A fault upstream of the chassis, such as the loss of the circuits feeding it, can also take down the whole node. That risk belongs to the correlated failures treated later in this chapter. The four subsystem rates follow from their MTTF values:

$$\lambda_{\text{GPU}} = \frac{1}{50{,}000} = 2.0 \times 10^{-5} \text{ failures/hour}$$

$$\lambda_{\text{PCIe}} = \frac{1}{200{,}000} = 0.5 \times 10^{-5} \text{ failures/hour}$$

$$\lambda_{\text{power/GPU}} = \frac{n_{\text{psu}}}{8} \times \frac{1}{100{,}000} = \frac{0}{8} \times \frac{1}{100{,}000} = 0 \text{ failures/hour}$$

$$\lambda_{\text{network/GPU}} = \frac{1}{8} \times \frac{1}{150{,}000} = 0.083 \times 10^{-5} \text{ failures/hour}$$

Because the subsystems sit in series, their rates add to a per-GPU total:

$$\lambda_{\text{total/GPU}} = (2.0 + 0.5 + 0.083) \times 10^{-5} = 2.583 \times 10^{-5} \text{ failures/hour}$$

Multiplying that total by the cluster size gives the system failure rate, whose reciprocal is the cluster MTBF:

$$\lambda_{\text{system}} = 10{,}000 \times 2.583 \times 10^{-5} = 0.2583 \text{ failures/hour}$$

$$\text{MTBF}_{\text{system}} = \frac{1}{0.2583} = 3.87 \text{ hours}$$

Under the model, the cluster experiences a failure every 3.9 hours on average. The expected failure cadence is 6.2 failures/day; a training run lasting one week has an expected count of 43 failures. Actual incident times vary, but the expected loss is large enough that recovery must be part of normal execution planning.

↪ The step-by-step composition of per-component failure rates into a fleet-wide system MTBF, reusable for any node design or cluster size, is developed in section E.1.3.

The cluster MTBF scaling in table 7.1 isolates the GPU-only baseline across cluster sizes. The full-system calculation is lower once PCIe and network failure domains are included. The same 10,000-GPU cluster therefore carries three MTBF values in this chapter. Each later calculation names the one it uses: the GPU-only 5 hours of this table, the full-system 3.9 hours of the cascade above, and the two-to-three-hour cadence that somewhat larger production runs report below. Two running scenarios carry the rest of the chapter. The 1,024-GPU Archetype A reference cluster sizes per-node state, restore paths, and the elastic and straggler examples, while the 10,000-GPU cluster of the cascade sets failure cadence and checkpoint intervals. The full-system MTBF is the default input; a calculation that uses the GPU-only value says so, usually because it compares cluster sizes on the common basis of table 7.1, and its failure count is then a lower bound.

Table 7.1: Cluster MTBF Scaling: GPU-only mean time between failures falls in inverse proportion to cluster size, transforming failures from rare events to continuous operating conditions at scale. Additional host, power, storage, and network failure domains reduce system-level MTBF further.

Cluster size (GPUs)	Individual GPU MTTF	Cluster MTBF	Expected failures per day
8	50,000 hours	6,250 hours (260 days)	0.004
64	50,000 hours	781 hours (33 days)	0.03
512	50,000 hours	98 hours (4 days)	0.25
1,000	50,000 hours	50 hours (2 days)	0.48
4,000	50,000 hours	12 hours	1.9
10,000	50,000 hours	5 hours	4.8
25,000	50,000 hours	2 hours	12

Production measurements confirm the $1/N_{\text{GPU}}$ trend of table 7.1 and show that the GPU-only line is optimistic. Plotted on log-log axes, measured MTTF values and fitted projections from Meta's clusters follow the slope of the $50{,}000\,\text{h}/N_{\text{GPU}}$ line across more than three orders of magnitude in job size but sit below it. The gap arises because a job can be interrupted by far more than its GPUs (figure 7.1). The Kokolis et al. (2025) study of Meta's Research SuperCluster reported measured MTTF values for observed RSC job sizes and projected a 1.8-hour MTTF for 16,384-GPU jobs. That projection lands next to the Llama 3 run previewed in section 1.1 (war story 7.2 follows its recovery). That run recorded 419 unexpected interruptions across a 54-day snapshot on 16,384 H100 GPUs, which gives an observed MTTF of about 3.1 hours. Together, the measured Llama run and Kokolis projection put 16,384-GPU training on a failure cadence of roughly two to three hours, bracketed by the 1.8-hour projection and the 3.1-hour measurement. This evidence turns the idealized $1/N_{\text{GPU}}$ relation into an engineering constraint that determines checkpoint frequency, recovery architecture, and infrastructure investment.

7.3 Failure Taxonomy

A network partition that clears in seconds and a permanent GPU failure both interrupt a training step, yet retrying the first succeeds while retrying the second wastes cluster time on dead silicon. Silent memory corruption that produces wrong gradients demands a different defense again from a node crash that stops responding altogether. While the MTBF calculations quantify *how often* interruptions arrive, which sets checkpoint intervals and spare-pool sizes, choosing the right recovery action requires distinguishing *what kind* of failure has occurred. In standard reliability terms, a fault is the underlying defect or disturbance, an error is the corrupted internal state it produces, and a failure is the externally visible misbehavior that the training or serving system must handle (Avizienis et al. 2004).

No single label captures all of these differences. Reliability decisions require three orthogonal axes (Constantinescu 2008; Lamport et al. 1982): persistence

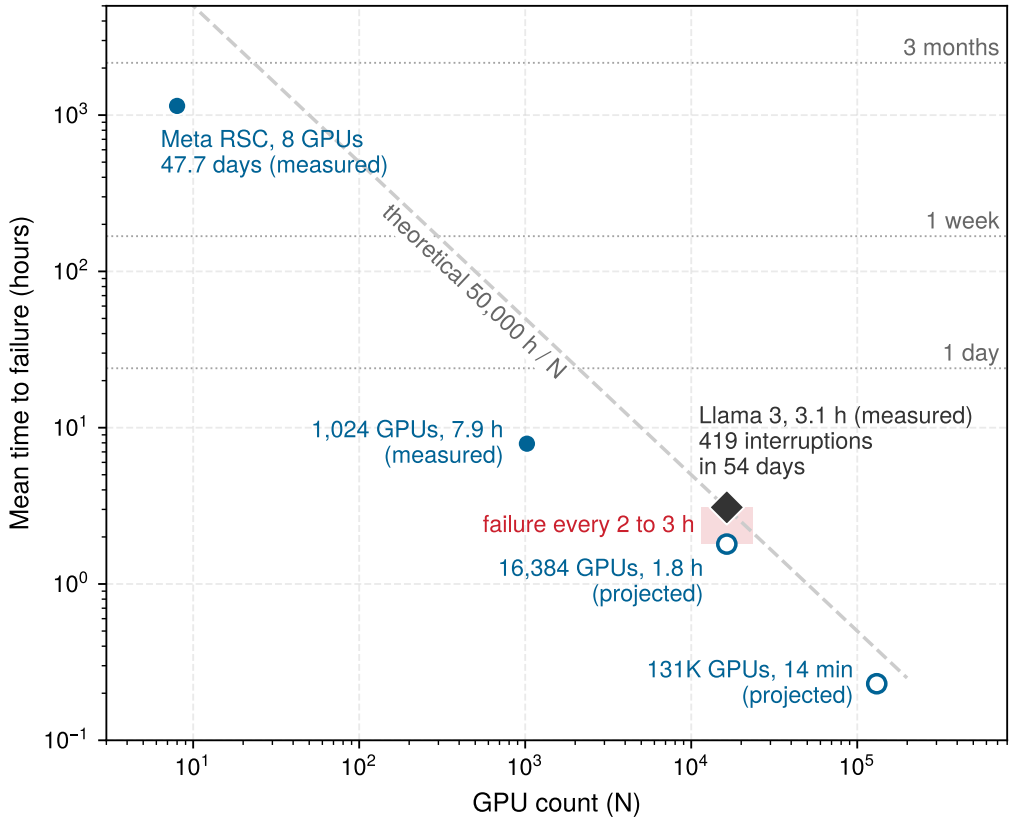


Figure 7.1: Published Failure Rates from Production Clusters: Measured MTTF values and fitted projections from Meta's RSC clusters (Kokolis et al. 2025) plotted with Llama 3 training measurements (Dubey et al. 2024) against the theoretical 1/N curve. At 16,384 GPUs, the Kokolis projection and the Llama 3 empirical measurement bracket a failure cadence of roughly two to three hours (the 1.8-hour projection and the 3.1-hour measurement), confirming that fault tolerance is a mathematical necessity, not an edge case. Data sources: Kokolis et al., arXiv:2410.21680; Meta, arXiv:2407.21783.

(transient, intermittent, or permanent), manifestation (fail-stop, degraded, or value-corrupting), and failure scope (one device, one node, a rack or power domain, or the whole job). Two manifestations need names because liveness checks cannot see them. A **gray failure** is a component that stays alive but runs slowly or erratically, so it keeps answering the liveness checks that would flag a crash while every peer that waits on it slows down. **Silent data corruption (SDC)** goes further, producing wrong values with no error at all. Because the three axes are independent, a single fault sits on all three at once: a transient disturbance can manifest as either a detected crash or silent corruption, while a permanent switch failure can remain confined to one rack or partition an entire job. Each axis governs a different operational choice. Persistence determines whether a fault clears on its own or requires hardware quarantine and replacement (section 7.4.1). Manifestation separates crashed ranks from slow stragglers (section 7.9.5) and from Byzantine value corruption, while scope determines when a single shared hazard can defeat naive redundancy.

Production logs show which of these failures a large run actually meets. During a 54-day period of Llama 3 405B pretraining on 16,384 H100 GPUs, Meta attributed each of 419 unexpected interruptions to a root-cause component (Dubey et al. 2024). Grouped by cause in figure 7.2, GPU components account for 268 of them, about 64 percent, led by 148 faulty GPUs and 72 HBM memory failures. Software caused 56, of which 54 were bugs and 2 were failed dependencies. Network switches and cables caused 35, unplanned host maintenance 32, and the remaining host hardware, from NICs to power supplies, 21. The last 7 were NCCL watchdog timeouts whose underlying cause was never found. Only 6 interruptions were attributed to silent data corruption, and that count includes only corruption that was caught. Most fault-tolerance effort therefore goes to frequent, detectable accelerator failures, while the rare silent ones demand a different kind of defense.

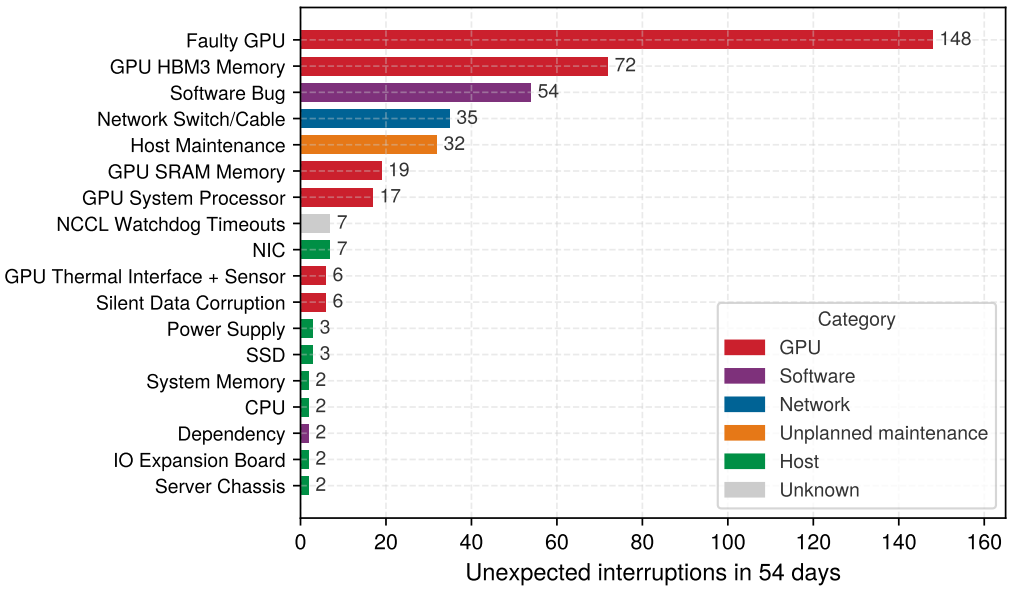

Figure 7.2: Root Causes of Training Interruptions: The 419 unexpected interruptions recorded over 54 days of Llama 3 405B pretraining on 16,384 H100 GPUs, by root-cause component and colored by category. GPU components dominate; silent data corruption appears only where it was detected. Counts are from Table 5 of Dubey et al. (2024); one percentage in that table (Faulty GPU) disagrees with its count, so shares here are computed from the counts.

7.3.1 Transient failures

A transient fault clears without physical repair, but the state it corrupts can persist after the disturbance ends, forcing recovery to retry or validate affected work before relying on that state. In large-scale training systems, temporary disruptions range from network packet loss, where dropped packets are recovered by transport retransmission, to memory bit flips triggered by cosmic-ray-induced single-event upsets.[4] Timing disturbances can be equally disruptive without corrupting bits directly. Under temperature spikes, thermal throttling reduces compute throughput without halting execution. Software timeouts fire when transient contention delays a collective beyond its allotted window.

[4] **Single-event upset (SEU)**: From particle physics, where "upset" denotes a nondestructive state change. Cosmic rays and alpha particles from chip packaging can flip bits in memory and logic; the observed rate depends on altitude, process technology, packaging materials, shielding, and workload (Ziegler et al. 1996; Baumann 2005). ECC memory corrects single-bit errors but cannot handle every multi-bit upset in the same word, leaving a residual silent-corruption risk that compounds across the terabytes of state in large-scale ML training.

Transient faults are particularly difficult to diagnose in ML training when they leave no explicit error signal. If hardware protection and the computation itself do not mask a memory bit flip during gradient computation, the corrupted value propagates into later updates while training continues. Large-scale SDC studies document such escaped corruption in production processors, and DRAM field studies confirm that memory errors occur frequently enough to require fleet-level monitoring (Dixit et al. 2021; Sridharan et al. 2015; Schroeder et al. 2009). In ML training, that undetected corruption surfaces as degraded gradients, anomalous loss curves, or rollback-worthy checkpoints rather than an explicit crash.

How the system responds to a transient failure therefore depends on whether the fault announces itself. Errors that raise explicit exceptions can be handled through bounded retry logic, whereas silent corruption requires end-to-end validation. Checksums catch altered bytes in storage or transport, cross-rank digests expose disagreement across a supposedly identical reduced buffer, and statistical or replay checks test whether the computation itself remains plausible. Because a rank that computes the wrong local gradient and then checksums those wrong bytes will pass an ordinary transport check, only independent recomputation, invariants, or model-level evidence can expose the error.

7.3.2 Fail-stop failures

In synchronous distributed training, a single participant that goes silent stalls the entire group's next update. A conventional AllReduce cannot complete until every rank supplies its input, so one dead GPU in a 10,000-GPU job can leave the other 9,999 accelerators waiting at the barrier until recovery begins. Smaller communication groups limit the immediate dependency, although pipeline or data-parallel stages soon propagate the stall across the rest of the job. Such **fail-stop failures** occur when a component ceases operation outright and stops responding to requests. A GPU hardware failure renders an individual accelerator unresponsive, and a host node crash terminates all training processes on the machine. A network partition severs communication between a healthy node and the cluster, and a storage failure blocks workers from reading or writing checkpoint shards.

A stopped component gives a clearer symptom than one that keeps returning plausible but incorrect values. Yet a stopped rank announces itself only through silence, so detection rests on timeouts that must separate an outright crash from a slow or isolated host, such as a GPU still writing a large checkpoint while the collective waits. Once a timeout flags the missing participant, the recovery system replaces or restarts it and restores the most recent valid checkpoint; section 7.9.1 sets that timeout threshold once the full recovery-time budget is in view.

7.3.3 Byzantine failures

Where a fail-stop component ceases to participate, a value-corrupting component can keep running while returning incorrect results. A GPU may return wrong gradients without raising an error, a link may deliver a corrupted packet whose error pattern the CRC happens not to cover, or a worker may compute different results for identical inputs and state. Byzantine failures allow arbitrary behavior,

including inconsistent messages to different participants (Lamport et al. 1982). ML systems can encounter this broader failure model through silent data corruption or adversarial corruption. Numerical instability and determinism violations also require validation when they break the execution contract, but ordinary rounding differences or intentionally stochastic outputs are not themselves evidence of a faulty worker. The recovery concern is a participant whose accepted contribution can corrupt shared state without a visible crash.

The two models leave different evidence (figure 7.3). A fail-stop worker such as W2 falls silent, and its missing heartbeats make it suspect. A Byzantine worker such as W6 keeps sending messages on schedule, so it passes every liveness check while the values it sends are wrong.

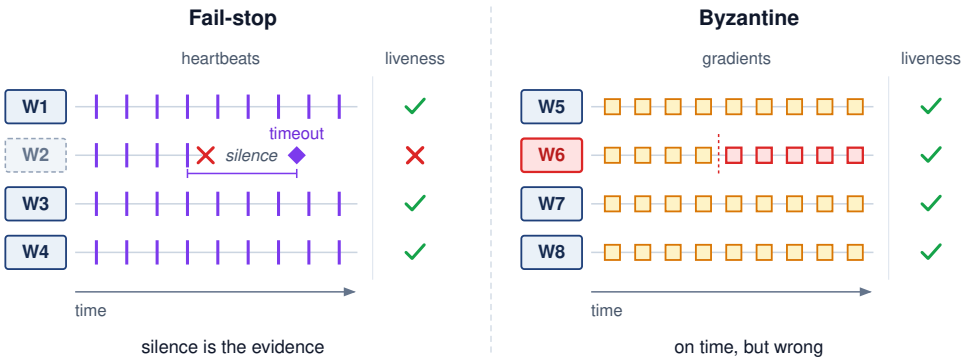

Figure 7.3: Fail-Stop vs. Byzantine Failures: In the fail-stop model (left), a failed worker simply ceases to send messages, which a timeout flags as suspect without distinguishing a crash from delay or isolation. In the Byzantine model (right), a failed worker continues to participate but sends incorrect data (for example, corrupted gradients reported as valid), which can poison the global model state if not detected by redundant validation.

In an ML fleet, the most common source of value corruption is not an adversary but hardware that changes a value without raising an error, the silent data corruption already met among transient failures. Its physical causes, the training signals that expose it, and the verification and hot-spare defenses that contain it are developed together in section 7.5, after the hardware faults that produce it. Whatever its source, a Byzantine contribution violates a contract that liveness checks never test. Ordinary data-parallel workers process different batches and need not produce identical local gradients; the required contract is that each contribution correctly represents its assigned computation. A single Byzantine worker can violate that contract and corrupt the averaged gradient, potentially causing training to diverge or converge to a poor solution.

Redundant computation supplies one form of evidence against Byzantine failures. Workers repeating a computation from matching inputs, state, and random-number streams can compare results under a stated numerical tolerance. Statistical outlier detection and invariants provide additional evidence without fully repeating the computation. Each method has a coverage limit. Agreement can miss shared faults, while a statistical anomaly can arise from legitimate data varia-

tion. Detection overhead must therefore be evaluated together with the faults the method can expose.

Byzantine-resilient distributed training algorithms exist but impose significant overhead. Krum (Blanchard et al. 2017) keeps the single worker gradient whose nearest neighbors lie closest to it and discards the rest, while coordinate-wise trimmed mean (Yin et al. 2018) drops the largest and smallest values in each coordinate before averaging what remains. Both compute aggregates that stay robust to a bounded number of Byzantine workers, but they require more communication and computation than simple averaging. Without such protection, corrupted gradients can push the optimizer toward an unreliable model state while the training job appears healthy. Reliability must therefore protect semantic correctness rather than process liveness alone.[5]

[5] **Byzantine-resilient ML**: Named after Lamport's 1982 "Byzantine Generals Problem," these algorithms (Krum, trimmed mean, and signSGD, which aggregates only the signs of gradient coordinates by majority vote) tolerate a bounded fraction of corrupted workers, with the exact bound depending on the rule and its assumptions. Krum's original analysis requires $2f + 2 < n$ for f Byzantine workers among n, while coordinate-wise median and trimmed mean rest on different robustness assumptions, so the tolerated fraction depends on the aggregation rule, dimensionality, and statistical model. For n workers, Krum requires pairwise distance computations over worker gradients, so overhead grows quadratically with worker count and directly competes with the throughput gains of data parallelism (Blanchard et al. 2017).

7.3.4 Correlated failures

The reliability calculations in section 7.2 assume independent failures, yet real systems depart sharply from this assumption when common physical or operational dependencies take down multiple components at once. Within a single node, a power fault that exhausts the chassis's redundant supplies, such as the loss of its feed circuits, removes every GPU in the chassis. Across a cluster, a top-of-rack network switch failure isolates all attached nodes, while a cooling system failure can trigger thermal shutdowns down an entire row of racks. Shared software and operational dependencies widen the blast radius further. A software bug in an updated CUDA driver can crash processes across nodes whenever they exercise the affected code path, and operator error during cluster reconfiguration can render an entire fleet unreachable.

Correlated failures violate the independence assumption underlying equation 7.3. A model that counts only independent device failures omits shared hazards and their potentially larger blast radius; incident frequency and the number of affected devices must be modeled separately. Correlated failures can also defeat redundancy strategies. Three replicas of a model provide no protection against a shared power failure if all three run on the same power domain.

Defending against correlated failures requires classifying each failure by its scope, the failure domain it takes down, and ensuring that redundancy spans independent domains. Common failure domains in ML infrastructure range from a single GPU to an entire data center region, and each calls for its own mitigation (table 7.2). These domains nest, so a physical disruption scales upward from one eight-GPU node to a rack and then to a multi-rack power and network envelope (figure 7.4).

Table 7.2: Failure Domains in ML Infrastructure: Understanding failure domain boundaries enables placement of redundant components across independent domains, preventing correlated failures from defeating redundancy strategies.

Failure domain	Impact scope	Typical recovery time	Mitigation strategy
Single GPU	1 GPU	Seconds (spare)	Hot spare, elastic training
Node (power/OS)	8 GPUs	Minutes	Checkpoint, node replacement
Rack (ToR switch)	32–64 GPUs	Minutes to hours	Cross-rack redundancy
Power domain	100–500 GPUs	Hours	Multiple power feeds
Data center region	All GPUs	Hours to days	Geographic distribution
Software version	All GPUs running version	Minutes (rollback)	Staged rollouts

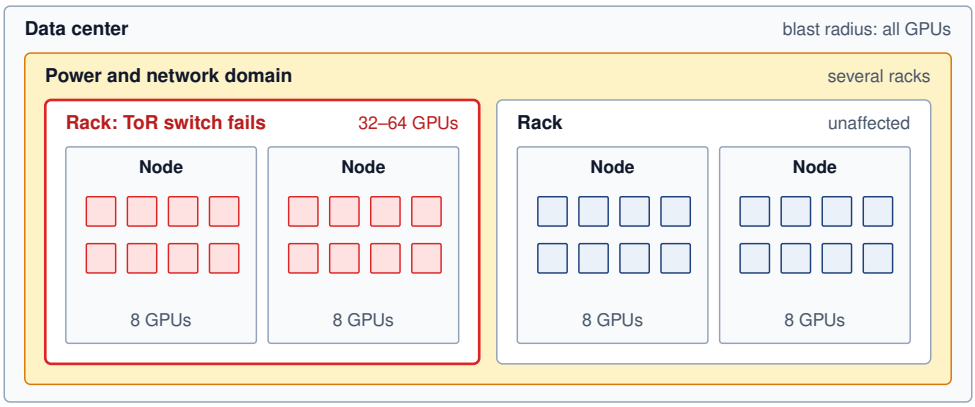

Figure 7.4: Hierarchy of Failure Domains: Failure domains are often nested or overlapping. A GPU failure affects one device. A node failure affects 8 GPUs. A rack switch failure affects 32–64 GPUs (each rack is drawn with only two of its four to eight nodes). A power distribution unit (PDU) failure may affect multiple racks. The red rack shows one such correlated failure: a single top-of-rack switch fault removes every GPU it contains, while the neighboring rack is untouched, which is why replicas must span independent domains (for example, different racks or rows).

The containment hierarchy in table 7.2 and figure 7.4 explains why replica placement must match the fault being tolerated: placing replicas within the same domain provides zero protection against that domain's failure mode. The highlighted rack in figure 7.4 contains nodes that share a top-of-rack (ToR) switch, so that switch's loss can disconnect every attached node from the job. A neighboring rack with a separate switch can remain reachable during that event even if both racks share a power domain, yet that same placement does not protect against loss of their shared power source. Redundancy must therefore cross the relevant failure boundary, not merely occupy different devices.

↩ The failure domain and its physical nesting from node to rack to building are established in section 2.5.5.

Checkpoint 7.1: Mapping failure domains

Verify your understanding of how failure domains nest and their operational impact:

- ☐ **Blast radius**: calculate how many 8-GPU nodes a rack switch failure typically affects in a standard data center configuration.
- ☐ **Power-domain correlation**: explain why placing all 3 model replicas in the same power domain fails to provide protection against a power outage confined to that domain.
- ☐ **Staged rollouts**: identify the failure domain addressed by staged rollouts rather than hardware redundancy.
- ☐ **Nested domains**: explain hierarchical containment and decide whether the rack failure domain still matters once the power domain containing that rack fails.

War Story 7.1: The supercomputer that swapped in spare cubes (2024)

Context: Google's Tensor Processing Unit (TPU) v4 machine-learning supercomputer used 4,096 TPU chips connected by a custom 3D torus inter-chip interconnect (ICI) fabric, and Google engineers published their operating experience with automatic fault resiliency and hardware recovery (Zu et al. 2024).

Mechanism: At 4,096-chip scale, machine and link failures could remove participants or paths required by a job's configured communication topology.

Impact: Losing a required participant can interrupt the synchronous job across the slice. Losing a link instead raises a routing question: whether the remaining fabric can still provide the required communication paths.

Fix: Google used optical circuit switches (OCS) to assemble replacement slices from spare healthy TPU cubes, the pod's building blocks of chips wired as a $4\times4\times4$ mesh, for machine outages, together with fault-tolerant routing for supported OCS outage patterns. The response depended on which resource failed.

Systems lesson: Fault tolerance is a topology-management problem. In tightly coupled accelerator fleets, recovery must preserve the communication graph, not merely replace an individual component; otherwise one local hardware fault can become a cluster-wide training interruption.

7.4 Hardware Faults at Fleet Scale

A cosmic ray that flips one bit in a GPU's high-bandwidth memory and a solder joint that cracks under thermal cycling are physical events, but the recovery system never observes them directly. It observes symptoms: a gradient spike with no process crash, a rank that disappears from the collective, or a node that fails only

after it heats under sustained load. The failure taxonomy of section 7.3 already classifies such events by persistence, manifestation, and scope. For hardware, persistence carries most of the operational weight because it decides whether the fleet should retry, quarantine, or replace a component, while manifestation decides whether the fleet notices the fault at all.

ML workloads raise the stakes of each fault. A training step performs trillions of arithmetic operations on state that persists into later steps, so a wrong value can survive beyond the computation that produced it. The damage depends on the affected value and its later use. Under the IEEE 754 format,[6] a sign-bit flip inverts a weight, while an exponent-bit flip can move a small gradient by many orders of magnitude. Fault-injection studies show that network resilience varies with model, layer, and bit position, so a few faults in vulnerable locations can cost disproportionate accuracy (Reagen et al. 2018). A valid-looking corrupted value can enter learned state without triggering the process failure that would otherwise initiate recovery.

Fleet scale turns these rare device events into routine operating conditions. Smaller geometries and lower operating voltages can reduce the charge needed to disturb a stored value (Baumann 2005). Fleet studies at Google and Meta found that a small but persistent population of processors, on the order of a few per several thousand machines, computes wrong results without raising any error (Hochschild et al. 2021; Dixit et al. 2021). Studies of accelerator training fleets reach the same conclusion: rare hardware faults appear often enough that software-level detection and recovery become part of the training system design (He et al. 2023). ML system architects must therefore treat hardware as an unreliable substrate and budget for end-to-end integrity checks, replayed computation on high-value paths, and periodic consistency checks as system requirements rather than high-performance computing specialties.

[6] **IEEE 754**: The IEEE 754 floating-point standard defines the binary32 format with 1 sign bit, 8 exponent bits, and 23 fraction bits (IEEE Standards Association 2019). Because bit positions differ so much in consequence, resilience mechanisms often prioritize the sign and exponent bits rather than treating all bits as equally important.

↪ How an FP16 exponent-bit flip rescales a value by 2^{16} and can saturate an attention softmax is developed in section E.6.

7.4.1 Fault persistence and the fleet response

Each persistence class from the taxonomy maps to a different fleet action, from retry for a fault that leaves nothing to repair, through quarantine for one that returns under load, to replacement for one that repeats on every attempt (figure 7.5). A transient fault, as section 7.3.1 established, leaves no lasting defect from that event, so the fleet's question is only whether its effect escaped. A single-event upset, a voltage droop on an unstable power path (Reddi and Gupta 2013), a timing violation, or a soft error in combinational logic (Mukherjee et al. 2005) can corrupt a tensor, packet, or instruction. Detection and correction can prevent propagation; affected state may otherwise require rollback. During training, an undetected error in weights or gradients can compromise convergence and contaminate subsequent checkpoints (He et al. 2023). During stateless inference, an activation error can remain confined to one request (Mahmoud et al. 2020). If that activation enters retained state such as a KV cache, later outputs can also depend on it.

A permanent fault announces itself through repeatability. The same accelerator, memory cell, or link fails again after retry, often at the same address or in the same workload phase. Manufacturing defects and wear-out mechanisms such as

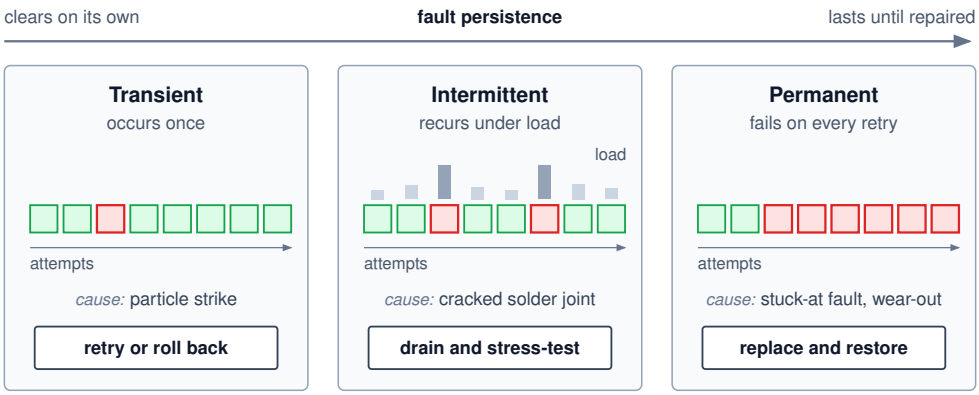

Figure 7.5: The ML Failure Spectrum: Hardware faults ordered by how long they persist. A transient fault leaves nothing to repair, an intermittent fault returns under the load that exposed it, and a permanent fault repeats on every retry. Persistence decides the fleet response, from retry through quarantine to replacement, and fault tolerance engineering must handle all three to keep a fleet making progress.

electromigration[7] and oxide breakdown produce this signature, and the stuck-at fault, in which a signal remains fixed at 0 or 1 regardless of input, is its standard abstract model (Seong et al. 2010). Repeatability helps locate the defect but does not make the result trustworthy. A permanent datapath fault keeps producing wrong gradients until the device is drained from the cluster (He et al. 2023), and rerunning the computation on the same device reproduces the error instead of exposing it. The fleet must stop trusting the component, quarantine it, and restore from a checkpoint that predates its first bad write.

Intermittent faults create the most operational ambiguity because they produce evidence and then disappear. A node may pass a reboot test, rejoin the fleet, and fail again only when the next job drives the package into the same thermal, voltage, or communication regime. Cracked solder joints, aging packages, and contamination between contacts create these load-dependent conditions (Constantinescu 2008; Rashid et al. 2015), and reduced voltage margins cause timing errors that are hard to reproduce (Zhang et al. 2018). Sporadic errors of this kind can accumulate across iterations and degrade convergence without any explicit failure (Rashid et al. 2015). An intermittent node should therefore remain suspect until evidence clears it. The fleet drains it from long jobs, correlates its error logs, and readmits it only after it passes stress tests under the load that exposed the fault. Otherwise one marginal component can make validation and recovery untrustworthy for every job that lands on it. Across the three persistence classes, the evidence that exposes a fault also determines the fleet's response (table 7.3).

[7] **Electromigration**: Gradual displacement of metal atoms in conductors by electron momentum transfer, first characterized in early electromigration studies and later modeled in Black's reliability equation (Black 1969). Mean time to failure decreases with higher current density and higher temperature, so sustained high-power accelerator workloads make thermal management a direct determinant of fleet lifespan.

Table 7.3: Hardware Fault Persistence and Fleet Response: The persistence class of a hardware fault determines the evidence that exposes it and the action the fleet takes. Manifestation is a separate axis: any of the three classes can surface as a crash or as silent corruption (Constantinescu 2008).

Persistence	Fleet signature	Detection evidence	Fleet response
Transient	One-time wrong value or lost message; retry succeeds	Corrected-error counters, checksum mismatches, gradient spikes	Correct or retry; roll back if durable state was contaminated
Intermittent	Recurring errors under specific load, heat, or voltage	Correlated error logs and repeated anomalies on one node	Drain and quarantine; readmit only after screening under load
Permanent	Reproducible failure at the same device, address, or link	Failed self-test or replay mismatch on the same device	Replace the component; restore from a checkpoint before the fault

7.4.2 Hardware lifecycle and the hazard rate

A newly unboxed accelerator rack is far more likely to fail in its first week of service than in its sixth month, and a multi-year-old rack that has endured thousands of thermal cycles becomes fragile again as packages and solder joints fatigue. While persistence classifies a fault after it strikes, the hazard function $h(t)$ describes *when* over a component's operating lifespan faults are most likely to occur, partitioning hardware longevity into three reliability regimes (figure 7.6). The first phase, infant mortality, brings elevated failure rates from manufacturing defects, improper installation, and early-life failure of marginal components. For electronic components it typically lasts days to weeks, which is why burn-in testing[8] stresses hardware before deployment to precipitate those early failures prior to production use.

After surviving infant mortality, components enter the useful-life phase, where failure rates remain relatively constant under the standard reliability-engineering model (Birolini 2017; Klutke et al. 2003). This phase spans the longest portion of a component's lifetime and is the regime where the exponential reliability model in equation 7.1 applies most accurately. For data center GPUs, the useful-life window is an operational planning concept shaped by refresh cycles, cooling, utilization, and observed fleet health rather than a fixed physical duration.

As components age, they enter the wear-out phase, where failure rates increase due to accumulated wear. For GPUs, wear mechanisms include electromigration in circuits, thermal cycling stress on solder joints, and degradation of thermal interface materials. The onset of wear-out depends heavily on operating conditions; components operated at high temperatures or with frequent thermal cycling enter wear-out earlier.

The practical implication for ML systems is that fleet-wide failure rates can depend on age distribution. Under the bathtub model, a new cohort passes through elevated early-life risk, a relatively stable period, and eventual wear-out. Screening, operating conditions, and replacement policy determine how much of that pattern

[8] **Burn-in testing**: A controlled screening procedure stresses components before deployment to expose early-life defects. Temperature, voltage, duration, and acceptance criteria depend on the component and its qualified test procedure; a generic semiconductor screening recipe is not an operating specification for an assembled accelerator. Screening reduces the defective population entering service but does not certify every later workload or fault mode.

appears in field data. Mixed-age fleets combine cohorts at different stages, so their aggregate hazard need not follow the curve of a single cohort.

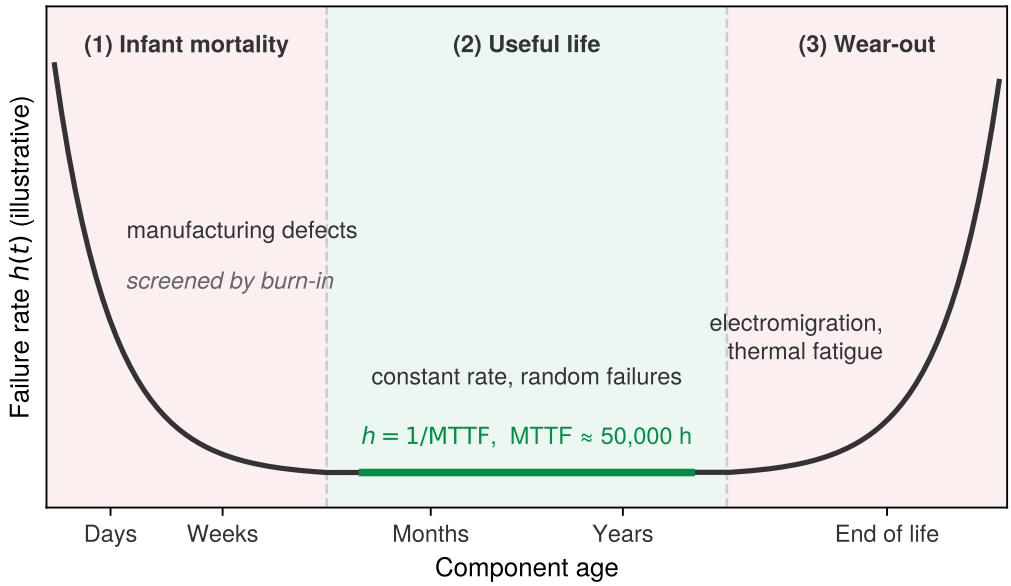

Figure 7.6: The Bathtub Curve: Hardware failure rates $h(t)$ vary over time. (1) Infant mortality: high failure rate initially due to manufacturing defects. (2) Useful life: constant, low failure rate where random failures dominate. (3) Wear-out: increasing failure rate as components age. Burn-in testing aims to filter out infant mortality failures before deployment.

These three hazard regimes in figure 7.6 translate directly into admission control and maintenance policies. Before assigning new or repaired nodes to a long training run, operators use matrix-multiply, memory, and communication stress tests to expose marginal components. During service, temperature trends, error counts, and performance degradation help identify devices for scheduled replacement. Screening moves failures out of expensive production runs. An infant-mortality failure caught during a few hours of stress testing costs only idle time, while the same failure weeks into a pretraining run forces a checkpoint rollback. For that reason operators often route fresh or repaired nodes to short jobs first. Monitoring then checks whether the constant-rate model remains appropriate as the fleet ages.

7.4.3 Fleet-scale detection and mitigation

Burn-in screening and lifecycle replacement keep the most failure-prone hardware out of long training runs, but even healthy mid-life devices still suffer random faults that compound across a fleet just as the interruption rates of section 7.2 do. Field studies of DRAM in large data centers found memory errors frequent enough that error-correcting memory, background scrubbing, and error-rate monitoring are standard fleet practice rather than optional hardening (Schroeder et al. 2009; Sridharan et al. 2015). Protection consumes some capacity and bandwidth for check bits and scrubbing, but that cost is small compared with a corrupted multi-week run.

Detection works in layers with different coverage and cost. At the hardware layer, error-correcting codes[9] (Hamming 1950) correct and detect the memory-error patterns covered by the implemented code, and link-level CRCs[10] check corruption in transit. These protections operate within their enabled storage and transport boundaries; they do not validate an incorrect arithmetic result merely because its bytes arrive intact. Before deployment, built-in self-test and the burn-in screening of the hardware lifecycle expose manufacturing defects and permanent faults (Bushnell and Agrawal 2002). During service, operators periodically pull nodes from production and run known-answer stress tests on arithmetic, memory, and interconnect, because defective processors often fail only on particular instruction mixes, data patterns, or operating points (Hochschild et al. 2021; Dixit et al. 2021).

The software layer draws its cheapest evidence from metrics the training loop already emits. Statistical checks on loss, gradient norms, and activations flag silent drift (Chandola et al. 2009), missed heartbeats identify suspected failures (Kawazoe Aguilera et al. 1997), and watchdog timers catch tasks that stall without crashing (Pont and Ong 2002). A node that stays alive but runs slowly or erratically, the gray failure of the failure taxonomy, can degrade progress while still meeting a liveness timeout, so section 7.9.5 treats it through straggler detection. Redundant computation adds stronger evidence on selected paths, either periodically or in response to an anomaly, by replaying a step on another device or comparing independently computed results. Its frequency depends on the residual corruption risk, the value of the protected state, and the cost of detecting an error late.

Checkpoint 7.2: Classifying a hardware fault

Verify your understanding of the transient, permanent, and intermittent fault categories and the fault, error, failure progression:

- ☐ **Transient fault**: classify a GPU that produces a wrong result once after a cosmic-ray strike and then computes correctly for the rest of the run, and justify why detection and rollback to a known-good checkpoint, not node replacement, match that fault.
- ☐ **Intermittent vs. permanent**: distinguish an intermittent fault from a permanent one when both can produce a stuck-at value, including the diagnostic signal that separates them.
- ☐ **Fault-error-failure chain**: trace a single bit flip through the fault, error, failure chain, identifying where error correction codes and checkpoint-restart each intervene.
- ☐ **Silent corruption**: explain why silent corruption sits apart from the other fault manifestations even when its underlying fault is an ordinary transient bit flip.

[9] **Hamming codes (1950)**: Richard Hamming developed error-correcting codes at Bell Labs after relay computers repeatedly detected errors in his unattended weekend jobs and abandoned them rather than repairing them. A Hamming code uses parity checks to locate a single-bit error with $\mathcal{O}(\log n)$ check-bit overhead; adding an overall parity bit yields the extended single-error-correcting, double-error-detecting form. Memory ECC implementations vary in code and coverage, so the system must account for both corrected errors and residual faults outside that coverage.

[10] **CRC (cyclic redundancy check)**: Polynomial checksum family introduced by Peterson and Brown (1961). CRC coverage depends on the polynomial, frame length, and error model; it is best understood as a low-cost detection layer rather than a universal guarantee. In distributed ML training, checksums or hashes can validate gradient payloads exchanged during collectives; without a verification layer, a corrupted gradient packet can silently poison the parameter update for every worker in the collective.

7.5 Check-and-Verify Defenses Against Silent Data Corruption

Of the hardware faults just classified, the costliest are the ones whose manifestation is silent. A corrupted value that raises no error passes every liveness check the fleet runs, and training keeps building on it. Defending against silent data corruption therefore requires checks that establish a correct result, not merely a live process, and choosing those checks starts with where the corruption comes from and how it surfaces in training.

7.5.1 The physics of silent corruption

An accelerator executes deterministic logic gates, yet the silicon carrying those gates operates under narrow physical margins where both random particle strikes and load-dependent defects can flip bits without halting the processor. Single-event upsets (SEUs), the particle strikes introduced with transient failures, create fleet exposure that grows with device count and operating time even when the per-device rate is low. Manufacturing variances can instead leave "marginal" chips that pass initial QA but fail under particular inputs or operating conditions. Voltage and temperature margins matter, including supply disturbances during rapid current changes (di/dt). Because these margin defects produce repeatable errors under specific workloads while particle strikes arrive at random, fleet reliability requires a probabilistic exposure model even when individual hardware faults are deterministic.

Facebook documented a pervasive SDC issue where a hardware fault caused a valid file to be reported as "size zero" during decompression (Dixit et al. 2021); the system "worked" without crashing, but data was silently deleted. In ML, the same failure manifests as valid-looking but numerically corrupted gradients. The pipeline trace in figure 7.7 follows a single ALU or memory bit flip as it corrupts an individual tensor entry, taints gradient reduction during the backward pass, commits into weights, and finally surfaces as degraded quality at evaluation. The comparative timelines beneath contrast this silent latency with a standard detected error. A hardware trap halts within milliseconds to restart cleanly from the last checkpoint, whereas silent corruption commits contaminated state into checkpoints over hours or days before an evaluation alert forces a costly rollback.

Telemetry from production training fleets shows this corruption is routine rather than anomalous. At modern training scales, hardware bit flips occur regularly, and erroneous computations from a single malfunctioning accelerator can propagate into the global model state, as Jeff Dean documented in his MLSys 2024 keynote on silent data corruption (Dean 2024) (figure 7.8).

In the Google training telemetry presented by Dean (2024), figure 7.9 identifies an abrupt gradient-norm anomaly as an SDC event. The plot shows the symptom without identifying the damaged bit or circuit. Corrupting a floating-point exponent is one mechanism that can greatly change a tensor value and subsequent updates. Gradient clipping can limit update magnitude, but it does not recon-

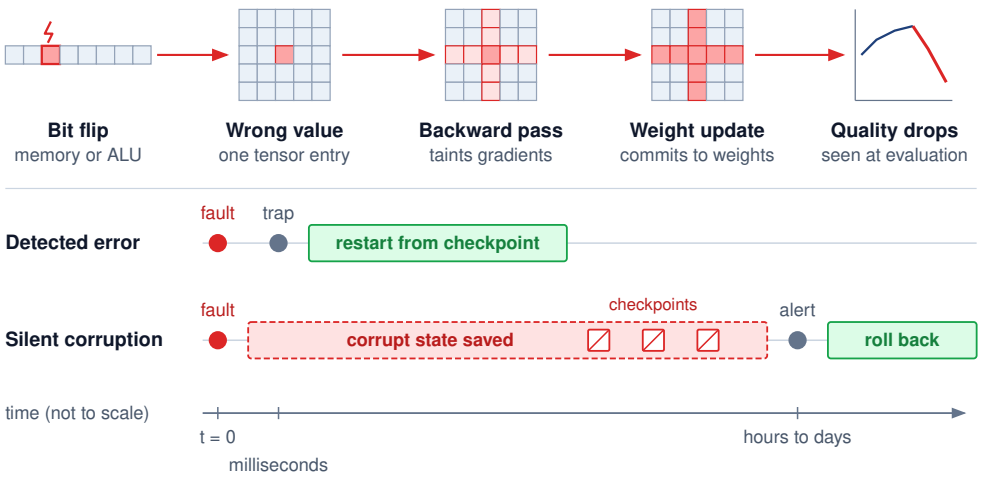

Figure 7.7: Silent Data Corruption Propagation: A hardware bit flip moves left to right from one wrong tensor value through the backward pass and the weight update, surfacing only at the final stage as degraded model quality. The two timelines below contrast a detected error, which traps within milliseconds and restarts from the last checkpoint, with silent corruption, which is saved into checkpoints for hours or days before an evaluation alert forces a rollback; the gap between the two is the cost of silence.

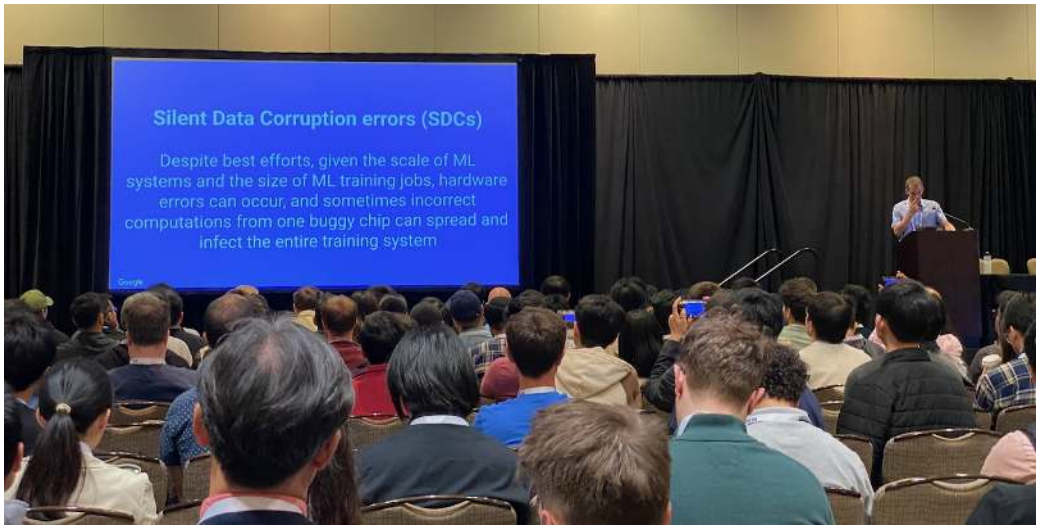

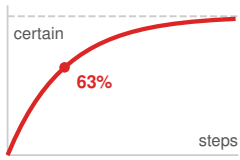

Figure 7.8: Silent Data Corruption at Scale: Jeff Dean presents on silent data corruption (SDC) at MLSys 2024, arguing that at the scale of large ML training jobs hardware errors occur routinely, and that incorrect computations from one buggy chip can propagate and infect an entire training run. Source: Jeff Dean, MLSys 2024 keynote (Google).

struct the correct gradient; an anomaly detector must trigger validation or recovery before suspect state is accepted.

7.5.2 Verification at fleet scale

Even a small per-GPU SDC rate accumulates across repeated collective operations, and the accumulation grows with fleet size. Any single collective is unlikely to contain an SDC event. Under the illustrative rate used in the analysis that follows, the per-step probability remains small while the cumulative probability grows

Cumulative SDC probability nears certainty over a long run.

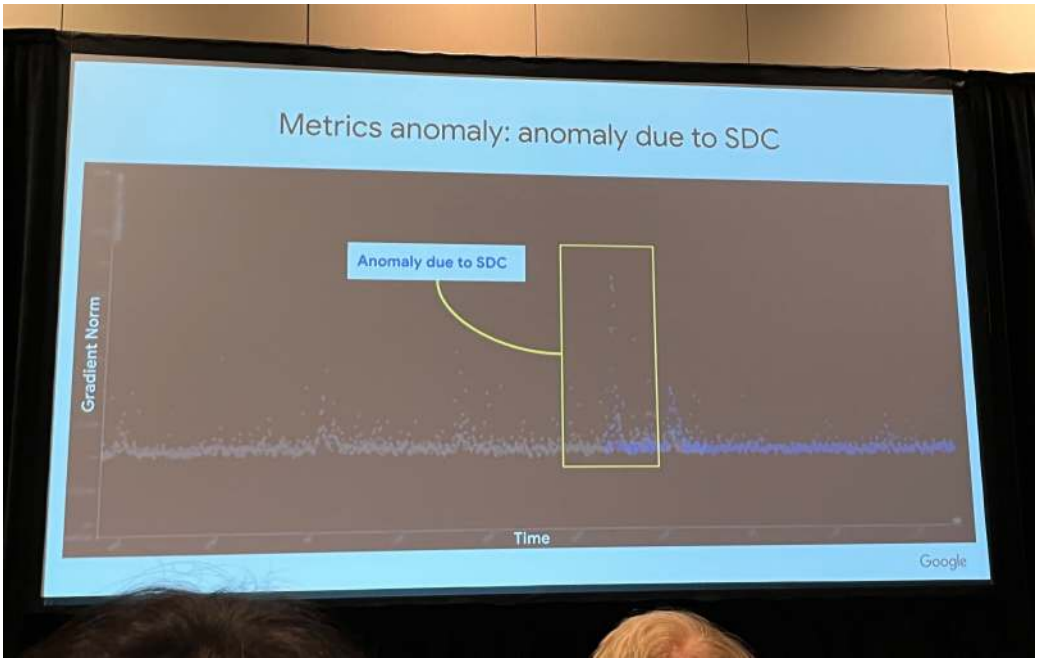

Figure 7.9: Gradient Norm Deviation: Transient hardware faults, such as silent data corruption (SDC), can disrupt optimization by causing abrupt changes in gradient norms. Google's production examples show SDC anomalies surfacing as visible gradient-norm spikes. Source: (Dean 2024).

over a long training run, reaching $1 - e^{-1} \approx 63$ percent once the expected number of events reaches one. On the chapter's 10,000-GPU cluster, that rate gives one expected event roughly every 100 hours, or about 22 over the three-month run of the chapter opening. The notebook below scales the same estimate to a fleet ten times larger to show where the trend leads, since the expected interval shrinks in proportion to fleet size. Standard AllReduce reduces the supplied contributions; it does not establish that an *alive* worker computed a *correct* gradient. The fleet therefore needs validation appropriate to its fault model in addition to liveness checks.

Check-and-verify methods test data-path invariants, subject to the boundary drawn for transient failures in section 7.3.1. Digests test byte integrity and agreement within their error-detection limits; they cannot establish that the original computation was correct. Independent computation, an algorithmic invariant, or replay tests that additional claim under a declared fault model. A quick estimate shows how much exposure those checks must cover.

Napkin Math 7.1: SDC risk accumulation

Problem: Under an illustrative generic SDC-rate assumption, calculate the probability that at least one GPU in a 100,000-GPU fleet experiences an SDC event during a single 2 s training step.

1. **Fleet size**: 100,000 accelerators.

2. **Individual risk**: 10^{-6} per GPU-hour (an illustrative generic SDC-rate assumption).
3. **The exposure**: In a 2-second window, the fleet has $100{,}000 \times (2/3600) \approx 56$ "GPU-hours" of exposure.
4. **The probability**: $\Pr(\text{at least one SDC}) \approx 0.0056$ percent.

Systems insight: Under this illustrative constant-rate assumption, a 100k-GPU fleet expects one SDC event every 18,000 steps (roughly every 10 hours), even though the per-step probability is only 0.0056 percent. A CRC or hash can protect each shard or reduced buffer against corruption in transit or storage, while a redundant reduction can test the arithmetic path independently. Robustness moves from being a *restart* problem to a *verification* problem only when the verification covers the failure mechanism being claimed.

Full replication protects a broader computation path at a correspondingly high resource cost. Dual modular redundancy runs every computation twice and compares the results, and triple modular redundancy runs it three times and takes a majority vote. These schemes pay 100 and 200 percent hardware overhead, respectively, to detect or mask a fault within a single control deadline (Sheaffer et al. 2007; Arifeen et al. 2020). These guarantees depend on the replicas avoiding a shared fault. The price is justified in safety-critical embedded control, such as a vehicle's onboard computers, where one wrong output can endanger people and the replicated hardware is a small computer. For fleet training, duplicating every step of a run on 10,000 GPUs doubles the compute devoted to those steps, before comparison and coordination costs. When corruption is rare and rollback can recover valid state, selective redundancy can protect useful progress at lower cost. Screening removes suspect devices, statistical checks run continuously, standby pools absorb drained nodes, and periodic or triggered recomputation checks selected execution paths.

Google's reactive hot-spare protocol shows how those pieces combine in three stages (figure 7.10). When runtime monitors flag an anomalous gradient and replay implicates a suspect accelerator (G2), the scheduler isolates that device and promotes a standby hot spare (S) into the active ring. It then provisions a replacement spare (S′) while the suspect unit undergoes hardware diagnostics (Dean 2024). The fleet pays in advance for one idle device per pool rather than for a duplicate of every computation, and the protocol shifts the burden of correctness from unverified hardware to system-level auditing. Even so, these hardware checks reduce only the risk of an unreliable physical substrate; they do not protect against faults that the software stack introduces itself, bugs that look like valid computation while corrupting the ML pipeline.

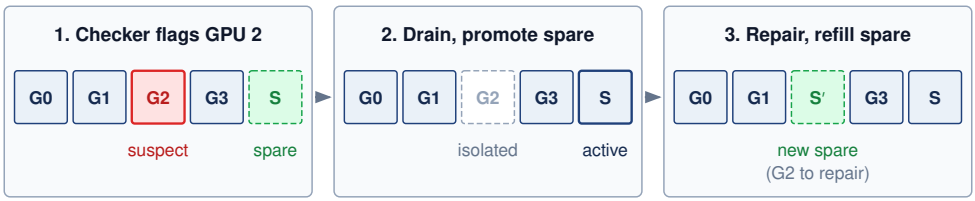

Figure 7.10: Hot-Spare Failover: An $N+1$ pool of four active GPUs and one standby spare. When loss or gradient sanity checks flag a suspect GPU and replay implicates it, the job drains that device and resumes on the spare from the last known-good state; the device goes to repair and a healthy unit refills the spare slot. Google's data-center examples use this reactive pattern to keep training moving despite hardware faults, in contrast to running every computation on two or three redundant units and comparing results (Dean 2024). The standing cost is the idle spare.

Checkpoint 7.3: Detecting silent corruption

Verify your understanding of Byzantine failures and SDC:

- ☐ **SDC danger**: explain why silent data corruption is more dangerous for ML training than a simple node crash.
- ☐ **Hot spare vs. restart**: compare a hot spare redundancy strategy with traditional checkpoint-restart in terms of recovery latency.
- ☐ **Sanity checker**: identify the metric used as a "sanity checker" to identify potential hardware faults: GPU temperature or gradient norm.
- ☐ **Byzantine scope**: assess the True or False claim that Byzantine failures only occur when a malicious actor intentionally sabotages the training cluster.

7.6 Software Faults

A team spends three months testing a large language model (LLM) against complex prompt-level failure cases, only to realize that its preprocessing script kept only the last 512 tokens of each input, silently discarding the system prompt on long requests. The example exposes an ordinary source of ML failure that algorithmic testing can miss. A logic error in a data loader or prompt assembler can preserve valid tensor shapes while changing the computation's meaning, allowing the pipeline to continue without a crash.

Software faults require a different recovery lens from hardware failures. Hardware faults enter from silicon, electrons, and physical wear; software faults enter through design choices, dependency versions, and pipeline glue. The fault-tolerance problem shifts from replacing a failed component to identifying which valid-looking transformation corrupted data, gradients, or predictions. Every boundary between framework, library, runtime, and distributed system is a place where such a transformation can hide.

7.6.1 Software fault properties and propagation

A single tensor reference leaked on every training iteration lets a correctly sized job drift toward the device memory limit over hundreds of steps and then crash with an out-of-memory error far from the code that leaked it. Across ML frameworks, software faults of this kind span logic errors, resource leaks, concurrency bugs, and integration mismatches that propagate across system boundaries. Race conditions in asynchronous updates can lose or overwrite parameter updates, and deadlocks[11] leave workers waiting on messages that never arrive. Because many of these faults surface only under high load, on particular hardware, or with a specific pairing of a high-level framework and a low-level numerical library such as cuDNN, root-cause analysis must treat the model code, the runtime, and its dependencies as one versioned artifact.

[11] **Pipeline deadlock**: In pipelined training, a deadlock can form when stage 1 waits for a free buffer to send activations to stage 2 while stage 2 waits for stage 1 to accept its backward gradients. Neither stage can proceed, and because every other stage depends on them, the whole job stalls with no error raised, which a collective timeout eventually converts into a detectable failure.

7.6.2 Software fault detection and prevention

The prompt-truncation bug from the opening example and the memory or synchronization bugs above should never survive unchallenged into a multi-week run. Because many software faults leave the pipeline running while corrupting inputs or gradients, each verification gate must establish which invariant holds and which recovery action is safe when it fails. A unit test catches the tokenizer boundary before launch, an integration replay verifies that a recorded batch reproduces the expected shapes and state on known-good hardware, and a fault-injection test verifies that a corrupted buffer or lost worker triggers rollback before tainting committed state.

Several of these gates also test the recovery machinery itself before an incident relies on it. A restore drill verifies a checkpoint manifest, the record that names every saved shard and the training step they share (section 7.8.5.2). A membership fault-injection test kills or partitions a worker and checks that, once replaced, the stale process can no longer write state the job will trust under the epoch, lease, and fencing rules of section 7.9.2. Every recovery drill is judged against two bounds formalized in section 7.8: how much completed work a failure may lose and how long recovery may take before useful execution resumes. Across all six gates, each test earns its place through the operational decision it authorizes (table 7.4).

Table 7.4: Reliability Evidence and Recovery Decisions: Tests earn operational value when each one establishes an invariant and authorizes a specific rejection, rollback, isolation, or restore decision.

Reliability evidence	Invariant exercised	Decision enabled
Boundary unit test	Tokenizer limits, tensor shapes, masks, and step metadata remain valid	Reject the change before distributed execution
Deterministic replay	A recorded batch produces equivalent state on known-good hardware	Separate input or software defects from suspect hardware
Checkpoint restore drill	A committed manifest restores every shard and resumes at its named step	Accept the generation as satisfying the recovery contract

Reliability evidence	Invariant exercised	Decision enabled
Membership fault injection	A killed or partitioned worker loses ownership and cannot write after replacement	Validate ownership handoff and communicator rebuild
Corruption injection	A changed shard, reduced buffer, or checkpoint fails the intended verifier	Block the optimizer step or roll back before propagation
Dependency rollback test	A versioned runtime and artifact set can return to the last known-good combination	Authorize automated rollback instead of manual repair

These safeguards matter only when each gate targets a concrete corruption path. A test that checks only whether the tokenizer runs is too weak; it must assert that system prompts, labels, masks, and sequence-length metadata survive preprocessing with the intended semantics. Integration replay then follows one recorded batch through loading, sharding, collation, and model input construction. Fault injection tests whether the detector fires before the protected commit and whether recovery stays within the named bounds on lost work and recovery time for the injected fault. Restore drills, stale-writer rejection, and corrupted-shard rejection therefore provide evidence that generic build success cannot supply, and section 7.14 exercises those claims directly once the recovery paths themselves have been built. Before building those paths, however, a fleet must decide how much protection each workload is worth.

7.7 The Cost of Failure

Losing an uncheckpointed day on a 10,000-GPU foundation-model run burns hundreds of thousands of dollars in accelerator time, whereas losing an hour on a small vision job costs a few hundred dollars and a failed update in an online recommender costs live revenue rather than batch rework. Hardware, silent corruption, and software together set how often a fleet fails, but the work a failure destroys determines what each incident costs. A defense is worth buying only where it removes more of that expected loss than it adds in standing overhead.

7.7.1 Failure cost by workload

Three workload properties set the price of a training interruption: the burn rate of the cluster running the job, the footprint of state that must be saved and reloaded, and how sensitive model quality is to lost or reordered updates. Those three factors separate multi-terabyte foundation models and continuous recommenders from smaller vision, speech, and scientific workloads (table 7.5).

Table 7.5: Failure Impact by Model Type: The cost of training failures varies dramatically by model type, driven by training duration, checkpoint overhead, and the value of accumulated training state. The Archetype A cost is one lost day on the chapter's 10,000-GPU cluster; the vision, speech, and scientific rows give illustrative ranges rather than measured values. These differences demand model-specific fault tolerance strategies.

Model type	Typical training duration	Checkpoint size	State sensitivity	Failure cost
Archetype A (GPT-4/Llama-3)	Weeks to months	2.45 TB (175B)	High (position in data order)	$0.5M compute per 24 hr loss
Vision (ViT-Large)	1–3 days	1.2 GB	Medium (augmentation state)	$10–50K per day loss
Archetype B (DLRM at Scale)	Continuous	10 TB+ (embeddings)	Very High (embedding freshness)	Revenue impact per hour
Speech (Whisper-scale)	3–7 days	5–10 GB	Medium	$50–200K per day loss
Scientific (AlphaFold)	Days to weeks	10–50 GB	High (exploration state)	Research delay

Large language model training illustrates how a costly allocation magnifies each hour of lost progress. The chapter's 10,000-GPU cluster at approximately $2/GPU-hour incurs $0.5M in compute costs per day. A job checkpointed only once a day can lose up to a full day of progress to one failure, which costs $0.5M in wasted compute plus schedule delay. At the checkpoint interval derived in section 7.8.1, the same failure costs minutes of rework instead of a day. The checkpoint overhead is correspondingly large. At the 14-byte-per-parameter resumable format that the checkpointing analysis uses (BF16 weights, FP32 master weights, and two FP32 Adaptive Moment Estimation (Adam) moments), the 175B-parameter running example writes 2.45 TB at every save.

7.7.2 Investing in protection

Every GPU cycle, network byte, and storage drive dedicated to checkpointing, standby nodes, or verification is a resource that is not training the model, yet skimping on protection leaves a multi-million-dollar run exposed to day-long rollbacks. Rational investment in fault tolerance therefore weighs what a failure destroys against what the defense costs to run.

When a failure strikes, its bill extends well beyond the GPU-hours burned on steps that must be replayed. Repeating lost work delays the delivery of the trained model, ties up accelerators that could have run other jobs, and pulls engineers away from research to diagnose faults and nurse manual restarts. On the other side of the cost account, prevention carries a continuous overhead even when the

cluster is healthy. Checkpoint storage scales with model size and save frequency, and checkpoint writes compete for memory and network bandwidth. Hot spares and automated recovery controllers consume standing infrastructure, and fault-tolerant coordination adds software complexity that must be maintained and debugged.

Optimal investment balances these two curves against cluster scale. For a small job on a few GPUs where hardware failures are weeks apart, infrequent checkpoints and manual restarts are cheaper than standing recovery infrastructure. On thousands of GPUs where failures arrive several times a day, frequent checkpoints, automated failover, and elastic resizing pay back their overhead many times over. The checkpoint interval derived in section 7.8.1 applies this exact marginal balance to a single decision variable, choosing the cadence where the cost of one more save equals the expected rework it prevents.

Equation 7.5 presents a simplified economic model for expected cost per training run:

$$C_{\text{total}} = C_{\text{compute}} + \mathbb{E}[N_{\text{failures}}] \times C_{\text{per-failure}} + C_{\text{ft}} \tag{7.5}$$

where C_{compute} is the base compute cost, $\mathbb{E}[N_{\text{failures}}]$ is the expected number of failures during training, $C_{\text{per-failure}}$ is the cost per failure, and C_{ft} is the cost of fault tolerance mechanisms. The cost per failure includes wasted compute plus overhead.

Equation 7.6 formalizes when fault tolerance investment is justified:

$$\frac{\partial C_{\text{ft}}}{\partial x} < -\frac{\partial(\mathbb{E}[N_{\text{failures}}] \times C_{\text{per-failure}})}{\partial x} \tag{7.6}$$

where x represents investment in fault tolerance mechanisms and the base compute cost is held fixed. The negative derivative on the right is the marginal reduction in expected failure cost. Additional protection reduces total expected cost while this reduction exceeds its marginal cost; an interior optimum equates the two when the cost functions have a suitable minimum.

One investment worked through the criterion shows what it decides. Let x be a hot-spare node held idle beside the chapter's 10,000-GPU cluster, so that a failed node's replacement no longer waits for the scheduler to find capacity. Its marginal cost is 8 GPUs idling all day, about $384 per day. Its marginal benefit is the recovery time it removes from each failure while every other GPU waits. At the cascade's 6.2 failures/day, each minute removed from every recovery is worth about $2,100 per day, so the spare pays for itself once it shortens each recovery by about 11 seconds, provided it is refilled before the next failure arrives some 3.9 hours later. The same node beside an eight-GPU job, whose GPU-only MTBF in table 7.1 is 6,250 hours (260 days), would sit idle far longer than it could ever save. Scale reverses the verdict on the same hardware, and three foundational principles distill how that shift guides design across the rest of this chapter.

Systems Perspective 7.2: Three rules of failure at scale

1. *At scale, failures are continuous, not exceptional.* A 10,000-GPU cluster experiences a failure every 3.9 hours on average. Systems must be designed expecting failure as normal operation.
2. *Checkpoint intervals have an optimum.* The Young-Daly interval (developed in section 7.8.1) sets checkpoint frequency from write time and system MTBF under its stated assumptions, and it shrinks only with the square root of a falling MTBF.
3. *Training and serving have fundamentally different fault tolerance requirements.* A long training job can budget minutes for recovery while preserving accumulated progress; an interactive serving request may have only milliseconds left before its deadline. Those budgets motivate checkpoint recovery for training and ready alternate capacity for serving.

These three rules organize the rest of the chapter: rules 1 and 2 govern long-running training jobs that must protect accumulated progress, rule 3 governs low-latency serving fleets that must protect live requests, and observability and fault injection verify that both recovery paths work under fire. Training resilience begins with the durable state that every restart or resize falls back on.

7.8 Checkpointing and Progress Preservation

When a top-of-rack switch dies two weeks into the training run of a 175-billion-parameter model, the cluster loses 64 GPUs instantly. Because a large cluster experiences such interruptions routinely (section 7.1), it cannot restart multi-week jobs from scratch; training fault tolerance must preserve state, detect and classify the failure, and resume or resize the worker group. Checkpointing supplies the first of those three obligations, and every detection, restart, and elastic-resizing path later in the chapter depends on the durable snapshot it produces. The first design question is what that snapshot must contain to make a restart valid.

Definition 7.1: Checkpointing

Checkpointing is the periodic serialization of the complete training state (parameters, optimizer state, data loader position, and random state) to persistent storage at a recorded training step.

1. **Significance**: It minimizes lost work after a system failure by trading checkpoint I/O against rework. Writing too often wastes accelerator time on storage traffic; writing too rarely risks replaying many completed steps after a failure. The Young-Daly interval developed in this section chooses the cadence that balances write cost against expected lost work.
2. **Distinction**: A resumable checkpoint captures a consistent execution state, including optimizer state, random-number generator state, data

position, and learning rate schedules. It can use full or incremental storage; bitwise replay additionally requires compatible deterministic execution.

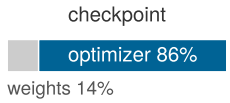
3. **Common pitfall**: A frequent misconception is that checkpointing is "just writing to disk." For large models it is a storage-system stress test, because the simultaneous write from thousands of GPUs can trigger a checkpoint storm (definition 4.5) that saturates the shared network and storage bandwidth (BW).

A checkpoint is useful only if it resumes the recorded step consistently. In distributed training, every shard must belong to the same recoverable state; a collection of files from different steps does not preserve progress. For the interval model, assume that writing a checkpoint completes durably before it becomes available for recovery and that a failure discards the work performed since the last completed checkpoint.

Two recovery objectives turn those obligations into a contract. The recovery point objective (RPO) bounds acceptable lost progress, so checkpoint age and replication lag must fit within it. The recovery time objective (RTO) bounds the delay until useful work resumes, which covers detection, resource replacement, restore, and warmup. A 20-minute checkpoint interval cannot promise an RPO below 20 minutes without a more frequent durable log or replica, and asynchronous flushing can leave the last durable generation older still. A five-minute RTO is impossible if checkpoint reload alone takes eight minutes. These objectives apply to a stated fault model. Corruption discovered after several saves can require rollback beyond the newest durable checkpoint. The Young-Daly interval derived next minimizes expected waste; RPO and RTO impose service constraints that the expected-value optimum must still satisfy (Beyer et al. 2016).

7.8.1 The Young-Daly checkpoint interval

When failures are expected during a job, the key engineering decision is how often to write that state, because every save costs I/O time and every unsaved step is work a failure can erase. The Young-Daly formula[12] (principle 13) gives a first-order estimate of that balance through a square-root rule:



$$T^*_{\text{ckpt}} = \sqrt{2 \cdot T_{\text{write}} \cdot \text{MTBF}_{\text{system}}} \tag{7.7}$$

T_{write} in distributed ML training is not the time to flush a small process state; it includes transferring model weights and optimizer state to durable storage. The reference format here stores BF16 weights, separate FP32 master weights, and two FP32 moment tensors per parameter for Adam. A single resumable checkpoint for a 70B-parameter model therefore approaches a terabyte at 14 bytes per parameter; for the later 175B-parameter running example, it exceeds two terabytes. Of those 14 bytes per parameter, the optimizer state[13] dominates the payload, exactly as in the storage sizing of the same resumable checkpoint in section 4.6. The optimizer

[12] **Young-Daly formula**: Young (1974) derived the first-order optimal checkpoint interval, and Daly (2006) independently refined it with tighter second-order bounds.

[13] **Adam optimizer state**: Adam's per-parameter first-moment (m) and second-moment (v) estimates are two FP32 values, 8 of the 14 bytes per parameter in the resumable checkpoint; with the FP32 master weights, optimizer-side state accounts for all but the 2 bytes of BF16 weights. For a 175B parameter model, the two moments alone reach 1.4 TB, which typically dominates checkpoint size and recovery time, making optimizer state the primary bottleneck in checkpoint I/O design.

state rather than the model weights therefore sets most of T_{write}. Reducing T_{write} requires a smaller payload or higher sustained write bandwidth, and T_{write} is the central constraint that determines how tightly the checkpoint interval can be set before I/O overhead displaces productive training compute.

Optimizer state, not weights, dominates checkpoint size.

To see the balance, consider an interval between saves. Doubling that interval approximately halves the checkpoint writes per unit of training, but a failure then loses twice as much work on average. Under the constant-rate, rare-failure approximation, failure occurs approximately uniformly within an interval, so the average lost work is half the interval. When write time is small relative to the interval, the wasted fraction from saving and replaying work is approximately the sum below. Detection, allocation, and restoration time require a separate recovery budget.

$$W(T_{\text{ckpt}}) \approx \frac{T_{\text{write}}}{T_{\text{ckpt}}} + \frac{T_{\text{ckpt}}}{2 \cdot \text{MTBF}_{\text{system}}} \tag{7.8}$$

Setting the first derivative to zero ($\frac{dW}{dT_{\text{ckpt}}} = -\frac{T_{\text{write}}}{T_{\text{ckpt}}^2} + \frac{1}{2 \cdot \text{MTBF}_{\text{system}}} = 0$) directly yields the square-root minimum of equation 7.7. As clusters grow, system MTBF drops, so the optimal interval shrinks, demanding higher-bandwidth storage to keep T_{write} small before checkpoint overhead consumes the cluster's compute capacity. Because the relationship is a square root, halving MTBF tightens the interval by only $\sqrt{2} \approx 1.4\times$, so doubling cluster size does not demand doubling checkpoint I/O bandwidth when checkpoint size and the other assumptions stay fixed. Substituting the optimum back into equation 7.8 gives a minimum waste of $\sqrt{2T_{\text{write}}/\text{MTBF}_{\text{system}}}$. Because $\text{MTBF}_{\text{system}}$ falls as $1/N$ under independent failures, that optimized overhead grows as $\sqrt{N}$, and doubling the cluster raises it by a factor of $\sqrt{2}$ even though the interval itself adapts.

7.8.2 Checkpoint interval from failure analysis

↩ The per-tier storage bandwidths that bound how quickly a checkpoint can be written are established in section 4.3.

The Young-Daly interval of equation 7.7 needs two inputs, the system MTBF and the write time T_{write}, and the chapter's 10,000-GPU cluster supplies both as computed values. The worked cascade (section 7.2.2) put full-system MTBF, including PCIe and network failures (the redundant power supplies add no term), at 3.87 hours. For the write time, the 175B running example's 2.45 TB resumable checkpoint drains to shared storage at the sustained aggregate write bandwidth this chapter assumes for the cluster, 100 GB/s, which takes 24.5 s. Substituting these into the Young-Daly formula gives a candidate interval for this cluster, which must still satisfy its RPO and RTO.

> **Napkin Math 7.2: The Young-Daly optimal interval**
>
> **Problem**: A 10,000-GPU cluster has an MTBF of 3.87 hours. A full model checkpoint takes 24.5 s to write. What is the optimal checkpoint frequency?
>
> **Math**: Apply the Young-Daly interval of equation 7.7 (principle 13).

1. **Convert to common units**: $\text{MTBF}_{\text{system}} = 3.87$ hours $\times$ 3600 s/hour = 13932 s.
2. **Substitute and solve**: With $T_{\text{write}} = 24.5$ s and $\text{MTBF}_{\text{system}} = 13932$ s, the formula gives $T^*_{\text{ckpt}} \approx 826.2$ s, or about 13.8 min.

Systems insight: At this interval, the checkpoint overhead (time spent saving plus time spent recomputing) is minimized to approximately 5.9 percent. Checkpointing every hour instead would lengthen the expected rework after each failure, wasting about 13.6 percent of the cluster's capacity.

The result connects measured or estimated interruption rates to checkpoint policy. At this interval, saving and expected replay together consume approximately 5.9 percent of training time in the first-order model, half from writes and half from replay, because at the square-root optimum the two terms of equation 7.8 are equal. Plotting those two terms for this cluster shows how forgiving the optimum is (figure 7.11). Write overhead falls hyperbolically and expected rework climbs linearly, so their sum has a shallow floor around 14 min. An interval slightly off the optimum costs little, while one several times too short or too long costs far more, which is why a rough MTBF estimate still yields a usable schedule. How far the estimate itself can be trusted depends on the simplifying assumptions behind it.

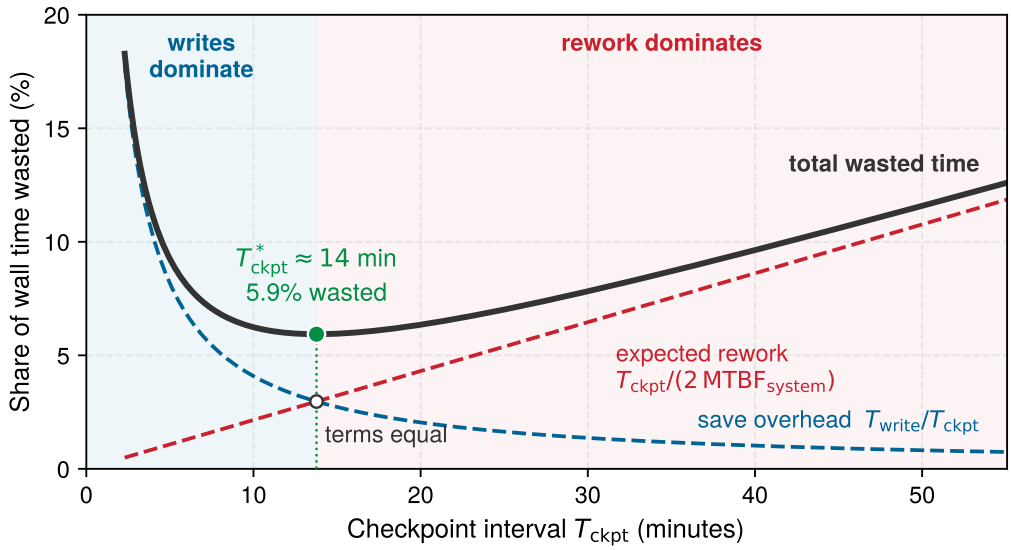


Figure 7.11: The Checkpoint Trade-Off: Checkpoint save overhead (dashed blue) falls as the interval lengthens, while expected rework after a failure (dashed red) rises; their sum (solid) is minimized at the Young-Daly interval. The curves use this chapter's 175B running example on its 10,000-GPU cluster, with a 24.5 s checkpoint write and a 3.9 h full-system MTBF, which put the optimum near 14 min. The minimum is shallow, so an interval somewhat off the optimum costs little, while a far shorter or far longer one costs a great deal.

Systems Perspective 7.3: Young-Daly formula assumptions

The first-order Young-Daly formula provides valuable intuition but rests on assumptions that may not hold when write times are non-negligible relative to MTBF; the renewal model derived in section E.5 shows how finite checkpoint time changes the optimum. The assumptions are:

- Exponentially distributed failures: Assumes a constant failure rate. Real hardware follows the bathtub curve, with higher rates during burn-in and wear-out phases.
- Deterministic checkpoint time: Assumes T_{write} is constant. In practice, checkpoint time varies from save to save with storage contention, network congestion, and memory pressure.
- Recovery cost is independent of the chosen interval: A fixed per-failure recovery cost does not change the first-order minimizing interval. Recovery can take longer than checkpoint writing because it also includes job scheduling delays, topology reconstruction, and warmup; it still belongs in the total-waste budget.
- Aggregate interruption process: Independent constant-rate failure sources can contribute to one job-interruption rate. Shared power, cooling, or switch failures require a model of incident frequency and recovery cost; adding per-device rates alone misses those common causes.
- Infinite timeline: Optimizes for long training runs. Short runs, where total time is comparable to MTBF, require different analysis.

When assumptions are violated, the optimal interval may shift significantly, but restart overhead should not be treated as if it were paid at every checkpoint. In the first-order lost-time model, restart time adds a per-failure recovery term to total expected waste; it does not replace T_{write} inside equation 7.7 unless a recovery-aware Daly-style model is explicitly derived and calibrated.

Along an execution timeline, a training run alternates productive compute intervals (T_{ckpt}) with synchronous save barriers (T_{write}), and a failure charges two distinct penalties (figure 7.12). Uncheckpointed progress is discarded as lost rework, and the restart latency (T_{recovery}) of job scheduling, checkpoint loading, and pipeline warmup follows before useful work resumes. Recovery latency therefore matters as much as write duration. Restart adds scheduling and warmup to reading the saved state back, so total restart time can exceed the checkpoint write time. It belongs in the total-waste and service-level objective (SLO) budgets as a per-failure term (perspective 7.3) rather than inside the per-checkpoint write term.

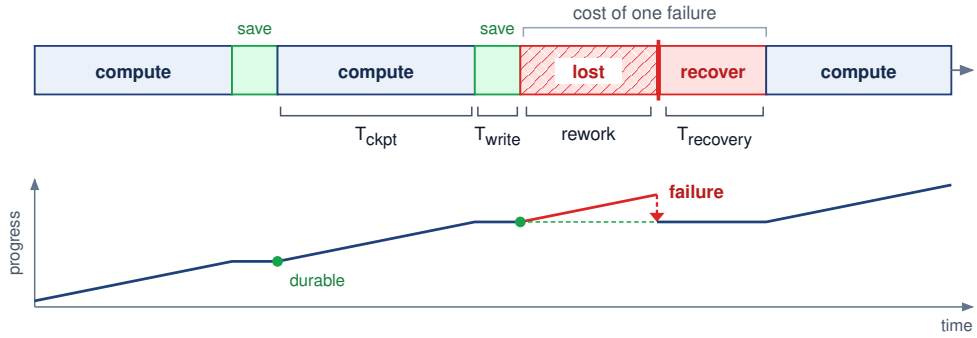

Figure 7.12: Checkpoint-Recovery Timeline: A training run alternates productive compute (blue) with durable checkpoint writes (green). When a failure strikes, all compute since the last completed checkpoint is lost (red hatching), and the job must then read the checkpoint and restart (red) before productive compute resumes. A failure therefore costs the rework since the last save plus the recovery latency; the Young-Daly interval trades the first of these against the write time paid at every checkpoint.

7.8.3 Checkpoint overhead analysis

The interval calculation chooses *when* the system preserves state; the write path decides what each save costs while training waits. Equation 7.9 generalizes the save-side term of equation 7.8 to include any pause beyond the write itself:

$$f_{\text{ckpt}} = \frac{T_{\text{write}}}{T_{\text{ckpt}}} + \frac{T_{\text{pause}}}{T_{\text{ckpt}}} \tag{7.9}$$

Here, f_{ckpt} is the dimensionless fraction of time lost to checkpointing, T_{write} is checkpoint write time, T_{ckpt} is the checkpoint interval, and T_{pause} is any training pause beyond the checkpoint write itself. This includes memory allocation, coordination, and serialization. Total first-order waste is then $W(T_{\text{ckpt}}) \approx f_{\text{ckpt}} + T_{\text{ckpt}}/(2 \cdot \text{MTBF}_{\text{system}})$, so checkpoint overhead in this section means the save side alone, with expected rework counted separately. How large f_{ckpt} becomes depends first on whether training waits for durable storage.

7.8.3.1 Synchronous vs. asynchronous checkpointing

Synchronous checkpointing resumes training only after every worker's portion reaches durable storage. Asynchronous checkpointing instead pauses the accelerators only long enough to copy the weights and optimizer tensors from GPU memory into host memory or local staging, then flushes that staged copy to remote storage in the background while training continues. The brief device-to-host copy is necessary because the next optimizer step updates the live GPU tensors in place, which would otherwise overwrite state that is still being serialized. Section 4.6.1 develops the write path behind both approaches. For recovery, blocking alone does not establish consistency, so the protocol must ensure that every shard belongs to the same recoverable training state. Recovery can use an asynchronous generation only after all required shards reach the storage tier that survives the modeled failure and the coordinator publishes completion. If a failure strikes

while the background flush is still in flight, recovery must fall back to the previous committed generation.

A synchronous save pauses every accelerator in the job for the full remote write, and section 4.6 prices that exposed pause on a slow shared tier. Asynchronous capture shrinks the exposed pause to the local staging copy and moves the remote flush off the critical path, which is why production systems stage checkpoints rather than block on shared storage. Write time also varies widely across model types, because larger models require longer writes but also earn longer optimal intervals (table 7.6).

The Archetype A row in table 7.6 uses the same 14-byte-per-parameter resumable checkpoint (2.45 TB) as the rest of the chapter. Its interval calculation uses the GPU-only cluster MTBF rather than the shorter full-system MTBF of the worked cascade, so the square-root rule gives a longer interval than the Young-Daly notebook. The table keeps the GPU-only basis because its purpose is comparison across model types. Switching every row to the full-system MTBF would shorten each interval, and raise each overhead, by the same square-root factor, leaving the ranking across rows unchanged. The ResNet-50 and BERT-Large rows count only FP32 weights, so their write times and resulting intervals are lower bounds for a resumable checkpoint. Their intervals of seconds describe the balance for that smaller payload; selecting a recovery cadence requires including optimizer, schedule, and input-stream state. Small-state jobs rarely run on a cluster this large, and their actual storage bandwidth and complete recovery state determine whether saves every few minutes or every epoch have negligible overhead. The large-state rows show why interval selection becomes consequential when each save moves hundreds of gigabytes or terabytes.

Table 7.6: Checkpoint Overhead by Model Type: The Archetype A row is the 175B running example at 14 bytes per parameter (weights, FP32 master weights, and Adam moments); the 20B, recommender, and vision transformer rows are representative scenario sizes, and the 4 TB embedding-heavy recommender is a smaller scenario than the 10 TB+ embedding tables of Archetype B (DLRM at Scale) in table 7.5; the BERT-Large and ResNet-50 rows count FP32 weights only and omit optimizer state, so their write times understate a full resumable checkpoint. Larger models require longer save times but also benefit from longer optimal checkpoint intervals. The percentage column reports the save-side overhead f_{ckpt} of equation 7.9 with no extra pause, not total Young-Daly waste; at the optimum, expected rework adds a comparable term.

Model type	Checkpoint size	Write time (100 GB/s)	Optimal interval (5 h GPU-only MTBF)	Save overhead
Archetype A (GPT-4/Llama-3)	2.45 TB	24.5 s	15.7 min	2.6%
20B dense transformer class	240 GB	2.4 s	4.9 min	0.8%
BERT-Large	1.4 GB	0.014 s	22 s	0.06%

Model type	Checkpoint size	Write time (100 GB/s)	Optimal interval (5 h GPU-only MTBF)	Save overhead
Embedding-heavy recommender	4 TB	40 s	20 min	3.3%
ResNet-50	102.2 MB	0.001 s	6 s	0.02%
Vision transformer class	1.2 GB	0.012 s	21 s	0.06%

These per-model overheads assume the write path is uncontended. When thousands of workers save at the same step, their combined burst becomes the checkpoint storm that section 4.6 defines and sizes; for recovery, the burst matters because a stalled write delays the generation that a failure would fall back on. Staging hides the write from training, yet a snapshot held only on local staging does not survive loss of its node, so where each copy lives decides which failures the saved state outlasts and how quickly it returns.

7.8.4 Checkpoint storage and recovery

Writing a checkpoint to node-local NVMe makes the save fast, but if the node itself fails, that local snapshot vanishes along with the hardware it was meant to recover. Writing only to a durable remote filesystem or object store survives the node failure, but pulling multi-terabyte state back across shared storage links slows every recovery. Recovery mechanisms therefore pair tiers from the storage hierarchy. Local NVMe provides fast staging and survivor reads, distributed filesystems provide durability across node failures, and object storage provides long-term retention. Together, the tiers let the saved state both outlast the fault and reload within the recovery budget.

↩ Tiered checkpoint storage designs and asynchronous write pipelines are established in section 4.6.

For fault tolerance, checkpoint placement determines which failures the saved state survives, while the restore path determines how quickly that surviving state becomes useful. On the 128-node Archetype A reference cluster, each node holds about 19.1 GB of the 2.45 TB checkpoint for the 175B running example. Reading that share from local NVMe at 5 GB/s takes about 3.8 s, with every node reading in parallel, while pulling the full checkpoint back through shared storage at 100 GB/s aggregate takes about 24.5 s. The local path is faster because it multiplies drive bandwidth by node count, but a sole copy on a lost node cannot restore that node's shard. The replacement node must read its share from a copy outside the failed domain, such as a distributed filesystem or object store, whose recovery time is set by sustained aggregate reads, network capacity, and deserialization. A sound placement therefore keeps a fast local copy for the survivors and a durable remote copy for whatever the failure took away, and these rates must still be measured under the job's own load.

7.8.5 Checkpoint coordination patterns

If workers in a sharded training job save their local shards at different steps without coordinating, rolling one failed worker back to its last save invalidates every peer that already consumed gradients or activations from its later steps. Rollbacks then cascade backward through the run in the classic domino effect (Elnozahy et al. 2002). Avoiding that cascade requires choosing how workers coordinate across two orthogonal dimensions. Workers can vary in whether they synchronize to capture a consistent cut (**coordinated** versus **uncoordinated checkpointing**). They can also vary in whether they funnel state through one writer or persist shards in parallel (centralized versus distributed checkpointing). Because distributed ML workers exchange state at every step, production training relies on **coordinated checkpointing**. In this scheme, workers synchronize at step boundaries or through an explicit two-phase commit protocol, so that all saved shards belong to a single globally consistent recovery line. Once coordination guarantees consistency, the remaining architectural decision is how those shards reach persistent storage: whether workers funnel their state through a single coordinator or write their partitions directly in parallel.

7.8.5.1 Centralized checkpointing

In centralized checkpointing, workers send their state to a coordinator process that assembles and writes the complete checkpoint. This approach simplifies checkpoint management and can produce self-contained checkpoint files, but all state crosses the coordinator's network links, and coordinator failure interrupts the save. A streaming writer can avoid buffering the entire checkpoint, although it cannot remove the ingress bottleneck. That bottleneck is structural. The coordinator receives through one node's network links, so its write time grows with total state volume, whereas independent writers each move only their own share of the state through their own links. The gap between the two patterns therefore widens in proportion to the number of writers. For the 175B running example, the 128 nodes of the reference cluster would funnel 2.45 TB through one node's links instead of 19.1 GB through each. The pattern is viable while that one path meets the checkpoint budget; state volume and sustained bandwidth determine the limit more directly than a fixed worker count. Centralized checkpointing is therefore attractive when operational simplicity matters more than aggregate bandwidth, whereas distributed and sharded approaches become necessary once the checkpoint itself is a fleet-scale object.

7.8.5.2 Distributed checkpointing

Distributed checkpointing eliminates this coordinator funnel by having each worker persist its own shard directly. Figure 7.13 contrasts the dataflow topologies: the centralized pattern concentrates traffic at the coordinator's ingress, while the distributed pattern writes in parallel to local NVMe and drains the shards to remote object storage in the background. With fixed per-worker shard sizes and sufficient independent staging bandwidth, adding workers need not lengthen the local write pause. Shared drain capacity and completion coordination can still

limit scaling. A coordinator signals when to checkpoint and confirms completion, but state flows directly from workers to storage without aggregation.

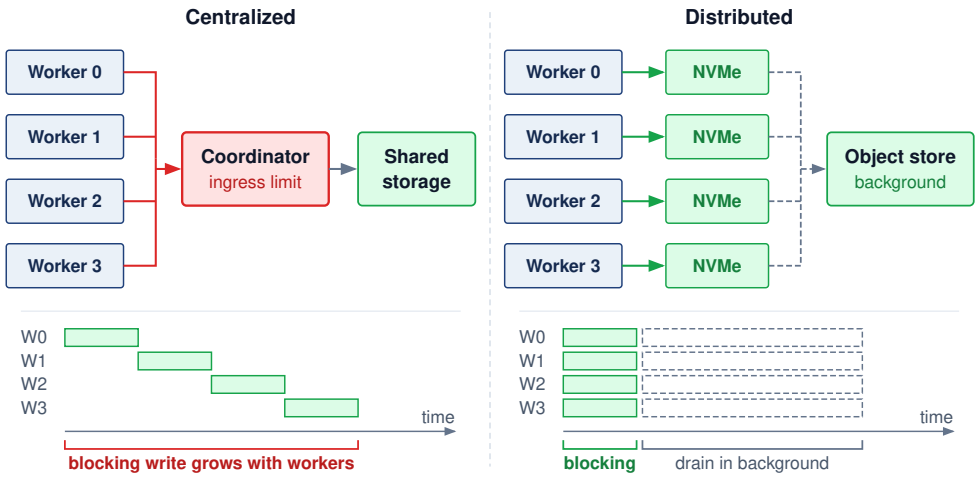

Figure 7.13: Distributed Checkpoint Architecture: Centralized vs. sharded checkpoint writes. In the centralized pattern (left), every worker funnels its shard through one coordinator, whose ingress bandwidth and buffering constrain the write path and whose failure halts the save. In the distributed pattern (right), each worker writes its own shard to local NVMe in parallel and a background process drains the shards to remote object storage, so the local blocking write time can remain roughly constant with fixed shard sizes and sufficient staging bandwidth; shared drain capacity still limits completion.

A synchronous version of the coordination protocol proceeds in six steps:

1. Coordinator broadcasts checkpoint request with checkpoint ID
2. Each worker reaches a consistent state (barrier synchronization)
3. Each worker writes an immutable shard to a generation-specific staging prefix and records its byte length and cryptographic digest
4. Each worker confirms durable write completion to the coordinator
5. The coordinator writes an immutable manifest after all confirmations; the manifest names the training step, topology, model and optimizer formats, data-loader position, random state, and the length and digest of every shard, then publishes a commit marker or atomic pointer to that manifest
6. Coordinator broadcasts checkpoint complete, training resumes

The idealized protocol assumes step 2 completes quickly. The barrier, however, waits for the slowest of thousands of arrivals, so a single slow worker can make it dominate the checkpoint pause even when the storage path has ample bandwidth. Measuring arrival skew separately from copying and writing reveals whether coordination or data movement limits the save.

The manifest, not the presence of a directory or a plausible set of shard names, defines a committed checkpoint generation. Restore accepts only a published manifest whose shards all match their recorded lengths and digests; staged shards without that final publication remain unreachable and can be garbage collected. This rule prevents a partially overwritten `latest` directory from masquerading as recoverable state and makes generation rollback explicit. PyTorch Distributed

Checkpoint follows this ordering, with storage writers persisting each rank's data before the coordinator's `finish()` operation writes the metadata and marks the checkpoint successful, while the storage backend supplies the publication semantics (PyTorch Contributors 2026a). The set of per-worker states a manifest names is a cut, and the cut is consistent when all of those states could have existed together at one moment of a valid execution. In a consistent cut, no shard reflects an update another shard has not yet seen. That consistency cut determines whether the system can claim strict, bounded-asynchronous, or eventual consistency.

> **Systems Perspective 7.4: Checkpoint consistency models**
>
> Strict synchronous: All workers checkpoint at exactly the same training step. Provides strongest consistency but highest overhead from barrier synchronization.
>
> Bounded asynchronous: Workers may progress at different rates while the checkpoint manager tracks which snapshots can form a consistent recovery cut. Bounding step skew alone is insufficient, because the system must retain compatible shard versions or enough replay information to reconstruct that cut. Asynchronous flushing can also preserve a single synchronized snapshot while its writes complete in the background, avoiding training stalls without relaxing recovery consistency.
>
> Eventual consistency: Workers save independently and recovery attempts to reconcile their versions. A usable design must retain enough compatible versions or replay information to reconstruct a valid state; arbitrary recent shards do not necessarily form a recoverable generation. Reduced coordination at save time therefore transfers work and storage requirements to recovery.

Steps 3 through 5 are two-phase commit,[14] the classic distributed-systems protocol for making one decision atomic across many participants (Gray 1978), applied to a checkpoint. Steps 3 and 4 form its prepare phase, in which each worker stages its shard and reports success, and step 5 is its commit phase, in which the coordinator durably records the decision by publishing the manifest. The manifest publication rule inherits the protocol's guarantee and its known weakness. If the coordinator crashes after workers prepare but before it records a decision, the system must not expose those shards as a valid checkpoint, and the prepared participants remain blocked until the original or a replacement coordinator recovers the durable decision. Uncommitted staged shards can be garbage collected only after recovery establishes that no commit decision exists. Atomic publication also does not by itself make the published shards consistent: synchronous gradient updates naturally create step boundaries where all workers have applied the same updates, whereas asynchronous training and pipeline parallelism require explicit coordination to define a consistent cut.

[14] **Two-phase commit (2PC)**: Formalized by Gray (1978), 2PC ensures all participants either commit or abort atomically. A timeout can trigger coordinator recovery, but it cannot by itself authorize unilateral rollback.

7.8.5.3 Sharded checkpointing

Modern distributed training frameworks partition model state across workers using techniques like ZeRO and FSDP, which shard parameters, gradients, and optimizer state instead of replicating them on every data-parallel worker. In these configurations, no single worker holds complete model state. Each worker holds only its assigned parameter shard plus corresponding optimizer state.

↩ How ZeRO and FSDP partition training state across data-parallel workers is established in section 6.3.3.

Sharded checkpointing[15] (Rajbhandari et al. 2020) uses this distribution. Each worker writes only its shard, which divides the per-worker write volume by the number of shards. Recovery loads shards and redistributes state to workers based on the recovery configuration.

Dividing state across the fleet keeps per-worker saves small even for multi-terabyte models. A 175B parameter model with a 2.45 TB checkpoint distributed across 1,024 workers requires each worker to write only 2.4 GB, achievable in seconds with local NVMe storage. When elastic scaling or hardware replacement changes the worker count between save and restore, shard redistribution must remap the saved partitions to the new worker configuration, which is why frameworks need flexible resharding support to recover across topology changes. Yet possessing a valid checkpoint is only half the recovery path. Sharding distributes the write work and staging controls the shared I/O burst, but the system must still detect the failure, trigger restoration, and coordinate the distributed shards before training can resume. The speed of detection and recovery therefore governs the cost of the interruption.

15 **Sharded checkpointing**: Each worker saves only its local partition rather than gathering state to a single writer, parallelizing I/O across all nodes. The trade-off is that recovery requires every shard to be available and consistent, making the checkpoint protocol more complex. Losing one storage device invalidates the generation only if a required shard cannot be recovered from another copy or sufficient storage redundancy.

Checkpoint 7.4: Reasoning about checkpoint overhead

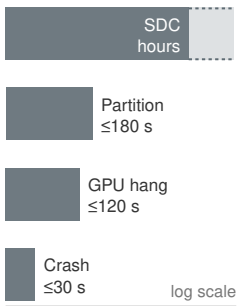
Verify your understanding of how failure rate and checkpoint cost set the optimal checkpoint interval:

- ☐ **Young-Daly shift**: use the Young-Daly formula to estimate how the optimal interval T^*_{ckpt} shifts when a cluster doubles in size and its system MTBF halves, with T_{write} held fixed. State whether the interval lengthens or shortens and by about what factor.
- ☐ **Two-sided overhead**: explain why writing checkpoints too frequently and writing them too rarely both raise checkpoint overhead, including the two costs T^*_{ckpt} balances.
- ☐ **Faster writes**: determine how an order-of-magnitude reduction in T_{write} from sharded checkpointing changes the optimal interval and expected lost work per failure.
- ☐ **Square-root scaling**: explain why the Young-Daly interval depends on the square root of MTBF rather than scaling linearly with it.

7.9 Failure Detection and Recovery

A GPU silently hangs, dropping its utilization to zero while its peer GPUs wait indefinitely at an AllReduce barrier. On the chapter's 10,000-GPU cluster, every

minute the system takes to notice this hung rank and reboot the node costs about $330 in idle compute. Checkpoints preserve state, but the recovery process itself determines how much compute a failure wastes. In the accounting of the Fleet Law (equation 1.3), that waiting belongs to the synchronization term $T_{\text{sync}}(N)$. Every surviving rank idles at the barrier until the group is whole again, so detection, restart, and reload add directly to step time averaged over the run. The goodput accounting of section 9.2.3 charges the same time to runtime goodput.



Equation 7.10 decomposes recovery time into four primary components:

$$T_{\text{recovery}} = T_{\text{detect}} + T_{\text{restart}} + T_{\text{load}} + T_{\text{warmup}} \tag{7.10}$$

where T_{detect} is the time between the physical hardware fault and system classification as a failure. The term T_{restart} is the latency required for the job scheduler to allocate resources and launch replacement processes. The term T_{load} is the I/O duration to read checkpoint state from distributed storage into GPU memory. The term T_{warmup} is the interval needed to refill data pipelines, compile just-in-time (JIT) kernels, and stabilize training throughput. Each component presents distinct optimization opportunities, and the dominant term varies by cluster configuration. Understanding this decomposition enables targeted investment in the bottleneck rather than uniform improvement across all components.

7.9.1 Failure detection mechanisms

To the rest of the cluster, a dead rank and a rank busy flushing a multi-gigabyte checkpoint shard both look silent. Every failure detector must therefore balance two expensive mistakes: setting timeouts too short kills healthy workers during transient network or storage stalls, while setting them too long leaves thousands of peer GPUs idling at a collective barrier. Heartbeat monitoring is the first detection layer and usually sets the floor on T_{detect}. Each GPU rank periodically signals liveness to a coordinator, and if no heartbeat arrives within the timeout period T_{timeout}, the coordinator declares the worker failed.

Detection latency climbs from seconds (crash) to hours (silent corruption).

For a heartbeat interval of H seconds and network-delay standard deviation σ_d in seconds, equation 7.11 defines the timeout heuristic:

$$T_{\text{timeout}} = H + k\sigma_d \tag{7.11}$$

Here, k is a dimensionless safety multiplier; values from three to five illustrate a tuning range rather than a guaranteed false positive rate. The heuristic treats the normal heartbeat delivery delay as small relative to the heartbeat interval. A deployment with substantial baseline delay or a heavy delay tail must account for those measurements as well as σ_d. Tuning T_{timeout} too tightly causes legitimate checkpoint writes or long collectives to trigger false failure declarations; tuning it too loosely extends the window during which other ranks wait for the missing contribution.

Collective communication timeouts provide a second detection layer. During synchronous training, a collective required by the next step remains an incomplete critical-path dependency if a required rank disappears. AllReduce needs every

rank's contribution before it can produce the reduced result; the progress and failure behavior of other collectives depends on the operation and runtime. Transport and process-group timeouts bound how long the job waits before declaring the operation failed and entering recovery. NCCL[16] provides configurable transport and reliability, availability, and serviceability (RAS) timeout parameters for this purpose, while higher-level frameworks may impose process-group operation timeouts. These settings are often set conservatively to avoid crashing jobs during legitimate periods of slow communication, which unfortunately extends T_{detect}.

Container orchestration health checks provide a third layer. Kubernetes, the container orchestration system, offers liveness probes (verifying that a process still responds and makes progress) and readiness probes (verifying that a process is ready to handle requests). Slurm, the batch scheduler common on HPC-style training clusters, instead runs a periodic node health-check program that can drain a node whose GPUs, links, or file systems fail their tests. Both operate independently of the training framework, catching failures that application-level heartbeats might miss; a liveness probe that tests forward progress rather than mere process existence can catch a process that is alive but deadlocked.

Loss spike detection exposes an anomaly, not its cause. Figure 7.14 contrasts an idealized healthy loss trend with gradient explosion, a premature plateau, and NaN divergence. Real stochastic training need not decrease monotonically, so a transient rise alone does not establish failure, and nonfinite values need not crash the process. Silent hardware corruption can produce an abrupt loss or gradient-norm spike, but so can a bad batch, an optimizer instability, a data-ordering defect, or a distributed-state mismatch. Robust systems therefore pause before the suspect update commits, preserve the input and worker evidence, and replay the step on known-good hardware. The system drains hardware only after that evidence implicates the device; otherwise, it repairs the data, optimizer, or synchronization path that produced the same symptom.

Table 7.7 pairs each signature, plus the silent hang that a loss curve cannot show, with a candidate cause and a first response. The pairing guides investigation without treating the curve as a unique diagnosis, and the operational question that follows is how long detection actually takes once these monitoring layers interact.

[16] **NCCL timeout**: NVIDIA's collective communication library exposes transport and RAS timeout controls such as `NCCL_IB_TIMEOUT` and `NCCL_RAS_TIMEOUT_FACTOR` (NVIDIA 2026c). Higher-level launch and distributed-training frameworks can add their own restart and operation-timeout behavior (PyTorch Contributors 2026c). Aggressive timeout settings accelerate failure detection but risk false positives during legitimate long collective operations on large models, forcing a trade-off between detection latency and training stability that has no universal optimum.

Table 7.7: Training Failure Response Map: Training-loss curves are operational evidence only when they lead to different recovery actions. The response map ties each signature to the failure class most likely to explain it and to the first action operators should take.

Signature	Likely interpretation	Recovery response
Spike followed by recovery	Transient input or numerical anomaly; the curve alone does not identify the cause	Preserve the suspect batch and step evidence, then replay before deciding whether to continue.
Spike followed by plateau	Optimizer instability, corrupted state, or a persistent data-path defect	Pause, replay from a known-good checkpoint, and compare input, optimizer, and worker evidence.

Signature	Likely interpretation	Recovery response
Gradual divergence	Data drift, numerical instability, corrupted state, or worker desynchronization	Compare per-rank telemetry and evaluation evidence; isolate hardware only when replay implicates it.
Hang without an error	Collective deadlock or crashed worker blocking synchronization	Use timeout detection and restart or reconstruct the worker group.

Systems Perspective 7.5: Realistic failure detection latencies

Failure detection includes more than the configured heartbeat timeout when the policy requires verification before recovery. The ranges in table 7.8 illustrate planning scenarios, not universal detection guarantees. Aggressive timeouts risk false positives (killing healthy-but-slow workers), while conservative timeouts delay real failure detection. A multi-stage policy can use an initial timeout to trigger investigation and a later threshold to trigger recovery. Its actual latency must be measured under the workload and failure conditions it is intended to handle.

Table 7.8: Illustrative Failure Detection Latencies: Planning ranges for detecting process crashes, GPU hangs, network partitions, and silent data corruption, with the dominant cause of latency for each category, showing why static heartbeat timeouts alone are insufficient. The ranges are illustrative assumptions, not measurements; a deployment must measure its own.

Failure type	Planning range	Why
Process crash	5–30 seconds	Heartbeat timeout + verification retries
GPU hang	30–120 seconds	Must distinguish from legitimately slow kernel
Network partition	60–180 seconds	Must distinguish from temporary congestion
Silent data corruption	Minutes to hours	Requires statistical anomaly detection

7.9.2 Recovery procedures

Once a failure is classified, a cold-restart recovery path executes a coordinated sequence to restore consistency. The warm-restart alternative developed next preserves surviving processes when their state can be trusted.

1. Job termination: A `SIGTERM` is broadcast to all surviving workers. This cold-restart path tears down the affected training group so that no survivor continues using the old membership or partially completed collective state.
2. Resource reclamation: The scheduler marks the failed node as "draining" to prevent immediate rescheduling and requests a replacement from the spare pool.

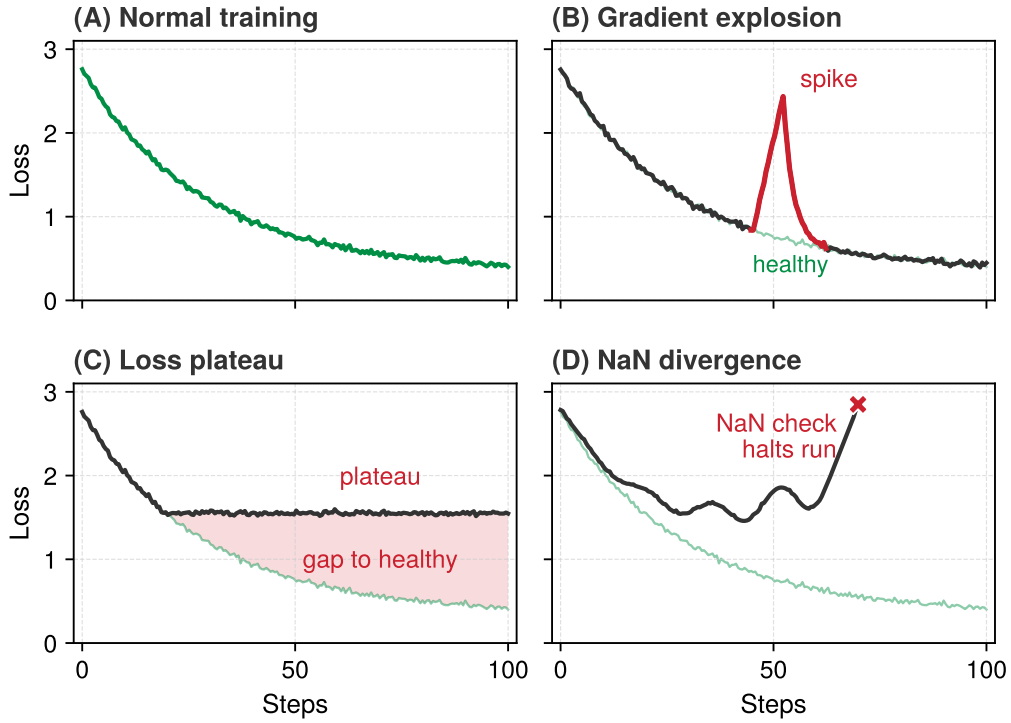


Figure 7.14: Training Failure Signatures: Common patterns of model loss over time that indicate underlying system or algorithmic failures. (A) Normal training. (B) Gradient explosion. (C) Loss plateau. (D) NaN divergence, ending where a nonfinite-value check halts the run; without such a check the process can keep running on NaN values rather than crash. Identifying these signatures automatically is essential for rapid recovery in autonomous training pipelines. The curves are synthetic illustrations of each pattern, not logs from a training run.

3. Job restart: New containers are launched (from cache if available), and the training binary is re-initialized on all nodes.
4. Checkpoint loading: Each worker reads the state assigned to it from the distributed filesystem. When membership or parallelism changes, recovery remaps the saved shards to the new partitions.
5. State synchronization: Ranks handshake to establish a new communicator (for example, `ncclCommInitRank`), and workers verify they are all at the same training step.
6. Training resumption: The data loader restores its recorded position and sampling state, and the training loop resumes from the checkpoint step. A batch index alone suffices only when it reconstructs the same logical input stream.

Automatic recovery systems perform these steps without human intervention. Modern training frameworks integrate with cluster managers to automate parts of the sequence. DeepSpeed documents save/load routines for model and ZeRO optimizer checkpoints, which provide the durable state needed after failure (DeepSpeed Developers 2026a). PyTorch's `torchrun` elastic launch documents failure and membership-change behavior through its rendezvous mechanism,[17] the

[17] **Rendezvous**: From French "rendezvous" (present yourselves), this coordination protocol lets restarted workers discover one another and establish a new group before training resumes. Recovery waits for the membership policy to be satisfied, so slow startup, delayed communication, and missing workers can extend this phase. Heterogeneity affects those delays but does not by itself imply a proportional latency law.

coordinator-backed protocol by which surviving workers agree on membership and ranks after a restart (PyTorch Contributors 2026c, 2026b).

Recovery validation tests whether the restored job behaves consistently with its recorded state. Parameter shapes, dtypes, and shard identities must match the manifest. A short replay or validation workload then checks loss and gradient statistics under the expected numerical tolerance; different batches need not reproduce the last prefailure loss. Immediate divergence is evidence to investigate the checkpoint, data state, and execution configuration, not proof that the snapshot is corrupt. Falling back to an earlier validated generation is appropriate when the newest state cannot be trusted.

Recovery must also prevent the failed ownership epoch from returning. A coordinator grants each worker-group incarnation a monotonically increasing epoch (a membership counter, unrelated to a training epoch over the dataset) and associates membership with a renewable lease. Every state-changing write carries that epoch as a fencing token. Before replacement writes proceed, the recovery protocol advances the enforced epoch at each protected resource, which rejects writes carrying an older token (figure 7.15). The old worker then cannot publish a checkpoint or update job progress, even if it resumes after a long pause; rendezvous likewise admits only the current membership. A lease alone is insufficient because expiration changes the coordinator's ownership decision, not the old worker's ability to reach storage. Fencing enforces that decision at the resource boundary (Kleppmann 2016).

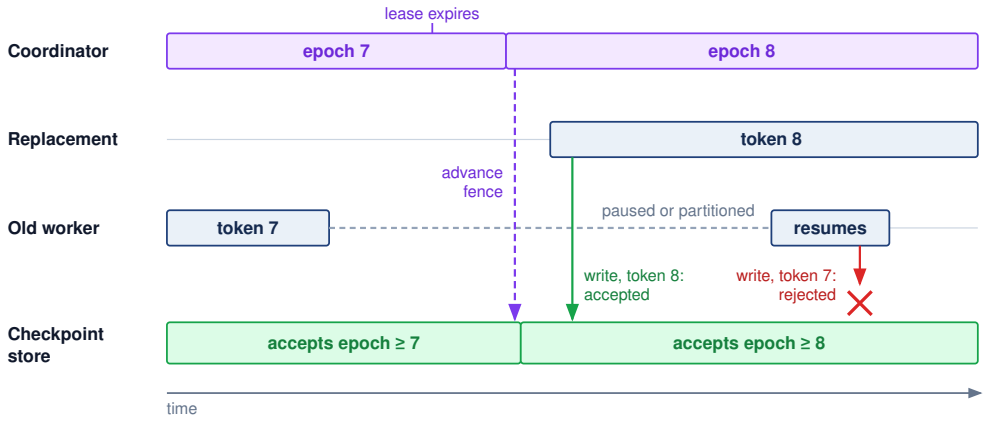

Figure 7.15: Epoch Fencing during Recovery: When the old worker's lease expires, the coordinator starts epoch 8 and advances the epoch the checkpoint store enforces before the replacement begins writing. The replacement's writes carry token 8 and are accepted; when the old worker resumes from its pause or partition, its write still carries token 7 and the store rejects it. The lease decides ownership, and the fence at the store enforces that decision even against a worker that never learned it lost ownership.

Retries complete the recovery contract. An operation may be retried automatically only when it is idempotent or carries a stable operation identifier that lets the receiver deduplicate repeated effects. Each attempt inherits the caller's absolute deadline rather than receiving a fresh timeout, and the system caps attempts with a retry budget shared across the request or recovery tree. Exponential backoff and jitter spread attempts in time, but they do not prevent overload if every layer

retries independently. The budget therefore belongs at one retry-owning layer; exhausted budget returns a failure or invokes degradation instead of amplifying the original incident (Beyer et al. 2016; Nygard 2007).

Napkin Math 7.3: The recovery time budget

Problem: Consider a 175B parameter model training on 1,024 GPUs. The checkpoint size is approximately 2.45 TB (BF16 weights, FP32 master weights, and Adam moments at 14 bytes per parameter). Estimate the cost of a single failure event.

Setup: The recovery budget T_{recovery} has four terms.

- $T_{\textbf{detect}}$: 60 s (conservative heartbeat timeout with verification retries).
- $T_{\textbf{restart}}$: 3 min (scheduler queue time + container launch + Python import overhead + NCCL initialization).
- $T_{\textbf{load}}$: 24.5 s (this is the aggregate-shared-storage read of the full 2.45 TB checkpoint at 100 GB/s aggregate). With sharded local-NVMe reads at 5 GB/s, one GPU's 2.4 GB shard alone would load in under a second. The GPUs of a node share its drive, however, so the node's 19.1 GB share takes about 3.8 s, and only on nodes that survived with their local copy).
- $T_{\textbf{warmup}}$: 2 min (JIT kernel compilation, data pipeline buffer fill, TCP connection re-establishment).

Total: $T_{\text{recovery}} = T_{\text{detect}} + T_{\text{restart}} + T_{\text{load}} + T_{\text{warmup}} \approx 6.4$ min per failure event.
Impact: For this recovery path, T_{recovery} is the operational MTTR term in the steady-state availability relation (perspective 7.1). It is not the whole cost of a failure. Every failure also discards the work done since the last completed checkpoint, on average half the checkpoint interval (figure 7.12), and the Young-Daly waste of equation 7.8 already counts that rework, so the figures below price only the recovery term. Recovery time optimization matters more as clusters grow. The GPU-only baseline from table 7.1 compares the two sizes on a common basis and understates both failure counts. On that basis, a 1,024-GPU cluster has MTBF of 49 hours and experiences about 0.49 failures/day, losing about 3 minutes daily, a modest 0.2 percent overhead. However, a 10,000-GPU cluster has GPU-only MTBF of 5 hours and experiences about 4.8 failures/day, losing about 31 minutes daily (2.1 percent overhead). That is equivalent to wasting roughly 5,127 GPU-hours every day (the daily lost minutes multiplied across all 10,000 GPUs).

7.9.3 Warm restart vs. cold restart

The recovery procedure described in section 7.9.2 is a cold restart: every process in the affected job group exits, and the group reloads state from a valid checkpoint. This simplifies recovery by avoiding dependence on surviving in-memory state, but it can discard useful state. After one GPU fails in the 1,024-GPU reference

job, every surviving worker may retain reusable values; an interrupted update or silent corruption, however, can make some of those values unsafe to keep.

A warm restart preserves the state of surviving workers. When a rank fails, surviving ranks detect the failure but do not exit. They enter a waiting state, preserving loaded model weights and optimizer states in GPU memory. The scheduler replaces only the failed node. The new node joins, loads its partition of the state from disk (or receives it via broadcast from a peer), and the communicator is rebuilt. The replacement and survivors must agree on the same committed training step before resuming. A shard restored from an older checkpoint cannot be combined with survivor shards that have advanced beyond it; the runtime must reconstruct the missing current state or roll the group back to a common recovery point. Training resumes only after that consistency check.

When the missing state can be reconstructed at the survivors' current step, warm restart avoids a full-cluster reload and repeated warmup. For the 1,024 GPUs example, that fast path avoids rereading the full 2.45 TB checkpoint through shared storage, whose cold-path T_{load} is 24.5 s. The replacement still needs state transfer and initialization, and all ranks wait until it is ready. If consistency instead requires a rollback, the recovery budget must include the corresponding survivor-state restoration and lost work.

The trade-off is software complexity. Survivor-preserving warm restarts require specialized application and runtime support for dynamic membership changes without leaking CUDA memory, corrupting shared state, or deadlocking during communicator reconstruction. Common training frameworks restart the worker group or reload a checkpoint rather than preserve survivors (section 7.10.1.2). A deployment that implements a warm-restart fast path still needs cold restart as a safety net. The cold-restart range in table 7.9 brackets the 6.4 min budget computed above. The warm-restart range is a planning range for the fast path, which avoids the full-cluster reload and warmup; its actual duration depends on how quickly the replacement receives its state and the communicator is rebuilt.

Table 7.9: Cold vs. Warm Restart Trade-Offs: Cold restart kills every process and reloads from disk; warm restart preserves surviving workers and replaces only the failed node. Warm restart cuts recovery from minutes to tens of seconds for the typical single-node failure but introduces software complexity around dynamic membership management. Mature deployments can run warm restart as the fast path and cold restart as the safety net. Recovery times are illustrative planning ranges, not measurements.

Aspect	Cold restart	Warm restart
Recovery time	4–10 minutes (full reload)	30–90 seconds (single node reload)
State guarantee	Clean: all state from checkpoint	Assumes surviving state is valid
Implementation	Simple: kill all, reload all	Complex: dynamic membership management
Failure during recovery	Retry cold restart	Fall back to cold restart
Best for	Correlated failures, SDC events	Single-node failures, GPU errors

7.9.4 Recovery automation pipeline

At the scale of 10,000+ GPUs, failures occur multiple times per day, so human operators cannot intervene manually on each incident. Recovery must be an autonomous control loop managed by the cluster control plane. Published reports from large training fleets describe multi-stage automation that classifies failures and selects the minimum viable remediation (Dubey et al. 2024; Kokolis et al. 2025; Zu et al. 2024).

The pipeline operates in four ordered stages:

1. Health monitoring daemon: Continuously scrapes GPU telemetry (ECC error counters, temperature, fan speed, NVLink status) alongside application metrics like training loss and step throughput, often from a sidecar container.
2. Failure classifier: Determines whether a signal indicates a fatal error (for example, NVIDIA Xid error 48: double-bit ECC error), a transient stall (for example, temporary network congestion), or a performance degradation (for example, thermal throttling).
3. Action selector: Chooses the cheapest response consistent with the affected state and communication group. A process hang on one rank usually requires restarting the whole communication group rather than one container, because every surviving rank still holds a communicator that includes the hung rank. A confirmed hardware fault requires draining the node and drawing a replacement from the spare pool, which is slower and consumes standby capacity. A network partition can justify a bounded wait that preserves in-memory state, but if the wait expires, replacement must fence the old ownership before accepting new writes.
4. Validation stage: Runs a recorded "canary batch" or validation workload under the expected numerical tolerance. Unexpected loss or gradient behavior triggers investigation of restored state and execution configuration, with fallback to an earlier validated snapshot when the new state cannot be trusted.

This automation removes the human page-diagnose-repair cycle from the recovery path for the common failure types, which shortens mean time to recovery. The classification stage matters most. Treating every failure as a cold restart wastes compute on transient issues, while treating a hardware failure as transient allows corrupted computation to continue. The Llama 3 pretraining run shows what such a pipeline buys at fleet scale.

War Story 7.2: The training run that failed every few hours (2024)

Context: Meta reports training Llama 3 405B on 16,384 H100 GPUs during a 54-day snapshot of pretraining (Dubey et al. 2024).

Mechanism: The snapshot recorded 419 unexpected interruptions, about one every 3.1 hours, with the root causes shown in figure 7.2.

Impact: Meta nevertheless reported more than 90 percent effective training time, measured as useful training time divided by elapsed time. Significant manual intervention was required only three times.

Fix: Meta reduced job startup and checkpointing time and developed automated diagnosis and recovery tools. Communication traces helped locate stalled collectives and slow workers before restarting useful work.

Systems lesson: At fleet scale, reliability is a property of the recovery system rather than of the hardware. Effective training time stayed high because automation, not operators, handled nearly every interruption.

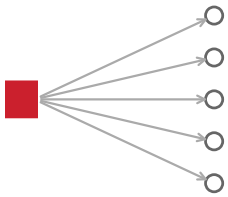
7.9.5 Stragglers versus fail-stop failures

Not every recovery decision starts from a crashed process. When one GPU in a synchronous job slows down without dying, every healthy peer still waits at the AllReduce barrier, forcing the recovery pipeline to decide whether the slow rank is a temporary straggler or an incipient failure (perspective 7.6).

Systems Perspective 7.6: Straggler or failure

A straggler, the slow rank of a synchronous step (section 6.3.1.5), bounds the throughput of every peer that waits on it, so one node running 10 percent slow can cost thousands of nodes 10 percent of their capacity. Fault tolerance must decide what that slowness means. A straggler can still produce correct results, so slowness alone establishes neither incorrect values nor a failed process, and its cause is often system jitter from background OS processes, network congestion, or thermal throttling rather than bad hardware. The decision is between mitigation, which keeps the job running and removes the slowdown, and recovery, which treats the rank as failed and pays for a restart.

Under the simplified no-overlap straggler model, the slowest rank sets the step time of the entire cluster because AllReduce cannot complete until every participant has submitted its gradients:



$$T_{\text{step,straggler}}(N) = \max(T_{\text{rank}_0}, T_{\text{rank}_1}, \ldots, T_{\text{rank}_{N-1}}) + T_{\text{comm}}(N)$$

Many stragglers are gray failures, the silent degradations named in the failure taxonomy, seen from inside a synchronous job, and none of their common causes raises an explicit error. Thermal throttling reduces clock speed, degrading interconnect cables increase communication latency, OS background processes (memory scrubbing, log rotation) consume CPU cycles, and data loading from a congested network filesystem introduces variable I/O delays. A slow worker can continue meeting a liveness timeout while reducing training throughput, or become slow enough to trigger the same timeout as a failed worker. Progress measurements are therefore needed alongside liveness checks.

Timeout policy governs where the system draws the line between *mitigation* (redistributing work or replacing the slow node) and *recovery* (checkpoint-restart).

Aggressive timeouts treat transient stragglers as fail-stop crashes, causing unnecessary job restarts that waste more compute than the slowdown itself, whereas conservative timeouts leave thousands of healthy GPUs waiting on a degraded node that will never speed up. The two responses also land in different places in the goodput accounting of section 9.2.3. A slow rank that stays in the job lowers program goodput, while replacing it spends runtime goodput on the restart. The replacement decision therefore weighs one loss against the other.

Straggler mitigation strategies change either the work assignment or the execution resources. Dynamic load balancing moves work away from slow workers while preserving the intended update, whereas bounded staleness allows delayed gradients under an algorithm that tolerates them; its convergence cost depends on the workload and delay bound. Backup workers replicate selected tasks and accept one result per logical contribution, trading extra GPU cycles for a shorter wait without double-counting gradients. At the infrastructure boundary, proactive replacement uses hardware telemetry, such as rising operating temperatures or growing correctable-ECC error counts, to identify suspect components and replace them when the expected benefit exceeds migration and recovery costs. A simple cost calculation shows why a severe straggler is often cheaper to replace than to tolerate.

One straggler stalls every healthy peer at the barrier.

Napkin Math 7.4: The cost of a straggler

Consider a 1,024-GPU cluster where a normal training iteration takes 1 second. A single GPU enters a thermally throttled state, clocking down to 50 percent speed, and now takes 2 seconds to complete its computation.

Because AllReduce cannot complete until every rank has submitted its gradients, the other 1,023 healthy GPUs sit idle waiting for the straggler.

Impact:

- Normal step time: 1 second
- Straggler step time: 2 seconds
- Effective cluster speed: 1 step/2s = 0.5 steps/sec

A single failing device (0.1 percent of the hardware) has reduced the throughput of the entire cluster by 50 percent. At $2/GPU-hour, this straggler wastes $1,024/hour in idle compute.

Systems insight: Replacement is worthwhile only when the expected time saved exceeds recovery and replay costs. Suppose the slowdown is expected to persist for the next K useful updates, whose step times are T_{slow} on the degraded allocation and T_{healthy} after replacement. The simplified break-even condition is then $K(T_{\text{slow}} - T_{\text{healthy}}) > T_{\text{restart}} + T_{\text{replay}}$. The right side includes waiting for capacity and restoring state. A short-lived slowdown may clear before replacement pays off; false-positive detection and uncertain persistence also affect the decision. MTBF describes failure recurrence, not how long this slowdown will last.

Replacing a slow node while maintaining the original GPU count requires available capacity. An $N+1$ redundancy model reserves a hot spare for the isolation and promotion stages of figure 7.10, reducing allocation delay. Promotion still requires compatible resources, valid state, and communication-group reconstruction; an idle device alone does not guarantee recovery within seconds. A cold spare adds startup work, while a job without a reserved spare depends on the scheduler finding capacity or on repair. The hot spare buys shorter waiting time with devices that sit idle while the fleet is healthy. Fixed-size checkpoint-restart recovery restores the original resource count. Elastic recovery relaxes that requirement by allowing the job to continue with fewer workers when the remaining allocation can support it.

Checkpoint 7.5: Tuning detection and recovery

Verify your understanding of how detection latency and recovery strategy trade against one another:

- ☐ **Timeout tuning**: given the heartbeat timeout rule $T_{\text{timeout}} = H + k\sigma_d$, explain what failure mode is traded away when k is lowered from 5 to 3, and which failure mode worsens.
- ☐ **Warm vs. cold restart**: choose a warm restart or a cold restart for a single GPU failure in a 1,000-GPU job with surviving state intact, and identify two conditions that push recovery back toward the cold path.
- ☐ **Hot spare cost**: explain why a hot spare cuts recovery latency relative to detect-then-restart, including the standing cost the cluster pays to keep that spare available.

- ☐ **Straggler decision**: determine what governs whether to wait out a slowed node or kill it and recover onto healthy hardware.

7.10 Elastic Recovery

Suppose a 1,024-GPU training job loses an 8-GPU node to a hardware fault, but the cluster has no spare nodes available. A fixed-size recovery policy leaves the remaining 1,016 GPUs waiting until replacement capacity becomes available or the allocation is released. Elastic recovery allows the job to resize and continue with less compute, provided its state and parallel decomposition fit the smaller allocation.

Definition 7.2: Elastic training

Elastic training is the capability of a distributed training job to adjust its worker count across membership changes, potentially through a coordinated worker-group restart.

1. **Significance**: It converts a permanent capacity loss into a temporary interruption followed by reduced throughput. A pure data-parallel 1,024-GPU job that loses 8 GPUs retains 99.2 percent of its device count and may resume if the remaining devices can hold the state. Tensor- and pipeline-parallel jobs additionally need a feasible partition and compatible group sizes; retained device count does not guarantee the same fraction of throughput. The recovery policy must either preserve the effective batch size through additional accumulation or validate the optimization changes caused by a smaller batch.
2. **Distinction**: Unlike fixed-size checkpoint-restart recovery, which waits for replacement hardware to restore the original allocation, elastic recovery can restart or resume with a different worker count. The optimization loop may pause while membership, ranks, and state are re-established.
3. **Common pitfall**: A frequent misconception is that elasticity is "automatic." In reality, recovery requires coordinated adaptation: the training framework, the data loader, and the orchestrator must all synchronize their state to ensure that no data samples are lost or double-counted during the resize.

A small example shows the lifecycle in three phases (figure 7.16). Execution begins with a balanced four-node AllReduce ring at full throughput. When Node 3 drops out, the survivors pause at a rendezvous barrier and reload the last consistent checkpoint. The group then contracts into a three-node ring in which each worker takes a one-third larger data shard, resuming productive training at 75 percent throughput if the per-worker rate remains unchanged.

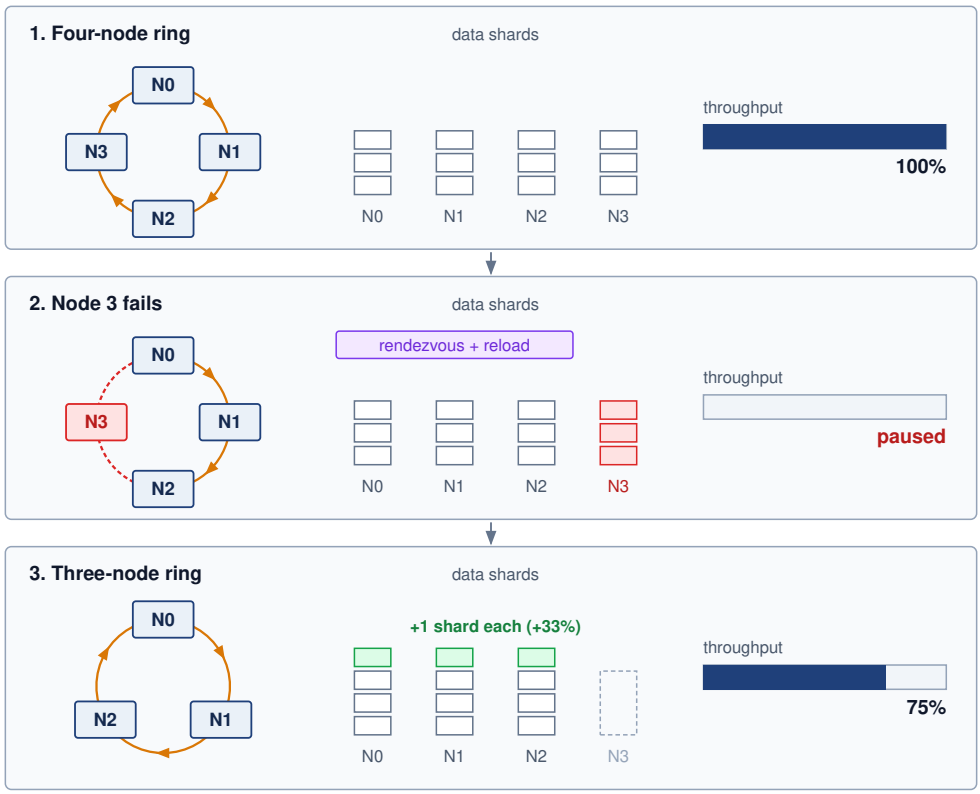


Figure 7.16: Elastic Training Recovery: Read the three phases top to bottom. Rather than restoring the original worker count before resuming, elastic training pauses when a node fails, reloads the last consistent checkpoint, re-forms the ring over the $N-1$ survivors, and redistributes the failed node's data shards among them. The job resumes at reduced throughput (75 percent here, assuming an unchanged per-worker rate), turning a hard failure into a temporary slowdown.

7.10.1 Recovery adaptation mechanisms

Shedding a lost node narrows the active ring instead of idling the whole allocation until replacement hardware arrives, so elastic recovery converts a job termination into a bounded capacity adjustment. The worker group may restart while the framework re-establishes membership, ranks, and state under the smaller resource allocation. When a failure reduces the worker count, the recovery path must adapt several training components before productive work resumes. Each adaptation addresses a specific consistency requirement that, if violated, would corrupt the model or waste computation.

Batch size adjustment comes first. With fewer surviving workers, either each worker must process more samples to preserve the global batch size, or the global batch size must shrink, which in turn may require recalibrating the learning rate to preserve convergence. Changing the global batch size changes the optimization regime as well as the amount of work per step. The linear and square-root learning-rate rules of section 6.4.5 are candidate policies for a resized job, with the worker-count ratio standing in for the batch ratio when per-worker microbatch size and

accumulation count stay fixed (Goyal et al. 2017). For a shrink, the square-root rule reduces the learning rate less than linear scaling does; that arithmetic does not establish which policy is more stable, and either policy requires validation for the optimizer, schedule, and workload. Preserving the global batch instead can avoid introducing this change in optimization regime.

Gradient accumulation offers that alternative. Each surviving worker processes additional micro-batches before synchronization to maintain the original effective batch size. If worker count drops by half, doubling the accumulation steps preserves the number of examples per update and can retain the existing learning-rate schedule. Each worker then performs twice as much micro-batch computation per update, although communication and overlap determine the wall-time increase. Equal batch size does not imply bitwise-identical updates or identical behavior from operations that depend on micro-batch statistics.

Data loader redistribution must agree with the recovered training step and new membership. When workers are lost, the loader reassigns the remaining logical input stream so that the resize itself neither omits samples nor counts them twice in an update. Replaying work discarded by checkpoint rollback is expected; duplicating contributions within the resumed stream is a different error. The saved data position and sampling state distinguish those cases.

State resharding adds further complexity when using sharded model parallelism (ZeRO/FSDP). When parameters and optimizer states are sharded once across the entire job without replication, losing a worker removes the only live in-memory copy of its shard, so the job must reload a complete durable checkpoint generation before repartitioning the state across the smaller worker set. When the job instead uses hybrid sharding that replicates each shard across two or more data-parallel groups, a surviving replica group still holds a live copy in GPU memory and can supply the missing shard over the network without reading from storage. Only after the missing values are recovered from a peer replica or a durable checkpoint can the runtime redistribute shard ownership across the surviving workers. Changing shard ownership alone cannot recover missing values.

7.10.1.1 Spot instance preemption as a failure class

Hardware faults are not the only event that removes workers from a running job. Cloud providers often price preemptible (“spot”) instances below on-demand capacity, with the caveat that they can be reclaimed with little warning. Once workers vanish, recovery faces the same missing-state and membership problems as a hardware failure. An advance notice, when available, can allow a coordinated save or drain before departure and therefore changes the recovery opportunity.

Both fixed-size and elastic jobs can recover from preemption using checkpoints, but a fixed-size job must regain its required allocation before restarting. An elastic job can instead resume at reduced scale if enough capacity remains and the training invariants survive the resize. Recovery still pays for detection, state restoration, and group reconstruction; repeated reclamations can erase the apparent price advantage. At the reference fleet prices of \$0.70/GPU-hour for spot capacity against \$2/GPU-hour for on-demand capacity, the savings can outweigh the lost

work and resizing delays; section 8.8.2 develops the full spot-versus-on-demand cost model. Where spot capacity makes worker departure frequent, federated training makes it the default.

Lighthouse 7.2: Archetype C (Federated MobileNet): Dropout as the normal case

Archetype C (Federated MobileNet) makes worker departure an expected part of training. Its phone-class clients train while charging, idle, and connected, so a client that disappears mid-round is an ordinary event rather than a fault to repair. The coordinator therefore selects more clients than a round needs and closes the round at a deadline. The round tolerates departures as long as enough compatible updates arrive; otherwise the coordinator abandons it (McMahan et al. 2017; Bonawitz et al. 2019). Model-version checks prevent updates computed against a replaced model from entering the current aggregate, the federated counterpart of fencing a stale epoch, while aggregation weights account for the examples contributed under the chosen learning algorithm. Version checks and weighting do not remove participation bias. Recovery must preserve the coordinator state needed to continue that algorithm, including the model, round position, and any persistent optimizer or sampling state, rather than assuming weights alone suffice. Section 11.7.1 develops the round design, including deadlines, participation requirements, and the bias that arises when some kinds of devices report less often than others.

7.10.1.2 Framework support for elastic recovery

Whether worker loss comes from a hardware fault or a spot preemption, training frameworks differ in how many of the resize invariants (group membership, shard ownership, data loader redistribution, and batch-size or learning-rate adjustment) they enforce automatically after a failure. PyTorch Elastic (TorchElastic) uses agents to monitor workers and a rendezvous mechanism to establish group membership (PyTorch Contributors 2026c, 2026b). On a failure or membership change, it stops all surviving workers, forms a new worker group, and starts its workers with new `RANK` and `WORLD_SIZE` assignments. It handles rank reassignment and communication-group reconstruction while leaving batch size, learning rate, and checkpoint semantics to user code. DeepSpeed (Rasley et al. 2020) provides ZeRO-based distributed training and checkpointing building blocks for large models (DeepSpeed Developers 2026a). Recovery reloads from the last durable checkpoint, and Universal Checkpointing addresses portability across some changes in parallelism and topology (DeepSpeed Developers 2026b), though elastic behavior still depends on the surrounding launcher and resource manager.

Ray Train, built on Ray's actor model, provides a checkpoint-oriented recovery path that restarts a worker group after a failure or preemption and resumes from the latest available checkpoint. The training function remains responsible for saving and loading sufficient state (Ray Project 2026). Horovod Elastic similarly builds on Horovod's data-parallel training system (Sergeev and Balso 2018) with an elastic

state API for worker additions and removals (Horovod Developers 2026). The API resets ranks and reconstructs communication while leaving convergence-sensitive choices such as learning-rate or batch-size policy to the training script. Across these four frameworks, restarting the worker group is largely automated, while state resharding remains manual, deployment-dependent, or tied to a checkpoint reload (table 7.10).

Table 7.10: Elastic Recovery Framework Comparison: Frameworks differ in how they detect worker failures and how much of the recovery sequence (group reconstruction, state redistribution, batch size adjustment) they automate.

Framework	Failure detection	Automatic recovery	State resharding	Cluster integration
PyTorch Elastic	Rendezvous timeout	Yes	Manual	Kubernetes
DeepSpeed	External	Checkpoint-based	Deployment-dependent	External schedulers
Ray Train	Actor supervision	Checkpoint retry path	Checkpoint reload	Ray Cluster
Horovod Elastic	Driver heartbeat	Yes	Manual	Slurm, Kubernetes

7.10.2 Model-specific training fault tolerance

Restoring model weights alone does not guarantee a valid restart: an LLM that reloads its weights but loses its curriculum cursor trains twice on the same documents, and a continuous recommender that rolls back its embedding tables serves stale user preferences. The checkpoint and recovery mechanisms of section 7.8 and section 7.9 must therefore adapt to the workload costs priced in section 7.7.1. The design question is not simply how often to checkpoint, but which state variable would make a restart mathematically or economically wrong. For recommendation workloads, incremental checkpointing, tiered checkpointing, and embedding versioning can reduce the cost of preserving fresh state. Incremental storage can still reconstruct an exact generation from a base and its required deltas; accepting stale or approximate state is a separate choice. For each workload, the state at risk determines what its checkpoint must contain (table 7.11).

Table 7.11: Training Recovery State Invariants: Workloads require different checkpoint contents because they make different state variables quality-bearing. The correct recovery policy starts from the state that would make a restart wrong, then chooses sharding, incrementality, or domain-state capture accordingly.

Workload	State at risk	Checkpoint implication
LLM training	Optimizer state, curriculum position, document position, long-context schedule	Preserve the FP32 optimizer state where precision matters, shard writes with ZeRO/FSDP, move serialization off the critical path, and include the data-schedule position so the optimization trajectory resumes correctly.

Workload	State at risk	Checkpoint implication
Recommendation	Embedding freshness, feature-store version	Preserve fresh state with incremental checkpointing, tiered checkpointing, and embedding versioning; accepting stale or approximate state requires a separate recovery contract.
Vision	Augmentation seeds, shuffling order, batch-normalization statistics, progressive-resizing schedule	Capture the stochastic and normalization state that controls the input stream; weights alone are not enough to reproduce the training trajectory.
Scientific ML	Simulator state, search frontier, explored configurations, validation seeds	Treat the model, simulator, search process, and random state as one consistency unit so recovery does not duplicate exploration or invalidate comparisons.

The common pattern is that recovery correctness is broader than weight restoration. LLMs can reload weights but resume with the wrong curriculum position. Recommendation models that train continuously can reload dense parameters but serve stale embeddings, so a failure that loses recent updates carries a freshness cost as well as a replay cost. The recovery budget must reflect the workload's measured sensitivity to stale state.[18] Vision models have smaller checkpoints, about 1.2 GB for the ViT-Large example, which permit more frequent saves on the same storage path. Yet reproducing their input stream requires the augmentation configuration, random-number generator state, and data position rather than only the initial shuffling seed. Scientific models can reload a neural network while losing the simulator state that made the data meaningful, and an iterative search must also retain which configurations it has evaluated when those results choose its next candidates. In every case the checkpoint boundary must include whatever prior decisions affect future work, wherever that state resides. Once the trained model is deployed to users, however, the operational calculus shifts from protecting *weeks of batch computation* to protecting *milliseconds of real-time latency*.

[18] **RecSys freshness**: Freshness makes recovery delay part of the model-quality budget. Its importance depends on how quickly useful user and item signals change and how strongly predictions depend on them. Comparing quality at different state ages establishes the permitted staleness; that measured limit determines how much checkpoint and replication overhead is justified.

7.11 Serving Fault Tolerance

When users ask a voice assistant to turn off the lights, they will not tolerate a five-minute pause while the inference server reloads from a checkpoint. Serving presents a different challenge, because users expect millisecond-level responsiveness even when backend GPUs crash. The C^3 budget for fault tolerance shifts accordingly. Training pays for coordination in synchronization time so that a failure does not erase completed compute, while serving pays in standing redundant compute and in routing coordination so that a failure does not break a latency contract.

A serving replica is a runnable copy of the model that can accept requests; the routing layer chooses a replica, and a readiness check determines whether that

replica can serve successfully. Replicas may share external state stores or keep request state in accelerator memory, so replacing compute does not necessarily replace the state a request needs. Serving fault tolerance asks how those mechanisms behave when replicas, GPUs, or state stores fail under live latency budgets. The focus here is narrower than a complete serving architecture: each mechanism is treated as a reliability boundary for real-time inference.

7.11.1 Stateless vs. stateful serving

The first serving decision is where request state lives, because that choice determines whether failover is a retry or a state-reconstruction problem. A stateless model worker retains no required per-session state between requests. It obtains the necessary context from the request or an external state store, so another ready worker can process the same request. A stateful application can therefore use stateless model workers, although its external store remains a reliability dependency.

The stateless pattern appears when the input itself carries all context: an image classifier processes one image, an object detector processes one frame, a single-turn text classifier processes one snippet, and an embedding service maps one input to one vector. Fault tolerance can then focus on replica health and request routing. Redundant replicas serve requests in parallel, load balancing sends traffic only to healthy replicas, health checks remove failed replicas from rotation, and automatic replacement starts a new replica when capacity falls. When a replica fails, in-flight requests to that replica can be retried elsewhere, because no quality-bearing session state has been lost.

Stateless serving offers the simpler architecture when the application permits it. However, many ML applications inherently require state across requests. Consider a chatbot: a single-turn question-answering system can operate statelessly, processing each question independently. A conversational assistant must preserve its history somewhere, but the model worker can still be stateless if each request carries the complete history or reads it from a durable external store. Worker-local state creates a stronger dependency when later requests rely on information available only at the selected replica.

Stateful serving appears when later work depends on retained session state. For a transformer, the key-value (KV) cache stores attention keys and values computed for earlier tokens so the worker can reuse them while generating subsequent tokens. This cache is derived state. If the authoritative token history and compatible model version remain available, a replacement can recompute it by processing that history again. Losing the history itself is a different failure because cache reconstruction no longer has its required input. Streaming speech recognition similarly maintains context from previous audio, recommendation sessions accumulate user context, and interactive editing maintains document state across edits. The fault-tolerance consequence is that failure loses quality-bearing state rather than serving capacity alone. KV cache loss requires reprocessing previous turns, session context loss forces users to repeat previous interactions, and accumulated user state loss degrades quality when context is unavailable. The mitigation choice follows the size, update rate, and quality value of that state. Session affinity routes a session to the

same replica, state checkpointing periodically saves session state, state replication maintains a standby copy, and graceful degradation keeps the service available at reduced quality if state cannot be recovered. Table 7.12 contrasts how that state boundary reshapes routing, failure impact, and recovery complexity. Whether the architecture is stateless or stateful, maintaining availability under live latency constraints requires deploying redundant capacity.

↪ How the KV cache grows with sequence length and concurrency until it fills accelerator memory is developed in section 10.7.1.

Table 7.12: Stateless vs. Stateful Serving Fault Tolerance: State recovery adds work after failure detection. End-to-end failover also includes probe timeouts, routing, replacement readiness, and request retry; neither worker category implies a fixed latency.

Aspect	Stateless serving	Stateful serving
Request routing	Any replica	Session-affine replica
Failure impact	Retry on another replica	Potential state loss
Recovery complexity	Restart and load weights	Reload state + reconstruct context
Redundancy approach	Active-active replicas	Replicated state + standby
Work after detection	Route or retry to a ready worker	Recover required state, then route or retry

7.11.2 Redundancy and replication

Redundancy buys availability only when replica placement and spare capacity match the failure domain being defended against. Turning multiple model copies into uninterrupted service requires sizing the replica count to the availability target, choosing how live traffic is split across healthy and standby workers, and placing those replicas across independent failure domains.

7.11.2.1 Availability calculations

Serving redundancy is the parallel composition of section 7.2.1 applied to interchangeable replicas, with availability in place of survival probability. For a single replica with availability A_{single} (probability of being operational at any given time), equation 7.12 quantifies how multiple independent replicas achieve higher system availability:

$$A_{\text{system}} = 1 - (1 - A_{\text{single}})^k \tag{7.12}$$

where k is the number of replicas. For a service whose single replica is available 99 percent of the time, redundancy compounds as follows.

For a single replica, availability of 99 percent corresponds to 3.65 days of downtime per year. Adding independent replicas changes the tail of the failure distribution quickly: two replicas give 99.99 percent, or 52.6 minutes of downtime per year, and three replicas give 99.9999 percent, or 31.5 seconds. The arithmetic assumes independent failures and enough capacity on any surviving replica to meet the service target; shared power, shared networking, and shared software bugs reduce actual availability below these theoretical values.

Redundancy turns days of downtime into seconds.

7.11.2.2 Replication strategies

The availability equation says how much redundancy can help; the replication topology determines how that redundancy behaves under normal execution and sudden hardware loss. Two fundamental designs make opposite bets (figure 7.17). Active-active replication splits ingress traffic evenly across live replicas, one-third each for three, which keeps every device busy but requires spare headroom so the survivors can absorb a failed replica's share. Active-passive replication sends all traffic to a designated primary and keeps a pre-warmed standby whose weights remain loaded in accelerator memory, which makes failover fast at the expense of a device that serves nothing while the primary is healthy.

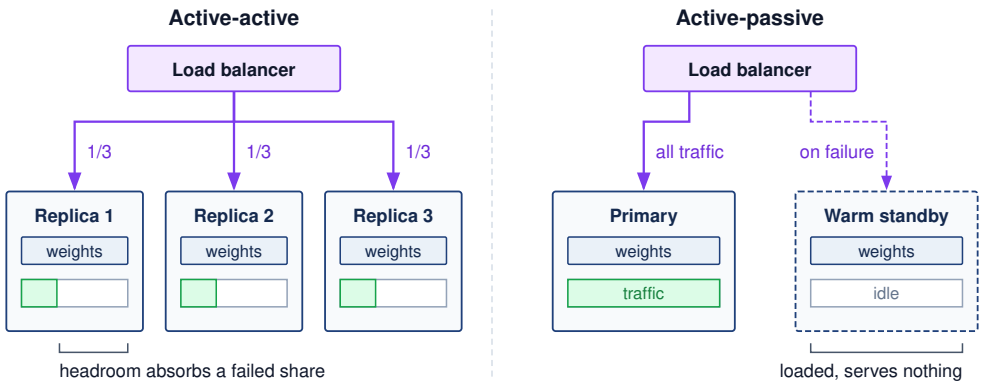

Figure 7.17: Serving Redundancy Strategies: Active-active (left) splits traffic across three replicas, each carrying about one-third, which uses every device but requires enough headroom for the survivors to absorb a failed replica's share. Active-passive (right) sends all traffic to one primary and keeps a warm standby with weights already loaded, which simplifies failover at the cost of capacity that serves nothing while the primary is healthy.

Geographic replication extends the same choice across regions. It protects against data-center or regional network failures, but requests routed to distant regions pay additional latency, and the active-active headroom problem reappears at regional scale. When a region fails, the surviving regions must absorb its traffic and, for stateful services, rebuild its sessions, so each region either carries spare capacity sized for the largest region it may absorb or accepts degraded latency during the failover. Traffic returns to a recovered region gradually, because its caches and warm replicas start empty and an abrupt shift back would overload it and trigger the same failover again. Multi-tier designs combine several replication policies at once: edge caches replicate for latency, regional serving clusters replicate for availability, and a global primary or coordination layer preserves consistency and freshness.

7.11.2.3 Replica placement and failure domains

Effective redundancy requires placing replicas in independent failure domains. Different machines tolerate individual machine failures; different racks tolerate rack-level failures from power or top-of-rack switch issues; different availability zones tolerate data-center-section failures; and different regions tolerate entire data-

center failures. The independence level should match the availability requirement and cost constraint: regional replication is expensive because it duplicates compute and network capacity, but it is necessary when regional failure must not become user-visible downtime. Placement alone, however, only creates the possibility of recovery; the serving system still needs a control loop that notices the failure, removes the affected replica from traffic, and preserves enough state that the user-visible service continues with bounded degradation.

7.11.3 Failover mechanisms

When a replica fails, traffic must be redirected to healthy replicas, and the speed and reliability of that redirection determine how much of the failure users see. The mechanism decomposes into two questions: how the system decides that a replica can no longer serve, and what happens to stateful sessions already attached to it.

7.11.3.1 Health checking

Health checks decide when traffic should move. The liveness and readiness probes of section 7.9.1 apply to a serving replica, where readiness means that its weights are loaded, its accelerator is initialized, warmup has completed, and dependencies such as feature stores (the services that supply precomputed model input features) are reachable. Serving adds an inference check, which runs a known input through the model and compares the output with the expected result, catching the silent failure in which the process is healthy but its answers are wrong. The load balancer acts on these signals.

The probe parameters set the failover budget. With a 5 s check interval, a 2 s timeout, and a failure threshold of 3 missed probes, a crashed replica leaves rotation 12–17 s after it fails, depending on where the crash falls between probes. Every request routed to it in that window fails or waits for a client retry. Shortening the interval or lowering the threshold speeds failover but raises the false-positive rate, marking healthy replicas unhealthy during transient stalls and removing capacity exactly when load is high. A success threshold of 2 clean probes applies the same caution in reverse, holding a recovered replica out of rotation until it has proved stable.

↪ What each probe must test on an accelerator replica, from process liveness to a fixed-prompt inference check, is developed in section 10.11.9.

7.11.3.2 Session affinity and stateful failover

For stateful serving, session affinity routes all requests within a session to the same replica. Load balancers maintain session-to-replica mapping through sticky sessions implemented with cookies, headers, or IP hashing. Affinity preserves locality but supplies no replacement copy when that replica fails. Checkpointing saves session state periodically, replication copies it to a standby, and external systems such as Redis or Memcached move it outside the model worker. The external store still needs its own availability and durability contract. Accepting state loss is valid only when the service can reconstruct derived state from retained history or explicitly begin a reduced-context session. Which option fits a workload depends on state size, update frequency, and the quality impact of state loss, as table 7.13 summarizes across the four common approaches.

Table 7.13: Stateful Failover Approaches: Recovery latency, state guarantees, and operational complexity distinguish four approaches to session-state failover. Checkpoint recovery may lose updates after the saved snapshot. Distributed storage can provide different consistency contracts, and synchronous replication provides its promised guarantee only under the specified acknowledgment and fault model.

Approach	Recovery latency	State guarantee	Operational complexity
State loss	Fast	None	Low
Checkpointing	Medium	Consistent snapshot; later updates may be lost	Medium
Synchronous replication	Fast	Strong	High
Distributed state	Fast	Configurable	Medium

7.11.4 Model-specific serving fault tolerance

Retrying a failed image classification request on another replica loses no session state, whereas losing the replica that holds a multi-turn LLM conversation drops gigabytes of live attention state and losing a recommendation feature store leaves the ranker with stale user signals. Model-specific serving policies therefore start from a state-loss budget: which state can be rebuilt within the latency deadline, which state must be replicated in advance, and which state may be degraded temporarily without violating the product contract. Each of the three common serving regimes answers that budget differently, setting both its fault-tolerance policy and its degradation path (table 7.14).

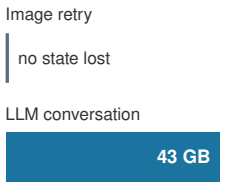

Table 7.14: Serving Recovery State Invariants: Serving fault tolerance starts from the state whose loss changes user-visible quality. LLMs protect live context, recommendation systems protect feature freshness, and vision services protect preprocessing and device correctness.

Serving workload	State expensive to lose	Fault-tolerance policy	Degradation path
LLM conversation	KV cache, conversation context, prefix state	Replicate or checkpoint high-value session state; regenerate only when the latency budget allows.	Rebuild from transcript, reuse cached prefixes, or ask for retry.
Recommendation	Fresh user features, item features, embeddings	Replicate feature stores, cache hot features, and monitor freshness as a reliability signal.	Serve stale or default features with measured quality loss.
Vision service	Preprocessing state, device health, edge input	Retry stateless requests on healthy replicas and fail closed on preprocessing or accelerator-health faults.	Use a smaller local model, defer prediction, or return low confidence.

The KV cache[19] can be substantial (gigabytes for long contexts across attention layers). Losing it requires recomputing attention state from the retained token history, which can take seconds to minutes; previously delivered text need not be generated again. During an in-flight response, recovery must also know which output tokens the client has already received so a retry does not silently duplicate or replace part of the response.

LLM serving choices trade KV-cache recovery latency against memory and storage overhead. The simplest strategy is to accept regeneration cost by rebuilding KV cache from conversation history after failure, but this can turn a long conversation into a multi-second or multi-minute restart. KV-cache checkpointing saves live state periodically and bounds the amount of regeneration, while KV-cache replication keeps a standby copy for fast failover at the cost of extra memory. Prefix caching, also offered as prompt caching, reuses state for common system prompts and shared context. A compatible cached prefix can reduce reconstruction work if it survives the failure and remains accessible to the replacement worker. Cache

[19] **KV cache**: Stores key and value projections for all previous tokens across all attention layers, with a per-token size derived in section 10.7.1. For a Llama-family 70B model at its 128K context in BF16, the KV cache is about 43 GB per conversation. Reconstruction can exceed serving latency service level agreements (SLAs) even when a replacement replica is already available.

A retried image loses nothing; a lost conversation loses 43 GB of KV cache.

reuse alone does not establish a failover guarantee or preserve the session-specific history.

Recommendation serving protects freshness rather than conversational continuity. Recommendations depend on user and item features from feature stores, so feature-store unavailability can either degrade ranking quality or block recommendations entirely. The serving decision is the staleness budget. Replicated feature stores keep recent features available across zones, local caches cover hot features, fallback to stale features accepts measured quality loss, and default features let the service return a lower-quality result when lookup fails. Real-time features such as recent user actions make freshness monitoring part of fault tolerance, because a pipeline that keeps serving old features is available operationally but wrong semantically. Large embedding tables may also sit behind dedicated embedding services, which need their own replication and failover plan.

Vision serving is usually closer to the stateless end of the spectrum because each image or frame can be retried on another replica. That simplicity changes where the checks belong. Thermal throttling threatens latency, while uncorrected memory errors threaten numerical validity; health policy must distinguish those consequences. Preprocessing checks must also prevent invalid resize, crop, color conversion, or normalization from producing apparently valid predictions. At the edge, disconnection can require a validated smaller local model, delayed nonurgent work, or abstention when the available computation cannot meet the prediction contract.

When redundancy cannot preserve full service, the remaining choice depends on the application contract. A validated reduced-capability response can preserve useful availability; if no such response is acceptable, the system must reject or defer the work. Graceful degradation makes the permitted reduction explicit before failure occurs.

7.12 Graceful Degradation

During a major regional network outage, an e-commerce site suddenly loses access to its heavy, GPU-accelerated recommendation cluster. Rather than showing users empty pages or crashing, the site instantly switches to serving precomputed, generic popular items. The serving fault tolerance mechanisms developed in section 7.11 aim to maintain full service, but graceful degradation dictates what happens when those defenses are overwhelmed.

Definition 7.3: Graceful degradation

Graceful degradation is a fault tolerance strategy in which a system responds to resource exhaustion or component failure by deliberately reducing service quality (falling back to a smaller model, serving cached results, or returning partial outputs) rather than failing completely, maintaining measurable availability at reduced capability.

1. **Significance**: Graceful degradation converts total outage risk into a controlled quality reduction. A recommendation system can fall back from a large ranker to a collaborative-filtering model on GPU failure, maintaining request availability with a quality penalty that must be measured for that workload. The engineering calculation includes both the requests served and the utility lost during fallback.
2. **Distinction**: Unlike complete system failure (where the service returns errors to all requests), graceful degradation provides a managed transition through a predefined capability hierarchy in which each fallback level has known accuracy, latency, and resource characteristics that allow the system to continue satisfying SLOs at reduced quality.
3. **Common pitfall**: A frequent misconception is that degradation is automatic in well-designed systems. Graceful degradation requires explicit preengineering. Fallback models must be preloaded or precomputed, switchover logic must detect the failure condition and trigger the transition without human intervention, and each degradation level must have been validated to satisfy its reduced SLO before it is needed in production.

7.12.1 Degradation dimensions

A degradation plan must name which service property will be sacrificed before an incident begins. The main levers in table 7.15 form a pre-incident design checklist, not an outage-time brainstorming aid. Each sacrificed property needs a measured quality budget, an activation condition, and a recovery path before the failure occurs.

Table 7.15: Graceful Degradation Dimensions: Degradation plans choose which service property can be reduced while still returning a useful answer. Naming the dimension in advance prevents the system from treating every failure as a binary serve-or-crash decision.

Dimension	What the system sacrifices	Typical fallback
Quality	Model accuracy or ranking quality	Use a simpler model, such as a collaborative-filtering fallback for a multi-tower recommender.
Latency	Response speed	Batch more requests together to preserve throughput and model quality under high load.
Coverage	Result completeness	Return top-10 search results instead of top-100.
Freshness	Recency of computed results	Serve cached or stale candidates, such as hour-old news recommendations during an outage.
Feature completeness	Input richness	Use content features when user history or real-time context is unavailable.

These dimensions are not interchangeable. A search product may sacrifice coverage by returning fewer results while keeping freshness intact. A recommender

may sacrifice freshness by serving cached candidates while preserving latency. An interactive assistant may sacrifice quality by using a smaller model while keeping the session alive. The correct fallback is therefore workload-specific. It follows the property whose temporary loss least harms the application and whose recovery path can be validated before the incident.

7.12.2 Graceful degradation strategies

The dimensions in table 7.15 become operational only when the service binds each sacrificed property to a specific fallback mechanism. The strategy ladder starts with model fallback when the primary inference path is too expensive or unavailable. It then moves to feature fallback when input quality degrades, and finally to load shedding when demand exceeds capacity and the system must preserve the highest-value requests first.

7.12.2.1 Model fallback

Model fallback turns quality into an explicit availability lever by maintaining multiple model versions with different resource requirements. The primary model provides full capability at the highest resource cost, a secondary model reduces capability and resource demand, a tertiary model preserves minimal capability, and a static fallback serves precomputed defaults with no inference at all. When the primary path is unavailable or overloaded, the policy descends only as far as resource pressure requires, then returns upward after the primary path is healthy again.

An image classification cascade makes the trade-off concrete. The primary path might run a ViT-Large model with 307 million parameters and 88 percent ImageNet top-1 accuracy. Under pressure, it might fall back to EfficientNet-B4 with 19 million parameters and 83 percent accuracy, then fall back again to MobileNet-V3-Large with 5.4 million parameters and 75 percent accuracy when only minimal classification remains affordable. If even that path cannot meet the SLO, the service can return cached labels, a coarse category, or "classification unavailable" rather than blocking the request indefinitely. For that ladder to be real rather than aspirational, the production system must keep multiple models deployed, route requests to the appropriate level, monitor fallback frequency, and measure the quality impact of each level.

Recommendation and ranking systems use the same pattern when a complex deep learning model falls back to a top-n popularity list, a linear ranker, or a cached response during primary serving failures. Complex models often fight for the last mile of accuracy while simple heuristics provide the bulk of the utility, so the fallback path must be monitored as a first-class quality signal rather than treated as a silent failover. Otherwise the product appears healthy while quality is silently traded for availability.

7.12.2.2 Feature fallback

Feature fallback controls how much input quality the model may lose before the request must be blocked. When feature retrieval fails, validated population-level defaults or cached values can substitute for missing user or item features. A

recommender might use genre-level item defaults for missing item attributes or the most recent cached value of a real-time signal. The model must have been trained or evaluated with those missing-feature semantics; an average embedding or a vector from another encoder is not automatically a compatible input. Approximate features are useful only when their representation and measured prediction quality satisfy the fallback contract.

The key design step is prioritizing features by their measured contribution to prediction quality. In a four-level policy, critical features block the request, important features use defaults, useful features use cached values, and optional features can be omitted (table 7.16). The table's quality-loss ranges are example policy budgets, not transferable properties of those feature categories. Deployment requires measurements showing that each permitted fallback meets its budget. When feature degradation alone is insufficient to maintain system stability under extreme load, the serving infrastructure must begin actively dropping requests.

Table 7.16: Graceful Feature Degradation Tiers: Features classified by importance to prediction quality, with the corresponding response when each tier is unavailable. Critical features block the request entirely; lower tiers allow the system to fall back to defaults, cached values, or omission with bounded quality impact. The tiers convert a binary "feature available or not" question into a four-step degradation ladder.

Tier	Example features	Missing action	Quality impact
Critical	User ID, Item ID	Block request	Cannot serve
Important	User history, Item attributes	Use defaults	5–10% quality loss
Useful	Real-time context	Use cached	2–5% quality loss
Optional	Secondary signals	Omit	$< 2\%$ quality loss

7.12.2.3 Load shedding

Load shedding protects the system by sacrificing selected requests before overload spreads to every request. Random shedding is the simplest policy: drop a fraction of incoming requests and preserve enough capacity for the rest. Its weakness is that it treats all requests as equally valuable. Priority-based shedding turns quality-of-service degradation into an explicit policy by serving premium users before free users, revenue-generating requests before analytics requests, and interactive traffic before background batch work. The system is still degrading, but it is degrading according to a predeclared service contract rather than whichever queue happens to fill first.

Admission control applies the same idea at system entry points. It rejects requests that would exceed capacity rather than accepting work that will degrade every request already in the system. Circuit breakers extend the same protection to individual dependencies by failing fast when a model replica, feature store, or supporting service is unhealthy, so that one failing dependency cannot exhaust connection pools across the fleet. Section 10.11.10 develops their states and the backpressure signals that accompany them.

7.12.2.4 Graceful degradation implementation

Implementation begins by turning the degradation ladder into a control loop. Tail-latency percentiles reveal delayed responses, dependency-specific error rates locate failed calls, resource utilization exposes pressure, and growing queues indicate a mismatch between arrivals and completions. These signals support entry and exit conditions for each degradation level: a trigger can justify load shedding before diagnosis is complete, even though the signal alone does not establish the underlying cause. Degradation triggers define conditions that activate degradation; three common triggers watch tail latency, error rate, and feature store health, and each one activates its own fallback mechanism (listing 7.1).

Listing 7.1: Progressive Degradation Triggers: Conditions that activate graceful degradation based on tail latency, error rate, and feature store health. Each trigger activates a different fallback mechanism appropriate to the detected problem.

```
# Monitor tail latency for user-facing impact
if p99_latency > threshold:
    activate_model_fallback()  # Switch to faster, simpler model

# Track error rates to detect downstream failures
if error_rate > threshold:
    activate_circuit_breaker()  # Fail fast, prevent cascade

# Feature store slowdowns degrade recommendation quality
if feature_store_latency > threshold:
    activate_feature_fallback()  # Use cached/default features
```

Degradation should increase progressively as conditions worsen rather than switch at one cliff. The system can raise the fallback percentage gradually as load increases, then require sustained improvement before traffic returns to higher-capability paths. Hysteresis prevents oscillation between primary and fallback modes when the service hovers near a threshold.

7.12.3 Degradation monitoring and alerting

Because graceful degradation trades quality for availability, monitoring must make that trade visible rather than letting the system appear healthy while serving lower-fidelity results. The monitoring surface must expose how much service quality has been traded away. Table 7.17 turns that surface into an action map: fallback share reveals how often model quality was reduced, default-feature share reveals input-quality loss, drop rate reveals capacity protection, and the primary-vs-fallback quality gap reveals whether the degraded path remains acceptable. Its escalation thresholds illustrate one policy; the service's permitted degradation duration and quality loss must determine the deployed thresholds.

Table 7.17: Degradation Monitoring Action Map: Graceful degradation is safe only when the quality trade is observable. Each signal ties a degraded serving mode to the escalation and postincident question that prevent silent quality loss.

Signal	Quality trade exposed	Escalation rule	Postincident question
Fallback-model request share	Model capability reduced to preserve serving	Sustained activation beyond 5 minutes becomes a warning.	Did the fallback preserve enough user value?
Default-feature request share	Input richness reduced because dependencies lag	Severe degradation affecting over 50% of requests becomes critical.	Which feature dependency needs replication or caching?
Load-shed request rate	Coverage reduced to protect the service	Any growth after the circuit breaker opens triggers capacity investigation.	Was admission control early enough to prevent cascade?
Primary-vs-fallback quality gap	Product quality lost during the incident	Degradation beyond 1 hour escalates even when availability metrics look healthy.	Is the fallback path still a valid product experience?

After the event, postincident analysis should identify the root cause, evaluate fallback effectiveness, measure user and business impact, and define improvements that prevent recurrence. Implementing these fallback mechanisms safely requires deep visibility into the system's runtime state. When a complex recommendation pipeline begins degrading, operators must rapidly determine which microservice is failing, and that diagnosis depends on distributed debugging and observability.

7.13 Distributed Debugging and Observability

At 2:00 AM, latency on the flagship generative API spikes from 200 ms to 5 seconds, but CPU, memory, and network metrics all look normal. The latency breach can justify immediate mitigation under a predefined policy; choosing a targeted repair requires locating the stalled work across hundreds of microservices. Distributed debugging and observability provide the diagnostic capability required to locate these invisible bottlenecks.

7.13.1 Diagnostic challenges in distributed ML systems

When a latency spike or stalled collective appears on one run and vanishes on the next, the evidence needed for recovery is split across timing, state, scale, and model behavior. Nondeterminism enters from multiple directions: network timing variations change execution order, thread scheduling differences alter race conditions, GPU kernel execution order varies across runs, and floating-point operation ordering changes numerical results. Consequently, a bug that manifests on one execution may not reproduce on subsequent runs, creating "Heisenbugs"[20] that appear to vanish when observed.

Partial failures turn that nondeterminism into a recovery problem. A single machine can also suffer partial failures, but distribution adds independently progressing workers and communication paths: one component can stop while others continue, leaving peers uncertain whether it has failed or become unreachable.

[20] **Heisenbug**: A pun on Heisenberg's uncertainty principle, popularized in Gray (1986)'s analysis of why production systems fail. Instrumentation perturbs timing, so observing the bug changes it. In distributed ML training, inserting gradient logging alters collective timing and can mask the very race that caused the silent corruption.

Scale then removes manual inspection as a viable debugging method. With thousands of components, automated tools must filter large telemetry streams and identify the few signals that explain the incident. ML systems add model behavior to the same diagnostic problem: silent accuracy degradation produces wrong results without errors, numerical issues like NaN and infinity propagate through computation, data-dependent bugs manifest only for specific inputs, and learning causes expected behavior changes that can resemble bugs. Isolating a fault across all four sources requires structured telemetry that links cluster-wide symptoms to individual requests and events.

7.13.2 Observability pillars

Observability supports both immediate mitigation and investigation of the cause. Suppose a recommendation service suddenly violates its latency SLO while the model replicas still report healthy GPU utilization. Metrics establish the timing and scope of the symptom, traces show which service span consumes the request budget, and logs record events inside that service. Figure 7.18 connects these streams to operational decisions. A single signal can justify an action, such as shedding load when a queue exceeds its budget. Joining request and trace context with model versions, deployment tags, and time windows strengthens the diagnosis when several causes could explain the same symptom. Correlated evidence narrows those possibilities; it does not by itself prove the physical or software cause.

↪ How metrics, logs, and traces become a fleet-wide observability architecture that routes evidence across many models and owners is developed in section 12.6.6.

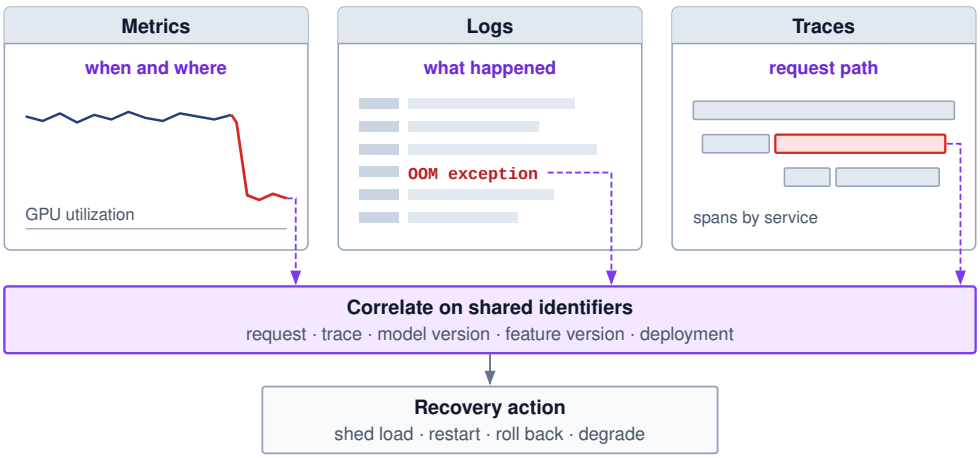

Figure 7.18: The Three Pillars of Observability: Diagnosis of fleet failures can combine three signal types. Metrics reveal *when* and *where* a problem occurs (for example, GPU utilization drops). Logs provide the *what* through event context (for example, an out-of-memory exception). Traces expose the *request path* by linking events across the distributed lifecycle (for example, identifying the request that triggered the memory spike). A single signal can justify immediate mitigation; joining signals on shared identifiers strengthens diagnosis without proving the cause.

Metrics are the first evidence because they compress fleet behavior into time series that can trigger action. A metric stream becomes fault-tolerance infrastructure only when an alert maps to a recovery decision. High p99 latency may trigger load shedding, a falling cache hit rate may trigger fallback features, and a sudden

prediction-distribution shift may block a rollout before it corrupts user-facing decisions.

Logs provide the event context that a metric intentionally discards. Structured logging uses formats such as JavaScript Object Notation (JSON) with consistent fields, so incident tooling can search by service, request, model version, GPU, feature store, or trace identifier. A GPU memory allocation failure logged this way records both the local failure context and the trace identifiers needed to connect the event to distributed metrics and spans (listing 7.2).

Listing 7.2: Structured JSON Log Entry: A structured log entry for a GPU memory allocation failure, including trace and span identifiers for correlation with distributed traces and resource metrics for diagnosis.

```
{
  "timestamp": "2024-01-15T10:23:45.123Z",
  "level": "ERROR",
  "service": "inference-server",
  "trace_id": "abc123",
  "span_id": "def456",
  "message": "GPU memory allocation failed",
  "gpu_id": 3,
  "requested_bytes": 4294967296,
  "available_bytes": 2147483648
}
```

For fault tolerance, the important logging property is consistent correlation rather than the particular backend. Log levels should map incidents to escalation consistently across components, but the recovery system depends more on whether operators can query events by the same request, trace, model version, feature version, and deployment identifiers that appear in metrics and spans. Log aggregation is therefore useful because it preserves the join between local failure context and fleet-wide symptoms.

Traces show where latency or failure propagated across distributed components. A trace is the end-to-end journey of a request, a span is one operation within that journey, and context propagation carries the trace identity across service boundaries. A trace through an ML inference pipeline illustrates how these spans compose:

```
Trace: user-request-12345
|-- Span: api-gateway (5 ms)
|   `-- Span: auth-service (2 ms)
|-- Span: feature-service (15 ms)
|   |-- Span: user-feature-lookup (8 ms)
|   `-- Span: item-feature-lookup (12 ms)
|-- Span: inference-service (45 ms)
|   |-- Span: preprocessing (3 ms)
|   |-- Span: model-inference (40 ms)
|   `-- Span: postprocessing (2 ms)
```

```
`-- Span: response-formatting (1 ms)
Total: 66 ms
```

Standard distributed tracing APIs such as OpenTelemetry carry this context across services, and a tracing backend stores and visualizes the traces. The durable requirement is not the particular backend but enough preserved context to answer whether the fault lives in request routing, feature retrieval, model execution, postprocessing, or a dependency outside the model service.

7.13.3 ML-specific debugging

Operational signals alone are not enough when a process stays healthy while its tensors, inputs, or per-rank execution times drift outside the model's contract. ML systems therefore add specialized debugging across three surfaces: numerical health inside the computation, semantic validity across the data pipeline, and straggler attribution across distributed stages.

7.13.3.1 Numerical debugging

Numerical debugging targets failures where tensors remain valid objects but contain invalid values. NaN detection[21] exposes values that can propagate through later arithmetic without a process crash. A minimal diagnostic check only flags the invalid output (listing 7.3), so the caller must act on the result and block its publication.

Listing 7.3: NaN Detection: This check flags NaN output for diagnosis. The caller must block publication or choose a fallback; a logged request identifier refers to an input retained by the application for replay.

```
# Check tensor for NaN values
# (propagate from any corrupted computation)
if torch.isnan(output).any():
    log.error("NaN detected in output", request_id=request_id)
    # Caller must retain a replayable input reference and block or replace this outpu
```

During training, per-step gradient statistics expose numerical faults before they corrupt the entire run. Tracking the global gradient norm catches sudden explosion or vanishing, histogramming the gradient distribution flags outlier spikes, and logging layer-wise gradient norms isolates which block in the network first destabilized. Mixed-precision training[22] can introduce related numerical issues when narrow dynamic range interacts with unstable updates. A dynamic loss scaler reduces its scale after detecting nonfinite gradients, indicating overflow or another invalid operation rather than proving underflow. Gradient magnitudes, skipped updates, and comparison with a higher-precision replay help distinguish range problems from other causes; ordinary FP16 rounding differences are not themselves faults.

7.13.3.2 Data debugging and validation

Data bugs surface as valid-looking but wrong inputs, so debugging must verify semantic correctness at each pipeline boundary in addition to numerical validity.

[21] **NaN propagation**: Many IEEE 754 arithmetic operations propagate a NaN operand, so an invalid gradient can contaminate dependent updates without stopping the process. The affected scope depends on the computation's data dependencies. Zero divided by zero and the logarithm of a negative real value produce NaNs; division of a nonzero finite value by zero or floating-point overflow can instead produce infinity, which may cause a later invalid operation. Checking only for a process crash therefore misses numerical failures.

[22] **Mixed-precision numerical issues**: FP16's exponent range is far narrower than FP32's or BF16's, which is why mixed-precision training scales the loss before backpropagation and dynamic scaling skips nonfinite updates. The formats and the mixed-precision recipe are recapped in section A.6.

Validation checks expected format, shape, value ranges, required fields, and encoding before data reaches the model, catching malformed examples while the failure is still local to the input path. Once the input passes those static checks, the system needs evidence about behavior over time. Distribution monitors track feature drift, null-rate changes, and outliers as they emerge, while transformation instrumentation logs intermediate shapes and statistics so teams can compare each stage against known-good data. Together, these signals separate a corrupted input path from a numerical failure inside the model.

↪ The validation gates and response policies that run these data checks continuously across a production fleet are developed in section 12.4.7.

7.13.3.3 Straggler detection and analysis

Perspective 7.6 treated a straggler as a slow training rank that holds up a synchronous step. The same idea extends to serving once "peer" means any component on a request's path, so straggler diagnosis there asks which replica or service stage is slow enough to become a failure-equivalent bottleneck. A slow serving replica delays requests routed to it and can trigger retries under load; its effect on the service's tail percentile depends on its traffic share and the routing policy. A request that waits for several required parallel branches is instead bounded by the last required completion. Operation-level timing instrumentation measures time for each operation, enabling latency attribution across pipeline stages. Wrapping each operation in a context manager that emits per-span timing metrics makes performance directly comparable across replicas (listing 7.4).

Listing 7.4: Operation-Level Timing: Context manager instrumentation attributes latency to individual pipeline stages, enabling straggler detection by comparing the same span across replicas.

```
# Wrap operations in timing context managers for latency attribution
with timer("feature_lookup"):
    features = feature_store.lookup(
        ids
    )  # Often the latency bottleneck
with timer("model_inference"):
    predictions = model(features)  # Host submission time for asynchronous GPU work
```

For asynchronous GPU execution, the host span around `model(features)` in listing 7.4 measures only the CPU time required to enqueue kernels onto the GPU stream, not completed device work. Because kernel launches return to the host before the GPU finishes executing them, a naive host timer can report a fast inference span even on a thermally throttled GPU and misattribute the delay to whichever later stage first synchronizes the stream or copies predictions back to host memory. Measuring actual GPU execution time requires recording hardware events on the stream before and after the forward pass and reading their elapsed time after the stream completes. Like-for-like component timing is then compared across replicas with percentile analysis: p50 shows typical performance, while p99 shows tail latency, and comparing p99 across replicas identifies workers whose slow path has become a fleet-wide bottleneck. The diagnosis must then separate

the causes that share this slow-worker symptom, which include the gray-failure causes of section 7.9.5 and data skew, in which some inputs are slower to process.

7.13.4 Serving failure patterns

Serving failures require a symptom-to-action mapping under much tighter latency constraints than the training-loss signatures of section 7.9.1. Common serving symptoms differ both in what each one reveals and in what the serving system must do first (table 7.18). Cascade failures are hardest to diagnose because the root cause is obscured by the secondary timeouts and retries it generates, as example 7.1 traces across metrics, logs, and spans.

Table 7.18: Serving Failure Response Map: Serving incidents must be classified quickly because every diagnosis competes with a user-facing latency budget. The table ties each symptom to the first operational response rather than treating all serving failures as generic errors.

Symptom	Likely interpretation	Immediate response
Latency spikes	Resource contention, garbage collection, cold caches, or model reloads	Check placement and capacity; repeated spikes usually mean the problem is no longer transient.
Rising error rates	Dependency failure, data-format change, or model bug	Investigate immediately because errors compound across dependent services.
Silent quality degradation	Model drift, feature degradation, or data-pipeline fault	Use quality monitoring beyond standard operational metrics.
Cascade failure	Timeout exhaustion, resource depletion, or error propagation from one failing component	Trip circuit breakers and preserve isolation boundaries before the failure spreads.

Example 7.1: Diagnosing a cascade failure

Scenario: A recommendation system experiences sudden latency spikes.

Diagnosis: The three observability pillars narrow the failure path. Metrics reveal the symptom: p99 latency jumped from 45 ms to 800 ms at 14:32, with error rate increasing from 0.1 percent to 15 percent. Traces locate the delay in the feature-service span, which consumes 700 ms instead of the normal 12 ms, while model inference remains at 40 ms. Logs show repeated connection timeouts to the user embedding cache at 14:31, followed by requests bypassing the cache and reaching the embedding database directly. That evidence identifies cache unavailability and increased downstream demand; it does not yet distinguish a failed cache process from a network or resource problem.

Systems lesson: Cache unavailability can transfer enough demand to overwhelm the embedding database. A circuit breaker and a validated default-embedding path can limit that cascade while diagnosis continues. The fallback

must also respect the quality budget and avoid sending the rejected demand to another saturated dependency.

Observability and diagnostic maps help operators isolate a failure once it strikes, but verifying that detectors, circuit breakers, and recovery paths actually hold under fire requires triggering those failures deliberately before production traffic meets them.

7.14 Fault Injection Tools and Frameworks

An injected failure is useful evidence only when it resembles the production failure the system must survive. A multi-node training cluster that claims to tolerate network partitions should have that connection severed in a staging environment so engineers can observe what the orchestration layer does. Fault injection is the engineering discipline of deliberately perturbing a system to empirically verify that robustness mechanisms work before production traffic discovers the gap. Fault-injection tools for tensors and accelerators cover bit flips, corrupted tensor values, and accelerator-oriented failures (Z. Chen et al. 2020; Tsai et al. 2021; Gräfe et al. 2023), while network partitions, latency injection, dependency termination, and API-response faults belong to chaos and distributed-systems testing practice (Basiri et al. 2016).

An injection experiment is evidence only at the level where it injects. Its fault model names the originating disturbance, such as a transient single-bit upset or a permanent multi-bit defect, and its error model names the corrupted state that results. Results for transient single-bit faults therefore do not establish resilience to permanent multi-bit defects (Sangchoolie et al. 2017). The injection level also decides which masking the experiment includes. Hardware absorbs many physical disturbances before software sees them, in unused units, overwritten values, and dead instructions (Mohanram and Touba 2003; Ko 2021). Hardware-based injection through field-programmable gate array (FPGA) emulation or particle-beam exposure (Velazco et al. 2010) passes through that masking, while software tools such as PyTorchFI (Mahmoud et al. 2020) perturb weights, activations, and gradients directly. They cover many model states quickly, but by skipping the masking they can overstate how often a physical fault corrupts the model. Frameworks such as Fidelity (He et al. 2020) narrow that abstraction gap by mapping hardware faults to the software-visible errors they produce. A tensor mutation still tests how the software responds to a corrupted value; on its own, it does not estimate production vulnerability.

For fleet recovery, the most valuable experiments inject faults at the level where recovery decisions are made. Killing a rank in the middle of a collective or delaying its heartbeat past the timeout exercises the detection layers of section 7.9.1. Partitioning a node from the rendezvous service exercises the membership and fencing rules of section 7.9.2. Corrupting one checkpoint shard exercises the manifest check of section 7.8.5.2. Each of these experiments tests one row of table 7.4. Running these experiments continuously in staging, and in controlled form in production,

keeps rarely executed recovery code from decaying between real incidents (Basiri et al. 2016). A recovery path is trustworthy only for the fault model it has been exercised against, which is why the case studies that follow report both the failures production fleets met and the machinery that absorbed them.

7.15 Case Studies

Training a 175-billion-parameter language model across 992 GPUs for two months, keeping a 4,096-chip supercomputer slice routable despite daily hardware faults, and serving low-latency recommendations across dozens of microservices each stress a different layer of the fault-tolerance stack. Public operational reports from Meta, Google, and Netflix show how production fleets combine failure detection, state preservation, topology reconfiguration, and chaos testing at scale. Their reported numbers are operational magnitudes that expose the design pressure on each system rather than universal hardware constants.

7.15.1 Large-scale LLM training at Meta

Over two months of training the Open Pre-trained Transformer (OPT-175B) on 992 NVIDIA A100 GPUs, Meta's engineering team reported at least 35 manual restarts and estimated 70 or more automatic restarts triggered by hardware failures including ECC memory errors, NCCL and InfiniBand network faults, and lost GPUs (Zhang et al. 2022). Alongside these restarts, more than 100 hosts were cycled (Zhang et al. 2022; Meta AI Research 2022). Numerical instability created a separate recovery problem. These counts establish repeated interruption, but cycling hosts and restarting jobs are different events; their totals do not directly measure one common MTBF. The recovery design had to preserve progress while distinguishing failed execution resources from suspect optimization state.

During the OPT run, the team monitored progress through train-log freshness checks. The public logbook records a 15-minute modified-file threshold, later relaxed to one hour, as part of restart monitoring (Meta AI Research 2022). For a hang that raised no error, this threshold contributed to T_{detect}; polling and response delays could extend the wait before restart. The logbook illustrates the trade-off of equation 7.11 in operational form, since relaxing the threshold reduced sensitivity to delayed logs while allowing longer idle windows.

Recovery procedures also had to account for loss spikes associated with numerical instability. Unlike a fail-stop event, this symptom made recent model state suspect without identifying a failed device. The team combined rollback to an earlier checkpoint with a lower learning rate to recover from divergence (Meta AI Research 2022). The paper separately reports approximately 147 TFLOP/s per A100 (about 47 percent of dense FP16 peak) (Zhang et al. 2022); that execution-rate metric alone does not establish end-to-end useful throughput after interruptions and replay. The enduring lesson is the distinction between recovery paths. A failed device calls for replacement and restoration of valid state, while numerical divergence can require an older checkpoint and a changed optimization policy. Retaining checkpoint history makes that second path possible.

7.15.2 Google TPU pod resilience

Google's TPUv4 supercomputer combines configurable topology with recovery software. A pod contains 4,096 chips organized as 64 cubes of 64 chips, each arranged in a $4\times4\times4$ 3D mesh (Zu et al. 2024). Losing one chip removes $1/4096$th of pod capacity, but can interrupt an entire job that requires that participant. The recovery unit therefore exceeds the failed device.

War story 7.1 traced the recovery mechanism, in which the OCS fabric assembles healthy cubes into job-sized slices, reallocating spare cubes after machine outages and routing around unavailable links for supported OCS outage patterns. The published study adds the software that runs that loop, components including `libtpunet` and `healthd` for topology setup and health monitoring. It also gives the operating statistics that show how often the loop runs. System availability was 99.98 percent, with hardware outages affecting approximately 1 percent of training jobs (Zu et al. 2024). Daily failure rates were 0.08 percent of TPU machines, 0.005 percent of ICI cables, and 0.04 percent of OCS units. Small daily fractions still add up across thousands of components, so the control plane absorbs a steady stream of reconfiguration events rather than an occasional emergency. The architectural lesson is to match each failure boundary to a feasible replacement or routing mechanism.

7.15.3 Netflix chaos engineering for serving dependencies

While training resilience focuses on long-running batch jobs, Netflix's published work on Chaos Engineering (Basiri et al. 2016) provides the serving-side contrast, and it is the production origin of the injection discipline that section 7.14 applied to training. The premise is simple but operationally demanding. Because production systems have many interacting dependencies, teams should validate steady-state behavior by deliberately injecting failures instead of waiting for real incidents to discover whether fallbacks work.

For ML serving, the same discipline applies to feature stores, model-serving dependencies, caches, and fallback paths. A model endpoint can be healthy while a feature service is slow, stale, or unavailable; if the system lacks a tested fallback, a local dependency problem can become user-visible latency or degraded recommendations. Chaos tests make those assumptions executable by injecting latency, terminating dependencies, or forcing fallback paths in controlled conditions.

The recovery procedure for these injected faults centers on fallback hierarchies. If the primary deep learning model fails or times out, the serving system can switch to a lighter model, cached response, or simple popularity-based default. The systems lesson is that resilience in ML serving is not a static property but a continuous practice of active verification. A fallback path that is never exercised is documentation, not fault tolerance.

Across these production case studies, three architectural patterns recur. First, detection speed belongs in the recovery budget. Meta's log-freshness threshold and Google's health monitors determine when recovery can begin, while Netflix's chaos experiments test detection and fallback for selected dependency failures. Checkpoint age and replication lag separately govern recoverable state. Second, the

atomic unit of failure shapes the architecture. Google combines cube replacement with fault-tolerant routing, the OPT run restarted from durable checkpoints and kept their history for numerical rollback, and Netflix validates service-dependency fallbacks. Third, fault tolerance is a spectrum rather than a switch. Exact state recovery trades normal-operation overhead against lost work and recovery time; graceful degradation additionally trades service capability against continued availability. Those distinct trade-offs help identify the misconceptions that follow.

7.16 Fallacies and Pitfalls

An infrastructure team might spend weeks hardening their storage layer against disk failures, only to have their entire training run destroyed by a subtle software bug in their PyTorch distributed backend. Fault tolerance for distributed ML systems involves counterintuitive mathematics and subtle trade-offs where conventional data center wisdom often fails. Recognizing the fallacies and pitfalls below prevents engineers from optimizing for the wrong failure modes before the chapter closes with a synthesis of its core quantitative rules.

Fallacy: *Hardware failures are the main concern.*

This intuition comes from traditional systems where disk failures, power outages, and network partitions dominate, whereas in ML systems hardware failures are only one part of a broader incident mix. Long-lived, stateful ML jobs expose failure paths that hardware redundancy cannot cover. A malformed checkpoint path can make recovery impossible, a mismatched collective library can hang all ranks, an undersized shared-memory limit can crash data loaders, and a stale feature schema can silently corrupt training. Their relative frequency depends on the deployment, but even an infrequent software or configuration fault can destroy the same multi-day job that hardware redundancy was meant to protect. Investing heavily in hardware redundancy while neglecting software robustness (input validation, gradual rollouts, configuration management) leaves many important failure modes unaddressed, which is why the most reliable ML systems treat software bugs as inevitable and design defensively.

Pitfall: *Setting checkpoint interval by intuition.*

Organizations commonly set checkpoint intervals based on "feels right": "every hour seems reasonable" or "every 1,000 steps." The Young-Daly formula reveals these intuitions are often wrong. For the 1,000-GPU cluster of table 7.1, whose GPU-only MTBF is 50 hours, with a checkpoint write time of 5 minutes:

$$T^*_{\text{ckpt}} = \sqrt{2 \times 5 \times 3000} = \sqrt{30000} \approx 173 \text{ minutes}$$

The intuitive "every hour" checkpoints nearly three times more often than the expected-waste optimum. It reduces potential lost work, but the added write overhead outweighs that benefit under this model. A tighter RPO can still justify the shorter interval. The same hourly policy was too infrequent in the Young-Daly notebook, and both verdicts follow from one rule. The optimum scales as

$\sqrt{T_{\text{write}} \cdot \text{MTBF}_{\text{system}}}$, so an hour is too long when a 24.5 s write meets a full-system MTBF of 3.87 hours, yet too short when a 5-minute write meets a GPU-only MTBF of 50 hours. If checkpoint time increases to 15 minutes (larger model, slower storage), the optimal interval stretches to 300 minutes, further still from the "every 15 minutes" that some teams adopt to "stay safe." The decision must balance expected waste with the recovery contract rather than treat either interval as universally correct.

Fallacy: *Component MTTF values predict individual failure timing.*

Engineers read a GPU MTTF of 50,000 hours and plan around a five-year replacement cadence per device. MTTF is a population mean, not a lifetime assigned to each component. A GPU with MTTF 50,000 hours might fail at 200 hours or last 100,000 hours. Under the chapter's independent constant-rate model, a fleet of 10,000 GPUs has an aggregate rate of approximately $10{,}000/50{,}000 = 0.2$ failures per hour, or roughly one failure every 5 hours. This planning model helps size recovery capacity and spare pools. It does not make device-health monitoring pointless: temperature, error history, and recurring anomalies provide condition-specific evidence that the population mean alone lacks.

Pitfall: *Using MTBF calculations as if failures were independent.*

The reliability equation $\text{MTBF}_{\text{system}} = \text{MTTF}_{\text{component}}/N$ assumes component failures are statistically independent, while production failures correlate through the shared power, switches, software, and cooling of section 7.3.4.

Correlated failures change two quantities that the simple MTBF equation hides: incident frequency and blast radius. A cluster with 1,000 independent GPUs each with 50,000-hour MTTF has a first-GPU-failure MTBF of 50 hours. If a shared power, cooling, or software hazard adds an incident rate 10 times larger than that independent first-failure rate, the effective incident MTBF drops to about 5 hours. Separately, a correlated incident may take out 10 GPUs at once, increasing recovery cost even if the independent GPU failure rate itself has not changed. Reliability engineering must identify and mitigate correlation through diversity: different power feeds, different network paths, different software versions in canary deployments.

Fallacy: *Every failure should be handled as a full restart.*

Engineers often treat all failures as "node crashed, restart from checkpoint," but different failure modes require different responses. Transient stalls such as network congestion can permit a bounded wait or safe retry when state and the communication group remain valid; a brief fault can still require recovery if it corrupts state or leaves the group unusable. Permanent device loss requires replacement or a feasible resize, together with restoration of the missing state. Silent corruption requires a trusted recovery point, which may precede the latest checkpoint and therefore motivates checkpoint history retention. Persistent resource exhaustion (OOM, memory fragmentation) needs reconfiguration before restart; otherwise the job can crash again immediately. As section 7.3 details, misdiagnosing failure

type wastes compute. Restarting for a harmless stall discards useful work, while continuing from corrupted state can contaminate later updates.

Pitfall: *Assuming checkpoints are consistent without validating state.*

Modern frameworks checkpoint transparently, creating the illusion of automatic consistency. In practice, distributed checkpoints require cross-node coordination that can fail subtly across multiple dimensions. Rank desynchronization occurs when workers record different training steps, such as rank 0 snapshotting iteration 1000 while rank 1 captures iteration 1001. Similarly, transient storage failures can cause partial writes that leave behind truncated shards, sharded optimizer state lag leaves optimizer states misaligned with model weights when captured asynchronously, and in-flight gradients from incomplete AllReduce operations can produce ambiguous reduction boundaries. Production systems must therefore implement checkpoint validation: verify all shards exist, verify iteration numbers match, and verify optimizer state matches model state. The reason is that organizations that discover corrupted checkpoints during recovery from a failure have no recourse except restarting from a potentially much earlier checkpoint.

Fallacy: *Overhead budgets are fixed fractions of training time.*

Reference tables that show "pipeline bubble: 10 percent, checkpoint overhead: 5 percent, failure recovery: 3 percent" are easy to read as physical laws and pass through as line items in capacity plans. They are engineering targets, not constants. Pipeline bubble overhead depends on the number of microbatches and the interleaved schedule, as its bubble fraction shows (section 6.5.2). Elastic recovery can reduce waiting for replacement capacity while still restarting workers and restoring state. Checkpoint overhead is a function of model size, storage bandwidth, and whether checkpointing is synchronous or asynchronous. Treating these numbers as fixed percentages leads to passive acceptance of avoidable inefficiency, because each one is set by a design choice.

Pitfall: *Using elastic training as a substitute for checkpointing.*

Elastic training adjusts parallelism degree when workers fail, but resizing still requires a consistent recovery state. Reducing the active worker count requires redistributing model shards, optimizer states, and data assignments, often through checkpoint reload. Below some minimum viable size, training becomes infeasible because the model no longer fits or the batch policy cannot be maintained; the job must wait for sufficient capacity before restoring. If a failure was caused by a software bug triggered by specific data, the bug persists in remaining workers. Elastic training is complementary to checkpointing, not a replacement. Resizing alone does not justify a lower checkpoint frequency, because the recovery contract, failure rate, and checkpoint cost still determine that choice.

Fallacy: *Silent data corruption is negligible because hardware has ECC.*

GPUs and memory systems include extensive error correction (ECC, CRC, parity), creating the intuition that silent data corruption is negligible. Large-scale CPU SDC and memory-error studies show that silent corruptions and memory faults still occur at fleet scale and can escape ordinary error reporting (Dixit et al. 2021; Sridharan et al. 2015). ECC and link CRCs remain necessary layers, but they protect stored and transmitted bits rather than arithmetic, so they are not an end-to-end correctness proof for a training run. A 10,000-GPU cluster executes enough arithmetic that even rare per-device corruption becomes an operating condition, which is why it needs the check-and-verify defenses of section 7.5 in addition to hardware protection.

Pitfall: *Adding GPUs without accounting for communication and recovery overhead.*

Capacity plans typically account for Amdahl's Law and AllReduce overhead but treat reliability as a fixed background condition. At extreme scale, each additional GPU increases the aggregate failure rate, which inflates the expected recovery and replay time per job. There exists a cluster size beyond which the time lost to failures and recovery exceeds the time saved by additional parallelism, and wall-clock training time increases rather than decreasing with N_{GPU}. This is the reliability version of diminishing returns, and it applies on top of the Amdahl ceiling, so the two effects must be modeled together. Whole-run useful goodput must count only retained progress and include recovery time in the denominator, and its reliability penalty generally grows with N_{GPU} under the independent-failure model. Section 9.2.1 composes that runtime loss with the scheduling and program losses without counting any of them twice.

7.17 Summary

Fault tolerance turns the statistical expectation of hardware failure into a manageable operational routine. Individual component reliability compounds across thousands of devices, driving system-level MTBF from years down to hours. At fleet scale, systems must bound lost work and recovery delay through recovery that is automatic, fast, and minimally disruptive to training or serving.

In training, progress is only as safe as the last state the fleet can prove it can restore. Checkpointing bounds lost work, and the Young-Daly interval (equation 7.7) prices that bound against write cost, shrinking only with the square root of a falling MTBF. RPO and RTO turn the expected-value optimum into a service contract. A manifest published last defines which generation exists, and fencing at the resource boundary decides who may still write to it. The retries that recovery triggers stay safe only when each operation is idempotent, inherits its caller's deadline, and draws on one shared retry budget, so the response cannot amplify the incident. Elastic recovery then trades capacity for continuity, valid only while the data, batch-size, and optimizer invariants survive the resize.

Serving inverts the budget. Training can spend minutes restoring state that satisfies its optimization contract; an interactive request has milliseconds, so serving buys availability with ready replicas and decides in advance which state it will

rebuild, replicate, or abandon. The KV cache is the clearest case, derived state that can be reconstructed from retained history only when the latency budget allows. When neither redundancy nor reconstruction fits that budget, graceful degradation keeps the service useful by sacrificing a named property that was validated before the incident.

Recovery depends on evidence about both the failure and the state being restored. A loss spike can originate in hardware, data, numerical behavior, or synchronization. Suspect state can justify a pause or rollback while investigation continues; attributing the cause to a device requires corroborating telemetry, replay, or integrity evidence. Restore drills and fault injection then test whether the selected response actually preserves valid state and meets its recovery budget. Passing those tests establishes evidence for the exercised fault model, rather than a guarantee against every failure.

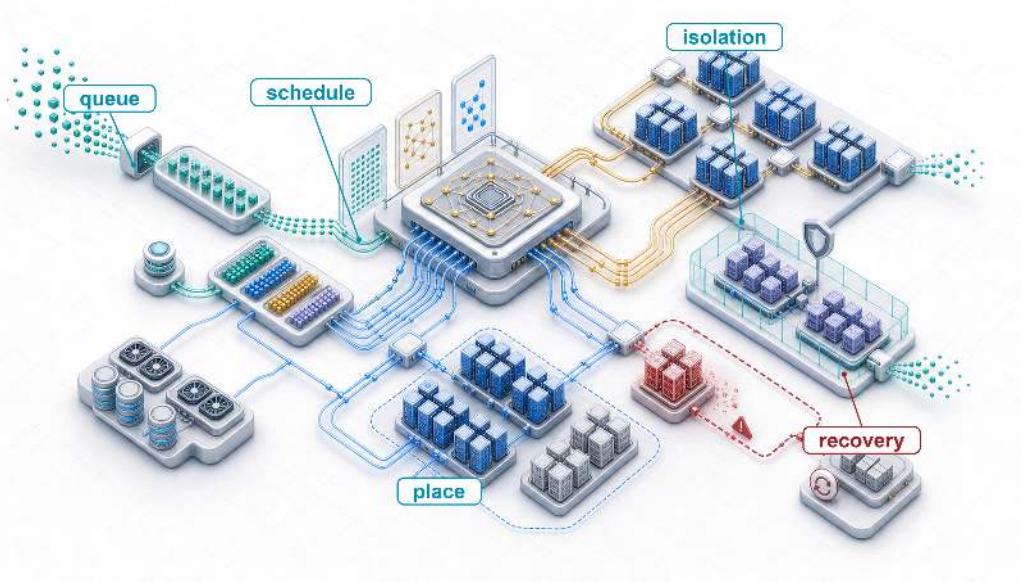
Key Takeaways: Failure is normal operation

- **Scale makes failure routine**: A 10,000-GPU cluster encounters hardware failures every few hours under the chapter's component-rate assumptions; software must treat failure as a normal state.
- **Liveness is not correctness**: A gray failure keeps answering heartbeats while every peer waits on it, and silent data corruption passes ECC while feeding wrong gradients into a correct AllReduce, so detection needs progress measurements and check-and-verify evidence beside liveness checks.
- **Recovery is a contract**: RPO bounds lost progress, RTO bounds recovery delay, MTTR combines with MTBF to determine steady-state availability, a manifest identifies committed state, and fencing prevents an expired worker epoch from writing after replacement.
- **Checkpoint cadence balances two costs**: Under the first-order assumptions, $T^*_{\text{ckpt}} = \sqrt{2 \cdot T_{\text{write}} \cdot \text{MTBF}_{\text{system}}}$ balances checkpoint write overhead against expected rework; for the 175B running example on a 10,000-GPU cluster it lands near 13.8 min. The selected interval must also meet limits on lost progress; recovery delay needs its own budget.
- **Elasticity enables persistence**: Designing training jobs to be "elastic" (rebuilding communication groups and rebalancing data shards as traced in figure 7.16) can reduce waiting for replacement capacity. The runtime must preserve valid state and data coverage, and either preserve batch size or validate the changed optimization policy. Checkpoint cadence still determines how much work must be replayed.
- **Serving recovery follows the state budget**: Preserve authoritative history, then choose reconstruction, checkpointing, or replication for derived state according to the latency contract (table 7.13). A ready replace-

ment provides useful service only when it can also recover the context the request needs.

- **Degradation is a designed mode**: When recovery cannot finish inside the latency budget, a fallback validated in advance (a smaller model, cached results, default features, or shed low-priority load) keeps the service useful, provided monitoring exposes how much quality was traded away.

Fault tolerance makes the cost of coordination a deliberate part of the execution budget. Section B.6.3 works a complete coordination-bound diagnosis, attributing a large run's lost wall time to checkpoints, failures, pipeline bubbles, and scheduling. In the Fleet Law (equation 1.3), checkpoint pauses, detection timeouts, and restarts all land in the synchronization term $T_{\text{sync}}(N)$, and in goodput accounting they are runtime losses. The chapter's mechanisms spend Coordination (C_3) so that a failure does not erase completed Compute, and asynchronous checkpointing and warm restart earn their complexity by moving part of that synchronization cost into T_{overlap} or shrinking it outright. The useful comparison is between time spent preserving and validating state during normal operation and time lost reconstructing trustworthy execution after a failure. A cheaper recovery mechanism is valuable only when it still meets the workload's limits on lost progress, response delay, and degraded quality.



What's Next: From resilience to resource management

Keeping the fleet running despite inevitable hardware failures requires three layers: checkpointing preserves progress, elasticity absorbs node losses, and redundancy protects stateful serving sessions. Each layer also assumed a decision made elsewhere: a spare pool deep enough to replace a drained node, a hot spare held idle, spot capacity that may vanish, and replicas placed across independent failure domains. Those are allocation decisions, made while many jobs compete for the same fleet, from month-long training runs to hour-long experiments. A fault-tolerant cluster therefore still needs orchestration to decide which jobs run where, when to preempt, and how to share capacity fairly among them.

Purpose

Why can jobs wait while expensive accelerators sit idle?

A thousand idle accelerators still incur ownership or reservation costs while queued experiments make no progress. More hardware does not resolve that waste when available resources cannot form the groups that pending jobs need. Free devices may be scattered across machines with unsuitable connections, or several jobs may each hold resources while waiting for the rest. On one machine, improving execution usually begins with the work already running. Across a shared fleet, useful progress also depends on which work can start, how long it waits, and what other work its allocation displaces. A short experiment needs a timely result, a long training run needs continuity, and a serving workload needs capacity before requests miss their deadlines. Favoring any one claim without considering the others can leave the fleet busy while delaying the results it exists to produce. Interrupting a job can free capacity, but preserving its state and restoring progress consume time and bandwidth. Waiting for a better placement can accelerate execution while extending completion time. Fair access therefore cannot be judged from device counts alone, and high utilization cannot establish that capacity is being used well. The engineering challenge is to honor these

competing claims under changing demand and uncertain resource availability, while keeping the allocation process itself reliable. In C^3 terms, orchestration pays coordination overhead to turn compute and communication capacity into useful progress while preserving fairness and latency headroom.

Learning Objectives

- Explain how batch and declarative control planes admit, place, and reconcile allocations under stale state and partial failure
- Apply gang, multi-dimensional fit, and topology constraints before dominant-resource fairness to find allocations a job can run
- Analyze conflicts among throughput, latency, fairness, and cost using slowdown, queueing delay, and ML-specific scheduling signals
- Design topology-aware placements that map tensor-, pipeline-, and data-parallel groups onto NVLink domains and switch tiers
- Design elastic, preemption, and spot policies whose throughput or price gains repay their transition and interruption costs
- Diagnose utilization losses by separating allocated, active, and productive capacity and tracing each gap to its cause
- Evaluate serving-capacity and quota policies that balance serving headroom, team guarantees, and reclaimable borrowed capacity

8.1 The Scheduling Problem

Consider two research teams sharing a 1,000-GPU cluster: Team A submits a 512-GPU job that will run for a month, while Team B submits hundreds of 8-GPU experiments that each run for an hour. If the scheduler continually admits whichever jobs fit, Team B's small experiments can indefinitely block Team A's large training run. The scheduling problem is to resolve this conflict among throughput, fairness, and cluster utilization.

Production traces show that this mix is the normal case rather than a contrived one. In the Kalos cluster that Shanghai AI Laboratory used for language-model development in 2023, 86 percent of 19,907 GPU jobs requested a single GPU, yet together they consumed 0.1 percent of the cluster's GPU time. Jobs of 256 GPUs or more made up 4 percent of submissions and consumed 96 percent of GPU time (Hu et al. 2024), two distributions that figure 8.1 plots side by side. Counted by jobs, the cluster is a stream of small experiments; counted by GPU-hours, it is a few percent of jobs that hold nearly all the accelerators. A scheduler must serve both views at once, which is why fairness, packing, and preemption policies cannot be judged by either count alone.

Mechanisms for synchronizing workers efficiently (chapter 5), partitioning computation across them (chapter 6), and recovering from hardware failures (chapter 7) solve the single-job scaling problem. Each of them assumed that the job already held its accelerators. Fault tolerance assumed more than that. Its recovery paths drew on a spare pool deep enough to replace a drained node and on spot capacity whose loss the job could absorb. Neither exists unless something outside the job grants it, holds it in reserve, or takes it back. That something is orchestration, the policy that decides which jobs run, where they run, when one is preempted for another, and how competing demands share the fleet. An allocation decision

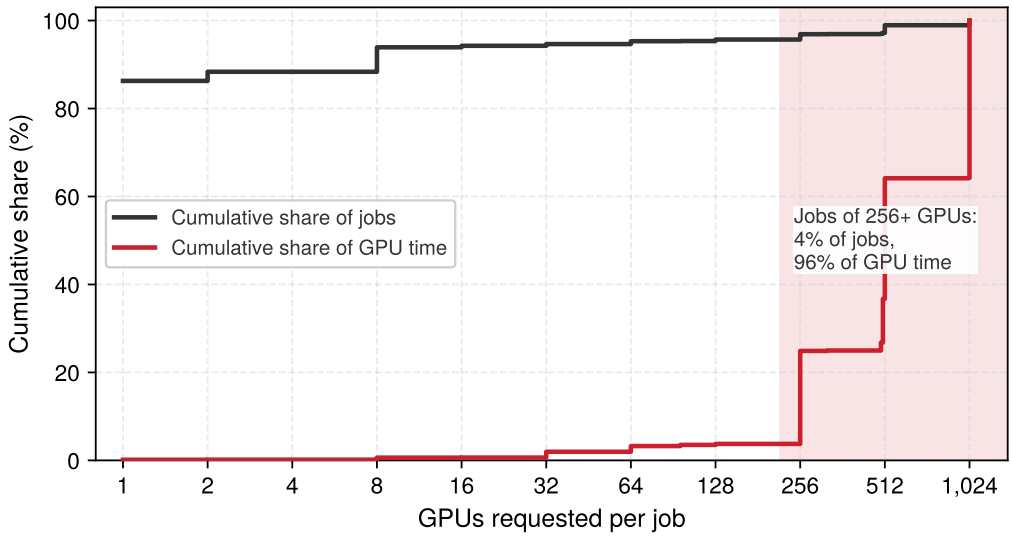

Figure 8.1: Jobs versus GPU Time by Job Size: Cumulative share of GPU jobs (gray) and of GPU time (red) against the number of GPUs each job requested, for the Kalos LLM-development cluster from March to August 2023. Almost every job is small, while almost all GPU time goes to jobs of 256 GPUs or more. Data from the AcmeTrace release of Hu et al. (2024).

must hold across unreliable nodes, balance competing fleet objectives, and satisfy each job's feasibility constraints before platform control planes, topology-aware placement, elastic and cost-aware policies, workload-aware ML schedulers, and serving, multi-tenant, and diagnostic practices can turn raw capacity into useful work. Training and serving draw on the same fleet, so the capacity envelope this chapter allocates is the one both depend on; how a serving system spends its share, request by request, is the subject of chapter 10.

In the fleet stack (shown in the margin), orchestration occupies the Reliability & Control row of the distribution band, but the infrastructure band beneath it constrains its decisions. The scheduler must account for GPU heterogeneity, NVLink topology, rack power limits, and network bisection bandwidth. When scheduling goes wrong, debugging can require examining all four bands to identify whether the root cause lies in infrastructure (hardware constraints), distribution (algorithm limitations), serving (workload mismatch), or governance (policy misconfiguration). Orchestration connects physical infrastructure to distributed algorithms, translating resource requests into placements that respect both hardware topology and organizational policy.

Translating those requests into placements grows harder as the fleet and its flagship workloads scale. In a 10,000-GPU cluster, a single pretraining run of a GPT-3-class 175B-parameter model (Brown et al. 2020), the running instance of Archetype A (GPT-4/Llama-3) throughout this book, can hold a 1,024-GPU allocation for weeks. Because the scaling laws of section 1.3 reward larger models trained on more tokens, each new generation of such runs asks for a larger gang held for longer, so the scheduler's hardest requests keep growing. When enough jobs of that class are queued that together they ask for more GPUs than the clus-

ter holds, alongside thousands of smaller experiments and inference workloads competing for the same pool, naive policies break down. A first-come-first-served policy without backfilling or preemption can let large jobs occupy the cluster for weeks, delaying smaller experiments that researchers need to iterate quickly. A fair-share policy that divides capacity without respecting each job's minimum resource bundle can leave many partial allocations and no runnable large job.

The economic stakes make these decisions consequential at every scale. A continuously provisioned 10,000-GPU cluster, valued at the chapter's cloud-equivalent rate of $2/GPU-hour, represents $480,000 per day in capacity, whether the GPUs are computing useful work or sitting idle while jobs wait in a queue. If scheduling inefficiencies leave 30 percent of GPUs idle, that translates to $144,000 per day in unused capacity value, or about $52.6M annually. Holding useful work per active GPU-hour constant, improving utilization from 50 percent to 80 percent adds 3,000 fully active GPU-equivalents of productive capacity without purchasing additional hardware. That count measures the gain in useful work. Procurement planning asks a different question, namely how much hardware the gain replaces. For that comparison the answer is 6,000 raw GPUs, because new GPUs run under the same scheduling policy would also reach only 50 percent utilization. Recovered capacity becomes cash savings only when it avoids purchases or billed resource time. Scheduling can therefore increase the useful work delivered by an existing investment, even when the fleet's immediate expenditure remains unchanged.

↩ Archetype A and its 175B-parameter running instance are established in section 1.6.1.1.

Workload semantics, rather than an ML-versus-high-performance computing (HPC) boundary, determine scheduling flexibility. Rigid synchronous jobs in both domains require a fixed set of co-scheduled ranks, whereas malleable jobs can make progress across a declared range of resource counts. Gang scheduling[1] is the central allocation constraint for a rigid training group: a job configured to require 1,024 GPUs cannot complete its distributed iterations with only half of them. Malleable data-parallel training can instead vary its replica count at explicit reconfiguration boundaries, but tensor- and pipeline-parallel groups usually retain a rigid base allocation. The scheduler must therefore model each job's minimum viable gang and permitted resize points rather than infer rigidity from the workload's field.

If gang scheduling determines which resources must be available together, topology awareness via placement groups[2] determines how efficiently they can communicate. Tensor-parallel groups benefit from placement within a high-bandwidth NVLink domain; a placement across slower links must still meet the job's communication budget. Two allocations of the same size can therefore deliver very different useful throughput.

GPU heterogeneity is the third dimension. Many clusters contain mixtures of A100 and H100 accelerators with different compute throughput and interconnect bandwidth. Their training-throughput ratio depends on the workload, numerical precision, and communication path, so the scheduler needs measured performance and the applicable allocation cost. Memory capacity adds a hard admission test once pools differ in it. The common A100 and H100 variants both carry 80 GB of high-bandwidth memory (HBM), but smaller-memory variants of the same

1 | **Gang scheduling**: Formalized by Ousterhout (1982) for parallel systems, where the "Ousterhout matrix" co-schedules related threads across processors in synchronized time slices. In a rigid ML training group, incomplete allocation prevents collective completion, so held resources can remain idle until the missing ranks launch.

2 | **Placement group**: A cloud-native abstraction that requests instances be placed within a high-bandwidth, low-latency network domain. For the ML Fleet, placement groups reduce placement scatter and may expose higher network limits than unconstrained placement. They do not guarantee workload-level bisection bandwidth: topology oversubscription, concurrent traffic, routing, and the collective pattern still determine delivered AllReduce bandwidth.

accelerator and older generations often share the fleet. A job whose working set fits only the larger devices cannot run on the rest at any priority. The debugging example in section 8.12 returns to exactly such a mixed fleet. The scheduler must match workloads to appropriate hardware based on actual requirements, not user preferences, while maintaining high utilization across heterogeneous pools. When users request specific GPU types out of habit rather than necessity, the mismatch between requested and required resources can leave entire hardware pools idle while queues overflow on preferred hardware.

Job durations are also uncertain: a training run may converge early and complete in days rather than weeks, hardware failures may abort jobs and return resources at unpredictable times, and hyperparameter searches may terminate unpromising configurations early. In both ML and scientific computing, fixed-step jobs with stable iteration times permit better release-time estimates than jobs whose stopping conditions or execution rates vary. The scheduler must therefore distinguish an estimated completion time from an enforced runtime limit when deciding whether another job can safely use a temporary gap in capacity.

The interaction between these challenges creates combinatorial complexity. A scheduler must simultaneously handle gang scheduling constraints (atomic allocation), heterogeneous resources (capability matching), topology requirements (NVLink locality for tensor parallelism), priority and fairness policies (organizational equity), preemption decisions (which running jobs to interrupt), and cost optimization (spot vs. on-demand placement). Each dimension constrains the others. A topology-optimal placement may violate fairness policies, a cost-optimal spot placement may violate reliability requirements, and a fairness-driven allocation may fragment resources in ways that prevent gang scheduling. The scheduler therefore does more than pack jobs onto GPUs. It must maintain a consistent, economically useful view of a failing, heterogeneous fleet. At that scale, placement stops being only an optimization problem and becomes a distributed systems problem of keeping state coherent across thousands of machines.

8.2 Distributed Scheduling Complexity

A single-machine scheduler works inside one operating-system boundary, where three properties hold closely enough to design around: it observes resource state directly and consistently, its allocation decisions take effect atomically, and failures are nearly binary (the machine is up or it is down). Device faults and delayed cleanup still occur, but they do not hide behind a network. A cluster scheduler surrenders all three properties. It coordinates independent nodes through delayed messages and uncertain observations, so an authoritative allocation decision does not establish that every node has received or completed it. Several distributed systems problems emerge from that gap.

Partial failures pose the first challenge. A node can fail between allocation and job start, creating a gap between the scheduler's decision and its effect. The scheduler may successfully allocate 32 GPUs across 4 nodes, only to have one node fail before the job launches. The remaining 24 GPUs sit idle while the scheduler

detects the failure, updates its state, and re-plans the allocation. Meanwhile, other jobs that could have used those 24 GPUs have already been placed elsewhere, potentially on suboptimal hardware. Before the first training step, recovery must repair allocation and launch state even though no new model progress exists to restore. Once execution begins, resource recovery must also coordinate with the framework's checkpoint and membership mechanisms.

Network partitions create a second problem. The scheduler may lose connectivity to a subset of nodes while those nodes continue operating normally. From the scheduler's perspective, their status is uncertain; from the nodes' perspective, jobs may still be running and producing useful work. Reallocating their GPUs risks double allocation if the partition heals while the old work still runs; waiting for reconnection leaves possibly healthy capacity idle. The partition's duration cannot be known in advance, so any fixed timeout is a guess about network behavior that may prove wrong. A timeout can trigger recovery, but it does not prove that the old execution has stopped. Reusing a GPU therefore requires confirmed cleanup or an enforced revocation of the old allocation. Restarting a job on reachable replacement nodes also requires fencing stale attempts from shared outputs. The recovery policy can choose how long to wait for reconnection, but each choice must preserve exclusive ownership where the workload requires it.

State inconsistency emerges as a third challenge that compounds the first two. Resource state may differ between the scheduler's view and reality on individual nodes. A GPU the scheduler believes is free may still be cleaning up from a previous job: flushing caches, deallocating device memory, running a zombie process from a failed container, or completing a CUDA driver reset after an error. Conversely, a GPU marked as "in use" may have been freed by a job that terminated between heartbeat intervals. The scheduler therefore operates on a model of cluster state that is always slightly stale. The degree of staleness varies across nodes with heartbeat frequency, network latency, and the complexity of cleanup operations.

Ordering without global time presents the fourth issue. Allocation messages issued before and after a partition can arrive out of order. Logical timestamps can describe an order, but do not by themselves prevent conflicting ownership. The control plane must serialize conflicting allocation decisions, and the resource manager must reject stale allocation generations before acting on them. Otherwise, an old launch request can revive work after a newer allocation has taken ownership.

These four challenges echo the CAP theorem of section 1.4.2.1, under which a partitioned system cannot guarantee both consistency and availability. CAP is a theorem about distributed data systems, not a literal proof about every scheduler, but the analogy draws attention to which allocation decisions remain safe when nodes cannot communicate. Slurm, an HPC workload manager, and Kubernetes, a container orchestration platform, both need authoritative allocation records and mechanisms that reconcile those records with execution. Optimistic concurrency permits schedulers to plan against potentially stale snapshots, then validate proposed changes before committing them. Rejecting a conflicting pro-

posal costs scheduling work; accepting conflicting ownership would violate a different, essential invariant.

The control-plane tension becomes concrete when the scheduler interacts with the ML framework's own distributed coordination plane during a partition. A scheduler may decide that a subset of nodes is unavailable while workers on those nodes are still blocked inside a collective operation. That creates a brief window of conflicting intent: the scheduler wants to recover the allocation, but the training job has not yet converged on a new membership view. Elastic launch and rendezvous mechanisms such as TorchElastic reduce this ambiguity. They use heartbeats and re-rendezvous so the framework can either reform a viable worker group or terminate cleanly, which gives the scheduler a clearer recovery signal than an opaque collective timeout (PyTorch Contributors 2026c, 2026b). This layered coordination, with scheduler-level policy for coarse allocation and framework-level membership for workers, is the characteristic architecture of production distributed training clusters.

8.2.1 Admission, placement, and reconciliation

When a single undifferentiated queue mixes quota checks, hardware binding, and crash recovery, operators cannot tell whether a pending job is blocked by team quota, fragmented topology, or a dead node whose lease has not yet expired. A stale retry can also assign the same accelerators to two jobs at once. A scheduler control plane avoids this ambiguity by separating three decisions. **Admission control** decides whether a job may enter the runnable set under quota, priority, gang, and safety constraints. **Placement** binds an admitted job to a feasible set of nodes while accounting for accelerator capability, topology, power, storage, and network capacity. **Reconciliation** compares desired allocations with observed node and job state, then starts, retries, evicts, or fences work until the two agree. Keeping these stages explicit makes it possible to distinguish admission denial from placement failure, while versioned decisions and resource-level enforcement prevent stale observations from authorizing competing owners.

Control-plane architectures distribute these decisions differently (Hindman et al. 2011; Burns et al. 2016). A centralized scheduler serializes admission and placement against one authoritative state, which simplifies conflict handling but concentrates scheduling latency and failure impact. A two-level design offers resources to framework schedulers, gaining policy specialization at the cost of delayed or rejected offers. A shared-state design lets several schedulers plan concurrently against a common state and resolves conflicts through version checks or optimistic concurrency. In every design, reconciliation closes the loop. Node agents must enforce allocation generations and lease validity so that an old decision cannot revive after a newer placement has taken ownership.

Feasibility also extends beyond free accelerator count. Power-aware admission rejects or delays a placement whose worst-case draw would exceed a rack or facility envelope; relying on average draw risks correlated throttling when colocated jobs enter compute-heavy phases together. I/O-aware placement treats dataset-read and checkpoint-write bandwidth as reservable capacity, so a gang that fits in GPU

memory does not start where concurrent input pipelines or checkpoint bursts will saturate the same storage path. These constraints can deliberately leave accelerators idle. The idle capacity is the cost of preserving the power and data-movement budgets required for the admitted jobs to make progress.

8.2.2 Failure as a scheduling input

A scheduler that allocates 10,000 GPUs as if every granted node will stay healthy until the job finishes will see a multi-thousand-GPU training gang stall every few hours waiting for replacement capacity that was already handed out to other workloads. As section 7.2 established, the fleet failure rate is the per-device rate multiplied by the population (equation 7.4), so a cluster of ten thousand GPUs loses a device every few hours (table 7.1). Where fault tolerance turns that failure rate into checkpoints, detection, and elastic recovery for a running job, the scheduler must plan for failure in every allocation decision. The scheduler uses two failure rates. It sizes spare capacity and replacement paths from the GPU-only count of devices it must replace. Job interruptions, by contrast, follow the shorter full-system interval of section 7.2.2, which adds PCIe and network failure domains.

The scheduler cannot treat the cluster as a static resource pool where resources, once allocated, remain available until voluntarily released. It must anticipate loss of allocated resources during execution and provide replacement capacity or rescheduling paths. The response depends on the fault and the validity of the surviving state. A transient disruption may permit recovery in place if the execution state remains usable; a persistent hardware failure requires replacement resources. Even a short disruption can force checkpoint recovery if the framework cannot safely continue (Tiwari et al. 2015).

When a node heartbeat is missed, the scheduler faces three recovery policies with different delay and capacity costs. It can wait to see whether the heartbeat resumes, though this delays recovery if the machine has permanently crashed. It can instead begin recovery promptly on replacement resources, provided stale execution is fenced before conflicting work resumes. An intermediate approach marks the node as suspect and prepositions replacement capacity while checking its status; this reduces launch delay if replacement becomes necessary, but holds capacity that could otherwise serve pending work. Whichever policy it picks, reuse of the node's GPUs still waits on the fencing that network partitions require. Historical failure and recovery measurements set how long to wait and how much replacement capacity to hold. The recovery-time decomposition of fault tolerance (equation 7.10) shows where scheduler policy intervenes most effectively. Of its detection, restart, load, and warmup terms, the scheduler owns most of T_{restart}, the time to allocate replacement resources and launch processes, and that is the term its spare-capacity policy shortens. Waiting longer on a missed heartbeat lengthens T_{detect} in exchange for avoiding a needless restart, so the wait is worth extending only while a transient fault remains more likely than a permanent one.

These requirements connect the scheduler directly to checkpoint and recovery infrastructure. Scheduling decisions about spare capacity, preemption policies, and elastic training support determine how quickly the system recovers from

↪ The same decomposition in scheduler-facing phases (detect, reschedule, reload, and replay of work since the last checkpoint) is developed in section E.3.1.

statistically expected failures. A scheduler that reserves spare capacity or supports elastic recovery can restore throughput much faster than one that requires every failed job to wait for a full fresh allocation and reload. The reserve fraction follows from the measured failure rate and recovery time of the fleet's own workloads. Once the control plane can maintain coherent ownership across admission, placement, reconciliation, and node failures, it still needs an explicit policy objective to decide which competing jobs receive capacity when demand exceeds what the fleet can run at once.

↩ Failure detection, recovery procedures, and spare pools are established in section 7.9.

8.3 Scheduling Objectives and Their Conflicts

Giving a large training gang an unbroken allocation for weeks amortizes launch and data-movement overhead, but leaves short interactive debugging jobs waiting hours in the queue. Preempting the large gang so short jobs start immediately burns cluster capacity on checkpoint saves and restarts. Every scheduling policy trades four competing objectives against one another: throughput, fairness, latency, and cost efficiency. Throughput benefits from allocations that sustain useful work and amortize launch, interruption, and data-movement overhead; a large allocation helps only while the job scales effectively. Maintaining fairness demands an equitable distribution of resources across competing tenants to prevent a single dominant project from monopolizing the fleet. Dominant resource fairness (Ghodsi et al. 2011) formalizes this balance by equalizing each tenant's largest normalized share across GPUs, CPU, and memory. Reducing queue latency helps short, interactive jobs complete promptly, but aggressive preemption can repeatedly interrupt long-running training. Pursuing cost efficiency introduces different costs for different policies: spot capacity risks interruption, off-peak scheduling delays admission, and dense packing can increase interference. Each policy must be evaluated against useful work completed and the delays it imposes.

Fairness requires an outcome metric rather than an input quota rule alone. For job j, **slowdown** $S_j = (W_j + T_j)/T_j$ compares its queueing-plus-running time with its isolated runtime T_j, assuming the running time is unchanged by sharing. A one-hour job that waits nine hours has $S_j = 10$, even if its team eventually receives its nominal GPU share. When contention or resizing changes execution time, the numerator must instead use the observed queueing-plus-running duration while the denominator retains the isolated baseline. A scheduler should report the distribution of slowdown by user and job class, together with the age of the oldest pending feasible job. Dominant-share parity detects unequal resource allocation, slowdown exposes unequal delay, and the maximum feasible wait exposes starvation risk. These metrics separate a policy that is fair in allocated GPU-hours from one that is fair in the time users wait to obtain useful results.

Each of the four objectives, pursued alone, schedules the same pool differently and gives up something the others protect (figure 8.2). Favoring a large unbroken allocation can delay short experiments, while repeatedly admitting short jobs can prevent a large gang from assembling. These conflicts depend on the workload and available capacity; improving one objective does not necessarily worsen every

other objective. Resource-share fairness and completion-delay fairness therefore need separate measurements.

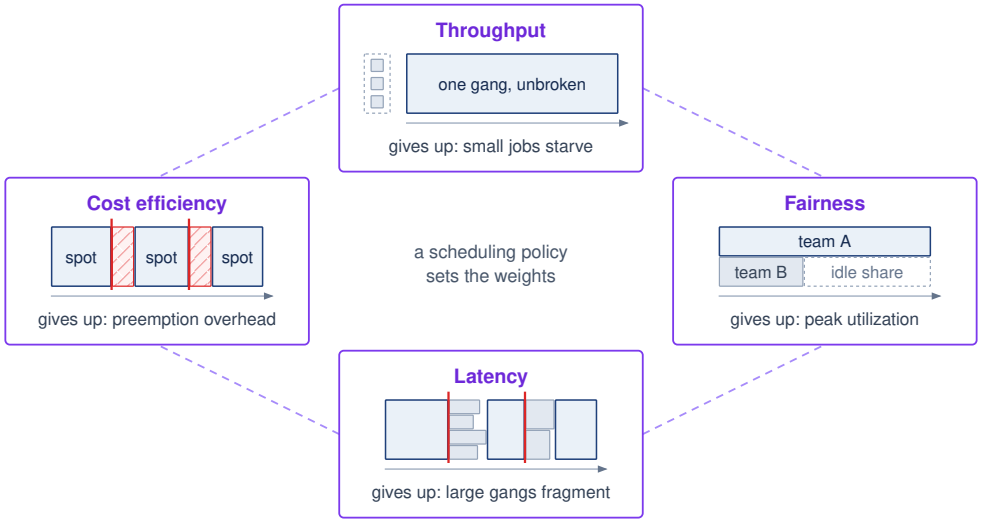

Figure 8.2: Scheduling Trade-Offs across Competing Fleet Objectives: A four-way trade-off diamond (Throughput, Latency, Fairness, Cost Efficiency) illustrates the tensions governing cluster scheduling. Throughput favors long, unbroken runs; Latency favors aggressive preemption for interactive jobs; Resource-share fairness can constrain placement to equalize shares; and Cost Efficiency uses discounted, interruptible capacity. Each vertex sketches a four-GPU pool over time as that objective would schedule it and names a possible cost of favoring it; the conflicts depend on workload and available capacity.

Consider a 64-GPU fine-tuning run of the same 175B-parameter model, a far smaller allocation than its 1,024-GPU pretraining run. If it sustains high utilization for days, an uninterrupted allocation amortizes launch overhead across a long execution. Admitting it may nevertheless require draining 64 suitably placed GPUs, delaying smaller experiments. Conversely, repeatedly filling available gaps with short jobs can prevent the large job from assembling its required group. Preemption or resizing can recover flexibility only if the job supports the transition and its cost is acceptable. The policy must therefore compare useful throughput with completion delay for both job classes. In scheduler terminology, those choices often appear as quality-of-service classes: job-priority tiers that decide which objective wins when throughput, latency, fairness, and cost collide.

Queueing adds a further conflict between utilization and latency, because a fleet run close to full load leaves arriving jobs little spare capacity. In a single-server queue with random arrivals, mean waiting time, expressed as a multiple of the mean job duration, is the product of a load factor $\rho_{\text{serv}}/(1-\rho_{\text{serv}})$ and a variability factor $(1+c_s^2)/2$. Here ρ_{serv} is offered load relative to service capacity, and c_s is the coefficient of variation of job duration. The load factor stays small through moderate load and grows without bound as load approaches capacity, so waiting time bends sharply upward near saturation instead of rising in proportion to utilization. The variability factor scales the whole curve. A queue that mixes minute-long debugging jobs with week-long training runs waits several times longer at the same load than a queue of similar-length jobs. Each added point of

utilization therefore costs more waiting time in an ML fleet than in a uniform one. Notebook 8.1 derives the relation and prices both factors.

Napkin Math 8.1: The queuing theory of GPU clusters

To isolate the effect of runtime variability, consider an M/G/1 queue with first-come-first-served service. Kendall notation names the queue by its arrival process, service-time distribution, and server count: M for memoryless (Poisson) arrivals, G for a general service-time distribution, and 1 for a single server. Treating a fleet as one server means modeling its aggregate capacity as a single resource that works through one job at a time, with each job's service time equal to its GPU-hours divided by the fleet's GPU count. That mapping ignores gang packing and parallel admission, so it isolates the variability effect rather than predicting a real fleet's wait. Jobs arrive according to a Poisson process (λ_{arr}), and independent service times follow a general distribution (G) with mean $1/\mu$ and finite standard deviation σ. When offered load is below service capacity, the Pollaczek-Khinchine formula gives the steady-state expected waiting time in the queue (W_q):

$$\frac{W_q}{1/\mu} = \frac{\rho_{\text{serv}}}{1-\rho_{\text{serv}}} \cdot \frac{1+c_s^2}{2}$$

Here, $\rho_{\text{serv}} = \lambda_{\text{arr}}/\mu$ represents offered load relative to the model's service capacity, $1/\mu$ is the average job duration, and $c_s = \sigma\mu$ is the **coefficient of variation** of job duration. The right-hand side is therefore the waiting time expressed as a multiple of the average job duration; a fleet's measured GPU-busy percentage is not automatically this model's load.

An exponential service-time distribution provides a reference case, yielding $c_s \approx 1$. A mixed ML queue can have much greater variability when short debugging jobs measured in minutes share capacity with training runs measured in weeks. The representative $c_s = 3$ calculation in this callout captures that variability without claiming a universal fleet constant. The impact on wait times is multiplicative. For the scheduling argument here, the single-server multiplier is sufficient; section F.1.1 develops an explicit single-server surrogate for batched serving and explains why multi-server, finite-buffer M/G/c/K systems require additional modeling.

At 80 percent utilization ($\rho_{\text{serv}} = 0.8$): with an exponential workload ($c_s = 1$), $W_q = 4 \times$ the average job duration. With an illustrative high-variability workload ($c_s = 3$), $W_q = 20 \times$ the average job duration. In this M/G/1 model, service-time variability multiplies waiting time at the same offered load. The example does not prescribe a universal GPU-utilization threshold or model gang placement directly. It explains why capacity planning needs the service-time distribution and queue-delay objective as well as average load.

8.4 Core Allocation Constraints

Awarding the 64-GPU fine-tuning run its fair share of the cluster delivers zero progress if those GPUs sit on nodes with exhausted host memory, lack the interconnect its parallel layout requires, or arrive only 32 at a time. A scheduling objective can choose only among allocations that a job can actually run. Fairness must be computed across every resource a tenant consumes, a request must fit every dimension of the node that receives it, a rigid group must arrive whole, and the resources each job holds must not block one another. Each of these constraints narrows the feasible set before any objective selects within it.

8.4.1 Dominant-resource fairness allocation

Equalizing GPU counts alone fails when one tenant's jobs saturate host CPU and memory while another's saturate the network fabric, leaving free GPUs unusable behind exhausted auxiliary resources. Dominant-resource fairness (DRF) makes a multi-resource entitlement comparable by normalizing each tenant's allocation against fleet capacity and taking its largest share (Ghodsi et al. 2011). Consider the deliberately small cluster in table 8.1: 8 GPUs, 32 CPU cores, 256 GB of memory, and 80 Gb/s of network capacity. Tenant A's replica requires 1 GPU, 4 cores, 32 GB, and 10 Gb/s; Tenant B's distributed worker requires 2 GPUs, 2 cores, 16 GB, and 20 Gb/s.

Table 8.1: Worked DRF Allocation: Progressive filling gives Tenant A four one-GPU replicas and Tenant B a pair of two-GPU workers. Both tenants reach a dominant share of 0.50 even though their CPU and memory allocations differ. GPUs and network are jointly saturated; CPU and memory remain available but cannot increase either allocation without exceeding a saturated resource.

Tenant	Allocation	GPU share	CPU share	Memory share	Network share	Dominant share
A	4 replicas	$4/8 = 0.50$	$16/32 = 0.50$	$128/256 = 0.50$	$40/80 = 0.50$	0.50
B	2 workers	$4/8 = 0.50$	$4/32 = 0.125$	$32/256 = 0.125$	$40/80 = 0.50$	0.50

For tenant i, define its dominant share as $d_i = \max_r(a_{i,r}/C_r)$, where $a_{i,r}$ is its allocation of resource r and C_r is fleet capacity for that resource. The calculation equalizes d_i, not every resource share. One A replica raises A's dominant share by $1/8$; one B worker raises B's by $2/8$. Progressive filling therefore grants roughly two A replicas for each B worker until both dominant shares reach 0.50. This is a fair policy target, but it is not yet a feasible placement. If B's two workers form one four-GPU gang, the four GPUs must become available atomically. If tensor parallelism requires one NVLink domain, four free GPUs scattered across nodes do not satisfy the allocation. If the job requires 80 GB HBM accelerators, four incompatible GPUs do not count at all. A production scheduler therefore applies capability, gang, and topology constraints to the feasible set, then uses DRF to choose fairly among allocations that can actually run. The order is not a convenience. Feasibility comes before fairness (principle 15) because a fair share of accelerators on which the job cannot run delivers no progress to the tenant who holds it. When no equal-share placement exists, the scheduler should report the constraint causing the deviation rather than silently presenting an infeasible entitlement as service delivered.

Lighthouse 8.1: Lighthouse archetypes: Placement changes fairness

The same resource share has different meaning across the three lighthouse workloads introduced in section 1.6.1:

- **Archetype A (GPT-4/Llama-3)** needs a rigid, topology-compatible gang. Fractional allocations below its minimum parallel configuration deliver no progress, so fairness must include maximum feasible wait for a contiguous placement rather than GPU-hours alone.
- **Archetype B (DLRM at Scale)** couples accelerator memory to sparse-routing bandwidth. A nominal GPU allocation is infeasible when embedding shards or network capacity cannot follow it, so network and memory must enter the dominant share and placement must protect the serving-latency envelope.
- **Archetype C (Federated MobileNet)** schedules participation rather than data-center GPUs. Eligibility filters for power, connectivity, and device

> capability can systematically exclude parts of the population, so fairness must be audited through participation and outcome rates across device and user groups, not equal device counts in a round.
>
> The common rule is to define the feasible bundle first and assess fairness over useful progress second. Treating every accelerator or client as interchangeable would conceal the constraint that makes each archetype difficult.

8.4.2 Bin packing

Even when a cluster has dozens of free GPUs in total, a pending 8-GPU job will sit blocked if previous placements scattered those free GPUs in 1- and 2-GPU remnants across partially occupied nodes. Fitting jobs of varying sizes into fixed-capacity nodes without stranding capacity is an instance of **bin packing**.[3] Because general bin packing is NP-hard, no known algorithm finds optimal solutions in polynomial time. Practical heuristics such as first-fit decreasing and best-fit decreasing offer tractable choices, but their performance depends on job sizes and placement constraints. How much usable capacity a heuristic recovers in a heterogeneous ML fleet has to be measured against that fleet's job mix, because the classical guarantees cover only one-dimensional packing.

Consider a 64-node cluster with 8 GPUs per node, totaling 512 GPUs. If every job requires 6 GPUs within one node, only one such job fits per node, leaving 2 GPUs unused and reducing effective capacity for this workload to 75 percent. The remaining 2 GPUs per node cannot be combined across nodes into another feasible six-GPU allocation, although smaller compatible jobs could use them. With a mix of 1-GPU, 3-GPU, and 7-GPU jobs, fragmentation depends on the placement and the pending requests; total free capacity can exceed a waiting job's demand while no individual node has enough space. Figure 8.3 maps this stranded capacity across an 8×8 allocation grid. Although 19 slots (30 percent of cluster capacity, dashed white cells) sit idle across nodes 0 through 7, active allocations (J1 through J15) leave every node partially occupied, which blocks a pending 8-GPU job that requires an entire unfragmented node.

ML placement is a multi-dimensional packing problem. Jobs require GPUs together with CPU cores for data preprocessing, host memory for data loading and augmentation pipelines, local SSD storage for dataset caching, and network bandwidth for gradient synchronization. A job requesting 4 GPUs, 32 CPU cores, and 256 GB of RAM may not fit on a node that has 4 free GPUs but only 16 free CPU cores because other jobs have consumed the host CPU for preprocessing. The scheduler must simultaneously satisfy all resource dimensions, and the job fits only if every dimension has sufficient capacity on the selected node. A bottleneck in any one dimension can therefore strand capacity in the others.

Locality constraints further restrict placement beyond simple resource availability. A training job may require tensor-parallel groups to remain within NVLink-connected nodes when its communication budget cannot tolerate the lower per-endpoint bandwidth of the external fabric (450 GB/s per direction intra-node vs. 50

[3] **Bin packing**: First-fit decreasing has a classical asymptotic $11/9$ approximation ratio for one-dimensional bin packing, with an additive constant in the finite-instance bound. That result does not guarantee the same ratio for ML placement with several resource dimensions, topology constraints, and indivisible gangs. A scheduler must evaluate its heuristic against feasible placements and the stranded capacity it leaves.

GB/s per port inter-node). On this topology, where NVLink does not connect the nodes, a job requesting "4 GPUs with NVLink connectivity" cannot use 2 GPUs from node A and 2 from node B, even if all 4 GPUs are individually available and the total capacity is sufficient. These topology constraints turn resource counts into a placement problem where which specific resources are available matters as much as how many. A capacity-feasible packing must also pass the job's locality constraints.

Schedulers address fragmentation through several complementary strategies, each targeting a different aspect of the problem. The first, backfill, lets smaller jobs run in the gaps while a large job waits for contiguous resources; section 8.4.3 develops it together with the reservation it must protect and the runtime estimates it depends on. A second strategy, periodic **defragmentation**, migrates or preempts low-priority jobs to consolidate free resources into contiguous blocks, analogous to memory compaction in operating systems. The scheduler identifies nodes where partial allocations leave stranded resources, preempts the jobs occupying those resources, and re-schedules them on nodes where they can be packed more efficiently. The cost includes state transfer and restart, plus replay of work not captured by a valid checkpoint. A graceful checkpoint can preserve recent progress, but still takes time and storage bandwidth. The scheduler must weigh these costs against the benefit of starting large jobs sooner, and low-demand periods reduce the number of competing jobs affected by the move.

A third strategy, **over-subscription**, admits more demand than a capacity dimension can sustain simultaneously, but only where the resource is divisible and the scheduler can bound interference. Average activity of a GPU's streaming multiprocessors (SMs), its compute units, does not create fractional whole GPUs. A job that reserves device memory, requires an exclusive CUDA context, or belongs to a rigid gang still occupies its assigned device while kernels are idle. Statistical multiplexing can be safe for explicitly shareable CPU, network, storage, or partitioned GPU capacity when tenants have measured, weakly correlated peaks and enforceable limits. It is unsafe to convert 70 percent average GPU utilization into a 1.4× device overcommit ratio. Whole-device capacity should instead be recovered through preemption, elastic resizing, or an isolation mechanism such as Multi-Instance GPU (MIG) hardware partitioning or NVIDIA's Multi-Process Service (MPS), which lets several processes' kernels share one device. Either mechanism helps only if the scheduler models its memory, compute, and fault-sharing contract explicitly. Both reappear with the serving workloads they suit best in section 8.10.1.

8.4.3 Gang scheduling

Partial allocation of rigid multi-GPU jobs creates a distributed scheduling failure mode in which two jobs each hold half the resources they need and block each other indefinitely while every allocated GPU sits idle. In the left panel of figure 8.4, jobs J1 and J2 each hold 4 of the 8 GPUs they require, and the whole pool stalls. Atomic gang scheduling (right panel) instead grants J1 all 8 GPUs as one allocation while J2 waits without holding any, which prevents this allocation deadlock.

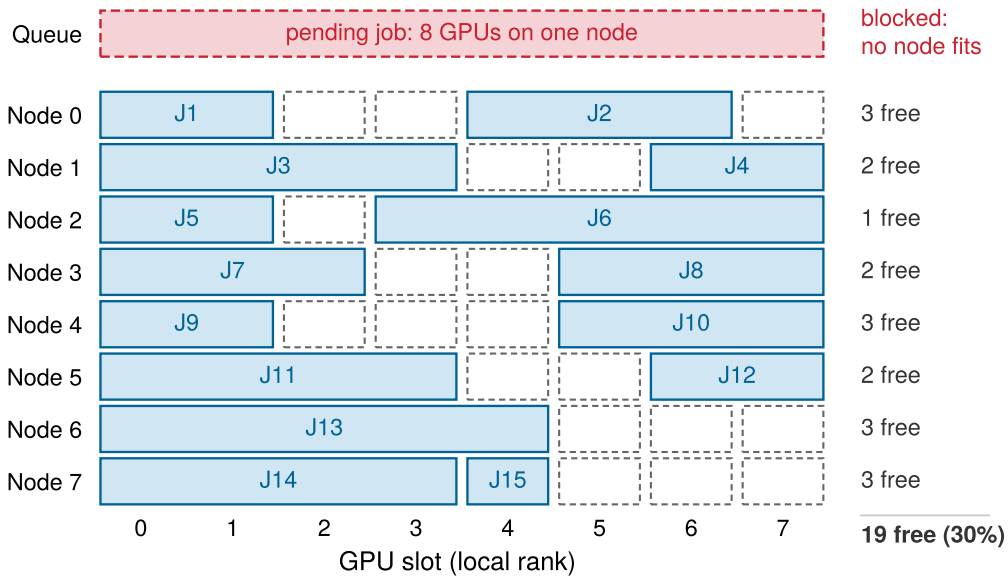

Figure 8.3: The Fragmentation Problem: A snapshot of an 8-node cluster (rows) with 8 GPUs each (columns). Blue blocks mark the slots each active job holds (J1 to J15); dashed white cells are free, and the count at the right of each row gives that node's free slots. Although 19 GPUs, roughly 30 percent of capacity, are free, every node still holds at least one busy slot, so the pending job above the grid, which needs a full node, cannot be placed. Fragmentation, not total capacity, sets what the scheduler can admit.

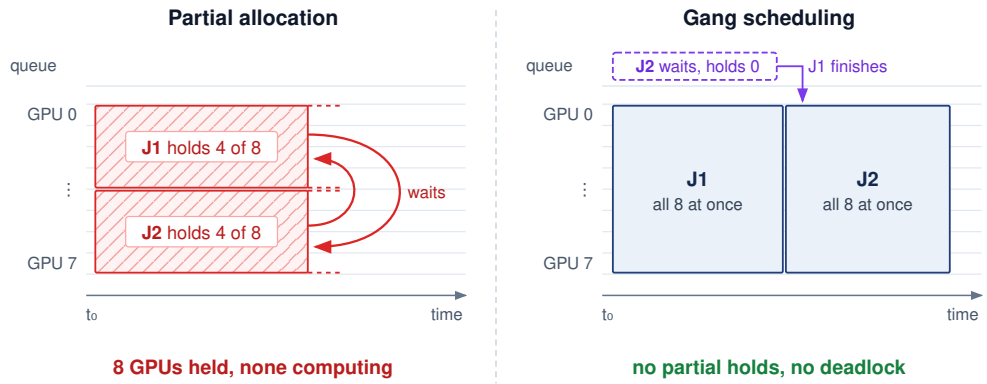

Figure 8.4: The Distributed Deadlock (Hold and Wait): In a non-gang scheduler (left), job J1 acquires half the cluster and waits for the rest, while job J2 acquires the other half and waits for J1 to release its GPUs. Neither can proceed, and 100 percent of the cluster sits idle. Gang scheduling (right) solves this by mandating atomic allocation: a job is either granted its entire N-GPU requirement simultaneously or it waits in the queue without holding any resources.

Definition 8.1: Gang scheduling

Gang scheduling is the ML cluster scheduling policy that atomically allocates the resources required by a job's minimum viable execution group, so a rigid group either receives its complete allocation or waits without retaining a partial one.

1. **Significance**: A rigid synchronous job configured for 1,024 GPUs but holding only 512 GPUs completes zero training steps, not half as many: each collective stalls until every rank in its communication group arrives, so the held GPUs consume power and capital at zero useful output. Without atomic allocation, two such jobs can each acquire half the cluster and deadlock, both at zero progress while consuming the full cluster's operating cost.
2. **Distinction**: Unlike a malleable service or parallel job that can make progress across a resource range, rigid synchronous training has step-function utility: the minimum viable gang or nothing. The distinction is a property of the execution graph, not of whether the workload is labeled ML, cloud, or HPC.
3. **Common pitfall**: A frequent misconception is that priorities or quotas alone solve this. Atomicity must extend to every co-scheduled resource the job needs to make progress (accelerators, high-bandwidth interconnect domains, network capacity for collectives); enforcing it at GPU granularity alone recreates the deadlock one resource layer down.

↩ Ring and tree AllReduce schedules, each of which completes only after every rank's contribution has been reduced, are established in section 5.6.

The partial-allocation pattern is a hold-and-wait deadlock[4] in which two jobs each hold half the cluster and neither can proceed. Its price is the whole allocation for as long as the cycle persists. At the scale of the chapter's reference workload, two 1,024-GPU gangs that have each acquired 900 GPUs from a pool too small to complete either one burn about $1,800 per hour apiece. The limiting case is two jobs that each request the entire cluster, the example OpenAI used to motivate group admission (war story 8.1). On the 10,000-GPU cluster, a deadlock that strands every device wastes $20,000 per hour at the chapter's rate while producing no progress for either job. Measured against the stake computed at the start of the chapter, raising utilization from 50 percent to 80 percent recovers about $144,000 per day in equivalent capacity value. About 7 hours of such a deadlock therefore erase a full day of that gain. Gang scheduling does not create the gain, but it protects it. For a rigid job J requiring N GPUs, the scheduler must grant all N GPUs atomically or leave the job queued without a partial allocation. This removes hold-and-wait for the resources covered by that allocation; it does not prevent later deadlocks in application code or auxiliary resources.

[4] **Hold-and-wait**: One of the four Coffman conditions (mutual exclusion, hold-and-wait, no preemption, and circular wait), all of which must hold for deadlock to occur (Coffman et al. 1971). Gang scheduling removes hold-and-wait through atomic allocation, which is why it prevents this deadlock by construction; the price is reduced packing flexibility.

Naive gang scheduling is wasteful in predictable ways. Atomic allocation means the waiting job holds nothing, yet a large gang will never assemble if every freed GPU goes to a smaller job. The scheduler therefore places a **reservation** for the job at the head of the queue, draining capacity toward it by declining to start new work on GPUs that the gang will need. If the cluster has 900 free GPUs and that job requests 1,024, the reservation keeps the 900 GPUs idle until 124 more become available, potentially wasting thousands of GPU-hours. Backfill scheduling addresses this by identifying jobs in the queue that can fit within the 900 available GPUs without delaying the large job's expected start time (figure 8.5),

an idea popularized in the ANL/IBM SP scheduling system (Lifka 1995). A 128-GPU job with an estimated runtime of 2 hours is a backfill candidate if the 124 additional GPUs needed by the large job will remain unavailable for at least 2 hours. Protecting the reservation requires an enforced runtime bound or a preemption contract that releases the backfill allocation in time, including any checkpoint and cleanup delay. The estimate identifies an opportunity; the release contract makes the reservation enforceable.

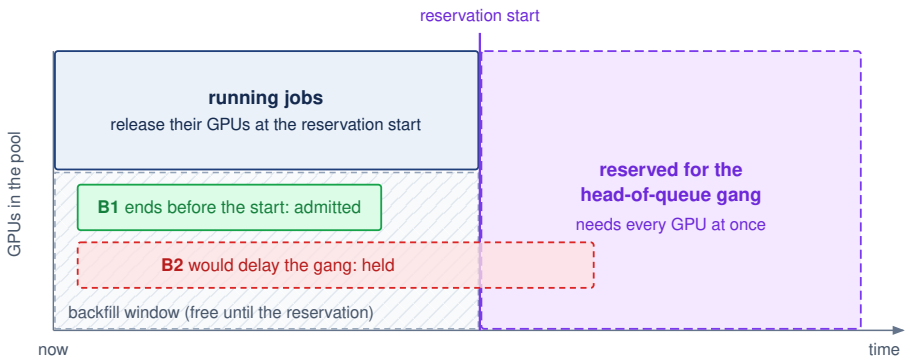

Figure 8.5: Backfill under a Reservation: The head-of-queue gang holds a reservation that begins when the running jobs release their GPUs. Until then, the free GPUs form a backfill window. A short job that ends before the reservation start runs in that window, while a job whose runtime bound would carry it past the start is held, because admitting it would delay the gang. The schematic carries no measured values.

The accuracy of runtime estimates determines backfill effectiveness, and this creates a game-theoretic challenge. If users overestimate runtimes, fewer jobs appear to fit a backfill window. If they underestimate, the scheduler may need to preempt a backfilled job to honor the reservation, paying recovery costs and losing unsaved progress. A policy that kills jobs at their declared limit encourages conservative estimates. Tiresias (Gu et al. 2019), discussed in section 8.9.1, avoids duration estimates when setting priority by using observed resource consumption. That choice addresses ordering under uncertainty, while reservation protection still needs an enforced runtime bound or release contract that says when a backfilled job will give its capacity back.

8.4.4 Deadlock prevention and detection

Gang scheduling eliminates the hold-and-wait condition for the atomically allocated bundle, but it does not immunize the cluster against all forms of resource contention. Later requests for auxiliary resources can still create a cycle of dependencies. Priority rules can also prevent a resource holder from making progress without creating a cycle. Distinguishing these cases matters because breaking a deadlock and providing a starved job with enough resources to exit require different interventions.

Priority inversion occurs when a high-priority job waits on a low-priority resource holder whose progress other work delays. Consider the 64-GPU fine-tuning run of the 175B-parameter model, submitted at high priority. The scheduler has

reserved 60 available GPUs, but the remaining 4 are held by a low-priority data processing job. Normally, the scheduler would preempt the low-priority job to satisfy the high-priority request. However, if a stream of medium-priority development jobs saturates the cluster's CPU or network bandwidth, starving the low-priority job of the resources it needs to checkpoint and exit, the low-priority job stalls. Its graceful release path cannot complete. The high-priority job waits for the low-priority job, which is effectively blocked by the medium-priority jobs. The 60-GPU idle block persists until the exit path receives resources or an enforced termination policy reclaims the remaining GPUs, potentially losing uncheckpointed work.

Priority inversion: the high-priority job waits on a low-priority holder that medium-priority work starves.

Definition 8.2: Priority inversion

Priority inversion is an ML cluster scheduling pathology in which a high-priority task is forced to wait for a lower-priority task to release a shared resource.

1. **Significance**: It ties the progress of a high-priority job, and the accelerators reserved for it, to the progress of the lowest-priority job in the wait-for chain. In ML clusters, this typically occurs when a low-priority job holding GPUs is starved of auxiliary resources (for example, bandwidth for checkpointing), preventing it from finishing and releasing the accelerators needed by high-priority workloads.
2. **Distinction**: Unlike standard queuing (where tasks wait their turn), priority inversion involves an active blockage: the high-priority task is ready to run but is transitively dependent on a task that the scheduler does not prioritize.
3. **Common pitfall**: A frequent misconception is that strict priority levels solve this. Raising the waiting job's priority does not supply the CPU or bandwidth that its lower-priority resource holder needs to exit; the preemption policy must protect that release path.

Prevention and detection address different parts of this problem. Atomic allocation prevents hold-and-wait for the resources included in the gang, while reserving checkpoint bandwidth allows a preempted job to complete its exit path. Timeouts instead bound how long the system waits before investigating or reclaiming an allocation; they do not prevent deadlock states from arising. Monitoring can trigger recovery when progress stops, but safe reclamation still requires enforcing the new ownership decision.

Detection, unlike exact placement search, is computationally cheap. Before feasibility filtering, a cluster with 10,000 GPUs and 500 pending jobs can have more than 10^{15} candidate allocations, which puts exhaustive allocation search out of reach. Detection instead works on a **wait-for graph**, a directed graph with one vertex per job and an edge from job A to job B whenever A waits for a resource that B holds. A cycle identifies a potential deadlock. It establishes deadlock when

every edge is an unavoidable blocking dependency and no alternative resource allocation can let a member proceed. Finding a cycle in an already constructed graph takes time linear in its vertices and edges. The difficulty lies in construction. Resource state changes continuously across a distributed control plane, so the scheduler rarely holds a complete, current graph, and a cycle detected on stale state may already have resolved while a real one goes unseen.

Large-scale schedulers therefore supplement wait-for detection with mechanisms that preserve liveness under incomplete state. A **lease-based resource** gives every allocation a time-to-live; expiry authorizes reclamation only when the resource manager enforces revocation and cleanup before reuse. **Progress monitoring** checks advancement through signals such as completed-step counters, using GPU utilization and heartbeats as supporting observations rather than proof of useful work. When the scheduler must preempt a lower-priority job, **holistic preemption** reserves the CPU, network, and storage bandwidth needed for that job to checkpoint and exit cleanly; otherwise, the victim can be too starved to release the accelerators. False failure suspicions can cost useful work, but must not bypass the ownership checks required for safe recovery.

8.4.5 Heterogeneous gang scheduling

In preference-training pipelines such as reinforcement learning from human feedback (RLHF), allocating the policy-training GPUs while the rollout-generation or reward-scoring workers sit queued stalls the workflow just as completely as a missing AllReduce rank. Homogeneous gang scheduling allocates N identical workers executing the same compute graph. Heterogeneous workflows instead combine trainers, evaluators, and inference-style workers that need different GPU counts, memory footprints, and lifetimes, yet still must run together as a single job.

↩ The models that alignment training co-locates, and their unequal resource demands, are established in section 6.7.

> **Systems Perspective 8.1: Routing over synchrony**
>
> Heterogeneous gang scheduling extends atomic allocation to the roles that must coexist for a workflow to progress. A viable group might pair high-HBM nodes for memory-bound generation with compute-oriented nodes for policy updates. The orchestration problem then shifts from packing a homogeneous ring toward routing data. Rather than reducing gradients among identical workers, the job streams rollouts from generation workers to the workers that compute policy updates, so placement must also support the data exchanged between those roles. Rollout and training stages may exchange work in batches or through a buffered pipeline; their measured production and consumption rates determine where queues grow or accelerators wait. The scheduler needs a minimum viable resource bundle and a supported scaling policy for each role, rather than an assumption that all workers are interchangeable or perfectly balanced.

Homogeneous and heterogeneous jobs share an allocation requirement: the scheduler must assemble a viable group before expecting progress. Backfill can use capacity while that group waits, provided runtime estimates or preemption contracts protect the reservation. Enforcing these policies requires a control plane that represents ownership and reconciles allocations after failures.

8.5 Orchestration Paradigms

A pending gang and a queue of small backfill jobs need both a policy for sharing capacity and a control plane that can enforce it. The policies just developed apply across platforms; the orchestration paradigm determines how the platform represents allocations and recovers when observed state diverges from them. Slurm, shaped by HPC batch systems, favors explicit resource requests and predictable allocation. Kubernetes, shaped by cloud-native service management, favors declared desired state and continuous reconciliation. The choice is therefore not Slurm vs. Kubernetes as products; it is which control model best matches the workload mix, failure behavior, and operational culture of the fleet.

The two platforms embody two control models (figure 8.6). Slurm follows an imperative batch model, in which the user states the resources a job needs and the central slurmctld dispatches that allocation through per-node slurmd daemons. Kubernetes follows a declarative model, in which the user states what should be running and controllers reconcile observed state toward that declaration through the API server and node agents. Both platforms accept explicit resource requirements and track execution state, so the useful distinction is which lifecycle the platform manages directly: an allocated batch job or a collection of workloads maintained by controllers. That distinction shapes how ML workloads are admitted, monitored, and recovered from failure, and distributed training still needs framework-level coordination under either model.

8.5.1 Slurm and HPC scheduling heritage

When a multi-node job needs an exclusive, non-overlapping block of accelerators for days at a time without partial-allocation deadlocks or conflicting node ownership, a centralized batch allocator is the most direct control plane. The Slurm Workload Manager[5] originated at Lawrence Livermore National Laboratory to solve that problem for Linux supercomputers (Yoo et al. 2003): long-running jobs, expensive shared hardware, and users who can specify resource needs in advance. In ML infrastructure, the same batch model maps to GPU training through partitions for heterogeneous accelerator pools and predictable atomic allocations for long-running distributed jobs.

Slurm's batch submission model makes resource requirements explicit. Users submit job scripts, and the scheduler allocates resources within eligible partitions according to policy and availability. A submission of `sbatch --gres=gpu:8 --nodes=4` requests 8 GPUs on each of 4 nodes, a 32-GPU allocation. The request supplies a capacity contract, but useful execution still depends on the selected hardware and the application's launch configuration. Overstating requirements strands resources; understating them can cause memory failures or poor performance.

5 **Slurm Workload Manager**: Originally "SLURM," an acronym for Simple Linux Utility for Resource Management, the project dropped the acronym capitalization in 2012. Developed at Lawrence Livermore National Laboratory beginning in 2002, Slurm's centralized controller (`slurmctld`) maintains a single authoritative view of resource allocations. At very large scale, operators may partition fleets or federate schedulers to keep scheduling latency, policy isolation, and failure domains manageable.

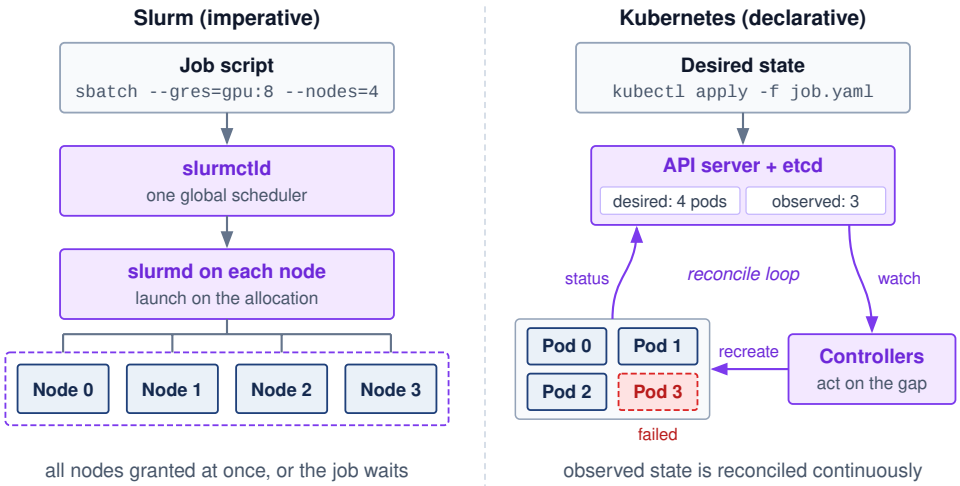

Figure 8.6: Architectural Paradigms: Slurm vs. Kubernetes: Slurm (left) uses an imperative batch model where users submit explicit resource requests to a centralized controller (`slurmctld`) providing deterministic atomic allocation. Kubernetes (right) uses a declarative service model where controllers continuously reconcile observed cluster state in `etcd` against desired state specifications.

Slurm's architecture consists of a central controller daemon (`slurmctld`) that maintains the global view of cluster state and makes scheduling decisions, and per-node daemons (`slurmd`) that manage local resources and execute jobs. This centralized architecture provides the authoritative allocation model discussed in section 8.2: the controller is the source of truth for resource assignments, reducing the risk of conflicting allocations. The cost is a potential single point of failure (addressed through active-passive failover) and a scheduling-throughput limit. As fleets grow, organizations may partition the cluster or federate schedulers to bound scheduling latency and failure impact; within a cluster, a typical ML configuration defines Slurm partitions by accelerator type and interconnect (table 8.2).

Table 8.2: Slurm Partition Configuration: Partitions organize heterogeneous accelerators into logical pools matched to workload characteristics. NVLink-connected partitions support tensor parallelism, while PCIe partitions serve workloads that rely primarily on data parallelism. Separating inference and debug partitions prevents experimental workloads from impacting production serving.

Partition	GPUs/node	Interconnect	Typical use
dgx-a100	8× A100	NVLink + IB NDR	Large LLM training
a100-pcie	4× A100	PCIe + IB HDR	Medium training
inference	2× A10G	Ethernet	Model serving
debug	1× V100	Ethernet	Development

Within a partition, a request specifies both the number of GPUs a job needs and the **allocation shape**: how those GPUs are distributed across nodes. In Slurm, `--gres=gpu:N` or `--gpus-per-node=N` requests a per-node count, while `--gpus=N`

requests a job-wide total. Whether the scheduler may split a node between jobs is a separate consumable-resource policy (Slurm's `select/cons_tres` plugin), and a node-exclusive policy strands the unused devices in the six-on-eight example of section 8.4.2. Shape decides communication. In an eight-GPU-per-node pool, a 16-GPU request that also fixes eight GPUs per node (`--gpus-per-node=8`) yields two fully populated nodes, whose NVLink domains follow from the node hardware rather than the count. A request for 16 GPUs with no per-node constraint gives the scheduler more freedom, so it can start sooner on partially occupied nodes, but it may spread the group across several of them. Whether that flexibility is useful depends on the parallelism configuration and its communication budget. Tensor-parallel groups with frequent exchanges may justify compact placement, while data-parallel groups with well-overlapped communication may tolerate a wider allocation.

The **fair-share scheduling** mechanism uses past consumption to influence future priority under contention. An illustrative heuristic combines base priority, the user's target fair share (F_{target}), recent actual consumption (F_{actual}), and a small stabilizing constant (ϵ_{stab}); it illustrates the feedback without reproducing Slurm's multifactor priority calculation:

$$\text{Priority}_{\text{effective}} = \text{Priority}_{\text{base}} \times \frac{F_{\text{target}}}{F_{\text{actual}} + \epsilon_{\text{stab}}} \tag{8.1}$$

With base priority and target share fixed, equation 8.1 lowers priority as recent consumption increases. Doubling consumption approximately halves this illustrative priority when the stabilizing constant is negligible. Actual admission also depends on other priority factors and feasible resources; low recent usage does not guarantee an immediate start.

The time decay of usage history determines how quickly the system "forgives" past heavy usage. A half-life of one week means that a researcher's heavy usage from two weeks ago contributes only 25 percent to their current usage calculation. Short half-lives make the policy more responsive to recent changes but can encourage alternating bursts of usage. Long half-lives retain the effect of a completed large project when its researchers return with smaller jobs. The useful decay window depends on the fleet's job durations and the period over which the organization intends to balance access. Usage itself need not count every device alike. **Trackable resources (TRES)** let accounting charge different accelerator classes different billing weights in fair-share usage, an administrative valuation that tracks economic cost only as far as the chosen weights do.

Preemption policies enable high-priority jobs to reclaim resources from running workloads, and for ML training the reclaim must leave time to save state. Slurm expresses that time as a grace period. It signals the selected job (`SIGTERM`), waits the configured `GraceTime`, and only then kills it (`SIGKILL`); under `PreemptMode=REQUEUE` it can also requeue an eligible job to run again later. Neither the signal nor the requeue saves model state. The application must handle the signal, publish a valid checkpoint within the grace period, and restore it on restart. If termination

precedes completion of that save, recovery uses the last valid checkpoint and replays subsequent work. Preemption therefore buys access for high-priority work with the victim's replay and restart time, a price that section 8.8.1 develops.

↩ Checkpointing for progress preservation, including the checkpoint interval and coordination patterns, is established in section 7.8.

Several Slurm features expose ML structure to the batch system. A hyperparameter sweep is the opposite of a gang. Job arrays submit many trials as one record (for example, `--array=0-99`), and each trial reads its index from the `SLURM_ARRAY_TASK_ID` environment variable to select its configuration. Slurm schedules the elements independently, so individual trials become ideal backfill candidates that fill small gaps in capacity, while the array keeps submission and management overhead low without making the trials one indivisible gang.

Heterogeneous jobs carry the heterogeneous gang of section 8.4.5 into a batch allocation. One job can contain components with distinct resource requests, admitted together. The 64-GPU fine-tuning run of the 175B model, for example, could request 8 GPU nodes for training and 2 CPU-only nodes for on-the-fly tokenization as a single allocation. It could then launch training on the GPU component and data workers on the CPU component (`srun --het-group=0` and `--het-group=1`). This separation helps only if the data workers and transfer path sustain the training stage's consumption rate; a heterogeneous allocation exposes that choice but does not itself balance the pipeline. At the boundaries of each allocation, prolog and epilog scripts turn job transitions into health checks. A prolog tests reported topology, ECC counters, and link status on each allocated node and drains a failing node before launch. An epilog removes the job's orphan processes and shared-memory segments. They apply the quarantine idea of section 8.6.4 at job boundaries, reducing exposure to known faults without establishing delivered bandwidth.

Slurm's strengths for ML training include explicit batch allocations, configurable fair-share policies, and integration with MPI-based distributed training frameworks. A mixed training-serving fleet also needs a service lifecycle that maintains ready replicas as demand and failures change. Inside a batch scheduler, adding or removing an inference replica means submitting or canceling a job, a far heavier operation than a controller adjusting a replica count, and a failed replica stays down until something resubmits it. Operators must integrate replica health, replacement, and demand-driven scaling with the batch scheduler, or assign those responsibilities to a service orchestration platform. Kubernetes starts from that service contract, in which users declare the desired state of services and jobs and controllers continuously reconcile the cluster toward it.

8.5.2 Kubernetes declarative container orchestration

When a cluster runs always-on inference services alongside training jobs, managing serving replicas as batch scripts forces operators to rebuild health checks, rolling updates, and replica replacement by hand. Kubernetes addresses this mixed workload by managing both services and batch jobs through a **declarative model** that expresses a workload's desired state and uses control loops to reconcile observations with that state (Burns et al. 2016; Cloud Native Computing Foundation 2024). The unit it places is the **pod**, one or more containers that share a

node and a network identity, and its default scheduler places pods one at a time. The name collides with the hardware pod of section 2.7, the many racks joined under one fabric. A Kubernetes pod is a software unit that never spans more than one node, so a 64-pod training job is 64 container groups placed onto nodes, all of which can sit inside one hardware pod. Controllers above the scheduler give groups of pods a purpose: a Deployment keeps a set number of identical replica pods running, while a Job runs pods until they complete, retrying failures under a stated policy. The workload controller therefore determines what completion, replacement, or continued availability means.

Failure handling reveals the importance of the workload contract. Slurm can detect node failures and requeue eligible jobs when configured to do so. Kubernetes controllers maintain workload-specific goals, such as a Deployment's replica count or a Job's completion and retry policy. A replacement pod still has to be placed, become ready, and rejoin the distributed training run before progress resumes. Training operators can coordinate worker creation, while the framework remains responsible for valid state and group recovery. Both platforms therefore require an explicit agreement between allocation, process lifecycle, and application recovery.

Kubernetes' control loop architecture uses the controller pattern:[6] controllers observe and update API objects through the API server, which persists cluster state in etcd, a replicated key-value store. Those objects contain desired state and reported observations, not instantaneous physical truth. The pattern repeats at every level: the Deployment controller reconciles the number of pod replicas, the scheduler binds pending pods to nodes, the kubelet (the agent on each node) keeps its assigned containers running, and the node controller marks nodes that stop reporting. Each component acts independently and communicates only through API objects, which makes the system resilient to the failure of any single controller. The price of that independence is that their interactions require clear ownership and retry behavior, particularly when a failed node's last reported state no longer describes its execution.

Kubernetes needs an explicit resource representation before it can place GPU workloads. In the device-plugin model, **device plugins** expose accelerators as schedulable extended resources. The NVIDIA device plugin registers GPUs with the kubelet, enabling pod specifications that request GPU resources declaratively through the standard Kubernetes resource model. A pod then asks for whole GPUs by naming the `nvidia.com/gpu` resource in its limits (listing 8.1).

[6] **Controller pattern (reconciliation loop)**: A "level-triggered" design reconciles the current desired and observed states rather than depending on every intermediate event. A restarted controller can resume from durable state if its actions tolerate retries and its observations expose unfinished work. Multiple controllers still need distinct responsibilities so that one controller's correction does not repeatedly undo another's.

Listing 8.1: Kubernetes GPU Allocation: Pod resource specification requesting GPUs through the NVIDIA device plugin. The `nvidia.com/gpu` resource name follows Kubernetes extended resource conventions, where the domain prefix identifies the device plugin vendor. This declarative syntax enables portable GPU workload definitions across any Kubernetes cluster with the NVIDIA device plugin installed.

```
# Kubernetes pod resource specification for GPU allocation
resources:
  limits:
    nvidia.com/gpu: 4  # Request exactly 4 GPUs for this pod
  requests:
    cpu: "32"
    memory: "256Gi"
```

When the device plugin exposes exclusive whole GPUs, a small model serving occasional requests can reserve a device while using only a fraction of its compute and memory capacity. Whole-device allocation suits workloads that need the capacity or isolation, but can strand resources for smaller workloads. The resource unit exposed by the plugin therefore matters, because sharing or partitioning changes what the scheduler can allocate and what isolation each allocation receives. Device plugins can also expose hardware partitions, such as MIG instances, as schedulable units, a choice that section 8.10.1 develops with the serving workloads it suits.

Kubernetes' default scheduler places pods independently, so it does not supply the group admission that section 8.4.3 requires. Under that default, a 64-pod training job receives 64 separate placement decisions, with no guarantee that all will succeed. If the cluster has resources for 60 pods but not 64, those 60 can occupy capacity while the remaining 4 wait. The platform must therefore configure a group-level admission and placement contract for a rigid job. PodGroup-style abstractions give that contract a unit matching the job's minimum viable execution group rather than an individual pod.

The mechanism that closes this gap is group admission. A **PodGroup** declares a group's minimum runnable membership. The scheduler tentatively reserves a placement for each member as it finds one but binds none of them to nodes until the minimum membership is placed, and it releases every reservation if the attempt fails or times out. Admission and placement thereby become two decisions, with the group admitted only when placement has succeeded for enough of it. The Volcano[7] batch scheduler and the Coscheduling scheduler plugin both implement this pattern. Group admission does not make physical launches simultaneous; nodes can still fail or start at different times, so the framework must establish the communication group before training proceeds.

War Story 8.1: OpenAI's gang-scheduling example (2021)

Context: OpenAI scaled Kubernetes clusters to 7,500 nodes for workloads including GPT-3, CLIP, and DALL-E. Its account explains that MPI-coordinated

[7] **Volcano**: Volcano provides a scheduler with batch and gang-scheduling mechanisms. Pods select it through their scheduler name, so it can coexist with Kubernetes' default scheduler. The operational contract must account for interactions between schedulers sharing the same nodes; installing Volcano does not automatically transfer every workload's scheduling to it.

optimizer groups needed all members scheduled before training could progress (Sigler 2021).

Mechanism: The account illustrates the risk with two experiments each requesting the entire cluster. Incremental pod placement could allocate half the capacity to each, leaving neither with a complete group.

Impact: In that example, both jobs hold capacity without making progress. It demonstrates the deadlock mechanism rather than documenting a particular pair of stalled production runs.

Fix: OpenAI reports adopting the coscheduling plugin to add group-aware admission to the Kubernetes scheduler.

Systems lesson: Distributed ML scheduling must encode the job's execution semantics. For MPI-style training, "some pods scheduled" is not partial progress; it is wasted allocation. Production schedulers need gang scheduling, quota controls, and workload-aware policies rather than generic pod placement alone.

Priority classes control scheduling precedence and preemption eligibility. A fleet might give inference higher priority than training to help protect serving service-level objectives (SLOs), but priority cannot replace ready capacity during a demand spike. With `preemptionPolicy: PreemptLowerPriority`, a pending pod can displace lower-priority pods when their removal makes placement feasible. With `preemptionPolicy: Never`, it retains queue precedence without initiating preemption and remains subject to higher-priority preemption. Termination, cleanup, and replacement startup take time. Training applications also need a checkpoint-aware shutdown path that fits the allowed grace period; assigning priorities does not create that path. The policy must balance serving readiness against repeated interruption of training.

Kueue[8] makes admission a separate control decision. It manages when workloads may consume quota, while a compatible scheduler binds their pods to nodes. The admission policy and placement policy must agree on resource types, group requirements, and topology. Separating these responsibilities lets each layer run its own policy, at the price of keeping the two consistent. Kueue represents each team or project as a queue with a configured quota (a ClusterQueue) and groups queues into cohorts whose members may lend one another unused quota, under the borrowing and reclaim contract of section 8.11.2.

8.5.3 Kubernetes ecosystem for ML training

Group admission handles one constraint that microservice orchestration leaves implicit and distributed training cannot. Four more remain. Workers must launch knowing their peers, collective traffic must avoid network layers built for request traffic, checkpoint writes need bandwidth rather than only storage capacity, and progress must be observable below the container. Operators and plugins add each constraint to the platform; the mechanism matters more than the product that happens to implement it.

[8] **Kueue**: Kueue separates workload admission from pod placement. Its all-or-nothing mechanisms include waiting for admitted pods to become ready and requeuing workloads that exceed the configured timeout. Aggregate quota admission alone does not prove that a gang fits the physical topology; the guarantee depends on the configured readiness, topology, and placement mechanisms.

Peer discovery is the job of the **training operator ecosystem**, which extends Kubernetes with job-specific resource types (custom resource definitions). In the Kubeflow Training Operator, a `PyTorchJob` declares the number of workers, the container image, and resource requirements. The operator creates the pods and injects the rendezvous address (`MASTER_ADDR` and `MASTER_PORT`), the group size, and each worker's rank (`WORLD_SIZE` and `RANK`), which the framework uses to form its communication group. If a worker pod fails, the operator can detect the deviation and create a replacement pod to restore the desired replica count, but training-state recovery still depends on the framework's checkpoint and rendezvous logic.

Collective traffic is the second constraint. The pod overlay network that the Container Network Interface (CNI) configures, designed for microservice requests, routes packets through software switching on the host CPU, which adds latency and caps bandwidth when it sits on the critical gradient-synchronization path. For bandwidth-sensitive training, **host networking** (`hostNetwork: true`) places pods in the host's network namespace, bypassing the ordinary pod overlay path. It does not itself allocate remote direct memory access (RDMA) devices or grant permission to use them; device exposure, resource requests, drivers, and access controls require separate configuration. Operators such as NVIDIA's Network Operator automate that exposure through RDMA device plugins and GPUDirect RDMA configuration, letting containerized workloads approach bare-metal interconnect performance once the rest of the stack is configured.

Checkpoint bandwidth is the third constraint, because storage integration must account for the checkpoint storm of definition 4.5, in which many workers write large amounts of state together. Kubernetes PersistentVolumeClaims (PVCs) request capacity on a configured storage system but do not reserve checkpoint throughput. A 1,024-GPU training job writing the 2.45 TB resumable checkpoint of the 175B model needs a measured write budget shared with other workloads. Backend bandwidth controls, client throttling, or staggered writes can limit interference; the platform must verify which controls the storage implementation enforces.

Visibility into progress is the fourth. The **observability stack** for training clusters combines general-purpose cluster monitoring (commonly Prometheus and Grafana) with accelerator telemetry such as the Data Center GPU Manager (DCGM) exporter, which reports utilization, memory bandwidth, temperature, and ECC errors. These observations locate symptoms. Correlating them with step progress, input waits, and communication traces is what distinguishes useful computation from stalls and identifies which dependency limits a training job.

The 1,024-GPU pretraining run for our 175B model illustrates how these responsibilities fit together. One possible deployment defines a `PyTorchJob` with 128 worker pods, each requesting 8 GPUs. Host networking removes the pod overlay from the gradient path, and the Network Operator exposes each node's InfiniBand adapters to the workers through RDMA device plugins. A PVC backed by Lustre provides access to the 6 TB tokenized training corpus and a checkpoint path whose sustained bandwidth must be validated. DCGM metrics stream to

↪ Fleet telemetry across device, network, and facility levels, and the correlation that narrows a failure domain, is developed in section 12.6.1.

Prometheus, supporting alerts on uncorrectable ECC errors and deviations from workload-specific communication baselines.

8.5.4 Paradigm trade-offs and selection criteria

Selecting a control plane requires matching its allocation and recovery contract to the workload mix. Rigid training groups need reliable atomic placement and checkpoint-aware interruption; serving replicas need readiness checks and continuous recovery. Existing operational expertise and the cost of running a second control plane also shape the choice. A fleet dedicated to long, homogeneous training runs that use bare-metal collectives, operated by a team fluent in batch scheduling, gains most from Slurm's authoritative allocation and mature fair-share. A fleet that mixes training with always-on serving, and already runs cloud-native deployment and observability tooling, gains more from Kubernetes with a gang-admission layer added for its rigid jobs. The Slurm vs. Kubernetes trade-off organizes around the dimensions most relevant to ML workloads (table 8.3).

Table 8.3: Slurm vs. Kubernetes for ML Workloads: The two paradigms reflect different design philosophies optimized for different workload characteristics. Most production ML platforms use elements of both, with Slurm managing dedicated training clusters and Kubernetes managing inference serving and pipeline orchestration.

Dimension	Slurm	Kubernetes
Scheduling model	Imperative: user specifies exact resources and scheduler allocates them	Declarative: user specifies desired state, system reconciles continuously
Failure handling	Configuration-dependent requeue and checkpoint workflows	Self-healing through control loops
Gang/atomic multi-node start	Atomic job allocation plus backfill; Slurm "gang scheduling" specifically refers to time-slicing/preemption	Production clusters commonly use PodGroup-based support such as Volcano, Coscheduling, Kueue, or upstream alpha gang scheduling
Fair-share	Mature multi-factor priority with configurable decay	Kueue provides basic fair-share with ClusterQueue borrowing
Container overhead	None from a container runtime when jobs run directly on nodes	Configuration-dependent networking overhead and container startup time
Service management	No native support for long-running services	Native Deployment, rolling updates, health checks
Ecosystem	MPI, OpenMP, scientific computing libraries	Cloud-native, microservices mesh, observability stack

The gang-scheduling row of the table compresses a naming collision that is easy to miss. This chapter uses gang scheduling for atomic allocation of a whole execution group, which is the requirement distributed training imposes. Slurm reserves the name for the older, Ousterhout-style meaning of the term, in which co-scheduled jobs share nodes by time-slicing in synchronized rounds. Slurm

provides atomic multi-node allocation under its ordinary job model, so the requirement is met even though Slurm's "gang scheduling" option means something else.

The choice of scheduling paradigm also reflects organizational trajectory. Teams starting with HPC-focused training infrastructure may begin with Slurm and add Kubernetes for serving. Teams starting from cloud-native application infrastructure may begin with Kubernetes and add HPC-oriented extensions (Volcano, Kueue) for training. Slurm has meanwhile added a REST interface and container support, so the two platforms now overlap in capability. Either path can reach a functional hybrid architecture, but the starting point determines which capabilities are strongest and which require the most investment to develop.

8.5.5 Hybrid architectures in practice

While the choice between Slurm and Kubernetes often appears binary, engineering organizations can deploy **hybrid architectures** that use the strengths of both systems. The relevant boundary again follows workload semantics rather than labels. Rigid, topology-sensitive jobs fit a batch scheduler's atomic allocation contract, while malleable services fit a reconciliation loop that adjusts replica count continuously. Some training jobs are elastic, and some serving replicas are rigid multi-accelerator gangs, so neither "training" nor "serving" selects a control plane by itself.

The **Kubernetes-over-Slurm** pattern wraps the HPC scheduler within a cloud-native control plane. Kubernetes manages the lifecycle of training jobs through custom operators while delegating batch admission and placement to Slurm. The central engineering problem is ownership: exactly one control plane must authorize each placement, while the outer controller reconciles lifecycle state without issuing a conflicting allocation. The arrangement combines a declarative management surface with Slurm's batch and topology policies, but it also creates a cross-control-plane failure boundary that operators must fence explicitly.

The **Slurm-alongside-Kubernetes** pattern takes a coarser-grained approach, maintaining separate clusters for training and serving that draw from a shared pool of physical nodes. A meta-scheduler or capacity broker acts as an arbitrator, dynamically reassigning nodes between the Slurm partition and the Kubernetes cluster based on demand signals. During intensive training campaigns, nodes are drained from Kubernetes and joined to Slurm; during product launches or traffic spikes, the flow reverses. The primary challenge is the mode-switching cost: draining a node, changing its ownership and configuration, and admitting it to the other control plane takes much longer than an ordinary placement decision. This latency limits sharing to planned capacity shifts rather than second-by-second inference bursts.

A shared application runtime such as Ray provides task and actor abstractions for both training and serving. Ray's placement groups, unlike the cloud network-locality abstraction of the same name, reserve bundles of logical resources for work that must run together, and serving replicas can also require multi-device groups. Inside a shared runtime the workloads keep their different state, latency,

and recovery requirements, so the platform must still coordinate Ray's logical allocations with the underlying resource manager and validate the isolation and recovery behavior needed by each workload.

Threading these patterns together, consider the lifecycle of our 175B parameter model. A hybrid platform can allocate the training gang through Slurm and later place serving replicas through Kubernetes. The orchestration boundary concerns resource ownership: the training job releases its allocation, and the serving control plane admits replicas against its own capacity and readiness requirements. Deciding whether the trained artifact is ready for production requires validation and release policy beyond the scheduler; section 12.5 develops those validation gates and rollout policies.

A hybrid platform is useful when its separate allocation contracts justify the additional ownership and recovery boundary. The cost to measure is the coordination between control planes, including node draining and reassignment, rather than a presumed performance advantage from either product name. Because Slurm and Kubernetes now overlap in capability, the paradigm choice is a workload-specific design decision, and teams must establish the allocation and recovery guarantees they need before layering physical placement constraints on top of them.

Checkpoint 8.1: Scheduling paradigm trade-offs

Before the chapter turns to topology-aware placement, review the core trade-offs:

- ☐ **Gang scheduling**: explain why a rigid synchronous execution group needs atomic allocation, and why the scheduler must still reserve capacity for a waiting gang that holds no GPUs itself.
- ☐ **Slurm vs. Kubernetes**: compare authoritative allocation with desired-state reconciliation, and explain why either design must prevent duplicate ownership during a network partition.
- ☐ **Group admission**: explain why a default scheduler that places pods one at a time can strand capacity for a 64-pod training job, and how a PodGroup's minimum membership prevents it.
- ☐ **Resource units**: explain how the resource unit a device plugin exposes changes what the scheduler can pack, and why a small model on an exclusively assigned GPU strands capacity.
- ☐ **Backfill incentives**: explain why backfill scheduling depends on accurate job runtime estimates and why users have game-theoretic incentives to provide inaccurate estimates.

A control plane can now represent, admit, and reconcile an allocation, yet it still counts accelerators as if any group of the requested size were interchangeable. Two allocations of the same size can meet very different communication budgets depending on where the devices sit in the cluster fabric. The next layer of the scheduler must therefore weigh physical location alongside resource count.

8.6 Topology-Aware Scheduling

A scattered allocation can place frequent collective traffic on shared cross-rack paths, exposing latency or bandwidth limits that a more compact allocation avoids. The penalty is set by how much of the job's traffic crosses those paths and how much capacity the fabric provisions there, not by the rack count itself. The earlier feasibility rules already required compatible topology; topology-aware scheduling makes that requirement explicit in the placement objective, accounting for communication paths as well as raw compute.

8.6.1 The topology hierarchy

Splitting a tensor-parallel group across node boundaries moves its per-layer activation exchanges off intra-node NVLink onto the external network fabric, where an H100's per-direction NVLink rate is 9× the rate of one NDR port (section 2.5.1). Each level of a cluster's communication hierarchy comes from the hardware that builds it and sets a distinct bandwidth and latency budget. GPUs inside a node exchange data over NVLink, the tier fast enough for the per-layer exchanges of tensor parallelism. Nodes under one leaf switch communicate over an external fabric such as InfiniBand or RoCE. Racks joined through spine switches add switch hops whose delivered bandwidth depends on concurrent flows and oversubscription even in a fat-tree. Cross-rack communication also adds tail latency variability: while median latency may be only slightly higher, p99 latency can spike during congestion events, creating straggler effects in synchronous training where the slowest communicator determines the pace for all workers.

A 64-GPU job within one rack can avoid cross-rack paths that a spread allocation must use. It outperforms the spread allocation only when those paths add exposed latency or bandwidth contention; a non-blocking, uncongested spine need not reduce sustained throughput. The performance difference stems directly from the hierarchical communication analysis in section 5.7.1: a flat ring AllReduce runs at the speed of the slowest link in the ring, and cross-rack hops introduce both higher latency and increased contention risk. For synchronous training, every iteration waits for the slowest worker to complete its AllReduce, so even occasional cross-rack congestion inflates the Fleet Law's communication term $T_{\text{comm}}(N)$ (equation 1.3) on every step it touches.

↩ Bisection bandwidth and fat-tree network topologies are established in section 3.5.2.

The scheduler must therefore model the cluster as a hierarchical graph with discrete bandwidth boundaries (figure 8.7). In the illustrated H100 fleet, per-direction bandwidth steps down from 450 GB/s across the NVSwitch inside a node to 50 GB/s per port under a leaf switch, and to roughly 12.5–25 GB/s per endpoint when balanced traffic saturates an oversubscribed spine. A node boundary can introduce a large bandwidth reduction, but a non-blocking rack or pod boundary need not reduce per-endpoint bandwidth. Oversubscription adds a separate constraint when traffic saturates shared uplinks. Topology-aware placement minimizes the communication cost of the job's actual traffic pattern rather than applying a fixed penalty to every boundary.

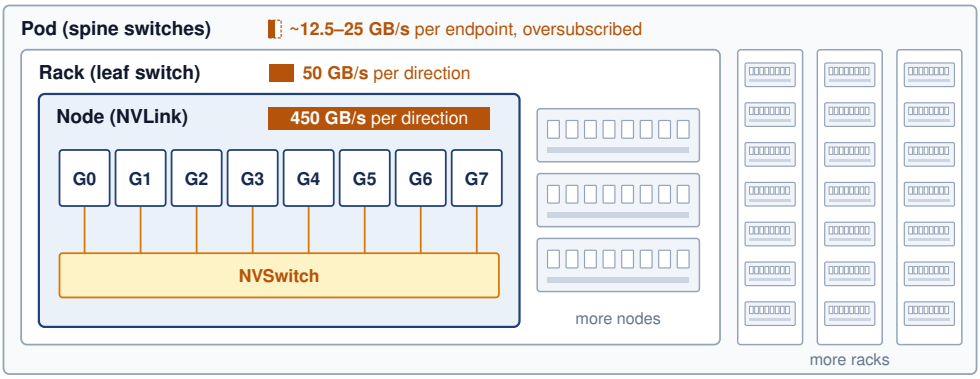

Figure 8.7: Physical Topology Hierarchy and Bandwidth Cliffs: Hardware boundaries dictate communication performance across three distinct domains. The example compares a 450 GB/s per-direction NVLink endpoint budget with a 50 GB/s per-direction external port. Under balanced load saturating a 2:1 to 4:1 oversubscribed spine, the external per-endpoint share falls to approximately 12.5–25 GB/s. A non-blocking spine need not impose this reduction. The bar in each domain's header draws its bandwidth on one shared linear scale.

For a 4-GPU collective group, the routing paths make that cost concrete (figure 8.8). In the illustrated contended fabric, scattering ranks across Rack A and Rack B forces a 3-hop leaf-spine-leaf path with about 12.5 GB/s of effective bandwidth per endpoint, a share of contended uplinks rather than a physical link rate. Consolidating all four ranks (G0–G3) under Rack A's leaf switch avoids those shared uplinks and provides about 50 GB/s per GPU under the example's load assumptions.

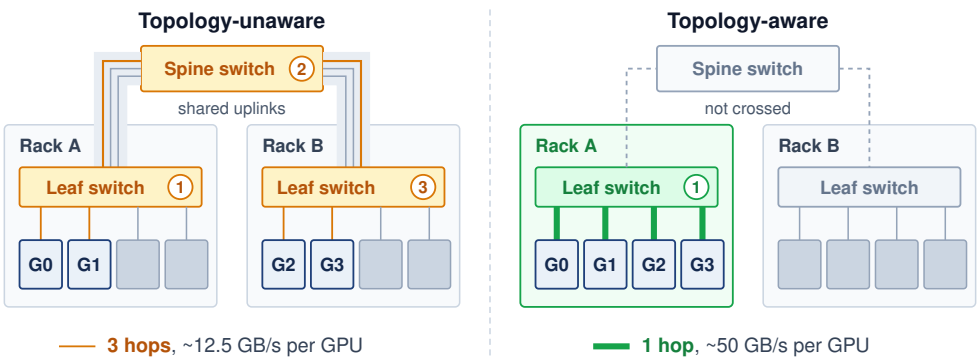

Figure 8.8: Topology-Unaware vs. Topology-Aware Placement: An illustrative 4-GPU job that permits inter-node placement and uses an oversubscribed cross-rack fabric, placed across two racks (left, topology-unaware) must traverse leaf-spine-leaf hops: 3 switch hops per AllReduce message at about 12.5 GB/s effective bandwidth. The same 4-GPU job packed within one rack (right, topology-aware) uses a single leaf switch: 1 hop at about 50 GB/s, roughly 4× faster. Blue squares are the job's GPUs; gray squares are GPUs held by other jobs.

8.6.2 Placement algorithms

The illustrated 4× bandwidth difference between the 1-hop leaf path and the 3-hop spine route (figure 8.8) stretches the transfer component by the same factor when transfer time is bandwidth-dominated. Crossing a spine does not impose that ratio

independently of load and topology. Whether communication exceeds computation also depends on the model and overlap schedule, and repeated exchanges can amplify the exposed cost. Topology-aware placement algorithms assign jobs to nodes that reduce this cost, turning resource packing into graph optimization over the physical topology. A simple **locality cost**, defined in equation 8.2, penalizes allocations spanning multiple topology domains:

$$\text{Cost}_{\text{locality}} = \sum_{i<j} w(d(g_i, g_j)) \tag{8.2}$$

where g_i and g_j are GPUs assigned to the job, $d(g_i, g_j)$ is their topological distance (0 for same node, 1 for same rack, 2 for different racks), and $w(\cdot)$ is a weighting function that increases with distance. The scheduler minimizes this score when selecting an allocation from the set of feasible placements. An illustrative heuristic assigns locality penalties of $w(0) = 0$ (same node, NVLink, no penalty), $w(1) = 1$ (same rack, one switch hop), and $w(2) = 10$ (different racks, multiple switch hops). These dimensionless weights are policy assumptions rather than measured latency or bandwidth ratios, so a deployment must calibrate them to its traffic and topology. An unweighted pairwise score still cannot distinguish heavily communicating rank pairs from pairs that rarely exchange data.

More sophisticated algorithms distinguish the communication requirements of different parallelism strategies. Frequent tensor-parallel activation exchanges favor a high-bandwidth, low-latency domain that meets the measured communication budget; that domain need not coincide with one server. Pipeline parallelism exchanges activations across stage boundaries rather than between every layer, but its tolerance for link delay depends on microbatch size and the pipeline schedule. Data-parallel gradient synchronization can overlap computation, making wider placement feasible when the exposed communication remains within budget. These patterns guide placement without establishing a universal ranking for every model or fabric.

Algorithm 8.1 combines the all-or-nothing gang constraint of section 8.4.3, the locality cost of equation 8.2, and an illustrative parallelism-to-topology mapping. Its enumeration expresses the decision conceptually: construct feasible rank mappings, score their allocations, and choose the lowest illustrative locality score, leaving the job queued when none fits. This surrogate does not guarantee minimum communication time or completion time. A fleet-scale implementation must restrict that search using heuristics rather than enumerate every allocation.

Algorithm 8.1 Topology-aware placement

Require: job requesting N accelerators with tensor-, pipeline-, and data-parallel groups; cluster topology with illustrative per-level locality weights $w(\cdot)$
Ensure: an all-or-nothing feasible placement with the lowest illustrative locality score, or the job stays queued

1: enumerate candidate slots: sets of N free accelerators that satisfy every resource dimension ▷ *gang: all or nothing*
2: retain only slots that admit a rank mapping satisfying the job's tensor-, pipeline-, and data-parallel communication constraints
3: **if** no feasible slot exists **then**
4: leave the job queued without holding any accelerators ▷ *prevents hold-and-wait deadlock*
5: **return** no placement
6: **end if**
7: **for** each feasible slot **do**
8: use a feasible rank mapping: tensor-parallel ranks within an NVLink domain, pipeline stages within a rack, data-parallel replicas across racks where permitted
9: score the slot by $\text{Cost}_{\text{locality}} = \sum_{i<j} w(d(g_i, g_j))$
10: **end for**
11: **return** the feasible slot of least $\text{Cost}_{\text{locality}}$ ▷ *minimum score among enumerated feasible placements; atomic allocation*

Applied to a whole job, the same reasoning ranks placement strategies. The latencies in this comparison are illustrative, not derived. They are constructed to stay above the ring-AllReduce bandwidth bound for the payload, and they show the order in which placement removes delay rather than values a reader could recompute from topology names. For a 0.5 GB gradient synchronization on 64 GPUs, random placement spans multiple racks and spine switches and takes an assumed 120 ms. Each successive strategy removes a source of delay that the previous one leaves. Confining the group to a single rack removes spine hops and reduces latency to 85 ms. Rail-optimized alignment maps ranks so that every member of each collective group sits at the same local GPU index and therefore on the same network rail (developed in section 8.6.3). Traffic that previously hopped between rails through the spine now stays within one rail's switches, which cuts latency to 40 ms. Topology-optimal placement additionally avoids leaf ports that other jobs are using and reaches 25 ms, a 4.8× reduction (figure 8.9, where each bar also carries its algorithm throughput). This ratio compares whole collectives under four assumed placements, so it need not match the link-bandwidth ratio of the two-rack paths above.

A **hierarchical placement** algorithm applies these constraints from the most restrictive communication domain outward, matching each 3D parallelism dimension to the interconnect tier its traffic can tolerate (figure 8.10). In the illustrated fleet, it places each tensor-parallel group within an NVLink-connected node, where

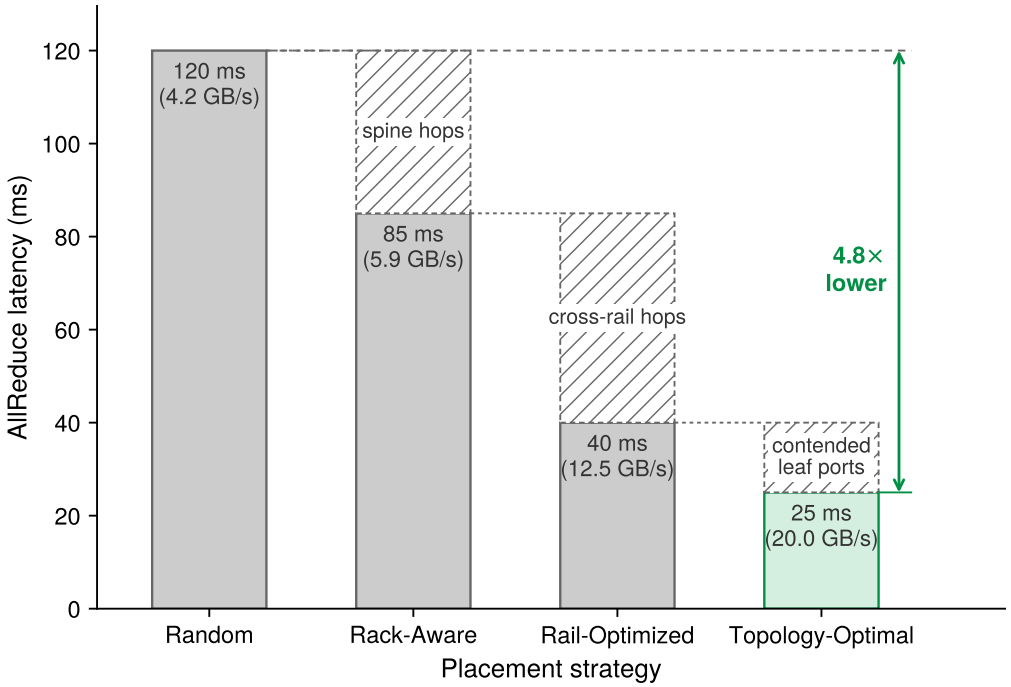

Figure 8.9: Topology Placement Impact: Assumed AllReduce latency across four placement strategies (Random, Rack-Aware, Rail-Optimized, and Topology-Optimal) for a 0.5 GB gradient sync on 64 GPUs. The assumed latency falls from 120 ms to 25 ms, a 4.8× ratio. Labels report payload divided by completion time (algorithm throughput), not physical link bandwidth. The dashed ghost above each bar names the source of delay that strategy removes.

the per-layer activation exchanges run at 450 GB/s. It places consecutive pipeline stages under the same leaf switch, where stage boundaries cross at 50 GB/s. It distributes data-parallel replicas across racks only when the once-per-step gradient synchronization fits the roughly 12.5–25 GB/s per endpoint that an oversubscribed spine leaves. This alignment reduces costly boundary crossings, but placement alone cannot reserve the fabric's full bisection bandwidth against other jobs.

Evaluating all possible placements for a 256-GPU job across a 10,000-GPU cluster is combinatorially intractable, so production schedulers rely on heuristic approaches. Common choices include greedy algorithms that build placements bottom-up (first fill NVLink domains, then fill racks, then spread across racks), tree-search algorithms with pruning that explore the most promising placements first, and scoring-based approaches that evaluate a sample of feasible placements and select the best. Long jobs can amortize a more expensive search, but frequent submissions, short jobs, and recovery bursts also consume scheduler capacity, making end-to-end completion time, including placement delay, the useful comparison rather than execution throughput alone.

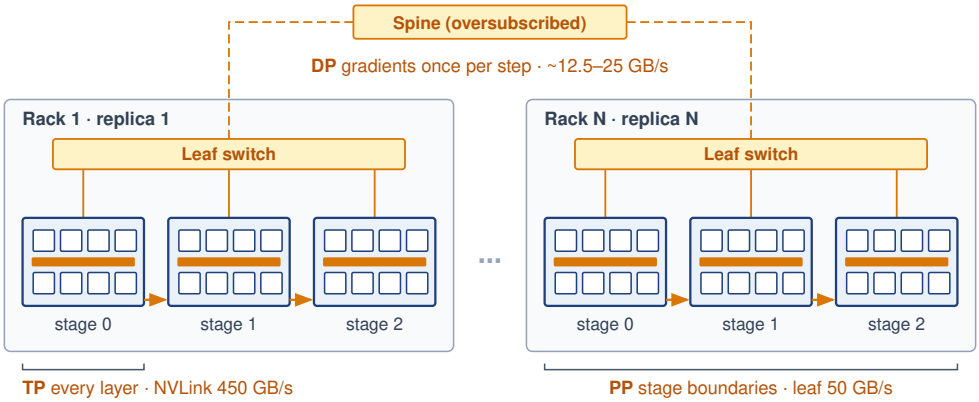

Figure 8.10: Hierarchical Placement for 3D Parallelism: This placement example maps distributed training dimensions to physical interconnect layers. Tensor parallelism (TP), which exchanges activations at every layer, stays inside a node on NVLink (450 GB/s); pipeline parallelism (PP) maps across adjacent nodes under one leaf switch (50 GB/s); and data parallelism (DP), which exchanges gradients only once per step, spans racks through the oversubscribed spine. Bandwidths are per direction, as in figure 8.7.

Napkin Math 8.2: Placement impact on 3D-parallel training

Scenario: Consider a 256-GPU training job using 3D parallelism: 8-way tensor parallel, 4-way pipeline parallel, 8-way data parallel.

Good placement (topology-aware):

- Tensor parallel groups: 32 groups of 8 GPUs, each confined to one 8-GPU node (NVLink: 450 GB/s per direction)
- Pipeline stages: 4 consecutive nodes within the same rack (1 switch hop, InfiniBand: 50 GB/s per direction)
- Data parallel replicas: 8 racks (3 switch hops through leaf-spine-leaf paths)

Bad placement (topology-unaware):

- Tensor parallel groups split across 2 nodes (InfiniBand instead of NVLink)
- Pipeline stages scattered across racks (3 switch hops instead of 1)
- Data parallel replicas randomly distributed

Math: The tensor parallel communication alone illustrates the impact. With NVLink delivering 450 GB/s per direction, a 1 GB activation transfer takes approximately 2.2 ms. Over InfiniBand at 50 GB/s, the same transfer takes approximately 20 ms, a 9× slowdown.

Systems insight: This calculation prices only the tensor-parallel component of the bad placement. Splitting a tensor-parallel group across nodes makes each activation exchange 9× slower, and the group performs such exchanges

at every transformer layer of every step, so the penalty multiplies with model depth rather than appearing once. How much of it reaches step time depends on how much of the exchange was hidden behind computation, and it is why hierarchical placement gives tensor-parallel groups the fastest tier first. The scattered pipeline stages and data-parallel replicas add their own penalties on top, and the scheduler must profile the complete job before assigning a throughput benefit to the placement.

8.6.3 Rail-optimized scheduling

Even when two nodes sit in the same pod, placing corresponding data-parallel shards on mismatched local GPU indices forces their gradient collective to cross between network rails through the spine instead of staying on a single rail switch. In rail-optimized topologies, corresponding GPU positions across nodes connect through parallel network "rails" that a suitable rank mapping can use concurrently. Balanced bandwidth depends on distributing traffic across those paths rather than concentrating it on a subset. Keeping a collective group on one rail avoids cross-rail transfers for that group, while the placement of other groups determines how much rail capacity it must share.

↩ Rail-optimized fabric architectures and rail-to-rail traffic isolation are established in section 3.5.3.

Rail-aware scheduling assigns corresponding model shards across data-parallel replicas to GPUs attached to the same rail. When intra-node parallelism partitions a model replica across the eight GPUs of a node, each data-parallel gradient collective reduces only one shard i across replicas rather than combining all eight GPUs on the node. In the eight-GPU-per-node example, local GPU index i connects to rail i. Placing every replica's copy of shard i at that same local index on its selected node means the data-parallel replica rank varies across nodes rather than across local GPU indices, so the collective for shard i stays entirely within rail i. This alignment removes cross-rail transfers for that group, though other groups or tenants can still contend for the same rail's links, and full dedicated bandwidth requires an explicit capacity and sharing contract.

Rail alignment therefore acts at two levels, and they belong to different components. Within a node it is a rank-mapping decision. The launcher or framework must give every member of a data-parallel group the same local GPU index on its node, which is what removes the cross-rail hops in the placement comparison above. A mapping that puts shard i at index i on one node and at another index elsewhere sends that group's traffic between rails. Across nodes it constrains the scheduler only when allocations are smaller than a node. When each replica's pipeline stage occupies a complete node and every node wires local GPU i to rail i, any free node already offers every rail, so rail alignment does not narrow which racks the scheduler can choose. With partial-node allocations, a job can receive different local indices on different nodes, and the scheduler must then choose GPU positions as well as nodes so that each group's members share a rail. Those positions can conflict with the tensor-parallel budget and the paths between pipeline stages when only particular GPU positions remain free. The packing cost therefore follows the allocation granularity and the available topology rather than

an inherent conflict among the three parallelism dimensions. Even a single-node allocation can have meaningful topology constraints when GPUs occupy different interconnect, PCIe, or non-uniform memory access (NUMA) domains, so packing efficiency should be optimized only among placements that satisfy the job's local and external communication contract.

8.6.4 Topology discovery and dynamic adaptation

When a spine switch fails or an optical link degrades and begins retransmitting, a static configuration file such as Slurm's `topology.conf` or Kubernetes node labels still reports the rack as healthy and full-bandwidth. The scheduler then places communication-heavy gangs onto a crippled path. Runtime **topology discovery** supplements static maps with information exposed by the operating system and device libraries. NCCL uses system topology information, including the PCIe hierarchy and network devices exposed through paths such as `/sys/class/infiniband`, to identify communication paths and network interface card (NIC) proximity. The discovered graph describes reported connectivity; health checks and traffic measurements must establish whether those paths deliver the expected performance.

Cluster topology is an operating state, not a fixed schematic. Hardware failures, maintenance windows, and thermal throttling change the paths and effective capacity available to the scheduler. A spine switch failure in a redundant Clos network can leave connectivity intact while removing capacity. The effect on our 175B parameter model's data-parallel AllReduce depends on rerouting, concurrent traffic, and how much bandwidth the job was using. If the failure increases exposed communication time, the scheduler must compare continuing at reduced throughput with the cost of moving to a healthier allocation. A degraded link can also pass binary up/down probes while cutting delivered bandwidth, so the scheduler needs performance evidence such as retransmission counts and collective bandwidth, the link-level telemetry of section 3.9.1, as well as reachability.

A checkpoint-and-restart migration spends time saving state, releasing the old allocation, obtaining a new one, and restoring execution. Its value depends on measured transition cost and remaining work. If migration takes 10 minutes and restores throughput after a sustained 20 percent penalty, it pays back in less than an hour of subsequent training. That comparison assumes a healthy destination is available and the gain persists. A practical policy also accounts for queue delay and requires evidence that placement causes the slowdown, such as rising collective time on the affected path, before it moves the job.

War Story 8.2: Performance-aware health checks (2021)

Context: OpenAI's account of scaling Kubernetes describes automated health checks that remove misbehaving nodes from the schedulable pool (Sigler 2021).

Mechanism: Passive checks monitor reachability, disks, and GPU errors, but error codes do not expose every hardware or driver problem. Active GPU

tests exercise the device before admitting ordinary workloads and periodically during its lifetime.

Fix: Nodes enter with a preflight taint, a node marking that repels ordinary pods, which blocks normal scheduling until the tests pass. Failed passive checks cordon a node; more serious failures can trigger eviction requests.

Systems lesson: Reachability alone is not a sufficient admission test. A scheduler needs health evidence that reflects the resources its jobs depend on, together with a policy for removing suspect nodes from placement.

The general scheduling idea is quarantine: when runtime evidence says a node, rack, or link is degraded, the scheduler should stop placing sensitive work there even if the nominal resource count still looks available. Kubernetes implements this pattern through taints and tolerations,[9] while Slurm clusters commonly use drain states, node features, or partition rules. The complementary problem is how jobs adapt when available resources change dynamically. Rather than treating resource allocation as fixed for a job's lifetime, elastic training allows logical jobs to grow, shrink, and recover. Whether worker processes restart depends on the framework; TorchElastic restarts its worker group when membership changes.

8.7 Elastic Scheduling

When cluster demand fluctuates, rigid allocation creates two categories of waste. During off-peak hours, a job running on 256 GPUs cannot absorb idle resources to speed up training. During peak demand, the same job cannot release excess resources to accommodate higher-priority work without being fully preempted. The scheduler's only options are "let it keep all its resources" or "kill it entirely," with nothing in between.

Elastic scheduling expands this binary choice. The recovery mechanics of elastic training show how a distributed job can adjust its worker count, adapt its batch policy, and reconstruct its communication group after a failure. From the scheduler's perspective, the same capability solves a resource-allocation problem under fluctuating demand. A training job might start with 128 GPUs, scale up to 256 when resources become available, and scale back to 192 when higher-priority work arrives, provided each allocation supports a viable worker group. Resizing may pause training and restart workers from saved state. The scheduler therefore chooses among supported allocation sizes, each with a transition cost, rather than assuming uninterrupted progress at any resource level.

8.7.1 The scheduler-framework contract

If a scheduler reclaims four nodes from a running job by abruptly killing their containers, or adds four idle nodes without triggering a new rendezvous, the surviving ranks treat the change as a fatal collective timeout rather than an elastic resize. Resizing a live job without crashing it requires an explicit contract between the scheduler and the training framework. For planned resizing, the scheduler and framework coordinate resource release through defined signals and an agreed

9 **Taints and tolerations**: Node taints can block scheduling of pods without matching tolerations. A toleration permits consideration of a node but neither requires placement there nor reserves it exclusively for training. Dedicated GPU pools also need controlled toleration assignment and placement constraints; removing existing workloads requires an eviction or drain policy appropriate to the taint's effect.

↩ Slow components that pass liveness checks while setting the pace of every synchronous step, and how to tell them from fail-stop failures, are established in section 7.9.5.

↩ Batch-size and learning-rate adjustment and communication-group contraction during elastic recovery are established in section 7.10.1.

adaptation window. Unexpected failures can bypass that window, so the framework must also recover from valid saved state. Its recovery path reconstructs communication groups and either preserves the global batch or applies a validated batch-size and learning-rate policy. The worker-membership lifecycle therefore behaves as a state machine centered on active training (figure 8.11). Idle GPUs trigger scale-up, preemptions trigger scale-down, and host timeouts or ECC errors divert ranks to worker replacement; each path returns to active training once the communication group is rebuilt or a spare node joins.

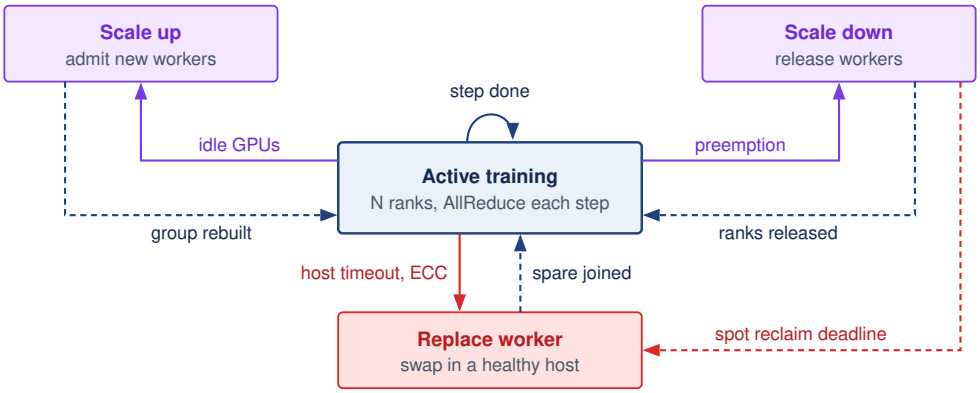

Figure 8.11: Elastic Training Worker Lifecycle and State Machine: The state machine governing dynamic worker membership. Active training loops on step completion and leaves that state along three paths: idle GPUs trigger scale up, a preemption for higher-priority work triggers scale down, and a host timeout or ECC error triggers worker replacement. Each path rebuilds the communication group and returns to active training (dashed arrows), and a spot reclamation deadline can force a shrinking job straight into replacement. Worker processes may restart during resizing, so recovery requires the application to restore valid training state.

From the scheduler's perspective, this contract is defined by three governing parameters: the elastic range, the transition cost, and the scaling efficiency curve. The elastic range, $[N_{\text{min}}, N_{\text{max}}]$, specifies lower and upper worker bounds; the job's parallelism layout determines the valid allocation increments within them. The transition cost includes any checkpoint, restart, state redistribution, and rendezvous required by the runtime. Measuring the full interruption determines how frequently the scheduler can trigger reallocations before transition overhead wipes out any throughput advantage. Finally, the scaling efficiency curve quantifies the marginal throughput gained from each added worker, indicating whether assigning idle GPUs to this job yields more aggregate progress than holding them for an assembling gang-scheduled workload. Together, these parameters provide the scheduler with the quantitative bounds needed to resize jobs dynamically without treating elasticity as free capacity.

The scheduler must also account for the effect of worker count on global batch size ($B_{\text{global}} = B_{\text{per-worker}} \times N$), where the per-worker batch counts examples contributing to one optimizer update, including gradient accumulation. Holding the global batch constant requires each remaining worker to process more examples after a shrink. Larger microbatches consume more memory; additional accumu-

lation steps extend the update time. Preserving the batch removes one source of optimization change but does not guarantee identical convergence. Allowing the global batch to change instead requires validating the learning-rate policy and resulting model quality, so throughput alone cannot determine the best allocation.

Listing 8.2: TorchElastic Launch Configuration: The `--nnodes=4:16` range configures the elastic worker group to admit 4 to 16 nodes, or 32 to 128 workers. A separate cluster scheduler or operator must acquire, launch, and release nodes within that range.

```
# Launch elastic training with min 32 to max 128 workers
torchrun \
  --nnodes=4:16 \
  --nproc_per_node=8 \
  --rdzv_backend=c10d \
  --rdzv_endpoint=head-node:29500 \
  --max_restarts=3 \
  train.py
```

TorchElastic sets the elastic range in its launch configuration as a minimum and maximum node count (listing 8.2). There, the `--nnodes=4:16` specification configures TorchElastic's rendezvous and worker-membership range as 4 to 16 nodes (32 to 128 workers with 8 processes per node). It does not acquire or resize cluster resources; a separate cluster scheduler or operator must place the nodes and start or stop elastic agents as capacity changes.

Systems Perspective 8.2: Elastic vs. rigid scheduling

Consider a congested cluster where a 128-GPU job waits 8 hours for a full gang allocation. This first comparison assumes throughput scales linearly with worker count, equivalent learning progress per processed example, and negligible resize overhead; the later scaling decision relaxes the throughput and transition assumptions.

Rigid scheduling: Wait 8 hours, then train for 24 hours at full throughput. Total wall-clock: 32 hours.

Elastic scheduling (min 32, max 128):

- Start immediately with 32 GPUs (throughput = 25 percent of full)
- At hour 2, when 64 GPUs free, scale to 64 (throughput = 50 percent)
- At hour 8, when the full gang frees and the rigid job would also start, scale to 128 (throughput = 100 percent)

Work completed during the 8-hour queue wait, in hours of full-scale training:

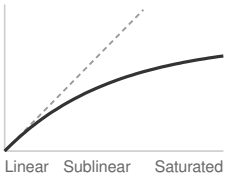
- Hours 0 to 2: 25 percent throughput $\times$ 2 hours = 0.5
- Hours 2 to 8: 50 percent throughput $\times$ 6 hours = 3
- Total: 3.5 hours of equivalent full-scale work

> The elastic job completes in approximately 28.5 hours (8 hours of partial-scale training plus 20.5 hours at full scale), saving 3.5 hours compared to rigid scheduling. This improvement of about 11 percent comes entirely from using resources productively during what would otherwise be idle queue time.

The scheduler cannot treat every worker count as a valid elastic configuration. Model parallelism constrains the allocation increment when the resize policy keeps tensor and pipeline layouts fixed and adds or removes whole data-parallel replicas. For a 175B-parameter job that relies on 8-way tensor parallelism within each node and 8 pipeline stages across nodes, this policy operates at the granularity of a whole model replica of 64 GPUs. The pipeline depth of 8 is the smallest power of two at which each GPU's share of the mixed-precision Adaptive Moment Estimation (Adam) training state fits in its HBM when that state is not sharded across replicas. The feasible layout of chapter 6 instead uses a shallower pipeline and shards optimizer state across the data-parallel group with ZeRO (section 6.3.3). Keeping each replica's state self-contained costs memory, but it lets the scheduler add or remove a replica without redistributing every other replica's optimizer shards. The job can scale between 128 nodes (1,024 GPUs) and 32 nodes (256 GPUs) one replica at a time, changing the data-parallel degree. Removing a single GPU from a tensor-parallel group would instead require a new sharding layout and redistribution of training state. Changing the pipeline degree would also require repartitioning stages and rebuilding the pipeline schedule. A runtime that supports these transitions can expose them to the scheduler, but their feasibility and measured costs belong in the resize contract rather than following automatically from data-parallel elasticity.

The transition cost also constrains the scheduler's resize frequency. Each scaling event can interrupt useful work while the framework reconstructs its communication group and restores or redistributes state. The duration must be measured for the chosen runtime and checkpoint path. The scheduler must amortize this cost over the subsequent run duration, so small resize increments are only worthwhile if the job will run at the new scale for significantly longer than the transition window. Section 8.7.3 shows the thrashing that results when a policy ignores this amortization.

8.7.2 Scheduler integration



Without scheduler integration, a job that declares an elastic range $[N_{\text{min}}, N_{\text{max}}]$ in its launch script still waits in the queue for its full node count and still gets killed outright when a higher-priority job arrives. Integrating the $[N_{\text{min}}, N_{\text{max}}]$ bounds into the scheduler lets it start a job early at the minimum, expand the job into newly idle capacity, or shrink it to release borrowed capacity without terminating the logical job. Which action wins depends on the job's scaling curve and transition cost, and the policies below compare the choices by the work completed over the same time window.

Each action must respect the framework contract. The most consequential of the three is **graceful preemption**: when higher-priority work arrives, the scheduler first shrinks an elastic job toward N_{min}, reclaiming whole replicas at the next resize boundary, and resorts to checkpoint-and-preempt only when the final viable group itself must yield. Quota borrowing across teams, developed in section 8.11, depends on this primitive whenever an owner reclaims capacity it lent. Scaling curves and transition costs determine whether the extra progress repays the disruption. Because batch changes can affect convergence, the test of a resize is time to target model quality, not throughput.

8.7.3 Elastic scaling policies

Adding resources to a running job does not always accelerate time-to-convergence. Communication and synchronization overhead limit throughput gains, requiring the scheduler to enforce elastic scaling policies based on empirical efficiency curves rather than resource availability alone. With fixed global work per step, a job's scaling efficiency $\eta_{\text{scaling}}(k)$ at k workers (definition 6.4) typically passes through three regimes. In the near-linear regime, per-worker computation dwarfs every fixed per-step cost. In the sublinear regime, pipeline fill and drain and the unhidden part of gradient synchronization become a visible share of each step. In the saturation regime, those fixed costs rival the shrinking computation itself. Assigning available GPUs to a saturated job can yield less useful progress than serving queued work. The lower allocation bound answers a different question. Below its **minimum viable scale**, a job may lack the memory or complete parallel groups needed to execute at all. A policy can impose a higher minimum to meet a deadline, even when a smaller allocation remains computationally efficient.

The 175B reference job shows these regimes with the chapter's own numbers. Modeled at a fixed global batch with the step-time decomposition of the Fleet Law (equation 1.3), its scaling efficiency falls from 87 percent at 256 GPUs to 83 percent at 1,024 GPUs and 69 percent at 4,096 GPUs (figure 8.12, panel a). Efficiency falls, yet quadrupling from 1,024 to 4,096 GPUs still raises throughput 3.3×, so a lower efficiency is a declining marginal return rather than a slowdown. Panel (b) locates the loss. Tensor-parallel communication shrinks along with each worker's computation, so its share of the step never rises above 11 percent. The decline comes instead from pipeline fill and drain and unhidden gradient synchronization, which take roughly fixed time per step while each worker's share of the batch shrinks. The pipeline bubble grows fastest of the three, for a reason the bubble fraction $(N_{\text{PP}}-1)/(m+N_{\text{PP}}-1)$ of section 6.5.2 makes explicit. With the global batch fixed, each added replica takes a share of the sequences, so the microbatch count m per replica falls while the stage count stays at 8, and the idle fraction rises. The shaded window from 256 to 1,024 GPUs is therefore a policy choice, not an interval derived from these efficiencies alone. A minimum allocation could follow from a completion deadline or the job's declared resource contract. It does not follow from insufficient per-worker computation at smaller scale, since with fixed global work fewer workers generally perform more work each. The upper limit likewise requires comparing additional useful progress with resize cost and the

Throughput falls away from ideal linear scaling and saturates.

value of serving queued jobs. A real scheduler must obtain those inputs from profiling and the workload's quality target.

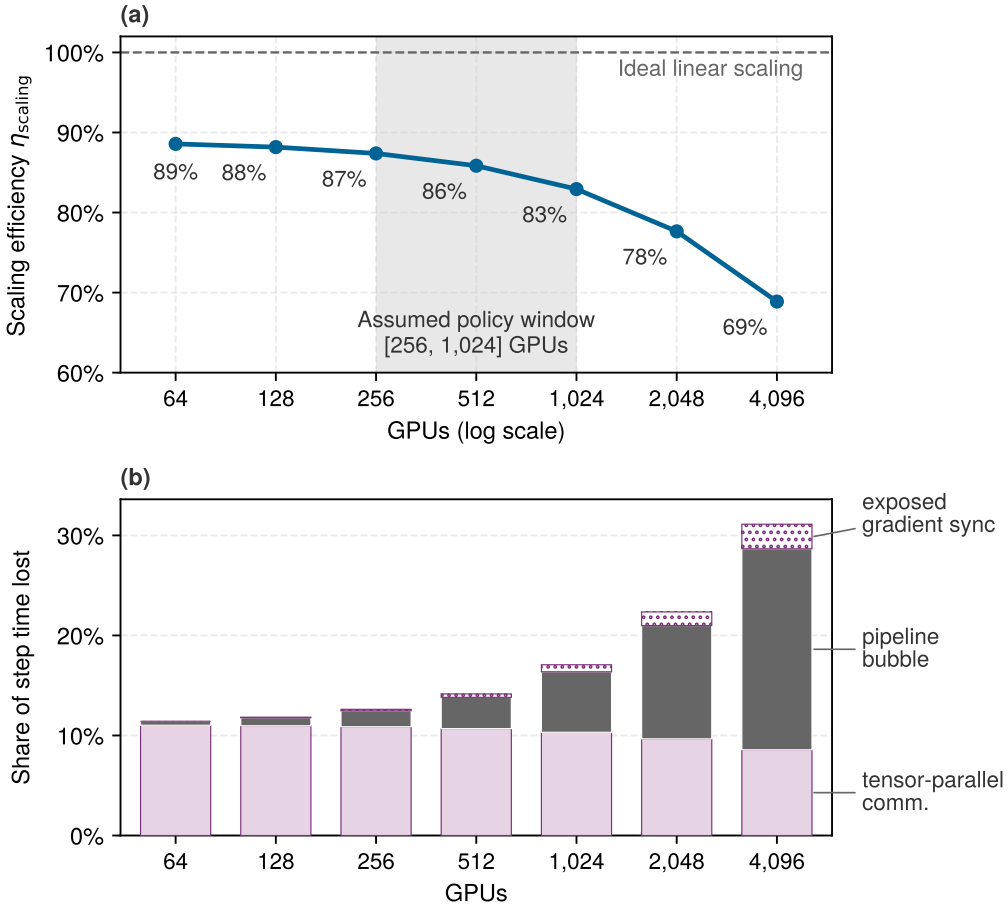


Figure 8.12: Modeled Scaling Efficiency and Elastic Operating Range: (a) Scaling efficiency ($\eta_{scaling}$) of the 175B reference job from 64 to 4,096 GPUs, computed with 8-way tensor parallelism within each DGX H100 node, 8 pipeline stages, HDR InfiniBand, and a fixed global batch of 1,536 sequences. The shaded window is an assumed admission policy; efficiency alone establishes neither its minimum nor its maximum. (b) Share of each step lost to tensor-parallel communication, pipeline bubble, and exposed gradient synchronization. Lower efficiency does not imply that adding workers reduces throughput.

This logic extends to the temporal dimension, where the scheduler must weigh the immediate progress of a smaller allocation against waiting for a larger one. If a 512-GPU job can start immediately with 128 GPUs or wait for the full request, the better choice depends on the integration of throughput over time. The resize overhead (the cost of stopping, checkpointing, and restarting when the runtime requires them) must be amortized over the subsequent run duration. A policy of "opportunistic scaling" that resizes a job every time a single node becomes free can lose its throughput advantage to repeated interruptions, completing less useful work than a stable allocation.

Napkin Math 8.3: The elastic scaling decision

The comparison of elastic and rigid scheduling above assumed linear scaling and free resizing; this decision drops both assumptions. Consider a training job with a target batch size that requires 512 GPUs for the highest throughput among the configurations considered. Three scheduling strategies are evaluated over a window of 24 hours.

Given: Throughput at 128 GPUs is 1 epoch/hour (baseline). Throughput at 256 GPUs is 1.8 epochs/hour (90 percent scaling efficiency relative to that baseline). Throughput at 512 GPUs is 3.2 epochs/hour (80 percent scaling efficiency). Re-scaling cost is 10 minutes (0.17 hours) to checkpoint, re-shard, and restart.

Strategy 1 (immediate start, no scaling): The job starts immediately with 128 GPUs and runs for the full 24 hours. Total work: $24 \times 1.0 = 24$ epochs.

Strategy 2 (wait for the full allocation): The job waits in the queue for 4 hours until 512 GPUs become available, then runs for 20 hours. Total work: $20 \times 3.2 = 64$ epochs.

Strategy 3 (elastic step-up): The job starts immediately with 128 GPUs. After 4 hours, the capacity that lets Strategy 2 start frees up, but the elastic policy caps growth at 256 GPUs so that the remaining GPUs stay available to queued jobs. The job pauses, scales up, and resumes. Phase 1: $4 \times 1.0 = 4$ epochs. Phase 2: $(24 - 4 - 0.17) \times 1.8 \approx 35.7$ epochs. Total work: 4 + 35.7 = 39.7 epochs.

The elastic strategy completes nearly 1.7× the epoch-equivalent work of the immediate small-scale run, but still trails the full allocation by about 38 percent. That comparison counts this job's epochs, not the GPU-hours spent on them. Strategy 2 holds twice as many GPUs as Strategy 3 for most of the window and runs them at 80 percent scaling efficiency against Strategy 3's 90 percent. The elastic job therefore does more work per GPU-hour, and the GPUs it leaves free serve queued jobs. Which strategy wins therefore depends on whether the fleet values this job's completion time or the total work completed across all jobs. That gap shrinks when queue waits grow or peak capacity stays scarce. Re-scaling overhead is only 10 minutes, so the step-up strategy keeps its lead over the immediate small-scale run unless slow checkpoint transfer or compilation stretches that overhead beyond about 9 hours.

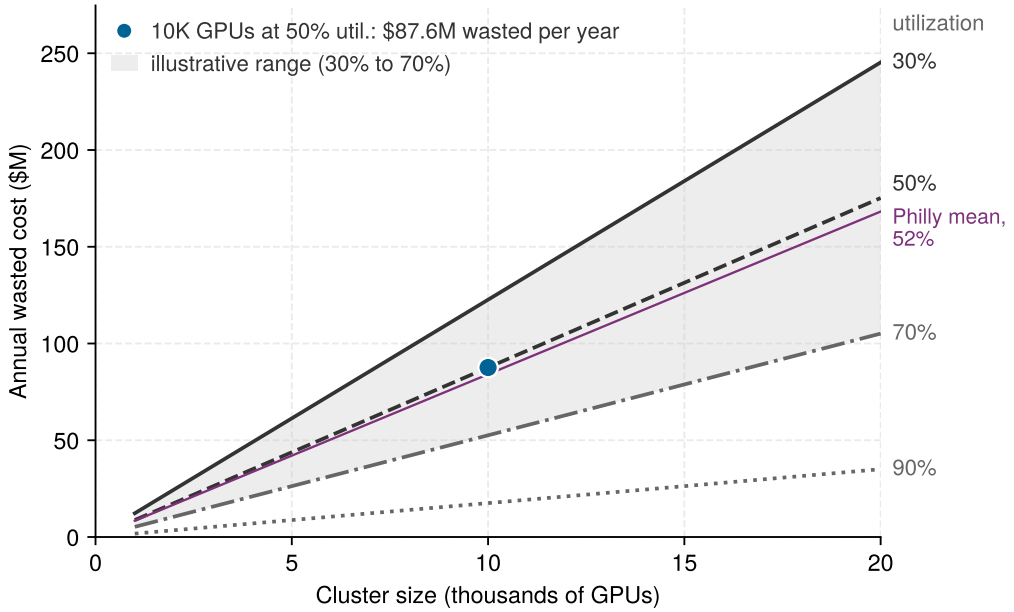
Placement and elasticity determine which allocations are feasible and how much useful progress they produce across competing jobs. Fleet economics adds the price of those choices. Every placement, preemption, and reservation consumes capacity that could serve another workload, so the scheduler must compare both useful progress and opportunity cost.

8.8 Cost Optimization

An idle accelerator in an enterprise fleet incurs operational costs every hour whether computing or blocked in a queue, turning placement and preemption

decisions into direct financial trade-offs. The orchestrator translates this utilization-to-dollars relationship from section 8.1 into an online scheduling signal, balancing resource prices, reservation commitments, interruption risk, checkpoint cost, and job deadlines to decide whether to admit, delay, preempt, or resize work. Capital planning, portfolio return, cost attribution, and lifecycle total cost of ownership are larger, slower decisions developed in section 12.9; the scheduler consumes their outcomes as prices and constraints.

At a fixed utilization, idle capacity grows linearly with fleet size, so the dollar cost of a scheduling inefficiency grows with every procurement (figure 8.13). At 10,000 GPUs operating at 50 percent utilization, annual waste reaches $87.6M under the chapter's $2/GPU-hour accounting scenario. Published measurements show that such underutilization occurs in production. Microsoft's Philly cluster study (Jeon et al. 2019) measured mean GPU utilization of approximately 52 percent. The 30 to 70 percent shaded band in the figure is an illustrative operating range for the cost model, not a universal empirical claim about all production clusters. Moving from 50 percent to 80 percent utilization, the improvement priced in the chapter opening, recovers over $52M annually in equivalent capacity value. That is the same 3,000 GPU-equivalents the opening counted as waste at 30 percent idle, and it becomes cash savings only when it avoids billed usage or a planned purchase.



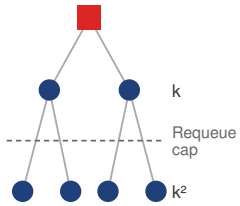


Figure 8.13: The Cost of Idle GPUs: Annual wasted cost as a function of cluster size for different GPU utilization levels, assuming $2/GPU-hour (cloud equivalent). The shaded region between 30 percent and 70 percent is an illustrative operating range for the scenario analysis. At 10,000 GPUs with 50 percent utilization, the model yields $87.6M in annual wasted capacity. The thin violet line traces the published Microsoft Philly mean GPU utilization of 52 percent across all cluster sizes; it is a utilization reference, not a measured cluster size or cost. Data source: Jeon et al. (2019).

Recovering that idle capacity requires pricing each scheduling lever against the disruption it causes. Because reclaiming GPUs from running jobs is the most direct way to admit higher-value work, the cost of a single preemption and the

cascades it can trigger come first. Discounted spot capacity then lowers the hourly price of restart-tolerant training, diversification and checkpoint policies keep correlated reclamations from erasing that discount, and capacity-reservation tiers combine with workload cost policies to route jobs across reserved, on-demand, and interruptible pools.

8.8.1 Preemption cost and cascades

When a high-priority job enters a saturated cluster, the scheduler must decide which running workloads to terminate to free up resources. This decision is rarely isolated. In tightly packed clusters, evicting a medium-priority job to accommodate a high-priority request often triggers a **preemption cascade**, where the evicted job immediately attempts to reschedule itself by displacing lower-priority workloads. The disruption multiplies with each level. If the urgent job displaces k medium-priority jobs and each of those, on rescheduling, displaces k lower-priority jobs, one admission interrupts $k + k^2$ jobs after two levels. Every one of them pays the preemption overhead quantified below and adds a checkpoint reload to the storage system at the same moment. Two dampening controls cap that growth. A rule that evicted jobs requeue without preempting anyone themselves stops the chain at the first level, so one admission costs at most k interruptions. A **preemption budget** limits how often any single job, or what fraction of capacity, may be displaced in a time window, which protects the jobs at the bottom of the priority order that every chain would otherwise reach.

Each eviction can evict again, so one admission reaches $k + k^2$ jobs.

The engineering cost of preemption extends beyond scheduling latency. The **preemption overhead** depends on the exit path. A successful graceful checkpoint adds the time to save and restart while preserving completed progress; a forced stop can instead discard work since the last durable checkpoint. Consider such a victim, a forced interruption of the 64-GPU fine-tuning run for our 175B parameter model. The scenario assumes lost work equivalent to 15 minutes of execution. The restart then repeats the cold-restart steps of the recovery budget in section 7.9.2, without its detection step because the scheduler itself stopped the job. These steps take 3 minutes to relaunch, 24.5 seconds to reload the 2.45 TB checkpoint with its optimizer state, and 2 minutes of warmup as data pipelines refill and just-in-time (JIT) compilation and runtime initialization complete. The calculation prices replay and restart across the same allocation; it does not also charge for a successful final save.

Reconstructing the distributed data pipeline also belongs in the preemption contract. The checkpoint must preserve the sampling and loader state needed to resume the intended data order, alongside model and optimizer state. If the restart path omits that state, it can repeat or skip samples and lose exact replay of the training trajectory. A different shuffle order does not by itself prove statistical corruption, but the recovery policy must specify which changes are acceptable. The scheduler should therefore measure restoration and pipeline warmup as part of recovery cost, rather than assume that reloading model weights alone makes the job productive.

The resulting 20.4-minute overhead combines discarded execution, its larger part, with relaunch, reload, and warmup time; it is not a measurement of continuous kernel activity after eviction. Spread over the run, it belongs to the Fleet Law's coordination term $T_{\text{sync}}(N)$ (equation 1.3), which counts scheduling decisions and failure recovery alongside barrier waits, so frequent preemption lengthens the average step exactly as frequent failure does. At \$2/GPU-hour, the scenario values each event at \$44 in allocation time. A low-priority run sits at the bottom of every cascade, so without a budget it can be struck many times a day. At the scenario's 12 forced preemptions per day, it loses 4.1 hours of equivalent allocation time, or 261 GPU-hours for this 64-GPU run. A per-job budget bounds that loss directly. When a budget binds, the scheduler must consider waiting, another placement, or a defined emergency exception. The trade-off is reduced recovery churn against delayed admission, measured under the workload's deadlines.

8.8.2 Spot instances and preemptible VMs

Renting on-demand cloud GPUs for a multi-week training run protects the job from provider reclamation, but pays full price even when spare GPUs sit idle in the provider's data center. Renting interruptible capacity cuts the hourly rate by 60 to 90 percent, but lets the provider reclaim those GPUs on best-effort notice. Cloud providers sell this spare capacity through spot instances[10] (AWS) or **preemptible VMs** (GCP), where actual discounts depend on the resource and market. The reference interruption windows range from up to 30 seconds for GCP preemptible shutdown to 2 minutes for AWS stop or termination notices, with best-effort delivery rather than a guaranteed recovery interval. At the scenario rates of \$0.70/GPU-hour instead of \$2/GPU-hour, the worked comparison below shows how savings can exceed half the on-demand cost after accounting for its assumed interruption overhead.

[10] **Spot instances**: The scenario's 60 to 90 percent discount purchases reclaimable capacity, not a guaranteed interval for saving state. AWS's best-effort stop or termination notice targets 2 minutes, while GCP preemptible shutdown allows up to 30 seconds; AWS hibernation begins immediately. If a job's measured checkpoint time exceeds the reference 30-second window, a notice-triggered save cannot be its only recovery path.

The viability of spot instances for ML training depends on two factors that determine whether the discount translates into actual savings. The first is the cost of each interruption (checkpoint overhead plus restart time plus lost work since the last checkpoint). The second is the frequency of interruption (which varies by instance type, region, time of day, and overall cloud demand). Equation 8.3 gives the **effective cost** of spot training:

$$C_{\text{effective}} = C_{\text{spot}} \times \frac{T_{\text{total}}}{T_{\text{productive}}} \tag{8.3}$$

where T_{total} is billed allocation time, including checkpointing, recovery, and work later discarded after an interruption, and $T_{\text{productive}}$ is the equivalent training time represented by retained progress. The ratio assumes a fixed allocation size and price, with unchanged useful throughput while training; variable allocations require summing the cost of each allocation interval. Waiting for replacement capacity extends completion time but contributes to billed time only while resources remain allocated. When checkpointing and interruption losses consume a small fraction of billed time, effective cost stays near the spot price. Frequent interruptions, expensive recovery, or substantial replay can instead erase the discount.

Spot savings and fault tolerance infrastructure are coupled. Fault tolerance mechanisms (frequent asynchronous checkpointing, fast checkpoint loading, elastic recovery) make spot capacity usable by lowering the cost of each interruption. Elastic training can resume a logical job with fewer workers after reclamation, provided the remaining allocation is viable, although the framework may still restart worker processes and restore checkpointed state, so elasticity reduces recovery cost rather than eliminating it. The same infrastructure therefore earns a double return. It protects against hardware losses, and it enables the deliberate use of interruptible capacity. Both benefits require measurement. The scheduler combines observed interruption rates, recovery costs, and retained training progress with resource prices to estimate whether spot savings repay the additional recovery infrastructure. The same evidence supports valuing protection against hardware failures; neither benefit follows from the discount or checkpoint mechanism alone.

8.8.3 Spot instance strategies for ML training

Spot capacity pays off only when an interruption rarely removes the whole job at once, so schedulers that use it diversify where capacity comes from instead of simply retrying on failure. Availability zone diversification reduces the probability of simultaneous fleet-wide reclamation. Cloud providers typically manage spot pools independently per availability zone (AZ). If a training job requires 1,024 GPUs, allocating them as a single block in one zone exposes the job to a complete stop if that specific zone's spot pool is reclaimed. Diversifying independent jobs or restart destinations across zones reduces exposure to one exhausted pool. Splitting a single synchronous gang across zones also changes its communication paths, so the scheduler must include cross-zone bandwidth, latency, and transfer costs before accepting that placement. The scheduler still must model correlation carefully: independent per-instance interruptions make large simultaneous losses unlikely, but pool-level or AZ-level reclamations can remove hundreds of GPUs at once and must be treated as elastic-shrink or failover events rather than ordinary isolated failures.

Instance type diversification expands the set of capacity pools a job can use, though availability across those pools can remain correlated. A job that requests only one instance type cannot use spare capacity in another pool. Accepting alternatives therefore requires a compatibility list that includes memory capacity, runtime support, communication paths, and measured throughput. An instance with more memory can still be an unsuitable substitute if its runtime support, communication paths, or throughput differ. The scheduler compares each feasible alternative's price and recovery cost per unit of retained progress; mixing devices within a synchronous gang also requires accounting for unequal worker speeds.

Spot capacity signals can guide placement but do not necessarily predict interruption frequency. For example, the AWS Spot Placement Score estimates the current likelihood that a capacity request will succeed in a region or availability zone; it explicitly does not predict interruption risk. A scheduler can use this signal to choose where to request capacity, but estimating interruptions per day requires separate historical measurements for the instance type and region. If

the resulting workload-specific recovery model shows that interruption overhead erases the discount, the scheduler should migrate the job to on-demand capacity or a different region.

Checkpoint frequency optimization for spot instances extends the reliability logic. The Young-Daly formula developed in section 7.8.1 models losses from unpredicted interruptions, whether caused by hardware failure or reclamation without a usable warning. Provider notices offer an additional opportunity to save state, using the reference windows of 2 minutes on AWS and up to 30 seconds on GCP preemptible VMs. A **two-tier checkpointing** approach combines periodic checkpoints, with an interval chosen for the workload's interruption model, and a best-effort checkpoint triggered by a notice. The notice-triggered checkpoint reduces lost work only if it becomes durable before reclamation; otherwise, the job restores its last durable state, whether produced by a periodic, asynchronous, or incremental checkpoint, and replays subsequent work. That contingency planning matters more when spot interruptions are correlated across a pool rather than isolated to single machines.

> Systems Perspective 8.3: Correlated spot risk
>
> **Context**: Spot capacity is cheap because it is reclaimable. That risk is not independent across instances: cloud regions, instance types, product launches, and deadline cycles can create correlated demand.
>
> **Failure mode**: A fleet that concentrates all interruptible training in one region and one instance type can lose a large fraction of workers at once, even if each individual worker appears restartable.
>
> **Consequence**: Checkpointing handles isolated interruptions; it does not solve fleet-wide preemption when every retry targets the same exhausted pool.
>
> **Systems insight**: A robust scheduler diversifies compatible restart destinations, monitors interruption risk, and plans an on-demand fallback when spot capacity cannot meet the job's deadline or cost target. That fallback still depends on available capacity and the time needed to restore state.

8.8.4 Capacity reservation strategies

Committing to long-term reserved capacity for 100 percent of peak demand leaves expensive GPUs idle whenever traffic dips, while relying solely on spot or on-demand pools risks capacity shortages during product launches and sudden reclamations during deadline crunches. To avoid paying for idle reservations or starving urgent workloads, organizations that rely on cloud infrastructure (or that price on-premises capacity in economic terms) combine three tiers of compute capacity. Each tier trades cost and commitment against availability and interruption risk (table 8.4).

Table 8.4: Cloud Capacity Reservation Tiers: Capacity tiers trade cost and commitment against availability guarantees and interruption risk, giving the scheduler a price ladder for routing workloads by urgency and restart tolerance.

Capacity tier	Cost and commitment	Availability and interruption risk	Best-fit workloads
Reserved capacity	Capacity reservation; price discounts require a separate purchasing contract.	Capacity assurance within the reservation terms; startup still takes time.	Predictable continuous workloads: 24/7 inference, scheduled training, CI and regression testing, jobs under service-level agreements (SLAs).
On-demand capacity	Full price with no long-term commitment.	Admission depends on available capacity; provisioning and startup add delay.	Urgent retraining, interactive debugging, and short-lived jobs that do not justify spot management.
Spot capacity	Discounted interruptible capacity.	Availability varies with cloud demand, and workers can be reclaimed.	Restart-tolerant jobs: hyperparameter sweeps, ablations, checkpointed pretraining, and exploratory research.

The constructed portfolio in figure 8.14 divides capacity into a reserved tier covering the steady 60 percent baseline, an on-demand band between 60 and 80 percent, and an interruptible spot tier serving peaks up to 92 percent. An organization with 60 percent steady-state utilization and 40 percent burst demand might reserve capacity for 60 percent of peak need, use on-demand for bursts whose deadlines tolerate admission and startup delay, and use spot for restart-tolerant work. These shares illustrate a policy rather than establish an optimal portfolio. The scheduler must match each workload's deadline and recovery contract to the capacity tier. Reserved capacity can support the steady serving load or a training job's base allocation, while spot can support elastic replicas or independent experiments that tolerate reclamation. A peak in urgent demand cannot automatically be assigned to spot merely because it lies above the reserved band.

Systems Perspective 8.4: Spot vs. on-demand training

Consider training a 70B parameter model, a smaller workload than the chapter's 175B reference, on 512 GPUs for 14 days. The scenario fixes the event budget at 196 interruptions over the run and treats each as graceful, so no progress is replayed.

On-Demand: 512 GPUs $\times$ 336 hours $\times$ \$2/GPU-hour = \$344,064

Spot (65 percent discount, 5 percent checkpoint overhead, 14 interruptions per day of useful training with 30 minutes restart):

- Base cost: 512 GPUs $\times$ 336 hours $\times$ \$0.70/GPU-hour = \$120,422
- Checkpoint overhead: $5\% \times$ 336 hours = 16.8 hours

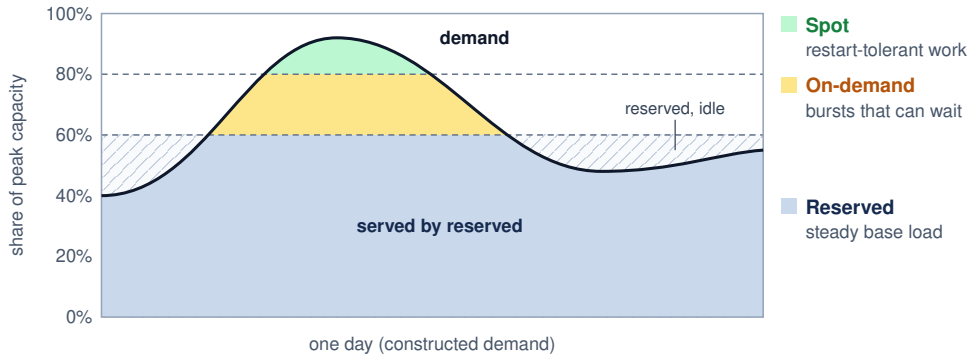

Figure 8.14: Capacity Reservation Tiers and Portfolio Optimization: This constructed portfolio combines reserved physical capacity, on-demand acquisitions, and interruptible workers. Reserved capacity covers the steady 60 percent base, on-demand the next 20 percent, and spot the peak; these shares and the demand curve are scenario assumptions. A discount commitment alone does not reserve capacity, and on-demand admission is not instantaneous. Schedulers map steady-state baseline demand to reserved capacity, diurnal spikes to on-demand instances, and restart-tolerant training to discounted spot pools. Hatching marks reserved capacity that is held while demand sits below it.

- Restart overhead: 196 interruptions $\times$ 0.5 hours = 98 hours
- Total time: 336 hours + 16.8 hours + 98 hours = 450.8 hours
- Total cost: 512 GPUs $\times$ 450.8 hours $\times$ \$0.70/GPU-hour = \$161,567

Savings: \$182,497 (53.0 percent), at the cost of approximately 34.2 percent longer wall-clock time.

These savings assume fault tolerance infrastructure is already in place. Without checkpointing, a single interruption forces restart from scratch, potentially wasting days of compute and negating all savings.

8.8.5 Cost-aware scheduling policies

Once a fleet spans reserved, on-demand, and spot tiers, a newly submitted job can often launch immediately on reserved A100 GPUs or wait two hours for spot H100 instances that deliver twice the throughput at half the execution cost. Deciding whether those savings repay the two-hour delay and interruption risk turns the purchasing tiers into an online scheduling decision. Alongside completion time, utilization, and fairness, a cost-aware orchestrator evaluates three recurring trade-offs: waiting versus running immediately, preempting lower-priority work on reserved capacity (such as a hyperparameter sweep) versus routing a high-priority training run to more expensive on-demand instances, and replacing reclaimed spot instances with on-demand nodes versus shrinking elastically. Each choice requires the costs of waiting, recovery, and displaced work as well as the price of the new allocation.

These decisions require the scheduler to model both the time-value of computation (the organizational cost of a 2-hour delay in researcher productivity, product launch schedules, or competitive position) and the financial cost of different resource allocations. Delaying a production model retrain by 2 hours might violate

a service level agreement (SLA), while the same delay to an exploratory experiment can postpone a research decision or block dependent work. A workload class's delay tolerance is therefore a policy input grounded in its dependencies and deadlines, not an assumption that exploratory work has no time cost.

Production systems can define **cost policies** per workload class that encode these trade-offs as configuration rather than requiring per-decision human judgment. One policy places steady inference demand on reserved capacity and maintains ready replicas to meet its latency target; the reservation alone does not guarantee application availability or latency. Large training runs can combine a reserved minimum viable allocation with interruptible elastic expansion, requesting on-demand replacements when a deadline justifies the cost and capacity is available. Exploratory workloads with flexible deadlines can use spot capacity while accepting interruptions and variable completion times. These assignments express the organization's priorities rather than a universal mapping from workload type to purchasing tier.

The scheduler does not implement the organization's financial accounting system. It consumes the resulting price and policy signals: the marginal price of each capacity tier, the reservation a project may claim, the interruption risk it may accept, and the deadline it must meet. Showback, chargeback, and attribution belong to that accounting system; the scheduler uses their outputs only to rank feasible scheduling actions. Lifecycle total cost of ownership (TCO) reaches the scheduler the same way, as per-resource opportunity costs and constraints that record whether capacity is owned, reserved, on demand, or interruptible, rather than as a scheduling mechanism.

↪ Tag-based cost attribution, shared-cost allocation, and chargeback are developed in section 12.9.7.2.

↪ The lifecycle TCO framework, which combines training, inference, data, and iteration costs, is developed in section 12.9.6.

Checkpoint 8.2: Cost-aware scheduling trade-offs

Before moving to ML-specific schedulers, review how the cost-optimization mechanisms interact:

- ☐ **Spot break-even**: identify the additional inputs needed to compute a break-even checkpoint interval for the 512-GPU, 14-day training job of the spot comparison above (65 percent spot discount, 14 interruptions per day, 30-minute restart overhead), including checkpoint duration, the interruption-rate clock, and lost-progress assumptions.
- ☐ **Double return**: explain why fault tolerance infrastructure has a "double return" for reliability and cost savings, and identify the minimum fault tolerance investment needed to make spot instances viable.
- ☐ **Reservation sizing**: starting from the constructed portfolio that reserves 60 percent of peak, identify the demand history, reservation terms, unit prices, and unused-capacity costs needed to decide whether raising the reserved share to 70 percent reduces total spending.

Spot pricing and reservation strategy reduce the cost of capacity, but they do not determine which competing job should receive it. Runtime uncertainty, unequal

completion delays, and the cost of interrupting an iteration remain even when prices are known. Resolving them requires signals from the workload itself, such as how much service a job has consumed, where its iteration boundaries fall, or how fast it is learning. A scheduler that tracks learning progress can optimize time-to-accuracy, the wall-clock time until a run reaches a target validation metric, rather than execution speed alone.

8.9 Custom ML Schedulers

A short experiment waiting behind a long training run can suffer even when every running job has an efficient placement. Improving that outcome requires a policy for deciding which job receives the next available resources. Custom ML schedulers use different signals to make that decision: consumed service can prioritize jobs without runtime estimates, iteration boundaries can make preemption cheaper, normalized finish time can expose unfair delay, and measured goodput can guide joint resource and batch-size changes. Only the last of these requires a model of learning progress; the others improve completion time, utilization, or fairness without predicting convergence.

8.9.1 Duration-agnostic scheduling (Tiresias)

When a researcher submits an exploratory training run without knowing whether it will fail in ten minutes or run for a week, scheduling policies that depend on upfront duration estimates (section 8.4.3) either mispack the queue or penalize inaccurate guesses. **Tiresias** (Gu et al. 2019) eliminates the requirement for duration estimates entirely. It uses a two-dimensional attained service[11] scheduler that makes priority decisions based on what a job has already consumed, not what it claims it will consume. Jobs accumulate "service" based on GPU-time consumed, with priority decreasing as service increases. The two dimensions are time (how long the job has been running) and resources (how many GPUs the job uses), capturing both elapsed duration and resource intensity.

A discretized version groups jobs into service bins (illustratively, less than 1 GPU-hour, 1 to 10 GPU-hours, 10 to 100 GPU-hours, greater than 100 GPU-hours), giving lower-service bins higher priority. When job durations are heavy-tailed, a job that has consumed little service is likely to be short, so favoring low-service jobs approximates shortest-remaining-processing-time ordering without any runtime estimate. New jobs can receive service before long-running jobs, but their eventual duration remains unknown, and a high-priority gang still needs a feasible allocation. Tiresias also promotes jobs that have waited too long, trading some average-completion-time benefit for protection against starvation. The priority rule therefore replaces runtime prediction with an observable signal and an explicit waiting-time policy; it does not guarantee that every short job starts promptly.

The Tiresias evaluation reports lower average job completion time (JCT) on its testbed and trace-driven workloads (Gu et al. 2019). The result depends on job arrivals, sizes, and the comparison policy. Prioritizing low-service jobs can delay long-running jobs, so average completion time must be evaluated alongside starvation prevention and the delay experienced by each job class.

[11] **Attained service scheduling**: A discipline that uses consumed service to set priority when remaining work is unknown. Unlike shortest remaining processing time (SRPT), it cannot distinguish a newly arrived long job from a short one before either receives service. Its benefit depends on the workload distribution; protection against starvation remains necessary when new jobs repeatedly displace older ones.

8.9.2 Iteration-aware scheduling (Gandiva)

Preempting a job in the middle of a training step either discards the partial step or requires saving gigabytes of temporary forward-pass activations alongside the model weights. **Gandiva** (Xiao et al. 2018) avoids that mid-step state transfer by exploiting repetitive training iterations to profile jobs and time-slice GPUs at iteration boundaries. To give a GPU to another job, Gandiva suspends the running job at the end of a minibatch, copies its live GPU memory to host memory, and resumes another job on the device; switching back reverses the copy. Several jobs can therefore take turns on one GPU, and the same suspend-and-resume path lets Gandiva migrate a job to better-placed devices or pack compatible jobs onto one GPU when their combined memory fits. The boundary is the cheap place to switch because temporary activations have been released, so far less state must move than in the middle of a step. Weights, optimizer state, and runtime allocations remain, so each switch still costs a transfer proportional to that persistent state, and a job whose persistent state nearly fills the device cannot share it. The scheduler must measure memory demand, interference, and transition cost before admitting additional jobs.

Gandiva also implements **grow-shrink elasticity**, applying the allocation mechanism of section 8.7 to jobs that explicitly permit resizing. It expands eligible jobs into idle capacity and shrinks them when demand returns, using profiles to estimate which jobs benefit. The published implementation limits growth to one server and waits through an idle period before expanding. Its contribution is the connection between measured job behavior and resource control, rather than a claim that arbitrary training jobs can resize cheaply.

8.9.3 Finish-time fairness (Themis)

Equal GPU-time shares can produce unequal completion delays when workloads respond differently to placement. **Themis** (Mahajan et al. 2020) measures fairness in normalized finish time. Each application, which can contain related training jobs, compares its completion time in the shared cluster with its completion time on an isolated $1/N$ share of the cluster, where N is the number of applications contending for it. The ratio has the same form as the slowdown S_j defined with the scheduling objectives, except in its denominator. Themis divides by the completion time on a fair share of the cluster rather than by the isolated runtime on the job's own allocation, so a ratio of one means the application finished no later than its fair share would have allowed.

Themis targets the worst finish-time fairness ratio across applications. Its auction rounds offer available resources to the applications farthest from fair completion, while allowing placement efficiency to influence which specific GPUs each one receives within a round. With two applications whose current estimates are 1.2 and 2.0, the second is projected to finish twice as late as its fair share would allow, so it enters the round ahead of the first. The first application's ratio rises while it waits, and once it overtakes the second it moves to the front of later rounds. The signal is relative completion delay, not proximity to completion or GPU-hours already consumed.

Within a round, contending applications bid on candidate GPU subsets by reporting the finish-time fairness ratio they would reach on each subset. Because a communication-heavy job finishes much faster on a compact subset than on a scattered one while a communication-light job sees little difference, these bids expose placement sensitivity rather than monetary willingness to pay. The arbiter can then assign compact subsets to the lagging applications whose finish-time ratios gain the most from locality. This auction trades short-term allocation efficiency against the long-term fairness objective, making the quality of completion-time and placement estimates part of the scheduler's operating assumptions.

8.9.4 Adaptive resource allocation (Pollux)

Adding GPUs to a running job by increasing its global batch size raises throughput in examples per second. Past the critical batch size, however, each example contributes less optimization progress, so the extra GPUs can slow convergence rather than speed it up. **Pollux** (Qiao et al. 2021) addresses this coupling by extending resource adaptation to training hyperparameters. Where Gandiva changes only device allocations, Pollux jointly considers allocation, batch size, and learning-rate scaling because a larger batch can use more devices efficiently while changing the amount of work needed to converge. The preferred configuration can therefore change with both cluster demand and the stage of training.

Pollux uses statistical goodput to connect system throughput, measured in training examples per second, with statistical efficiency, which measures progress per example relative to a reference batch size. It is a third use of the word, and section 9.2.4 sets it beside the others. The run-level goodput of section 1.5.4 discounts work lost to failures and restarts, and Google's ML productivity goodput multiplies program, runtime, and scheduling factors. Statistical goodput instead discounts each example by the optimization progress it contributes at the current batch size. Statistical efficiency falls as the batch grows past the critical batch size of section 6.4.6, which is why more GPUs at a larger batch can raise throughput while lowering goodput. Pollux estimates how allocation and batch changes affect both quantities, then uses those estimates to guide resource sharing across jobs. Additional GPUs are valuable only when their throughput gain survives the corresponding change in statistical efficiency and the cost of changing the allocation.

The Pollux evaluation reports average job completion times 37 to 50 percent lower than the state-of-the-art deep learning schedulers it was compared against, which do not make the same combined adjustment of resources and batch size (Qiao et al. 2021). The number belongs to that testbed and trace. Its durable lesson is the coupling: an allocation can increase samples per second while reducing progress per sample. The scheduler must estimate both effects and validate completion time at the same target quality, rather than transferring a reported improvement to a different workload.

8.9.5 Scheduler comparison framework

Each research scheduler pursues a different objective, and each objective requires its own observations and controls (table 8.5). Consumed service can be obtained from resource accounting, while iteration timing and learning-progress estimates require closer runtime integration. The choice therefore turns on what the platform can observe and control, not on a ranking of scheduler sophistication.

Table 8.5: Custom ML Scheduler Comparison: A taxonomy of research schedulers based on the specific workload characteristic they exploit. Tiresias uses attained-service accounting, Gandiva profiles iterations, Themis estimates relative finish times and placement effects, and Pollux models goodput under allocation and batch-size changes.

Scheduler	Key insight	Scheduling signal	Optimization target	Integration requirement
Tiresias	Attained service informs priority	GPU-hours consumed	Minimize average JCT	Resource accounting and queue reprioritization
Gandiva	Iteration boundaries enable sharing	Iteration timing	Improve utilization	Runtime profiling and coordinated time slicing
Themis	Completion delay defines fairness	Normalized finish time	Improve worst fairness	Finish-time estimates and allocation auctions
Pollux	Batch size and allocation are coupled	Goodput	Maximize cluster goodput	Runtime resizing and batch-size adaptation

The common lesson is to match the policy signal to the scheduling objective. Attained service addresses runtime uncertainty and can work from accounting records. Iteration boundaries lower the cost of interrupting work but need reliable timing profiles. Normalized finish time measures unequal delay, and goodput couples resource allocation to learning progress, which requires the training loop to accept allocation and batch-size changes. Each added control creates a failure mode of its own: inaccurate profiles can increase interference, and an inaccurate learning-progress model can choose allocations that fail to improve convergence. A platform should therefore test the chosen policy against queue delay, starvation risk, and measured recovery cost before adopting it.

8.9.6 From research to production

A production cluster containing V100s alongside A100s and H100s, with both InfiniBand and Ethernet paths, gives the same GPU count very different performance across placements, while live jobs crash, hang, or exceed declared memory needs. Because a research scheduler's evaluation establishes results on a specific testbed, workload trace, and set of runtime controls, a production fleet must test whether its own hardware and failure conditions preserve those gains. Deploying a policy therefore requires integrating its decisions with admission, failure recovery, and the existing orchestrator, then measuring its benefit under the fleet's actual workload.

Consider applying adaptive allocation to our 175B-parameter model training run. The runtime must first expose viable resize configurations and their costs. A

checkpoint-and-restart path can require persisting and restoring large optimizer state, while other state-transfer mechanisms impose different costs. Repeated resizing can consume the expected throughput gain before the job benefits from its new allocation. The policy should therefore compare predicted additional progress over the expected allocation duration with the measured transition cost, retaining a stable placement when resizing does not repay that cost. The decision follows the workload and cluster demand, not a universal training phase.

The production decision is whether a specialized policy improves marginal allocation enough to justify its operational burden, judged by the measures this chapter has already built: queue delay and slowdown, useful GPU-hours, preemption overhead, and placement efficiency. Group admission settles whether a gang can start at all; the research schedulers answer the next question, which feasible group to admit, and each imposes different requirements on the runtime. Selecting a policy therefore means matching its objective and assumptions to the fleet rather than choosing a single scheduler as universally best.

Checkpoint 8.3: Custom scheduler design space

Consider the trade-offs between the four research schedulers:

- ☐ **Estimate-free scheduling**: identify the information Tiresias sacrifices by eliminating runtime estimates, and describe when that sacrifice hurts scheduling quality.
- ☐ **Time-slicing limits**: identify workloads for which Gandiva's iteration-boundary time-slicing fails, and explain why.
- ☐ **Job starvation**: explain how waiting changes an application's finish-time fairness ratio in Themis, and why this differs from favoring jobs that are nearly complete.
- ☐ **Goodput-model risk**: describe the failure mode when Pollux's goodput model is wrong.

The training policies just compared balance completion time, fairness, utilization, and learning progress. Serving adds a different deadline: capacity must be ready before an arriving request exhausts its latency budget. That requirement makes provisioning delay and burst headroom central to how the fleet allocates capacity to serving.

8.10 Serving Capacity in the Shared Fleet

When an e-commerce platform launches a major sale, requests can arrive faster than its serving replicas can process them. A training job may tolerate waiting in the admission queue; a serving request misses its deadline while additional capacity is still starting. To the fleet orchestrator, serving is therefore a claim on accelerators that must be honored quickly and that competes with training gangs for the same devices.

The orchestrator's unit is the serving replica, a ready execution group with a loaded model that may occupy one accelerator, a device partition, or a multi-accelerator gang. A 175B-parameter model may make an eight-GPU tensor-parallel group the schedulable replica. Archetype B (DLRM at Scale) imposes the same constraint through its embedding tables: a replica whose tables are sharded across several accelerators can serve only when every shard is placed. Each replica has a measured request-processing capacity at a specified workload mix and latency target, and that measured capacity is the quantity the orchestrator uses to size and place replicas. It decides how many such groups exist, where they reside, how they are protected from interference, and which lower-priority allocations yield when serving demand grows. Language models add a memory dimension to the claim. Each in-progress response retains per-token attention state, the key-value (KV) cache, whose footprint grows with context length and concurrency even though the weights stay fixed, so a replica can exhaust its memory before it exhausts its compute.

How many replicas to run at each moment is a control problem with its own signals and delays. Accelerator utilization alone does not identify the capacity needed to meet a request-latency target, and loading large models can delay a new replica's readiness. The controller must combine demand signals with measured startup time and ready reserve capacity; section 10.13 develops that control loop. For the orchestrator, the immediate consequence is that reclaiming a device from training does not instantly make it available for serving. Three fleet-level questions follow, namely how serving workloads share devices without unacceptable interference, when sharing pays for itself, and where the boundary between training and serving pools should sit.

8.10.1 Resource isolation

When multiple inference workloads share physical hardware, noisy-neighbor contention[12] arises whenever one workload's resource consumption degrades another's execution speed. On GPUs, shared execution units can limit concurrent kernels, while saturated HBM interfaces constrain memory-bound work. Contending working sets can evict lines from the shared L2 cache, and simultaneous host-to-device transfers can compete for PCIe bandwidth. Aggregate power and temperature limits can also reduce operating clocks. These mechanisms connect the placement decision to the request's critical path. A placement that fits every model in memory can still miss its service-level objective if sharing extends execution or queueing enough to exhaust the latency budget.

Multi-Instance GPU (MIG)[13] closes several of these channels in hardware by partitioning A100 (80 GB) and H100 (80 GB) GPUs into hardware-isolated instances. Unlike software-based GPU sharing, such as time-slicing that context-switches several processes over one whole device, MIG dedicates memory, cache, and compute resources to each instance, reducing interference through those partitioned resources. The A100 MIG profiles in table 8.6 show the scheduling consequence. A single physical A100 becomes several fixed-size resources that the device plugin of section 8.5.2 can expose as independently schedulable accelerators.

[12] **Noisy neighbor**: In GPU clusters, interference arises when one job's bursty network traffic or memory bus utilization slows down a co-located job on the same node. In synchronous training, a delayed flow can extend collective completion when it lies on the communication critical path, propagating one tenant's interference across a worker group.

[13] **Multi-Instance GPU (MIG)**: Introduced with the A100 (2020), MIG partitions a single GPU into up to 7 hardware-isolated instances with dedicated memory controllers, L2 cache slices, and compute units (NVIDIA Corporation 2020). The isolation is enforced at the hardware level, not by time-slicing, reducing noisy-neighbor interference relative to software-only sharing. Changing the partition layout requires stopping affected GPU workloads; the scheduler must include that disruption when adapting profiles to a changing workload mix.

Table 8.6: A100 MIG Profiles: Multi-Instance GPU configurations trade GPU memory and compute resources for increased sharing density. Each profile provides hardware-isolated resources, making MIG suitable for multi-tenant inference clusters where workloads from different teams or customers must not interfere. The streaming multiprocessor (SM) count determines compute throughput within each instance.

MIG profile	GPU memory	SM count	Typical workload
1g.10gb	10 GB	14 SMs	Small inference
2g.20gb	20 GB	28 SMs	Medium inference
3g.40gb	40 GB	42 SMs	Large inference
7g.80gb	80 GB	98 SMs	Training

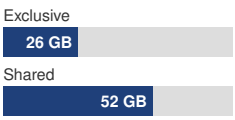
MIG therefore sits at the strong resource-isolation end of this design space. The operational implication is that hardware partitioning reduces cross-workload interference but turns partition choice into a placement constraint. MIG is available on supported MIG-capable NVIDIA data-center GPUs, profiles may require draining affected workloads before reconfiguration, and fixed partition sizes may not match workload requirements. The memory-fit and sharing examples use the displayed device and profile capacities as conservative decimal-GB admission budgets, rather than as conversions of their modeled byte capacities. A workload that needs 15 GB of GPU memory leaves 5 GB of a 20 GB MIG instance budget unused or exceeds a 10 GB instance budget.

Software sharing offers different controls over execution, memory, and fault isolation; these do not form a single performance-versus-security scale. At the simplest level, **CUDA time-slicing** allows multiple processes to share a GPU by context-switching the compute resources. While flexible, it offers weak performance isolation because contexts compete for the entire device over time. NVIDIA's Multi-Process Service (MPS)[14] allows kernels and memory copies from different processes to overlap, reducing context-switch overhead and improving utilization when one process cannot fill the device (NVIDIA 2026d). In the shared-resource MPS configuration considered here, Volta and newer clients have distinct GPU virtual address spaces but compete for execution and memory-system resources. Additional partitioning controls depend on the hardware, software version, and selected mode, and those configured limits, not address-space separation, determine how much performance and fault isolation MPS provides.

GPU memory accounting must still prevent one model from consuming capacity reserved for another. A distinct virtual address space blocks direct addressing of another client's allocations, but it does not create a fixed memory-capacity partition. Without enforceable per-client limits, a memory leak or unexpectedly large batch can exhaust shared device memory and disrupt colocated workloads. MPS therefore fits mutually trusting workloads whose aggregate memory footprint and interference have been measured; MIG or full-device assignment fits stronger trust and predictability requirements. At the host level, CPU core pinning and

[14] **CUDA MPS (Multi-Process Service)**: NVIDIA's runtime supports concurrent CUDA clients, with distinct virtual address spaces on Volta and newer GPUs. Its isolation contract depends on configured resource limits and partitioning support; the shared-resource mode used in this example does not reserve an independent hardware slice for each client. A deployment must also account for its fault domain, since address-space separation alone does not contain every GPU fault (NVIDIA 2026d).

NUMA-aware placement complement these device controls by keeping inference processes off contended cores and away from remote memory, which shortens tail latency whenever those host paths lie on the request's critical path.



The GPU mechanisms form a spectrum from flexible software sharing (time-slicing and MPS) through hardware partitioning (MIG) to exclusive assignment, and each point gives up packing efficiency for isolation (table 8.7). For serving, the choice turns on interference and memory accounting; when colocated workloads belong to different teams, it also becomes a trust-boundary decision, which section 8.11.3 takes up with the rest of multi-tenant security.

Table 8.7: GPU Virtualization Isolation Spectrum: GPU sharing mechanisms trade device-resource isolation against packing efficiency. External tenant isolation additionally depends on the host, driver, identity, network, and storage security boundaries.

Option	Isolation strength	Efficiency and flexibility	Suitable workload or trust boundary
Time-slicing	Separate contexts; shared performance and device fault domains.	Flexible; no spatial reservation.	Trusted, bursty jobs.
MPS	Separate address spaces; shared performance and GPU fault domains.	Concurrent kernels; configurable limits.	Mutually trusting jobs with measured demand.
MIG	Hardware-partitioned memory, cache, and compute.	Predictable; fixed profiles.	SLO-sensitive work; external tenants also need platform security controls.
Full device passthrough	Exclusive access to the GPU.	Strongest device isolation; lowest packing efficiency.	Jobs that saturate the device or forbid sharing.

8.10.2 GPU sharing economics

The decision to co-locate multiple models on a single GPU trades potential capacity savings against interference. Choosing **exclusive access** avoids competition from another device tenant but can leave capacity unused when one workload cannot fill the device. Production evidence suggests such stranded capacity is common. On NERSC's Perlmutter supercomputer, Li et al. (2023) found that 50 percent of jobs used less than 25 percent of their allocated GPU memory. Moving to **aggressive sharing** (via MPS or time-slicing) can admit more work, provided contention does not erase the gain or violate latency objectives. Exclusive device assignment still depends on the surrounding host, driver, identity, network, and storage controls for tenant security. The scheduler must therefore evaluate memory fit and measured service capacity together.

Sharing packs two tenants, cutting the unused memory budget from 67.5 percent to 35 percent.

Using the same conservative admission budget, consider an A100 GPU with a 80 GB memory budget serving a 7B parameter model. The model weights in FP16 consume approximately 14 GB. With the scenario's assumed KV cache and activation overhead, the total runtime footprint is roughly 26 GB. Exclusive access leaves 54 GB (67.5 percent) of the memory budget unused at this load. That

budget is reclaimable only to the extent that it exceeds required runtime and burst headroom. A MIG partition (for example, a `3g.40gb` profile) leaves roughly 35 percent of the assigned partition budget unused; the remaining device capacity is subject to valid partition combinations. Packing two such models onto the same 80 GB device through MPS consumes 52 GB, leaving 35 percent of the device memory budget unused under the same footprint assumption. Reducing the device count also requires enough compute and bandwidth headroom to preserve throughput and latency under concurrent demand; fitting the models in memory is only the first admission condition.

This density introduces interference. When two workloads share execution and memory resources through MPS, their demands can overlap on SMs and memory bandwidth. A compute-bound model paired with a memory-bound model is a candidate for complementary placement because, in isolation, each saturates a different resource, but the bottleneck labels describe isolated behavior, not a guarantee of compatibility. Both workloads still use multiple resources, and concurrent demand can change the limiting resource. The scheduler must measure the pair's throughput and tail latency across its expected load range before treating memory density as usable capacity.

For a heterogeneous fleet, this logic dictates a bifurcated strategy. Our 175B parameter model requires about 350 GB for FP16 weights alone; with the 80 GB per-device admission budget that means at least 5 GPUs before KV cache, activation buffers, runtime workspace, and tensor-parallel granularity are included. In practice, an 8-GPU tensor-parallel replica is the cleaner scheduling unit and is a candidate for exclusive access. Conversely, the dozens of 1B to 7B parameter support models, such as toxicity classifiers, query embedding encoders, and auxiliary generation models, are candidates for sharing. Packing these smaller models onto shared utility nodes frees the high-performance nodes for foundation-model replicas.

Napkin Math 8.4: GPU sharing ROI

Consider a fleet serving 100 distinct 7B models (26 GB footprint each) and 10 distinct 175B models (350 GB footprint each). Assume load testing has established that each proposed co-resident pair meets its throughput and tail-latency objectives with the required headroom and isolation. The memory-utilization percentages use the same conservative admission budgets. The example computes the resulting capacity reduction under the load-testing assumption; memory fit alone would not establish it.

Strategy A (exclusive access, one model per GPU): The 7B models require 100 A100 GPUs (80 GB each), achieving only 32.5 percent memory utilization (100 $\times$ 26 GB used out of 8000 GB total). The 175B models require 80 GPUs (10 models $\times$ 8 GPUs each for tensor parallelism). Total fleet: 180 GPUs.

Strategy B (MPS for small models, exclusive for large): Pack 2 models per A100 for the 7B models (2 $\times$ 26 GB = 52 GB, well within 80 GB), requiring

only 50 GPUs at 65 percent memory utilization. The 175B models remain unchanged at 80 GPUs. Total fleet: 130 GPUs.

Under the load-testing assumption, sharing reduces the required fleet size by 27.8 percent (50 fewer GPUs). At $2/GPU-hour, the released capacity is worth approximately $876,000 annually at the scenario rate. It becomes a cash saving when the organization releases billed resources or avoids purchasing that capacity.

8.10.3 The training-serving resource boundary

Separate training and serving pools simplify capacity ownership but can leave useful work queued beside idle devices. Consider a serving pool reserved for peak traffic while a training pool remains backlogged. This **static partitioning** protects serving capacity from training demand, but unused serving resources cannot help the training queue. **Dynamic sharing** allows that borrowing only when the orchestrator can return ready serving capacity before it is needed. The mode-switching cost determines how much capacity can safely move between the pools.

Repurposing a GPU from training to serving can require saving training state, releasing the old allocation, launching the inference runtime, loading weights, and warming the replica. The orchestrator must measure the complete path to readiness, including any overlap between these operations. If that path takes minutes, reclaiming training capacity cannot cover a burst that exhausts the serving reserve in seconds. Forecasts can schedule transfers ahead of predictable demand, while already-ready headroom covers shorter bursts; the required reserve depends on forecast error and measured reclaim time.

Consider a daily traffic pattern with low demand at 3 AM, growth at 8 AM, a peak at 2 PM, and a decline at 10 PM. A forecast with a 30-minute lead allows the orchestrator to begin reclaiming training allocations at 7:30 AM, provided measured replica startup fits within that lead time. As traffic falls, it drains surplus replicas before returning their devices to training. Pricing that policy against a static split needs three quantities: what serving reserves, what it uses on average, and how much of the difference training can absorb without eroding the surge buffer. The example below assumes its surge buffer suffices; a production policy must size the buffer against its own burst distribution and forecast errors.

Napkin Math 8.5: The diurnal GPU shift

Consider a fleet of 1,024 GPUs managed under two regimes:

Scenario A (static partitioning): The serving pool reserves 400 GPUs. That reservation is the forecast peak of 283 GPUs plus a 117-GPU surge buffer that absorbs forecast error and bursts shorter than a replica's startup time. Average usage is only 150 GPUs (37.5 percent utilization). The training pool takes the rest of the fleet after the serving reservation and 6 GPUs held back as

maintenance headroom, which leaves 618 GPUs, and its backlog keeps them at 100 percent utilization. Result: 150 GPUs + 618 GPUs = 768 active GPUs. Fleet utilization: 75 percent. The maintenance headroom stays unallocated in both scenarios.

Scenario B (dynamic sharing): Serving holds forecast demand (average 150 GPUs) plus the same 117-GPU surge buffer. Training reclaims the rest of the serving reservation, which is the unused 250 GPUs on average minus the buffer and averages 133 GPUs over the course of the day (the medium-blue band in figure 8.15). Because each role switch costs minutes, the orchestrator moves this capacity on the forecast rather than chasing individual traffic spikes. Result: serving (150 GPUs) + training (618 GPUs + 133 GPUs) = 901 active GPUs (the second training term is reclaimed serving capacity). Fleet utilization: 88 percent.

Dynamic sharing recovers 133 GPUs of effective capacity. At $2/GPU-hour, this creates approximately $2.3M per year in value without purchasing a single additional accelerator.

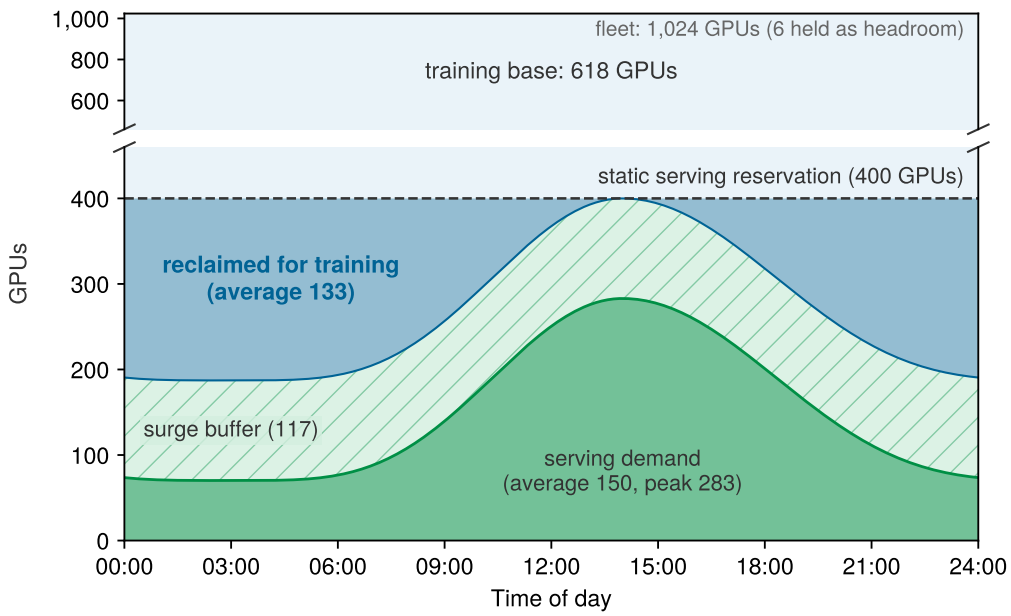


Figure 8.15: Training vs. Serving Diurnal GPU Capacity Shift: One day on the 1,024 GPUs fleet of the diurnal GPU shift notebook, drawn from the same numbers. Serving demand (green) averages 150 GPUs and peaks at 283 GPUs; the orchestrator keeps a 117-GPU surge buffer above the forecast, so the serving side never exceeds the 400 GPUs a static partition would reserve (dashed line). Everything between the buffer and that line returns to training, averaging 133 GPUs over the day, on top of the 618 GPUs training base. The remaining 6 GPUs of maintenance headroom at the top of the fleet are too thin to draw and are named in the upper panel. The shape of the daily curve is illustrative; its average and peak are the notebook's.

Safe sharing requires both a measured interference budget and an enforceable right to reclaim capacity. Isolation mechanisms address the first requirement; they do not decide which team owns a device or when a borrower must release it. That

second requirement is an allocation contract across teams, and it applies to every pool the orchestrator manages, serving and training alike.

8.11 Multi-Tenancy and Quotas

When the computer vision team hoards 500 GPUs for a week while the natural language processing team sits blocked trying to push a critical bug fix to production, shared clusters devolve into a tragedy of the commons. Teams with the most aggressive job submission rates, the largest jobs, or the most persistent resubmission scripts consume disproportionate resources, while teams with more modest or intermittent needs find the cluster perpetually occupied. The result is organizational friction and underinvestment in slower-moving but potentially higher-value projects whose teams cannot compete for capacity on submission volume alone. A static serving reservation faces the same pressure from the other direction, since a training team that sees idle serving devices will want them.

Multi-tenancy and quotas turn organizational priorities into rules for resource allocation, borrowing, and reclamation that the scheduler can enforce. A quota defines an entitlement or a limit. Whether that entitlement becomes prompt, productive access depends on borrowing that lends idle guarantees to other teams and on reclamation that returns them within a bounded time, both developed below. Accounting that separates the capacity a team holds from the capacity it uses well belongs with utilization debugging in section 8.12.1.

8.11.1 Hierarchical fair-share

Assigning fixed GPU quotas at the namespace or project level (for example, 500 GPUs to Team A, 300 to Team B, and 200 to Team C) gives each team a clear entitlement, but leads to systematic underutilization whenever workloads fluctuate. If Team A's 500-GPU allocation sits 50 percent idle during a quiet period while Team B's queue overflows with urgent work, rigid quotas leave 250 GPUs wasted that Team B is forbidden to use. Allocating smaller static quotas to each team creates the opposite failure: teams are blocked from running legitimate work during peak periods even when the cluster has spare capacity overall.

Hierarchical quotas, which Slurm expresses through its account hierarchy and fair-share accounting (equation 8.1) and Kueue through ClusterQueues grouped into borrowing cohorts, separate a team's guaranteed share from its maximum permitted allocation. In equation 8.4, Q_{team} denotes a team's maximum burst cap rather than its guarantee, $Q_{\text{department}}$ is the department's total capacity limit, and $U_{\text{allocated}}$ is each sibling team's current active allocation. Assuming those allocations remain within the department limit, the smaller of the team's burst cap and the department's currently unallocated capacity sets the team's admission ceiling before any reclamation:

$$Q_{\text{effective}} = \min\left(Q_{\text{team}},\, Q_{\text{department}} - \sum_{\text{other teams}} U_{\text{allocated}}\right) \tag{8.4}$$

The second term inside the minimum is what lends idle guarantees across sibling teams. If Team A uses only 60 percent of its 500-GPU guarantee, its active allocation $U_{\text{allocated}}$ drops below its guarantee and leaves the remaining 200 GPUs in $Q_{\text{department}} - \sum_{\text{other teams}} U_{\text{allocated}}$ for sibling teams to claim, up to each borrower's own cap Q_{team}. This ceiling bounds what a team may hold at admission, and it encodes neither fair-share weights nor guarantees. When several teams contend for that spare capacity at once, the scheduler still applies its fairness policy, the dominant-resource calculation of section 8.4.1, to the feasible gangs that fit under each ceiling.

8.11.2 Burst capacity and quota borrowing

Lending turns unused guarantees into burst capacity. Suppose a small team holds a guarantee of 64 GPUs but needs 256 for a weekend-long training run while a sibling team's guaranteed share sits idle. The small team may borrow idle whole devices up to its maximum quota. Those devices remain part of physical cluster capacity rather than becoming virtual capacity, and they carry lower preemption priority than owned resources. When the sibling team submits work that needs its guarantee, the scheduler reclaims the borrowed devices by preempting or shrinking the borrower's opportunistic jobs.

Borrowing resolves that static-quota dilemma only when the lent capacity remains reclaimable within the platform's response-time objective, safety headroom, and current physical capacity. A team entitled to 500 GPUs can reclaim borrowed devices according to that contract, but the scheduler must not promise an immediate 500-GPU allocation when failures, nonpreemptible reservations, or recovery headroom reduce reclaimable capacity.

Burst capacity therefore expands aspirational maxima and fair-share weights, not simultaneous guarantees. The sum of guarantees that the platform promises to honor concurrently must fit reclaimable physical capacity after nonpreemptible reservations and safety headroom. Teams may advertise higher maximums or weights because borrowed jobs yield when guaranteed demand returns, but those values are not guarantees. Fractional sharing is a separate mechanism that requires an explicit MIG, MPS, or time-slicing contract.

Reclamation couples quota policy to the checkpoint infrastructure. The admission controller separates guaranteed jobs from opportunistic jobs. Guaranteed jobs run on the team's owned quota and face preemption only from higher-priority work. Opportunistic jobs run on borrowed capacity, yield first, and must checkpoint often enough that reclamation wastes little work, since every forced reclaim pays the preemption overhead of section 8.8.1. Elastic jobs soften reclamation further through the graceful preemption of section 8.7.2, shrinking one replica at a time toward their minimum viable allocation rather than terminating.

One policy for quota borrowing uses four tiers. Production serving (Priority 0) holds capacity protected from routine preemption. Production training (Priority 1) yields only under a defined serving-failover policy. Interactive and debug sessions (Priority 2) receive short execution limits to preserve iteration speed without indefinite resource occupation. Batch and research tasks (Priority 3) use surplus

capacity and yield under their reclamation contract. These numbers label this example's tiers; they are not Kubernetes priority values, where larger integers indicate higher priority. The hierarchy establishes precedence, but deadline protection still requires feasible capacity and bounded reclamation time, while lower-priority work needs an explicit starvation policy.

As the over-subscription discussion in section 8.4.2 showed, a partly idle device is still a whole allocated device, so the safe burst limit follows from reclaimability rather than average SM utilization. The scheduler must measure how quickly borrowed jobs can checkpoint, shrink, or terminate, and it must reserve the I/O and network bandwidth required for that transition. Only then can it bound the amount of opportunistic capacity that is safe to lend while still honoring the guarantee's response-time objective.

8.11.3 Security and namespace isolation

Teams that share a fleet must also be kept from observing or altering one another's model weights, training data, and inference traffic. A namespace provides only an administrative boundary that host, device, network, and storage controls must enforce. Network policy must cover the collective paths an admitted gang actually uses, and host networking moves the enforcement point off the pod network, so each path needs its own verification.

Across teams, the isolation spectrum of table 8.7 becomes a trust-boundary choice, because colocated workloads now belong to owners with different exposure to one another. Side-channel attacks on shared GPUs are a documented vulnerability; by monitoring contention on shared caches or memory controllers, a malicious tenant can infer the architecture or even data properties of a co-resident model. In sensitive environments, MIG or dedicated devices can strengthen device-resource isolation, but neither creates a complete external-tenant security boundary by itself. A multi-tenant platform combines device partitioning with VM or container isolation, IOMMU configuration, driver and runtime hardening, authentication and authorization, and network and storage controls. Single-organization workloads with a narrower trust boundary can use MPS or time-slicing when weaker fault and performance isolation is acceptable.

↩ Fabric-level isolation, through virtual lanes and traffic classes that keep one job's bursts from stretching another job's collectives, is established in section 3.8.2.

↪ The attack surface of shared accelerators, and which sharing mechanisms leave co-resident tenants observable to one another, is developed in section 13.6.3.

8.11.4 Quota governance and organizational dynamics

Even when a scheduler enforces quotas accurately, a guarantee set six months ago can leave 60 percent of a team's reserved GPUs underused after its flagship model ships while another team's urgent launch queue backs up. While the scheduler manages immediate resource assignments, **quota governance** revises the entitlements and limits those assignments must honor. Periodic **quota review cycles** compare observed use, forecast demand, and the cost of meeting each team's capacity promise. A team using only 40 percent of a 128-GPU guarantee does not necessarily block other teams if unused devices can be borrowed. The governance question is whether the guarantee remains justified and whether its reclamation contract lets the fleet use spare capacity productively between demand peaks.

The central tension in quota management is the **hoarding problem**, in which teams retain idle reservations to avoid queuing again when work becomes ready. A workflow that pauses policy training while awaiting human annotations or a training run delayed by unfinished tokenization can leave its reserved accelerators unused, reflecting dependencies in particular workflows rather than an unavoidable idle phase of all training. Utilization-based reclamation can release idle physical allocations to borrowers, provided the platform preserves any promised return time; revising the team's longer-term guarantee instead requires comparing expected demand with observed use. Clear return contracts reduce the incentive to hold idle devices without making low activity alone grounds for breaking a capacity promise.

Quota accounting should remain close to the scheduling decision. Every admitted job needs an owner, project, workload class, and preemption contract so the scheduler can apply quota and recovery policy consistently, and Kubernetes labels and Slurm accounts carry this scheduling identity. GPU-hours charged against a reservation, borrowed share, or preemption class then make the opportunity cost of hoarding visible and let the control plane reclaim idle guarantees.

Example 8.1: Quota hoarding

Scenario: A research team reserves a static block of 500 GPUs for an upcoming model refresh.

Diagnosis: Upstream data delays postpone training, but the team retains the reservation to ensure future availability. The GPUs sit idle for 3 weeks, accumulating $504,000 in capital waste while other teams' queues back up.

Systems lesson: An idle reservation should trigger a review of lending eligibility and future demand. The orchestrator can admit opportunistic borrowers under a bounded reclamation contract without changing the owner's guarantee. Reducing that guarantee is a separate governance decision; lending owned capacity does not turn it into cloud spot capacity.

A "use it or lose it" reclamation policy addresses the most visible symptom of quota hoarding. Lending idle capacity to another team, however, requires the system to distinguish borrowed capacity that is preemptible on short notice from guaranteed reservations protected by SLOs. Defining borrowing, preemption, and guaranteed tiers as first-class policy primitives is the core multi-tenancy design decision.

Checkpoint 8.4: Multi-tenancy design decisions

Consider a 2,000-GPU cluster shared between a research team (60 percent allocation) and a production team (40 percent allocation):

- ☐ **Idle reclamation**: decide whether the production team can borrow the research team's allocation while half of it sits idle, and describe the preemption behavior when the research team submits a large job.
- ☐ **Priority classes**: configure priority classes for a production inference workload that needs 100 GPUs with guaranteed latency SLOs and a research training job that can tolerate preemption.
- ☐ **Sharing contract**: explain why 65 percent average SM utilization does not justify whole-device overcommitment, then identify which measured resource and isolation constraints would make statistical multiplexing safe.

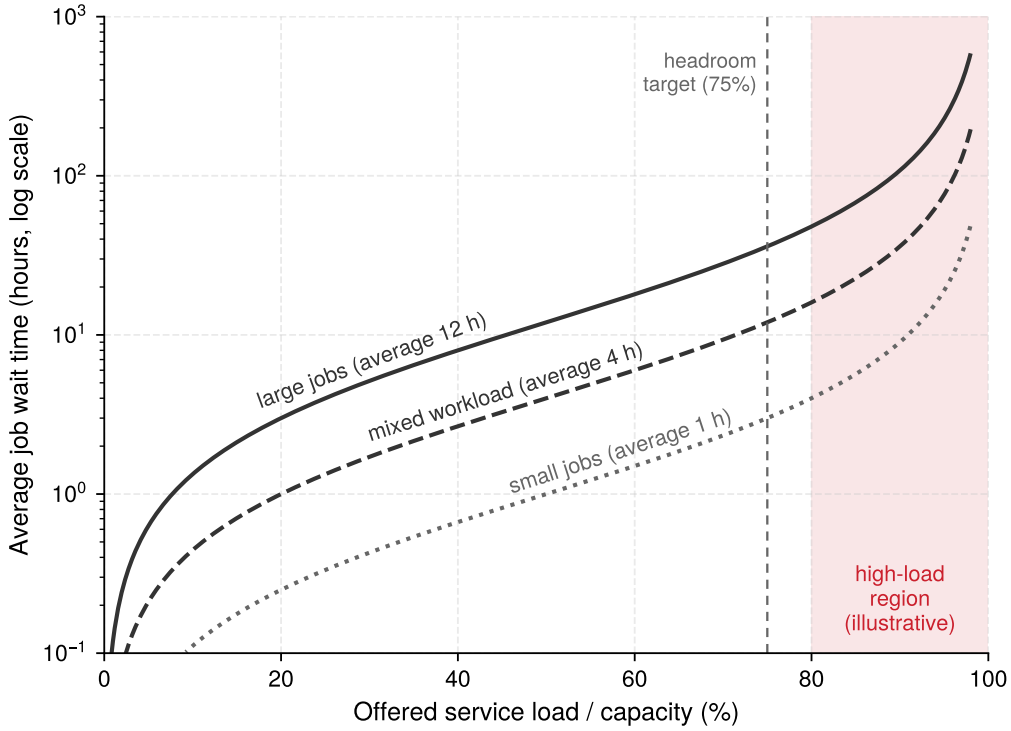
Even with isolation, quotas, and dynamic sharing in place, a cluster can report low utilization beside a full queue. Top-level dashboards rarely explain why pending jobs cannot claim the free devices. Locating that loss requires systematic utilization debugging across hardware pools, scheduler constraints, and user request habits.

8.12 Debugging Cluster Utilization

A cluster dashboard shows average GPU utilization stuck at 60 percent, yet developers complain about three-day queue times for small debugging jobs. Hundreds of GPUs sit idle, but no jobs are starting. Explaining the gap requires tracing the interactions among hardware topology, scheduler policies, and user behavior. Part of the paradox is the queueing arithmetic of notebook 8.1. The $\rho_{\text{serv}}/(1-\rho_{\text{serv}})$ factor grows without bound as offered load approaches service capacity, so mean wait rises gently through moderate load and then steeply above 80 percent for small, mixed, and large workloads alike (figure 8.16, plotted on a logarithmic scale). The curves use the notebook's exponential reference case ($c_s = 1$), so they are the gentlest version of the effect. A mixed ML queue with the notebook's representative $c_s = 3$ multiplies every curve by the larger variability factor, shifting each one upward without changing where it bends. The curves also describe offered service load rather than allocated or kernel-active GPU percentages, and their 75 percent headroom marker is an illustrative choice rather than a universal cluster threshold. Queueing explains why a busy fleet waits. A fleet whose queue is full while devices sit idle is waiting for a different reason, and finding it requires looking past the dashboard.

8.12.1 Allocated, active, and productive utilization

The 64 GPUs that sat idle for a weekend because a researcher forgot to cancel a reservation represent invisible waste in a multi-tenant cloud fleet. In a dedicated cluster, such waste is at least visible to the team that owns the hardware. In a shared environment, the cost is hidden and compounds across thousands of jobs. Effective governance requires moving beyond simple "allocation" metrics to a tiered accounting model that distinguishes between what was requested, what was used, and what was useful.



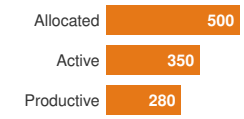


Figure 8.16: The Utilization Paradox: As cluster utilization approaches saturation (100 percent), job wait times increase hyperbolically and diverge near saturation, not linearly. The shaded region above 80 percent and the dashed 75 percent target illustrate headroom choices in this toy queue model, not measured GPU-utilization thresholds. Real queue delay also depends on job sizes, gang constraints, and arrival variability.

Three tiers of measurement expose this gap between requested hardware and actual progress. Allocated capacity counts resources held by complete allocations, so devices assigned to a gang that still waits for its remaining members do not count. Active utilization measures hardware activity under a stated counter definition, which can include communication kernels or work later replayed. Productive utilization requires a workload-level measure of retained training progress or serving work that meets its objective, normalized to the job's own fault-free step rate. For example, a team allocated 500 GPUs might average 350 active-device equivalents (70 percent activity) while delivering 280 device-equivalents of useful work at its fault-free rate (56 percent of its allocation). These are time-averaged equivalents, not necessarily distinct sets of active and productive devices. The gap motivates profiling; it does not identify its cause or imply that necessary communication and recovery can all be eliminated. Section 9.2.3 uses the allocated and productive tiers as the boundaries of scheduling and runtime goodput.

Allocated, active, and productive capacity in GPU equivalents, each tier counting less than the one above.

This data feeds the utilization dashboard, the cluster operator's primary instrument for fleet health. This view must synthesize per-team utilization against quotas, queue depth by priority class, and the **fragmentation index**, a measure of free GPUs that cannot be allocated due to topology constraints. It must also track preemption rates, spot interruptions, checkpoint traffic, and the recovery overhead

they induce. These measurements let the scheduler distinguish idle capacity it can reclaim from allocated capacity whose apparent idleness reflects communication, I/O, or a rigid gang dependency.

Automated anomaly detection turns these metrics into investigation triggers. A sudden spike in a team's consumption to 3× its historical norm might reflect a runaway submission script or an intentional experiment. A growing queue can indicate insufficient capacity, but it can also reflect quota limits, fragmented placements, or a stalled dependency. A sudden power drop can accompany a shared storage stall, though job completions and changes in workload mix can produce a similar signal. Operators must correlate these alerts with admission decisions and job progress before changing capacity or policy.

> **Systems Perspective 8.5: The three utilization metrics**
>
> Each tier narrows the investigation. Low allocated utilization calls for checking demand, quotas, device health, and placement feasibility. Low active utilization on allocated devices calls for tracing input supply, communication waits, and runtime execution. Low productive utilization despite busy kernels calls for comparing retained progress with replay, synchronization, and other overhead. The metric selects the next evidence to collect; it does not by itself select the remedy.

8.12.2 Policy-infrastructure mismatch

When a cluster adds a new generation of high-memory GPUs alongside older pools, job templates written for the newest hardware can leave the older pools sitting idle while dozens of jobs queue behind the newest partition. Diagnosing this **policy-infrastructure mismatch** requires comparing scheduler state with physical capability and inspecting job requests against each hardware pool. A full queue and idle accelerators can coexist when the scheduler is honoring constraints that the top-level dashboard has aggregated away. The cluster at the center of example 8.2 runs the heterogeneous hardware in table 8.8, accumulated across three procurement cycles.

Table 8.8: Cluster Hardware Inventory: Three procurement generations create distinct resource pools with different capabilities. In this inventory, A100 nodes have NVLink and the V100 pool uses PCIe. That difference changes tensor-parallel communication cost; it does not make tensor parallelism impossible on V100 devices.

GPU type	Count	Memory	Interconnect	Nodes
A100-80 GB	400 GPUs	80 GB HBM2e	NVLink (600 GB/s)	50 nodes × 8 GPUs
A100-40 GB	424 GPUs	40 GB HBM2e	NVLink (600 GB/s)	53 nodes × 8 GPUs

GPU type	Count	Memory	Interconnect	Nodes
V100-32 GB	200 GPUs	32 GB HBM2	PCIe Gen3 (15.8 GB/s)	50 nodes × 4 GPUs

Example 8.2: Debugging low GPU utilization

Scenario: A 1,024-GPU cluster reports 60 percent average utilization despite over 50 pending jobs in queue.

Diagnosis: Over-specification (users copying A100-80 GB templates for 35 GB memory jobs), pool fragmentation, and legacy V100 avoidance leave A100-40 GB and V100 nodes idle while large jobs wait for A100-80 GB allocations. The scheduler correctly enforced policies written for a homogeneous fleet that no longer matched the heterogeneous infrastructure.

Systems lesson: Surface-level diagnosis often mistakes policy-infrastructure mismatches for scheduling algorithm bugs. Updating scheduler policies to support automatic capability matching, dynamic memory profiling, and backfilling raises cluster utilization to 84 percent, recovering $7M in annual compute capacity. Table 8.9 breaks that gain out pool by pool, using the allocated and active tiers of section 8.12.1.

Table 8.9: Utilization Recovery Results: Before the fix, A100-80 GB GPUs were almost fully allocated but less than fully active, while strict job templates stranded the other pools. Pool rows report allocated utilization, and for the A100-80 GB pool also the active share of its allocated GPUs; the A100-80 GB change is in that active share, the others in allocation. The cluster-wide row is the fleet's separately observed average utilization, so the pool rows are diagnostic signals that locate the loss rather than terms that add up to the total.

Pool	Before	After	Change
A100-80 GB	95% allocated, 72% active	89% allocated, 94% active	+22 pp
A100-40 GB	64% allocated	88% allocated	+24 pp
V100	0% allocated	71% allocated	+71 pp
Cluster-wide	**60%**	**84%**	**+24 pp**

For this capacity valuation, assume that each active GPU-hour delivers the same retained useful work before and after the policy change, including across hardware pools. Under that simplifying assumption, the observed utilization gain is equivalent to approximately 246 fully active GPUs of productive work (table 8.9). A heterogeneous production fleet must validate that conversion against workload

progress and measured throughput in each pool. As at the start of the chapter, procurement planning compares the gain with the hardware it replaces, here 410 additional raw GPUs, because new devices under the old policies would also run at only 60 percent utilization. At $2/GPU-hour, that avoided purchase represents approximately $7M in annual recovered value, achieved through policy changes requiring zero additional hardware investment.

8.12.3 Common utilization anti-patterns

Fixing policy-infrastructure mismatches gets queued jobs onto GPUs, but a dashboard reporting 85 percent allocation still says only how much capacity is assigned, not whether those allocations deliver productive work. Inside allocated capacity, four runtime patterns commonly widen the gap between the allocated, active, and productive tiers, and separating them requires correlating device telemetry with execution timelines.

A zombie job retains an allocation after its useful execution has stopped. In a distributed run training a 175B parameter model, a rank failure can leave a 128-GPU group idle if worker cleanup or failure propagation does not complete. The surviving ranks may block inside a collective that will never finish, or a process left behind by a driver-level fault may resist reaping by the container runtime, so the devices stay allocated until a timeout or node-level remediation clears them. Persistent memory allocation combined with low SM activity is an investigation signal, not proof of a driver fault; valid input or communication waits can look similar. The operator must compare runtime health, step progress, and the workload's timeout contract, then verify that old workers have stopped before releasing or reassigning their devices.

The data starvation pattern manifests as a high-frequency sawtooth wave in GPU utilization, where the device oscillates between 100 percent load (forward/backward pass) and 0 percent load (waiting for the next batch). While the average utilization might appear acceptable at 60 to 70 percent, the GPU is effectively idling for a third of its life. This occurs when the CPU-bound data pipeline cannot sustain the throughput required by the GPU, a common scenario in computer vision where JPEG decoding and augmentation saturate host CPUs. The data stall ratio of equation 4.4 quantifies the loss as the fraction of each step spent waiting for input. A timeline that aligns the idle intervals with input waits supports the diagnosis; utilization variance alone does not identify the cause. The remedy depends on whether decoding, storage, or transfer limits the input path.

A communication bottleneck can leave ranks waiting for collectives, though communication kernels can also keep SM activity high. Per-rank gradient traffic depends on gradient precision, sharding, and the parallelism layout, so the ratio of step time to compute-only time (forward plus backward passes in isolation) is a quicker first bound on exposed overhead. If total iteration time exceeds $1.5\times$ compute-only time, non-compute overhead exceeds $0.5\times$ compute time, which is material but not dominant. Setting $T_{\text{sync}}(N)$ and T_{overlap} to zero in the Fleet Law (equation 1.3) leaves $T_{\text{step}}(N) = T_{\text{compute}}/N + T_{\text{comm}}(N)$, under which communication exceeds per-device computation only when the ratio is greater than $2\times$.

Real steps also contain synchronization waits and input stalls, so profiling must separate communication from those before the ratio is read as a communication diagnosis. Placement can reduce exposed communication when it improves the relevant paths. Gradient accumulation can reduce synchronization frequency only when the runtime defers gradient exchange across accumulation steps.

Memory fragmentation can prevent a serving replica from admitting new requests even when its HBM occupancy suggests free capacity. The KV-cache allocator, rather than the aggregate occupancy percentage, decides whether a new sequence fits in contiguous or paged memory blocks. For the fleet scheduler, the allocator matters through its result, the number of concurrent requests a replica can hold, because that measured capacity sets how many replicas the serving envelope needs.

↪ Paged KV-cache allocation and its effect on replica concurrency are developed in section 10.7.3.

The debugging example connects scheduling mechanics to fleet governance. Technical policies (GPU type matching, gang scheduling timeouts, preemption grace periods) interact with organizational policies (team quotas, priority hierarchies, cost allocation) and human behavior (job template reuse, resource request habits, queue submission patterns). Effective fleet orchestration requires attending to all three layers simultaneously, because the most expensive scheduling bug is often not a software defect but a policy that was correct for the old infrastructure and was never updated for the new one.

8.13 Fallacies and Pitfalls

Those policy-infrastructure mismatches recur as a small set of misconceptions that can make an apparently healthy scheduler waste expensive fleet capacity. A cluster running at 98 percent utilization can look healthy while researchers have stopped submitting jobs because wait times have stretched into weeks. Each misconception below follows the same pattern, in which optimizing one visible metric degrades the outcome the fleet exists to deliver.

Fallacy: *More sophisticated scheduling algorithms always improve utilization.*

Engineers facing low utilization often reach for more advanced schedulers, assuming the algorithm is the bottleneck. As the debugging example in section 8.12 demonstrates, the root cause is frequently policy misconfiguration, not algorithmic limitation. A simple FIFO scheduler with correct policies (capability-based matching, backfill with timeouts, appropriate gang scheduling constraints) often outperforms a sophisticated scheduler with incorrect policies. Before upgrading the scheduler, audit the policies: confirm that users are not requesting resources they do not need, that heterogeneous resources are properly exposed, and that gang-scheduling timeouts are configured. The audit recurs as workloads evolve, because a preemption grace period that suffices for one model can be too short for another to save state, and placement weights suited to an earlier topology can strand capacity after an expansion.

Pitfall: *Treating all GPU-hours as equal when measuring utilization.*

An unlabeled "GPU utilization" percentage can conflate allocation with activity or useful work. For example, 80 percent of fleet capacity might be assigned to jobs while 15 percent of the fleet sits in groups still waiting for their remaining members and another 5 percent waits for input. Only 65 percent is then allocated to complete groups, and at most 60 percent executes useful training in that snapshot. Such a breakdown comes from scheduler and runtime evidence, which an activity counter cannot supply. The allocated, active, and productive tiers of section 8.12.1 keep these measurements distinct, with productive capacity tied to a stated workload objective and the job's fault-free rate.

Fallacy: *Gang scheduling is always necessary for distributed training.*

Gang scheduling prevents partial-allocation deadlock for a rigid synchronous group, but the required group need not equal the job's maximum requested size. Asynchronous workers may progress independently, while elastic training can begin with its minimum viable gang and resize at supported boundaries. Independent hyperparameter trials can also run separately. The scheduler gains flexibility by admitting the actual unit of progress, while preserving atomic allocation wherever synchronous dependencies require it. Changes to worker count or synchronization policy still require convergence validation.

Pitfall: *Setting static quotas based on peak demand.*

Organizations commonly set team quotas to handle worst-case demand, reasoning that teams need guaranteed access during crunch periods. If Team A's peak demand is 500 GPUs and Team B's is 300 GPUs, the cluster needs 800 GPUs with static quotas. In practice, peaks rarely coincide. A 600-GPU cluster can accommodate either peak when the other team's simultaneous demand leaves enough capacity, but it cannot guarantee both peaks concurrently. Hierarchical fair-share with borrowing uses that statistical opportunity only when the declared guarantees fit physical capacity and borrowed work can yield within the reclamation contract. In this example, sizing static quotas to the sum of the peaks provisions 200 GPUs, a quarter of the 800-GPU cluster, as guarantees that sit unused whenever the peaks do not coincide.

Fallacy: *Spot instances are always cheaper for training.*

Actual savings depend on the billed overhead each interruption adds, not on the scenario's 60 to 90 percent discount band. Consider 15-minute checkpoint overhead to slow storage and 30-minute restart overhead to reacquire capacity and reload, far longer than a restart on a cluster's own file system, totaling 45 minutes of billed nonproductive time per event. If each event follows 2 hours of retained training progress, the nominal 65 percent discount becomes about 52 percent savings under the fixed-allocation model. This illustration assumes a successful save and no replay; a real interruption budget must also include discarded progress when the save cannot finish. The scheduler must separately account for unbilled capacity waits when evaluating deadlines. Sufficient billed overhead can erase the discount, regardless of the advertised rate.

Pitfall: *Ignoring topology when scheduling distributed training.*

Schedulers that ignore connectivity can place communication-intensive groups across paths with less available bandwidth or more contention. On a fleet with NVLink confined to each node, spreading a tensor-parallel group across nodes moves its traffic onto the inter-node fabric; other hardware can expose larger NVLink domains. Crossing a spine switch does not itself prove congestion, so the placement decision must compare effective path capacity and competing traffic. A measured throughput penalty accumulates over a long run and may exceed the delay of waiting for a more suitable allocation. The scheduler must weigh that gain against queue delay and fragmentation.

Pitfall: *Using elastic training to avoid gang-scheduling decisions.*

Elastic training complements gang scheduling by moving between viable execution groups. With a fixed 8-way tensor-parallel layout, each group still requires eight workers; changing the number of data-parallel replicas does not relax that requirement. A runtime that changes the tensor or pipeline layout must also redistribute state and establish a new viable group. The scheduler must honor the supported resize granularity, atomic admission requirements, and placement budget for each configuration. Elasticity adds feasible choices; it does not make an incomplete group productive or an arbitrary placement efficient.

Pitfall: *Treating high utilization as proof of cluster health.*

A high allocated-GPU percentage does not establish that the cluster has enough headroom to admit new work promptly, because waiting time climbs steeply as offered load nears capacity (figure 8.16). That queueing model does not turn a GPU-busy percentage into a prediction for a gang-scheduled fleet. Real headroom targets depend on arrival bursts, job sizes, placement constraints, and the queue-delay or serving-latency objective. Measuring those outcomes instead of applying a universal utilization threshold keeps platform teams from optimizations that improve a dashboard metric while delaying the work the fleet exists to complete.

8.14 Summary

Fleet orchestration turns data center capacity into useful ML work by deciding which jobs hold which accelerators, where, and for how long. Orchestration spends Coordination, the third axis of C^3, so that Compute and Communication capacity turn into useful progress. In Fleet Law terms (equation 1.3), placement sets the communication term $T_{\text{comm}}(N)$ of every step, and preemption and recovery, amortized over the run, enter the coordination term $T_{\text{sync}}(N)$. Queue wait and gang admission are coordination costs too, but they delay the first step rather than lengthening any step, so they appear in end-to-end completion time rather than in the per-step Fleet Law. Multi-tenancy and quota policy decide how much of that time allocated compute spends doing useful work. Hardware capability sets the feasible choices; the scheduler turns those choices into useful allocations by preserving ownership, coordinating recovery, and matching placement to workload demand.

Feasibility is the first filter. Gang size, topology locality, multi-dimensional fit, and accelerator compatibility decide which allocations a job can actually run, and only then can a fairness policy choose among them (principle 15). Quota borrowing extends the same reasoning across teams, since a guarantee is worth what the platform can reclaim within its response-time objective rather than the number printed on the quota.

Placement changes the physical paths available to a workload. Aligning model parallelism with the network hierarchy reduces exposed communication when placement is the binding constraint, but it cannot create fabric capacity that is not there. Elastic resizing and spot capacity widen the set of feasible choices by trading worker continuity for flexibility and price. ML-aware schedulers sharpen the choice among them with workload signals such as attained service, iteration boundaries, finish-time ratios, and goodput. Every one of these levers pays a transition or integration cost that must be measured against the progress it buys.

At serving time, the fleet scheduler preserves a capacity envelope of indivisible replicas with SLO headroom and moves the training-serving boundary on measured demand, leaving request-level routing and batching to the serving system. When that envelope, the quotas around it, or the placements inside it go wrong, the visible symptom is usually a full queue beside idle accelerators. In practice, the root cause is more often a policy written for an earlier fleet than a defect in the scheduling algorithm.

Key Takeaways: Scheduling is systems engineering

- **Distributed scheduling is hard**: Cluster scheduling must coordinate allocation ownership across machines despite partial failures, network partitions, and stale observations. Control planes balance prompt recovery against the risk of authorizing a replacement while an old worker still runs.
- **Gang scheduling prevents deadlock but reduces flexibility**: Gang scheduling gives rigid execution groups atomic resource allocation to prevent hold-and-wait deadlocks, while backfilling and elastic resizing recover flexibility within the job's minimum viable gang and transition constraints.
- **Fairness is measured over feasible bundles**: DRF equalizes each tenant's dominant normalized share across GPUs, CPU, memory, and network, but only among bundles that already pass gang, topology, and compatibility constraints (principle 15). Slowdown and maximum feasible wait test whether the resulting policy avoids delay and starvation, and a quota guarantee holds only as far as lent capacity can be reclaimed in time.
- **Topology determines performance**: Where GPUs are placed within the cluster hierarchy changes the communication paths available to a job. Locality can reduce exposed communication, but waiting for a compact

placement also costs time; compare end-to-end completion rather than iteration throughput alone.

- **Scheduling signals must match the objective**: Workload characteristics support different improvements: attained service addresses runtime uncertainty, iteration boundaries reduce interruption cost, finish-time ratios expose unfair delay, and goodput guides adaptive allocation. Each policy requires validation against the fleet's workload mix and recovery costs.
- **Useful utilization creates economic capacity**: Reducing avoidable idle time can deliver more useful work from an existing fleet. Distinguish allocated, active, and productive capacity before valuing an improvement, and preserve the headroom required for recovery and latency targets.
- **Policies must evolve with infrastructure**: Scheduling algorithms are only as effective as the policies they implement. When infrastructure changes (heterogeneous hardware additions, topology upgrades, workload mix shifts), policies must be re-evaluated and updated.

The same placement decision makes the displacement of overhead (principle 14) concrete. Co-locating a tensor-parallel gang keeps its collectives on NVLink and shrinks the exposed communication of every step, but the scheduler pays for that locality in coordination time while it waits for a feasible contiguous allocation. The bottleneck moves from collective bandwidth to queue delay or fragmentation rather than disappearing, so the right placement is the one that minimizes end-to-end completion time, not iteration time alone.

What's Next: From allocation to useful work

An allocation is the start of fleet efficiency, not evidence of it. A training job can hold a complete allocation while it restarts, waits for input, or exposes communication in every step. A serving replica can hold a full node while its decode steps stream weights and leave most of its arithmetic idle. The productive tier says how much of an allocation became useful work but not which part of a job's life lost the rest. The owners of scheduling, recovery, and execution therefore each see their own loss, and none can see which is largest. Those separate reports become one product whose levers can be compared once every hour of capacity is followed from the moment the fleet offers it until it becomes useful work, with each loss charged to the boundary where it occurs.

↪ How much of an allocation becomes useful work, and whether scheduling, runtime, or the program loses the rest, is developed in chapter 9.

III

THE FLEET IN PRODUCTION

Part III

8

Fleet-in-Production Principles

Parts I and II built the fleet, coordinated its distributed state, and executed the training run. Training, however, opens a model's lifecycle rather than completing it, and production deployment is where the model must repay its cost under real demand. Part III shifts the focus from the single, large training run orchestrated across a dedicated cluster to the deployed fleet. That fleet comprises the thousands of geographically distributed servers that answer requests in real time, the billions of edge devices that run and adapt models locally, and the operational machinery that keeps every deployed version accountable. The transition changes the engineering constraints. A training run must finish a coordinated workload. A deployed fleet must sustain useful throughput on a dynamic request stream while meeting latency targets, keep models current as data and devices change, and govern how each change reaches production.

A serving fleet depends on the runtime behavior of each replica (one deployed copy of the model, potentially spread across devices), whose execution time and memory footprint determine how many requests it can accept and how much capacity the fleet must provision. Part III therefore begins with fleet efficiency, which follows the fleet's capacity through scheduling, runtime, and execution to measure how much of it becomes useful work. Serving at scale uses that measured capacity to coordinate request queues, batching, serving precision, and distributed model state. Edge intelligence extends the argument to fleets of varied client devices with intermittent connectivity, including federated learning that coordinates training while data remains on participating devices. Production operations then governs rollout, monitoring, and recovery across the deployed fleet.

The principles below preview the constraints that each chapter of Part III makes quantitative, turning replica-level mechanisms into fleet-wide capacity and latency models rather than assuming that local efficiency alone guarantees an efficient fleet. Before optimizing any serving mechanism, the part establishes a measure of how much of a fleet's capacity becomes useful work. Without an end-to-end accounting rule, losses in cluster scheduling, runtime recovery, and kernel execution hide behind separate team metrics.

Principle 16: The ML goodput decomposition

Invariant: A fleet's ML productivity goodput, the fraction of its capacity-time that becomes useful work, is the product of three factors, each counted at a stated boundary so that every loss belongs to exactly one. Scheduling goodput $\eta_{\text{scheduling}}$ is the share of capacity held by complete allocations. Runtime goodput η_{runtime} is the share of allocated time retained as progress after startup, input stalls, checkpoint pauses, restarts, and rework. Program goodput η_{program} is the fraction of the ideal rate that retained steps achieve, measured as MFU.

$$\text{MPG} = \eta_{\text{scheduling}} \times \eta_{\text{runtime}} \times \eta_{\text{program}}$$

Implication: Lost capacity must be located before it is recovered, because each factor has a different owner. A faster kernel recovers nothing that a job loses waiting for a complete gang, and a better scheduler recovers nothing that a job loses running below its hardware's rate. A change that moves a loss from one factor to another helps only if the product rises. The decomposition applies to a training step and to a serving replica alike; serving adds the latency targets that each completed request must meet.

Over a deployed model's lifetime, serving can consume more of that capacity than training did, and serving also carries the book's scaling thesis into the request path. When quality is bought with test-time compute, by spending more computation on each query, the scaling curve that drove the training fleet moves into serving, and its cost recurs with every request.

Principle 17: Serving cost dominance

Invariant: For high-traffic production models, cumulative inference cost can exceed the one-time training cost over the model's lifetime.

Implication: Inference efficiency often becomes the dominant lifecycle optimization target. When traffic volume, product lifetime, and retraining cadence make serving cost dominate, engineers should focus quantization, distillation, and sparsity on the inference path. The quantity to reduce is the cost per completed request at a fixed quality and latency target, not the cost of an individual operation.

Within each request, the mechanics of generation impose the first limit. Autoregressive generation produces each new token from the preceding tokens while a key-value cache retains intermediate attention state for reuse, so a single serving replica can saturate either memory bandwidth or memory capacity long before its arithmetic units are full.

Principle 18: The autoregressive bottleneck

Invariant: In low-batch dense transformer decode, weight streaming often makes throughput memory-bandwidth bound because every decode step must stream the model weights from device memory to the compute units. Higher batch sizes amortize weight streaming, and key-value (KV) cache traffic shifts the binding constraint at long context.

Implication: Throughput initially improves with batch size by amortizing weight reads across requests, until per-device latency budgets, KV cache capacity, or sustained compute become the binding ceiling. Serving systems therefore need batching, cache-management, and memory-layout policies that keep bandwidth useful without violating latency SLOs.

At scale, routing policy becomes another lever for protecting latency. Even well-tuned replicas develop long queues if incoming queries land on busy servers while neighboring replicas have spare capacity.

Principle 19: The power of two choices (P2C)

Invariant: In the idealized process that sequentially places R independent requests into R replicas, with each request sampling replicas independently and uniformly at random, querying two replicas and selecting the least-loaded one reduces the maximum load from the one-choice bound $\Theta(\log R / \log \log R)$ to $\Theta(\log \log R)$ with high probability.

Implication: Simple randomized load-balancing algorithms produce dramatically lower maximum-load bounds with $\mathcal{O}(1)$ coordination overhead. Under serving queueing assumptions, the lower maximum load translates into reduced tail latency at scale. Serving requests differ widely in remaining work and load probes go stale, so the two probes must read a work signal, such as active tokens or KV-cache pressure, rather than a request count.

Moving learning onto phones and other battery-powered devices adds a constraint that no data-center scheduler faces. The device belongs to its user, so background learning runs only when the device can spare it.

Principle 20: The participation selection principle

Invariant: An edge device contributes to on-device or federated learning only in windows its admission policy accepts, when the predicted update energy fits the remaining energy slack, the added power stays within the thermal limit, and foreground latency still meets its deadline (equation 11.2). Those conditions correlate with hardware class, charging habits, and connectivity, so the population a shared model learns from is the admitted population, not the deployed one.

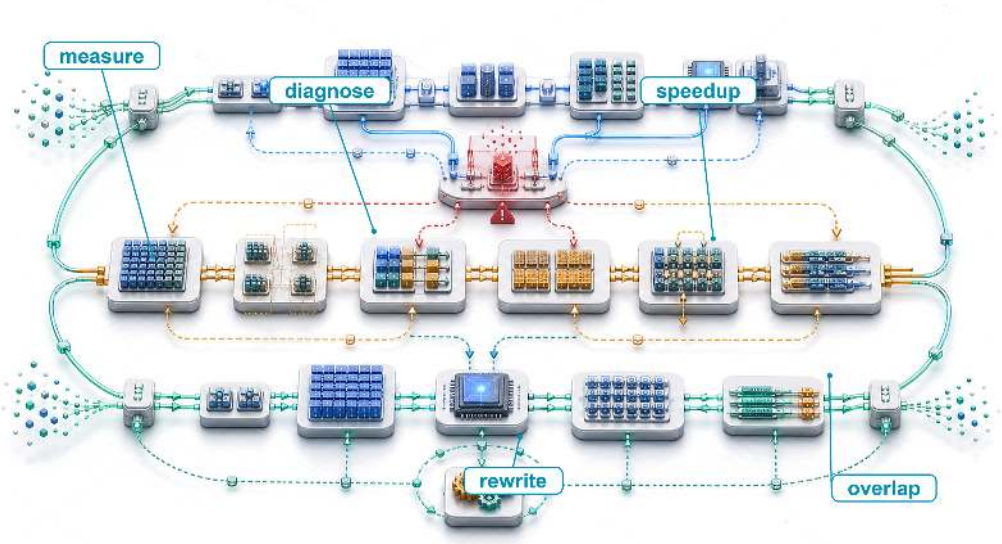
Implication: The admission policy that protects each device also selects the training population, which makes admission a fairness decision as well as a resource decision. A fleet must measure participation and completion rates per device and user cohort against the deployed population and correct the skew through stratified selection, participation quotas, or reweighting. Loosening admission is not a remedy, because it spends the energy, thermal, and latency budgets the policy exists to protect.

Whether a model is trained in the data center or across a population of devices, every change must eventually be released to the deployed fleet, and at fleet scale that release needs a single standard of evidence. Shipping a candidate on scattered benchmarks or informal spot checks leaves operators unable to tell whether a production incident reflects a bad release or an unmeasured shift in traffic.

Principle 21: The evaluation contract principle

Invariant: At fleet scale, a release decision is valid only when all of its evidence refers to one versioned evaluation contract that pins the model and its dependencies, the workload, the metrics and statistical design, the acceptance thresholds, the rollback conditions, and the accountable owners. Reliability under that contract is a vector of budgets over availability, latency, freshness, and quality. With B_i denoting the fraction of observations that violate target i divided by the violating fraction that target allows, the service is inside its reliability envelope only when

$$\max_i B_i \leq 1.$$



Implication: No single accuracy number can authorize a release. Averaging the dimensions would hide a quality regression behind perfect uptime, and evidence gathered on different datasets, load profiles, or configurations certifies no single candidate. Thresholds and rollback conditions are fixed before exposure, an exhausted budget in any dimension stops promotion, and a change that leaves the contract's validated envelope reopens the decision.

Part III takes the trained model from the cluster to the world. The path begins with fleet efficiency, which charges every lost hour of capacity to scheduling, runtime, or the program and so determines how much of the fleet's capacity becomes useful work. It then moves to serving at scale, where request batching, cache management, serving precision, routing, and sharding turn single-device efficiency into fleet-level latency control. Edge intelligence extends this discipline to phone-class devices that adapt models locally and coordinate through federated learning under unequal memory, power, and connectivity budgets. Operations at scale closes the loop by monitoring the deployed fleet, coordinating platform ownership, and responding when production behavior diverges from design

assumptions. Measured against the Fleet Law, these chapters shift from the training step to the serving request. Fleet efficiency charges each term of a step to the factor that loses it and shrinks the exposed ones. Serving at scale trades batching against the queueing and routing delays that play the role of $T_{\text{sync}}(N)$. Edge intelligence faces communication costs set by intermittent wireless links rather than a data-center fabric. Operations bounds the coordination cost of every rollout and rollback. Together, these chapters develop the operational discipline that turns a trained model into a durable production system.

Purpose

Why can a fleet that is fully allocated and visibly busy still turn only a fraction of its compute into training progress and served requests?

Expensive accelerators can spend much of a training step or a request waiting for data, software dispatch, or communication while their arithmetic units remain underused. Adding more machines may raise cost without removing the delay, and a faster isolated kernel may leave the step's or request's critical path unchanged. The engineering stakes are useful fleet capacity, the training progress and completed service an existing fleet produces while preserving model quality. A dashboard that counts every held accelerator as busy cannot see that waste, so a fleet can look fully used while turning only a fraction of its capacity into useful work. These interactions make optimization a question of measured constraints rather than a search for the fastest component. On one machine, a local improvement can be tested against a relatively contained execution path. Across a fleet, its value also depends on scheduling, recovery, communication, synchronization, and the distribution of work across devices. The cost of a mistaken diagnosis grows when the same inefficient execution repeats across many replicas and many weeks of training, and when the remedy is applied by a team that does not own the loss. A

saving that looks large in isolation is worth only the part that survives along the complete step or request path. In C^3 terms, fleet efficiency holds every compute gain accountable to the communication and coordination costs that decide how much of a fleet's capacity becomes useful work.

Learning Objectives

- Explain how a job's or fleet's useful output decomposes into scheduling, runtime, and program goodput, with each loss charged to exactly one factor
- Measure goodput under a reproducible contract and localize the lost factor from scheduler records, job timelines, and step traces
- Attribute scheduling and runtime losses using the owners' results, without re-deriving them
- Measure program goodput with MFU and MBU and find the Fleet Law term a fix must shorten
- Select fleet-level program levers (compiler partitioning, overlap under contention, compilation) and recognize kernel-level levers by the term they shorten
- Evaluate a change that trades one factor against another by its effect on the product, and place the result on the efficiency frontier

9.1 Where Fleet Capacity Goes

A fleet can be fully allocated and visibly busy while most of its capacity never becomes training progress or completed service. When thousands of accelerators run a single workload, losses accumulate before a job starts, between the steps it executes, and inside the steps it keeps. The size of that gap is clearest in a run whose engineering is not in doubt.

Lighthouse 9.1: Archetype A (GPT-4/Llama-3): Held capacity versus progress

Meta's pretraining of Llama 3 405B on 16,384 H100 GPUs is one of the best-documented large training runs, and its two most quoted efficiency numbers measure different things. Across a 54-day snapshot, the job kept more than 90 percent of its elapsed time as effective training time despite hundreds of unexpected interruptions, as section 7.9.4 records. In the steps it kept, its arithmetic achieved a model FLOPs utilization (MFU) of about 41 percent of the accelerators' peak rate (Dubey et al. 2024). Multiplied, the two figures show the run turning roughly 37 percent of the peak-rate capacity it held into training progress. Because the two figures come from different measurement windows, the product is only an estimate. Yet it shows one of the most carefully engineered runs on record losing about two-thirds of the capacity it held, mostly to steps that ran below the hardware's rate rather than to the failures that dominate its reputation. Its two figures therefore bound what a well-run job of this archetype loses during execution.

Even that one-third figure overstates what a shared cluster delivers, because the Llama 3 numbers begin only after the job holds its accelerators. On a multi-tenant fleet, the setting of chapter 8, capacity is also lost before a job starts. Accelerators sit unallocated when no queued job fits the free pool, or a job holds part of its gang while waiting for the remaining members and cannot execute a single step. The orchestrator's accounting separates allocated capacity from productive work, yet it cannot see where inside a running job the missing work went. Allocated capacity is where fleet-efficiency accounting begins, not evidence that the fleet used those accelerators well.

↩ The allocated, active, and productive tiers of fleet resource accounting are established in section 8.12.1.

Earlier chapters examined the mechanisms of a fleet one layer at a time: data delivery (chapter 4), collective communication (chapter 5), parallel work partitioning (chapter 6), fault recovery (chapter 7), and cluster scheduling (chapter 8). Each subsystem reports performance in its own local unit—input stall ratio, link bandwidth, scaling efficiency, availability, or cluster occupancy—and none of those isolated metrics tells an organization what fraction of its fleet investment becomes useful progress. Worse, when subsystem reports are read separately, their denominators overlap in some places and leave gaps in others. An hour lost to a restart can be penalized in two reports at once, while accelerators held idle by an incomplete gang vanish between the scheduler's log and the job's step timer. As we enter the Serving band of figure 1.4, performance engineering requires a single end-to-end accounting framework that follows every accelerator-hour from offered hardware to useful output and ranks every optimization lever across the stack on one common scale.

↩ The Fleet Law, where these multiplicative efficiency factors are first previewed, is established in section 1.5.4.

To make that accounting concrete, one recurring training job carries the numbers through this chapter: pretraining Llama 2 70B, a smaller Archetype A model than the archetype's 175B reference, on 128 GPUs (16 nodes of eight GPUs each) in a shared cluster. The job uses 8-way tensor parallelism within each node and data parallelism across nodes. Because it competes with other teams for complete gang allocations, absorbs cluster failures and preemptions, and executes steps whose exposed communication grows with node count, every stage of fleet loss appears in a single workload on a single pool.

↩ Archetype A and its 175B-parameter reference model are established in section 1.6.1.1.

A serving replica of the same model provides the running example's inference twin. The replica spans one node of eight H100 GPUs, so a single tensor-parallel node forms one complete serving unit. Because a dense Archetype A transformer cannot fit on one accelerator, the eight GPUs exchange activations in every layer. The cluster scheduler must place the replica as an indivisible gang, the replica must load weights and warm up before taking traffic, and its decode steps can leave most of the node's arithmetic idle while weights stream from high-bandwidth memory (HBM). Its capacity losses therefore arise at the same stages as those of the training job.

The serving twin also marks where fleet-efficiency accounting stops and request-level serving design begins. In production serving, requests share execution across dynamically formed batches, occupy key-value cache memory, and must satisfy tail-latency targets; chapter 10 develops how a serving engine manages uneven

arrivals under those constraints. Here, the boundary test is whether a loss would persist even under a steady, uncontended stream of work. A replica held off-line while loading weights, or a decode step that reads weights more slowly than the node's memory bandwidth allows, fails to use held hardware even without arrival bursts and is counted here over windows of hours to weeks. By contrast, a request delayed behind an oversized batch is a queueing phenomenon caused by uneven arrivals and belongs to serving analysis. Headroom that a replica holds in reserve to absorb traffic spikes appears in goodput accounting as ready capacity running below its ideal rate, whereas choosing how much headroom a latency target requires is a serving decision.

This chapter builds the measurement and optimization discipline that turns those scattered losses into one engineering budget. We begin by defining *ML goodput* (section 9.2), which factors useful fleet output into scheduling, runtime, and program goodput on non-overlapping boundaries. We then establish the reproducible measurement contract and hierarchical fleet profiling needed to localize which factor moved without drowning the cluster in trace data (section 9.3). From there, we trace the three factors in chronological order. We attribute scheduling losses (section 9.4) and runtime losses (section 9.5) to the orchestration and fault-tolerance mechanisms developed in earlier chapters, and then diagnose (section 9.6) and recover (section 9.7) the program-goodput losses that this chapter owns directly. Finally, we compose all three factors into a whole-fleet waterfall and cost per useful accelerator-hour (section 9.8) and evaluate optimizations that trade one goodput factor against another along the fleet's efficiency frontier (section 9.9).

9.2 ML Goodput

Across a fleet, capacity disappears at three successive stages in the life of a job. First, a job must acquire a complete set of devices: an accelerator produces no progress while it sits unallocated, while cluster fragmentation strands it in a shape no queued gang can use, or while a partially allocated gang holds it idle waiting for the rest of its peers. Second, once a job holds a complete allocation, its execution must produce durable progress: initialization, input stalls, synchronous checkpoint pauses, failure recovery, and steps re-executed after a rollback all consume held device-hours without advancing the last saved checkpoint. Third, the steps that do survive in a checkpoint must execute near the rate the hardware can sustain. A step that exposes collective communication, waits on a straggling rank or a pipeline bubble, stalls on memory traffic, or dispatches long chains of tiny kernels occupies healthy accelerators while extracting only a fraction of their capability.

9.2.1 The three goodput factors

Run-level goodput, introduced with the Coordination dimension in section 1.5.1.3, tracks a single job across its execution and discounts time lost to failures and replayed steps. Because that measure starts only after the job holds its accelerators and stops at the boundary of a completed step, it misses both the capacity the job never received and the execution efficiency of the steps the job kept. Google's fleet-efficiency framework extends the measurement window backward to the capacity

offered by the fleet and forward to the ideal execution time of each retained step, factoring useful fleet output into three multiplicative terms (Wongpanich et al. 2025).[1]

[1] **ML productivity goodput origin**: Google introduced the three-factor decomposition to measure its Tensor Processing Unit (TPU) fleet, calling it an iron law of performance for ML fleets by analogy with the processor iron law that splits execution time into instructions, cycles per instruction, and time per cycle (Emer and Clark 1984; Wongpanich et al. 2025). The paper reports the factors across the whole fleet and segmented by job size and by workload phase, with real-time serving and bulk inference alongside training. The boundaries themselves name no accelerator, so this chapter applies them to any accelerator fleet, for serving replicas as well as training jobs.

Definition 9.1: ML productivity goodput (MPG)

ML productivity goodput (MPG) is the fraction of a fleet's capacity-time that becomes useful work at the hardware's ideal rate, expressed as the product of scheduling, runtime, and program goodput, each measured on a fixed accounting boundary so that every lost interval is charged to exactly one factor (Wongpanich et al. 2025).

1. **Significance**: It converts the losses that scheduling, recovery, and execution each report in their own units into one fraction of fleet capacity, so a loss at one boundary can be compared directly with an equal loss at another, and an accelerator-hour's price divided by it is the cost of one ideal-rate hour of useful work.
2. **Distinction**: Unlike utilization, which counts an accelerator as used whenever it is allocated or busy, it counts only retained work at its ideal rate. Unlike run-level goodput, it also charges the capacity a job never received and the rate at which its kept steps ran.
3. **Common pitfall**: A frequent mistake is to multiply factors measured over different windows or against overlapping denominators, such as a run-averaged MFU that already includes restart time and a runtime factor that charges the same restarts again. The product is meaningful only when each factor divides by exactly what the previous one passed.

The three factors follow a job chronologically, and each factor takes as its denominator the capacity-time that survived the stage before it. **Scheduling goodput** ($\eta_{\text{scheduling}}$) is the fraction of fleet capacity-time held by complete allocations—intervals in which a job holds every resource its synchronous execution requires, which the fleet-efficiency literature calls all-allocated time (Wongpanich et al. 2025). **Runtime goodput** (η_{runtime}) is the fraction of that all-allocated time spent on steps that a checkpoint retains, excluding initialization, input stalls, synchronous checkpoint pauses, failure recovery, and work discarded after the last checkpoint; its numerator is productive time. **Program goodput** (η_{program}) is the ratio of the predicted ideal execution time of those retained steps to their actual productive time, capturing the efficiency of code, compiler, and communication against a named hardware ideal. In the Llama 3 405B run, effective training time serves as runtime goodput and MFU serves as program goodput; on a shared multi-tenant cluster, a scheduling factor below one multiplies both. Equation 9.1 combines the three factors into MPG:

$$\text{MPG} = \eta_{\text{scheduling}} \times \eta_{\text{runtime}} \times \eta_{\text{program}} \tag{9.1}$$

The three factors multiply cleanly because each factor's denominator is the preceding factor's numerator. Scheduling goodput divides held all-allocated time by offered capacity-time, runtime goodput divides retained productive step time by all-allocated time, and program goodput divides predicted ideal time by productive step time. Adjacent numerators and denominators cancel, leaving the ideal-rate time of useful work divided by the total capacity-time the fleet offered (figure 9.1). MPG is therefore a dimensionless fraction of fleet capacity rather than a raw throughput rate: useful fleet output equals peak capacity multiplied by MPG, and the effective cost per unit of useful work equals the cost of raw capacity divided by MPG. That telescoping cancellation also defines when the product is valid. If two factors include the same lost interval in their denominators, that loss is counted twice; if a gap falls between one factor's numerator and the next factor's denominator, the loss goes uncounted in both.

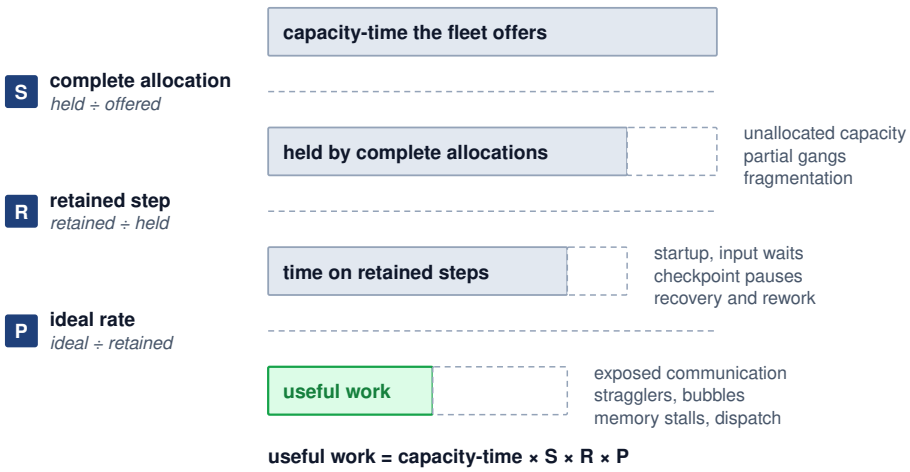

Figure 9.1: ML Goodput as a Chain of Three Boundaries: Capacity-time becomes useful work only by crossing three boundaries in the order a job meets them, and each factor divides what crossed its boundary by what reached it. The dashed slice at the end of each row is the capacity-time lost at the boundary above that row, and the losses beside it are charged there and at no other boundary, so the three factors multiply into the share of offered capacity-time that becomes useful work. Widths are schematic, not measured.

Each factor captures the losses from one stage of a job's lifecycle (section 9.1), and the three goodput boundaries cut across the C^3 taxonomy rather than mapping one-to-one onto its axes. Hiding collective communication behind computation raises program goodput, whereas checkpointing and failure recovery—which the Fleet Law places under Coordination—reduce runtime goodput. Goodput factors identify *when* in a job's execution capacity was lost, while the C^3 dimensions identify *which physical mechanism* caused the loss; diagnosing a fleet bottleneck therefore names the goodput factor first and the C^3 mechanism inside it second.

Because the three factors multiply, the share of total fleet capacity lost at any boundary equals that boundary's fractional loss weighted by the capacity share that reached it. Equation 9.2 partitions the total efficiency gap $1 - \eta_{\text{scheduling}}\eta_{\text{runtime}}\eta_{\text{program}}$ into three additive shares—the scheduling loss on offered

capacity, the runtime loss on held capacity, and the program loss on retained step time:

$$\begin{aligned} 1-\eta_{\text{scheduling}}\eta_{\text{runtime}}\eta_{\text{program}} = {} & (1-\eta_{\text{scheduling}}) \\ & +\eta_{\text{scheduling}}(1-\eta_{\text{runtime}}) \\ & +\eta_{\text{scheduling}}\eta_{\text{runtime}}(1-\eta_{\text{program}}) \end{aligned} \tag{9.2}$$

The three right-hand terms sum to the total gap, reflecting the rule that every lost device-hour is charged at exactly one boundary. Although the product $\eta_{\text{scheduling}}\eta_{\text{runtime}}\eta_{\text{program}}$ is commutative, the additive share attributed to each stage depends on the order in which capacity passes through the boundaries. The decomposition therefore follows the chronological order in which a workload encounters the three losses. Applied to the published Llama 3 405B telemetry, equation 9.2 shows immediately which boundary consumed most of the cluster's held capacity.

Napkin Math 9.1: Where Llama 3's held capacity went

Problem: Llama 3 405B trained on a dedicated cluster of 16,384 GPUs, kept more than 90 percent of its elapsed time as effective training time, and ran its kept steps at about 41 percent MFU (Dubey et al. 2024). What share of the capacity it held was lost at the runtime boundary, what share at the program boundary, and what share became progress at the ideal rate?

Variables:

- Scheduling goodput $\eta_{\text{scheduling}}$ is one, because the cluster was dedicated to the run, so the first term of equation 9.2 vanishes.
- Runtime goodput η_{runtime} is about 0.90, from effective training time (a stated lower bound).
- Program goodput η_{program} is about 0.41, from MFU at full scale.

Math:

- Runtime boundary, $1-\eta_{\text{runtime}}$: $1-0.90=0.10$.
- Program boundary, $\eta_{\text{runtime}}(1-\eta_{\text{program}})$: $0.90\times 0.59\approx 0.53$.
- Useful work, $\eta_{\text{runtime}}\eta_{\text{program}}$: $0.90\times 0.41\approx 0.37$.

Result: About 10 percent of the held capacity was lost at the runtime boundary, about 53 percent at the program boundary, and about 37 percent became progress at the ideal rate.

Systems insight: Removing every interruption would have recovered at most a tenth of the capacity the run held, while the steps it kept left more than half unused, so for one of the most carefully engineered runs on record the program boundary, not reliability, held most of the gap.

This calculation treats Meta's reported effective training time as runtime goodput.[2] That identification holds when the job retained its full allocation throughout the elapsed window and when input stalls were already excluded from effective time. The calculation's second identification, using MFU as program goodput, rests on how retained steps are compared against a named hardware ideal.

[2] **Effective training time**: Meta's report defines it as the time spent on useful training over the elapsed time and states only that it exceeded 90 percent over a 54-day snapshot (Dubey et al. 2024). It is a per-job figure, so it says nothing about capacity the job never held, and the report does not say whether input waits count as useful. Its MFU comes from the scaling-configuration table rather than from that snapshot, which is why the measurement contract (section 9.3.1) requires every factor to name its window.

9.2.2 Program goodput and its measure

Hardware activity counters cannot measure how efficiently a retained step ran, because an accelerator registers as busy whether it is waiting on a collective, recomputing dropped activations, or executing arithmetic far below its peak rate. Measuring program goodput instead requires comparing actual step time against a named hardware ideal for the resource that limits the workload. For training steps and for the prefill pass over a prompt, arithmetic dominates, so the ideal time of a step is the time the accelerators would need to execute the model's required mathematical operations at their peak rate. MFU measures against that ideal by counting only the operations the model architecture requires.[3] In Google's fleet-efficiency methodology, the ideal operation count is fixed before compilation from the program as written—before the compiler fuses kernels or rematerializes activations—so that a compiler optimization that shortens the step raises program goodput instead of shifting its own baseline (Wongpanich et al. 2025). For the same reason, program goodput is not measured against a per-operation roofline. A per-operation roofline rewards kernels that run near their local ceiling and would therefore penalize a rewrite that executes fewer operations at lower utilization while finishing the step sooner. The roofline remains a diagnostic for individual kernels (section 9.6.3) rather than the efficiency measure of a whole program.

Definition 9.2: Model FLOPs utilization (MFU)

Model FLOPs utilization (MFU) is the fraction of the hardware's theoretical peak throughput (R_{peak}) consumed by FLOPs that directly advance model training or inference, excluding overhead from recomputation, padding, and synchronization.

1. **Significance**: Measured over a job's retained steps against the arithmetic ideal, MFU is that job's program goodput. A one-percentage-point MFU increase across 10,000 identical GPUs adds useful throughput equivalent to 100 GPUs at peak, and whether that saves money depends on whether the recovered capacity displaces hardware or shortens paid runtime.
2. **Distinction**: Unlike hardware utilization, which reports how often the accelerator is busy, MFU relates the model's required FLOP rate to hardware peak. It excludes recomputation and padding from useful work even when they make a configuration feasible or faster.
3. **Common pitfall**: A frequent misconception is that high GPU utilization implies high efficiency. A system can show 90 percent hardware utilization while achieving 30 percent MFU when busy intervals include

communication or arithmetic far below peak. MFU exposes the gap but does not explain its cause, which traces must find.

The equality between MFU and program goodput under an arithmetic ideal follows directly from that definition. A retained step across N accelerators performs O_{useful} of required model work, which would take $O_{\text{useful}}/(NR_{\text{peak}})$ at peak throughput, whereas the step actually runs in wall-clock time T_{step}. Equation 9.3 expresses program goodput as the ratio of ideal step time to actual step time:

$$\eta_{\text{program}} = \frac{O_{\text{useful}}/(NR_{\text{peak}})}{T_{\text{step}}} = \text{MFU} \tag{9.3}$$

That identity holds only when MFU is measured over the retained steps that survived the runtime boundary, with input stalls already excluded. Published MFU numbers are often averaged over an entire wall-clock run that includes restarts and synchronous checkpoint pauses; multiplying such a run-averaged MFU by a separate runtime goodput factor would penalize those interruptions twice. Hardware FLOPs utilization (HFU), which counts all executed floating-point operations including activation recomputation, remains a useful diagnostic alongside MFU because the gap between HFU and MFU isolates the cost of recomputation. In goodput accounting, that recomputation gap is a program goodput loss even when trading extra compute for memory capacity is the right engineering choice. Similarly, when capacity planners size a training run in accelerator-hours by scaling peak throughput by retained-step MFU (section 2.4.1), they must still multiply by runtime and scheduling goodput to account for the hours lost outside steady-state steps.

The MFU that published training runs report stays below half of peak across every generation of frontier hardware (figure 9.2). Even for the same model architecture, expanding Llama 3 405B onto twice as many GPUs lowers its reported MFU as cross-node communication claims a larger share of each step.

An arithmetic ideal does not fit workloads that the hardware cannot make compute bound. An autoregressive decode step generating one token for a small batch must stream every parameter of the model from HBM to perform only a handful of operations per weight. Memory bandwidth therefore sets the step's floor (section 2.3.1.3), and at that bandwidth floor the accelerator's matrix units run at well under 1 percent of peak arithmetic throughput. Charging that arithmetic shortfall to the program would blame kernel implementation for a gap that only a larger batch can close—and maximum batch size is constrained by the serving latency target rather than by the kernel. For bandwidth-bound decode, the natural reference for a single replica is the bandwidth floor: the time required to stream the step's mandatory weight and KV-cache bytes at peak memory bandwidth. Program goodput against that ideal is **model bandwidth utilization** (MBU), defined as the achieved rate of required byte transfers divided by peak memory bandwidth. A decode step with high MBU and low MFU has saturated the limiting hardware resource rather than wasted it.

[3] **MFU and HFU**: The PaLM report proposed MFU in place of hardware FLOPs utilization (HFU), which counts every executed operation, because the executed count depends on implementation and compiler choices, most visibly rematerialization, which recomputes activations to save memory (Chowdhery et al. 2022). MFU's reference rate depends only on the model architecture and the published peak rate, so runs of one model on different software stacks compare directly. For goodput accounting, the choice means that recomputation which lets a layout fit in memory is charged to program goodput as lost time rather than credited as work.

↩ The compute axis, where the memory wall limits MFU, is established in section 1.5.1.1.

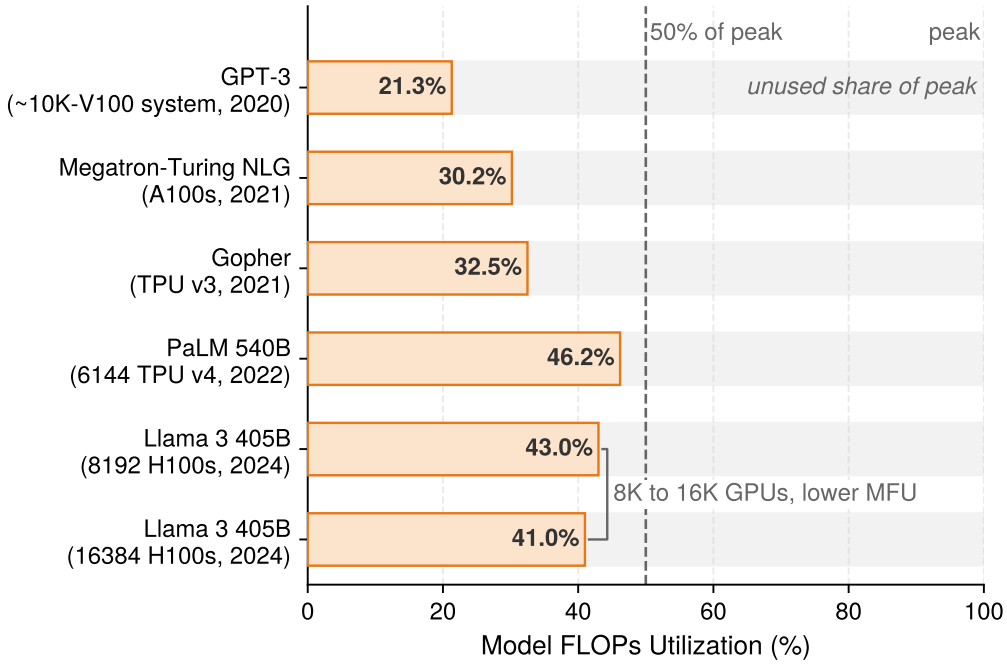

Figure 9.2: The MFU Progression: Model FLOPs Utilization across published training systems, ordered chronologically. Reported MFU rises from 21 percent (GPT-3, 2020) to 46 percent (PaLM, 2022), with later illustrated runs near 40–45 percent. These systems differ in hardware and workload, so the comparison does not isolate the effect of parallelism or overlap. The Llama 3 data points show lower reported MFU at the larger scale: MFU drops from 43 percent at 8,192 GPUs to 41 percent at 16,384 GPUs. Interpreting the difference requires the batch, execution configuration, and measurement convention. Data sources: Chowdhery et al. (2022), Dubey et al. (2024).

Choosing a named ideal also determines what can be aggregated across a multi-workload cluster. A fleet that evaluates training against peak arithmetic and decode against peak memory bandwidth cannot average the two into a single program goodput factor, because the two denominators measure different physical resources. Fleet-wide reporting must therefore either keep program goodput segmented by workload class or evaluate every workload against the arithmetic ideal and recognize that small-batch decode carries a structural batch-size penalty. Google's fleet-efficiency framework takes the second path for its fleet-wide aggregate, measuring all workloads against a compute-based ideal (Wongpanich et al. 2025), while MBU provides a direct diagnostic for individual bandwidth-bound decode replicas. Throughout this chapter, MFU serves as the default program goodput metric because it composes across the fleet, and MBU is reported alongside it whenever memory bandwidth sets the hardware ceiling.

For the chapter's running Llama 2 70B training job, program goodput is the fleet MFU of its retained steps across all 128 GPUs. That fleet MFU averages about 48 percent, down from the 65 percent achieved by a single-node baseline, because distributing each step across 16 nodes introduces inter-node collective communication that a single node never pays. Section 9.6.2 isolates and quantifies that scaling loss.

Program goodput also connects directly to the efficiency expressions derived earlier in this book. In equation 1.4, the numerator of the compute-time fraction can be defined in two ways. When that numerator is the ideal time required at peak hardware throughput, the compute-time fraction equals the program goodput of a single step. When that numerator is the measured execution time of a single device instead, it treats the single device's own memory and dispatch losses as part of the baseline and isolates multi-device scaling efficiency alone. Multiplying that scaling efficiency by the single device's MFU recovers program goodput. The effective fleet throughput in section B.11.2 makes the same split explicit by multiplying peak cluster capacity by single-device MFU, multi-node scaling efficiency, and runtime goodput. The product of those first two terms equals the job's fleet MFU, which is its program goodput, while scheduling goodput is absent only because that expression starts from accelerators the job already holds.

9.2.3 Accounting boundaries

Without sharp boundaries between the three factors, two engineering teams analyzing the same lost accelerator-hour—such as devices held idle by a gang waiting for its remaining ranks, or a step stretched by a straggling peer—will either assign the loss to different factors or subtract it twice. Every hour of fleet capacity must cross three sequential boundaries before it becomes ideal-rate useful work, and a loss is charged to the single factor whose boundary it fails to cross. Table 9.1 pairs each factor boundary with the losses charged there, the telemetry that measures it, the corresponding utilization tier from section 8.12.1, and the chapter that owns the engineering levers to recover it. The final three rows apply the same boundaries to a serving replica.

Table 9.1: Goodput Accounting Boundaries: Each factor ends at one boundary, every loss is charged to the factor whose boundary it fails to cross, and the evidence column names the cheapest record that measures it. Kernel-active time is evidence that helps split runtime and program losses, not a factor. Serving rows apply the same boundaries to a replica, with headroom charged to program goodput and sized by the serving system.

Factor	What ends at its boundary	Losses charged	Evidence	Utilization tier	Lever owner
Scheduling goodput	Fleet capacity-time becomes time held by complete allocations	Unallocated capacity (absent demand, quota limits); devices held by a gang waiting for members; fragmentation; capacity left idle while queued gangs cannot be placed (a job's own queue wait costs only time to result when other jobs hold the capacity)	Scheduler records: allocation intervals with gang-complete timestamps; held capacity per pool; fragmentation index	Allocated, counting complete allocations only	chapter 8

Factor	What ends at its boundary	Losses charged	Evidence	Utilization tier	Lever owner
Runtime goodput	Held time becomes time on steps a checkpoint retains	Startup and compilation before the first step; input stalls; synchronous checkpoint pauses; failure detection and recovery; rework after a failure; work lost to preemption; idle reservations	Job timeline: step log with retained-checkpoint markers; restart, preemption, and input-wait logs	Productive, normalized to the job's own fault-free step rate	chapter 7; chapter 4 for input and checkpoint writes
Program goodput	Retained step time becomes ideal-rate time	Exposed communication and synchronization; stragglers; pipeline bubbles; memory stalls; host dispatch; recomputation; contention from asynchronous checkpoint writes	Step traces and device counters; MFU, or MBU for bandwidth-bound decode	Beyond the three tiers	This chapter; chapter 5 and chapter 6 for collectives and layout
Kernel-active time	None; evidence only	None	Device activity counters	Active	None
Scheduling goodput, serving replica	Capacity becomes whole-node replicas held	Devices that cannot form a complete replica; replicas waiting for placement	Scheduler records per replica	Allocated, complete replicas only	chapter 8
Runtime goodput, serving replica	Held replica time becomes ready time	Weight loading, warmup, and compilation; restart after failure; draining before an update	Replica lifecycle log	Productive, at the replica's ideal rate	chapter 7; chapter 10 for cold-start latency
Program goodput, serving replica	Ready time becomes ideal-rate serving time	Decode below its named ideal; headroom held for bursts; cache fragmentation that limits admission	Per-step traces; tokens served against the named ideal; MBU for decode	Beyond the three tiers	This chapter; chapter 10 decides how much headroom a latency target requires

These boundary definitions refine two of the orchestrator's utilization tiers from section 8.12.1 so that the three factors multiply without overlap. First, scheduling goodput counts only complete allocations. Accelerators held by a gang still waiting for its remaining ranks appear as allocated on a basic cluster dashboard, yet they

are charged here as a scheduling loss because no synchronous step can execute on them. Second, the orchestrator's productive tier measures retained work against a declared reference rate. When that reference is the job's own fault-free step rate (with input ready and no interruptions), dividing productive capacity by complete-allocation capacity yields runtime goodput directly. When the reference is hardware peak throughput instead, the same ratio collapses runtime and program goodput into a single number and obscures which boundary lost the capacity. In the orchestration example of 500 GPUs allocated, 350 active, and 280 productive, the productive-to-allocated ratio of 56 percent represents runtime goodput only when the productive tier is normalized to the job's own steady-state step rate.

By contrast, the orchestrator's active tier does not correspond to a goodput boundary. An accelerator whose execution engines are active may be performing required model arithmetic, spinning in a collective while waiting on a straggler, recomputing discarded activations, or re-executing steps lost after a node failure. Those four activities represent useful work, two program goodput losses, and a runtime goodput loss; device activity counters therefore serve as diagnostic evidence for separating runtime from program losses rather than as a goodput factor in their own right.

The boundary between runtime goodput and program goodput also governs how delays inside a step are classified. The duration of a retained step includes any time spent waiting on a slow peer, a pipeline bubble, or a collective operation, but excludes stalls waiting for the storage pipeline to deliver the next batch. Input stalls are carved out and charged to runtime goodput because the data pipeline prevented the step from starting, and the data stall ratio of equation 4.4 in section 4.4 quantifies their share. Every other slowdown within a retained step is charged to program goodput, even when its root cause originates outside the user program.

In short, the accounting boundary determines *where* a loss is counted, whereas the physical cause determines *which system layer* fixes it. Stragglers illustrate why the two must remain distinct. Section 7.9.5 treats a degraded accelerator as a reliability problem and evaluates when replacing the slow node justifies paying for a restart. In goodput accounting, however, a straggler is charged to program goodput: the job holds a complete allocation and retains every step in its checkpoints, yet those steps execute more slowly than the hardware ideal. Recording the straggler in program goodput captures the slowdown where it manifests. Program goodput drops while the straggler is present and recovers once the node is replaced. The remediation decision stays with the reliability controller, which weighs the recovered program goodput against the runtime goodput lost to draining and restarting the job. Preemption reverses the pairing: the cluster scheduler triggers the eviction, yet the discarded steps since the last checkpoint and the subsequent reload are charged to runtime goodput because the job held a complete allocation while those hours were spent. By the same rule, a synchronous checkpoint that halts step execution is a runtime loss, whereas an asynchronous checkpoint that competes with the running step for memory or network bandwidth slows the retained step and is charged to program goodput. Ahead-of-time compilation

before the first step reduces runtime goodput, while the execution speed of the compiled kernels governs program goodput. Across all of these cases, the three boundaries keep MPG internally consistent, though MPG itself is only one of several metrics in this book that carry the name "goodput."

9.2.4 One word, several measures

Quoting "goodput" without qualification leaves a reader unable to tell whether a job preserved its progress across restarts, used its share of the cluster effectively, met its serving latency targets, or extracted statistical progress from each training example. Across this book, the term appears in four distinct forms, each answering a different engineering question:

- *Run-level goodput* (section 1.5.1.3) measures a single job's rate of useful training progress after discounting time lost to failures and replayed steps.
- *ML productivity goodput (MPG)* measures the fraction of total fleet capacity-time that becomes useful work at the hardware's ideal rate.
- *Service-level objective (SLO) goodput* (section 10.3) measures the rate of completed inference requests that satisfy both time-to-first-token and per-output-token latency targets.
- *Statistical goodput*, which the Pollux scheduler maximizes in section 8.9.4, weights raw training throughput by the convergence progress each training example contributes at the current batch size.

These four measures complement rather than replace one another. SLO goodput applies on top of MPG: a serving fleet that operates at a high fraction of its ideal hardware rate on average can still violate latency targets in the tail if batches are formed too aggressively. Similarly, statistical goodput evaluates progress per example rather than operations per second, so enlarging the global batch beyond the critical batch size can raise program goodput while reducing statistical goodput. Any quantitative efficiency claim must therefore state which goodput measure it reports, which denominator defines its boundary, and which time window it spans. The measurement contract of section 9.3 pins down the workload, boundary, and measurement window so that two goodput numbers can be compared fairly.

9.3 Measuring Goodput

↪ MPG applied across a whole portfolio of jobs, in fleet dashboards and chargeback, is developed in section 12.8.5.

Two measurements of the running Llama 2 70B job taken a week apart can report noticeably different program goodput because they traced different ranks, spanned a framework upgrade, started timing before compilation finished, or averaged across a failure recovery. The job's real efficiency on the cluster need not have changed at all. A goodput factor can guide engineering decisions only when repeated measurements are directly comparable and when a drop can be traced cleanly to the boundary that lost the capacity. Measuring goodput at fleet scale therefore requires three elements: a measurement contract that holds confounding variables fixed, a diagnostic hierarchy that identifies the losing factor before probing its internal mechanism, and a telemetry sampling strategy whose collection overhead the production fleet can afford.

9.3.1 The measurement contract

An apparent speedup between two trials can easily stem from altered input distributions, a warmer machine state, host timers that miss asynchronous kernel execution, or a relaxed convergence target rather than from the optimization under test. Distributed fleets introduce further confounding variables that single-machine benchmarks never encounter: two runs may receive placements with different switch hops, share fabric links with different neighbors, execute under different preemption policies, or span a window too brief to capture routine hardware interruptions. Industry benchmark suites prevent these confounds by locking down the workload, quality target, and timing rules before any system comparison begins (Mattson et al. 2020; Reddi et al. 2019), and production fleet engineering requires the same discipline for every goodput factor it tracks.

Definition 9.3: Measurement contract

Measurement contract is the set of conditions a performance measurement fixes and reports, the workload and its quality gate, the system state and software version, the timing boundary, and the goodput factor measured over a named window with its statistical spread, so that two measurements under the same contract differ only in the change being evaluated.

1. **Significance**: A contract makes the difference between two results attributable to the change under test, so a gain can be priced in accelerator-hours and repeated on another job.
2. **Distinction**: Unlike a benchmark score, which reports one configuration under one set of rules, a contract governs every measurement a team takes, including the before and after of each change. Unlike a monitoring threshold, it states what a measurement must hold fixed to support a claim.
3. **Common pitfall**: A frequent mistake is to fix the workload and hardware while letting the window drift. A runtime goodput measured over a day with no failures describes a better job than the one that runs for weeks on a shared fleet.

A complete measurement contract specifies the five categories in table 9.2, pairing each required record with the misattribution it prevents. The workload envelope locks down the model revision, input and sequence-length distributions, global batch size, and the convergence or output-quality gate that defines valid work. The system-state record captures accelerator count and placement topology, clock and power limits, software, driver, numerical precision, and compiler versions, and—when evaluating scheduling goodput—the cluster pool and scheduling policy in effect. The timing boundary defines which initialization steps fall inside the timed region and how the host synchronizes with asynchronous device streams. Finally, the statistical report identifies the goodput factor, its denominator,

and its calendar window alongside the trial count, central tendency, dispersion, and quality verification.

Table 9.2: Reproducible Performance Measurement Contract: Every goodput result fixes workload, correctness, system state, timing, and statistical reporting, and names the factor and window it measures, before two implementations or configurations are compared.

Contract field	Evidence to report	Failure prevented
Workload and correctness	Model revision; representative input and sequence-length distributions; global batch or concurrency; quality or output-equivalence gate	Comparing different work or accepting an invalid numerical shortcut
System state	Device count and topology; clocks and power limit; software, compiler, driver, precision, and kernel versions; for scheduling goodput, the pool and scheduler policy	Attributing a hardware, software, or policy change to the optimization
Timing boundary	Included setup; device synchronization; warmup; cold-start and steady-state definitions	Under-timing asynchronous execution, or hiding startup and compilation inside a steady-state number
Statistical report	Factor measured and its denominator; window; trial or window count; median or mean; dispersion; step-time percentiles	Promoting a favorable single run, or multiplying factors measured over different windows or overlapping denominators
Load generation (serving)	As specified for serving measurements in chapter 10	Load that eases off while the replica stalls

The required measurement window varies sharply across the three factors because each boundary loses capacity on a different timescale. Program goodput captures inefficiencies that repeat on every training step or decode iteration, so a window of several hundred warmed steady-state steps estimates it reliably. Runtime goodput captures episodic events such as node failures and rollbacks to the last checkpoint. A window shorter than the mean time between cluster interruptions can miss those events entirely and report a misleadingly high factor, so its window must span days to weeks at fleet scale (chapter 7). Scheduling goodput tracks cluster contention, which fills queues during peak working hours and drains them overnight or between project deadlines, requiring a window that spans full demand cycles. Multiplying the three factors yields a job's true MPG only when all three cover the same calendar window, even when program goodput within that window is estimated by sampling representative retained steps.

The timing boundary likewise determines whether startup overhead is attributed to runtime goodput or program goodput. End-to-end trials that start the clock before graph compilation and cache warmup measure the delay before the first productive step, which belongs to runtime goodput, whereas warmed steady-state trials isolate the per-step execution rate, which belongs to program goodput.

Mixing cold-start and warmed runs can credit a code change for a speedup when the second trial simply hit a warm compiler cache; the measurement contract therefore reports cold-start duration and steady-state step time separately. When a more aggressive compiler pass speeds steady-state steps at the cost of a longer initial compile, it trades runtime goodput against program goodput—a trade-off that section 9.9 prices explicitly.

Industry benchmark suites illustrate how a strict measurement contract operates in practice. MLPerf Training measures wall-clock time to train a reference model to a specified validation target, and MLPerf Inference measures throughput under explicit latency bounds across standardized serving scenarios, evaluating complete hardware-software systems rather than isolated chips (Mattson et al. 2020; Reddi et al. 2019). Closed-division submissions hold the model architecture and optimizer fixed so that systems can be compared directly, while open-division submissions relax those constraints to showcase algorithmic and systems co-design. Because a benchmark submission runs on a dedicated, pre-warmed cluster allocation without multi-tenant queueing or long-run preemption churn, it primarily measures program goodput and reveals very little about scheduling or runtime goodput (perspective 9.1).

Recording exact software versions in the system-state contract is essential because software upgrades alone can shift delivered throughput by a large multiple on identical silicon. Between September 2023 and April 2025, NVIDIA submitted the same eight-GPU DGX H100 node to four consecutive MLPerf Inference rounds while upgrading its inference stack from TensorRT 9.0 to 10.8 (Reddi et al. 2019; MLCommons 2025a). Across those four rounds, offline throughput rose 2.7× on GPT-J, 1.4× on Llama 2 70B, and 1.2× on Stable Diffusion XL (figure 9.3), whereas ResNet-50 and BERT—whose kernels were already mature—remained flat. Any before-and-after experiment that straddles a framework or compiler upgrade therefore confounds the upgrade with the optimization under test.

9.3.2 Localizing the lost factor

Even when a contract-controlled measurement confirms a genuine slowdown, knowing that a training run fell behind its schedule does not reveal which goodput boundary lost the capacity. An engineering team that opens a kernel profiler first will always find some exposed gap inside a step. The team can easily spend a week shaving milliseconds off a collective while most of the missing capacity was lost waiting for a complete allocation or recovering from unlogged restarts. Effective localization instead inspects telemetry from the cheapest, broadest record down to the most expensive, narrowest trace, matching each record to one boundary of table 9.1.

At the top of that hierarchy sit scheduler records. For every submitted job, the cluster scheduler logs submission time, individual device assignments, the timestamp at which the minimum gang became complete, final release, and the resource pool, quota, and priority class under which the job ran. Pool-level logs add unallocated capacity and the fragmentation index from section 8.12.1. Because the control plane already writes these records for admission control and charge-

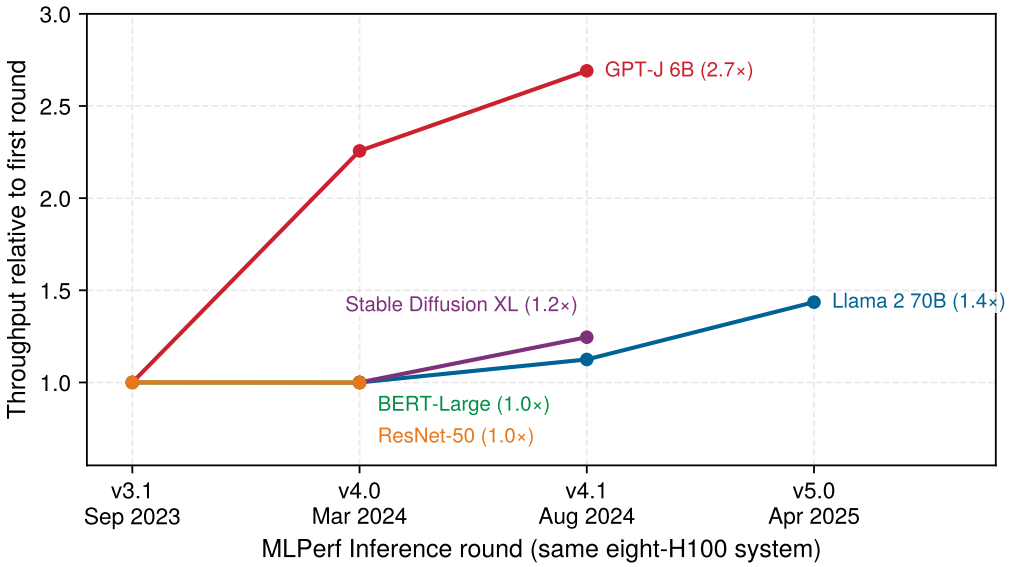

Figure 9.3: Software-Only Gains on Fixed Hardware: Offline throughput of one NVIDIA DGX H100 system (eight H100 SXM GPUs with 80 GB of memory each) across four MLPerf Inference rounds, relative to each benchmark's first submission on that system. The hardware is identical in every round; the software stack changed from TensorRT 9.0 to 10.8. Llama 2 70B uses the 99.9 percent accuracy target. Data from MLCommons (2025a).

back, they carry zero extra instrumentation overhead and cover every job in the cluster. Scheduler records establish scheduling goodput directly and supply the all-allocated held time that forms the denominator of runtime goodput. What they cannot see is anything that happens *inside* a complete allocation: a wedged job that holds a full gang without executing a single step looks identical in scheduler logs to a job running at peak efficiency.

The second rung is the job timeline, the structured lifecycle log emitted by the job itself between its gang-complete timestamp and its release. The timeline records when the first training step began, the completion timestamp of every step, which steps each committed checkpoint retained, every failure, restart, and preemption event, and the time each step spent waiting on the input pipeline. Because it stores only a few scalar fields per step or lifecycle event, the timeline is compact enough to retain for every production job. It settles runtime goodput. The interval before the first step measures startup and compilation, pauses at checkpoint commits measure synchronous write overhead, steps repeated after a rollback measure rework, and the input-wait counter yields the data stall ratio of equation 4.4. Because the timeline also logs the wall-clock duration of every retained step, it flags a program goodput loss whenever retained steps run longer than their baseline target. It cannot distinguish, though, whether that slowdown came from exposed communication, memory stalls, or a straggling rank.

The third rung consists of step traces, the only telemetry that looks inside an individual step. Over a selected time window and set of ranks, a step trace captures every kernel launch, collective operation, memory copy, and host dispatch interval alongside hardware performance counters such as achieved HBM bandwidth.

That detail partitions a retained step into computation, exposed communication, peer or pipeline waits, memory stalls, and host dispatch overhead, pinpointing which term of the Fleet Law (section 9.6.1) an optimization must shorten. Because full tracing generates gigabytes of data and perturbs execution timing, it is reserved for short windows on sampled ranks; a clean step trace taken during a healthy hour says nothing about whether the job lost half its week to restarts.

Table 9.3: Records That Localize a Goodput Loss: Each record matches one accounting boundary, and the cheaper records come first because they cover the whole fleet continuously. A loss is traced to its factor before its mechanism is studied, and the step trace is collected only for a program loss the job timeline has already detected.

Record	Coverage and cost	Establishes	Cannot establish	Factor it settles
Scheduler records	Every job and pool, continuously; written for admission and chargeback	Capacity not held by complete allocations; queue wait; gang-complete times; held time per job	Anything inside a held allocation, including whether any step ran	Scheduling goodput; the denominator of runtime goodput
Job timeline	Every job, for its whole life; a few fields per step or event	Startup, input waits, checkpoint pauses, restarts, preemptions, rework; retained step time; step-time distribution	Why a retained step takes as long as it does	Runtime goodput; detects but does not explain program loss
Step traces	Selected ranks and short windows; large volume and some perturbation	Intervals inside a step (computation, exposed communication, peer and stage waits, memory stalls, host dispatch)	Losses outside the traced window (scheduling waits, restarts, checkpoint pauses, intermittent episodes)	Program goodput, and the Fleet Law term to shorten

Reading these three records from top to bottom (table 9.3) is a methodological requirement, not merely a cost-saving habit. Each rung settles one goodput factor and hands the remaining unexplained gap to the rung below, so engineers collect step traces only after scheduler logs and the job timeline confirm that retained steps themselves are running slowly. Skipping rungs leads to two classic diagnostic blunders. Starting with a step trace can pronounce a job healthy while it loses a third of its held hours to unexamined restarts. Starting and stopping at queue logs can blame the cluster scheduler for a week-long slowdown that the job timeline would immediately trace to a compiler regression. In both failure modes the local data are accurate, yet the diagnosis fails because the chosen telemetry cannot observe the boundary where the loss occurred.

For these three records to enforce the accounting boundaries of section 9.2.3, their instrumentation must align with those boundaries. If a job timeline logs only total step duration without separating data-loader stalls, every input wait is folded

into step time and a runtime goodput loss masquerades as a program goodput loss. Similarly, because a single straggling accelerator stretches synchronous step time across every peer in its collective group, identifying which rank caused the slowdown requires lightweight per-rank step timers inside the job timeline.

Our running Llama 2 70B training job illustrates how the three rungs work together. Suppose that after one week on the shared cluster, the job has retained substantially fewer steps than predicted by a plan that assumed full-week allocation at the single-node step rate. Consulting the scheduler records first reveals that the job held partial node allocations before its full 16-node gang assembled—a scheduling loss quantified in section 9.4.3. Reading the job timeline from that gang-complete timestamp next isolates the initial startup delay, synchronous checkpoint pauses, steps re-executed after failures, and a modest input-stall fraction, which section 9.5.2 composes into runtime goodput. The same timeline also shows that every retained step ran longer than the single-node baseline from day one, proving that part of the shortfall lies in program goodput. Only at that point does the team trigger step traces on one data-parallel group over a brief window. Because per-rank timeline counters show no single outlier rank, the team inspects intervals common to all ranks and finds inter-node gradient collectives extending past the backward pass—the exposed communication analyzed in section 9.6.2. Each rung answers the exact question that the others cannot (figure 9.4).

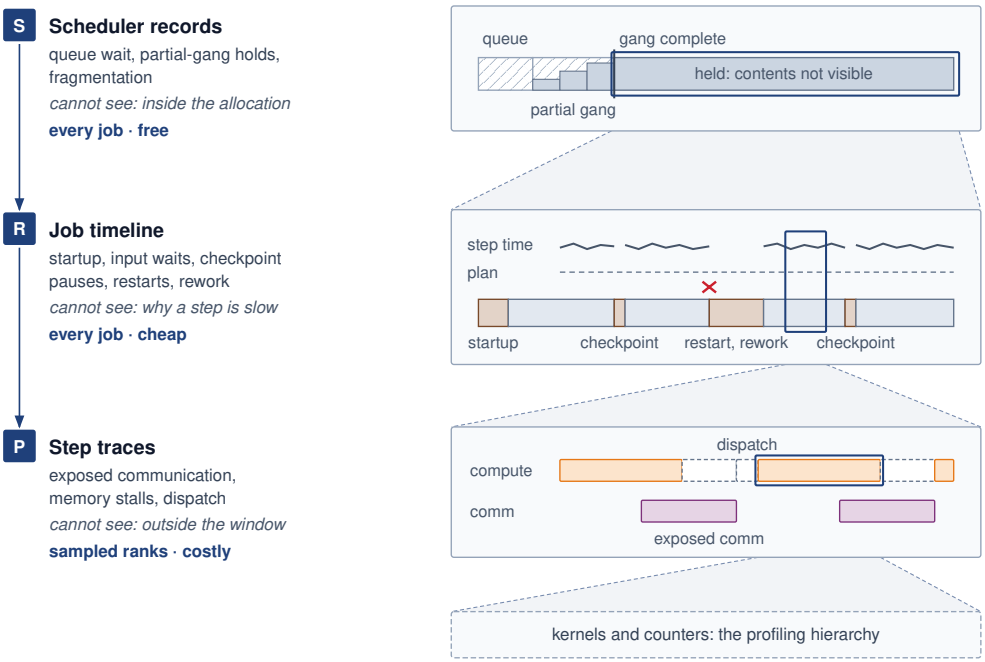

Figure 9.4: Localizing a Lost Factor: The three records are read from the top, cheapest and most complete first, and each settles one factor of goodput. Scheduler records cover every job and settle scheduling goodput, but they see a held allocation only as a closed block. The job timeline settles runtime goodput and shows that retained steps run slower than planned without showing why. Step traces, collected for sampled ranks over a short window, settle program goodput, and their highlighted window expands into the profiling hierarchy of figure 9.6. Widths are schematic, not measured.

Diagnosing the eight-GPU serving replica follows the exact same three-rung progression. Cluster scheduler logs measure how long the replica waited for a full unfragmented node, the replica lifecycle log tracks weight loading, warmup, ready service, and restarts to establish runtime goodput, and decode step traces—evaluated against peak HBM bandwidth via MBU—measure how closely ready execution approaches the hardware ideal.

9.3.3 Fleet profiling by sampling

The first two rungs of the localization ladder scale effortlessly with cluster size because a scheduler log entry or a step-timeline record occupies only a few bytes whether a job spans one node or a thousand. Step traces do not scale in that way. When a job expands from 8 GPUs to 1,024 GPUs, multi-node bottlenecks emerge that no single-node trace can capture—such as fabric-crossing collectives and ranks stalled behind a distant straggler—so profiling must span many ranks at once. Yet if a 5-second Nsight Systems trace on one GPU produces 500 MB, capturing that same 5-second window across 1,024 GPUs generates roughly 512 GB of telemetry. No production cluster can ingest or store traces at that rate continuously, and logging every kernel launch perturbs the very step timing under study (perspective 9.2). Deciding *which* ranks and time windows to trace is therefore a core part of fleet measurement.

Production fleets resolve this tension through hierarchical profiling, splitting telemetry between lightweight, always-on counters that detect an efficiency drop and targeted traces that diagnose its cause. Within a strict overhead budget, the always-on layer continuously records step duration, retained-step MFU, per-rank step timers, and hardware health telemetry (HBM bandwidth, power draw, and die temperature) across every active job. Once those counters flag that a goodput factor has degraded and narrow down where, targeted profiling captures a short trace window from specific ranks chosen to test a hypothesis. Comparing a suspected straggler directly against a healthy peer in the same collective group isolates the stall far more cleanly than tracing an arbitrary rank. ByteDance's MegaScale system[4] exemplifies this workflow. Lightweight CUDA-event timers record critical operations on every rank throughout production training, summarize per-rank latencies as a cluster-wide heat map, and drill into a synchronized timeline only for the parallel group that exhibits an anomaly (Z. Jiang et al. 2024). Below the step-trace rung, diagnosis then descends through framework operators, kernel timelines, and hardware performance counters along the profiling hierarchy of figure 9.6 (section 9.6.3).

To inspect inside steps continuously without paying for full traces, fleets rely on statistical profiling. A sampling policy selects a small fraction of kernels, steps, or ranks for detailed timing, and aggregating those samples reconstructs where step time is spent across the fleet. Google-Wide Profiling pioneered this approach across warehouse-scale computers by continuously sampling a small fraction of machines and aggregating the results into fleet-wide execution profiles (Ren et al. 2010). Applied to an ML accelerator fleet, fleet-wide aggregation ranks kernels and collectives by their share of total retained step time across all jobs. A collective

[4] **MegaScale stragglers**: The heat map of per-rank forward and backward latency showed about 0.5 percent of machines running substantially slower than the rest, and excluding them made peak MFU consistent across runs (Z. Jiang et al. 2024). Separately, a few hosts took about 10 percent longer on the same forward computation, and removing them raised MFU by about 0.7 percent. A fraction of a percent of machines thus set the step time of every rank that synchronized with them, a program loss that only per-rank timing on every step could locate.

primitive that consumes a modest slice of every job's step often represents a far larger fleet-wide optimization target than a specialized kernel that dominates a single workload.

Statistical sampling is only as trustworthy as its stratification. A fleet sampling policy must stratify across job sizes and model architectures, pipeline stages and parallel groups, warmup and steady-state phases, and hours of the day. Sampling only rank 0 (which often performs extra logging and checkpoint coordination) or only the opening minutes of a job characterizes a special rank or phase rather than the fleet. Furthermore, because rare anomalies that occur once every several thousand steps can easily slip between periodic random samples, continuous sampling is paired with threshold triggers that automatically dump a detailed trace whenever an always-on timer crosses an anomaly bound.

Intermittent stragglers illustrate why triggered capture is essential. An accelerator can slow down for brief episodes due to thermal throttling, recoverable memory errors, transient fabric congestion, or host OS pauses such as page reclamation. Because a synchronous step completes only when its slowest participant finishes, a single rank running slower during an episode delays its entire collective group by up to that same fraction. The job's cumulative program goodput loss scales with both the slowdown severity and the episode frequency. A periodic trace captured between episodes sees completely healthy execution. Always-on per-rank step timers catch the episodes as latency spikes, and crossing a duration threshold immediately triggers synchronized traces on both the lagging rank and a healthy peer. Correlating those triggered traces with device telemetry, switch counters, and host kernel logs then separates the rank that originated the stall from the peers that merely waited at the collective barrier.

9.3.4 Detecting regressions

A production fleet changes continuously even when a model team leaves its training script untouched. Framework and compiler releases alter the kernels a model dispatches, driver and firmware updates modify clock management and collective algorithms, storage migrations shift input and checkpoint bandwidth, and scheduler policy updates reshape how allocations form. Any of those changes can erode a goodput factor across every job it touches—often only at multi-node scale, where a slight increase in peak activation memory triggers allocator defragmentation on one rank or a longer host pause stalls an entire synchronous gang. Systematic regression detection applies the measurement contract to every infrastructure or software change and monitors each goodput factor in the telemetry record that settles it (table 9.4).

↪ How fleet telemetry is organized into monitoring levels that route an alert to the team that owns it is developed in section 12.6.3.

Table 9.4: Regression Test Tiers by Goodput Factor: Program regressions are caught by canaries and fleet baselines of MFU and step time; runtime and scheduling regressions are caught only by baselines kept over long windows in the job timelines and scheduler records, because their losses are rare per step and appear across many jobs.

Testing tier	Factor	What it measures	Regression caught
Small-scale canaries	Program	Step time and MFU on one node and on a small multi-node allocation, establishing a scaling efficiency curve	Code changes that look harmless on one GPU but bend the curve before full-fleet launch
Fleet baseline comparison	Program	Every production run's MFU of retained steps against the reference baseline for that architecture and software version	Architecture, compiler, or configuration changes that reduce useful fleet work
Gray failure detection	Program	Distribution of step times and per-rank step timers across the fleet	Straggler nodes; one node slowed by some fraction can lower synchronous data-parallel MFU by about that fraction
Startup and recovery baselines	Runtime	Time from gang completion to first step; checkpoint pause per commit; restarts, rework, and data stall ratio per day	Compiler or framework upgrades that lengthen compilation, storage changes that slow checkpoint writes or input, recovery automation that stops working
Allocation baselines	Scheduling	Queue wait to gang completion; capacity held in incomplete gangs; fragmentation index per pool over whole demand cycles	Scheduler policy or job-template changes that strand capacity or delay complete allocations

The program-goodput tiers catch most regressions introduced by model or kernel changes within minutes, because any per-step slowdown repeats on every iteration and manifests on a small multi-node canary. The runtime and scheduling tiers catch regressions that short canary runs cannot observe: a compiler release that adds minutes to graph compilation leaves steady-state step time untouched, and a quota policy that strands nodes in a shared pool surfaces only across a full diurnal demand cycle. Maintaining per-software-version and per-pool baselines under the same measurement contract allows engineers to tie any shift in scheduling, runtime, or program goodput directly to the release or policy change that introduced it. That same gap between short, clean benchmark runs and long production runs also governs capacity planning, because a cluster sized from benchmark numbers inherits every runtime and scheduling loss that the benchmark omitted.

↩ Gray failures, the silent degradations that surface as stragglers rather than crashes, are established in section 7.9.5.

Systems Perspective 9.1: What a benchmark run measures

Benchmark results, including MLPerf submissions, describe one tuned run under a specified protocol on a dedicated allocation. In goodput terms they measure program goodput, and useful work through the quality target, with scheduling goodput equal to one by construction and few of the interruptions a long production run accumulates. They are a reference for the program factor, not a capacity guarantee.

Production adds what the reference leaves out. Startup, checkpoint pauses, failures and rework, preemptions, and input waits are runtime losses, monitoring and contention with neighbors can lower program goodput further, and waiting for complete allocations is a scheduling loss no benchmark sees. As a planning scenario, if useful throughput is 10–20 percent below the rate that implied 30 days of training, the same work takes about 33.3–37.5 days. Section 9.5 sizes the runtime share of that gap for a well-run job.

Detecting a regression and verifying an optimization are the same measurement performed in opposite directions. Every candidate change must be evaluated at the accounting boundary it targets—in retained step time and MFU for a program change, in the job timeline for a runtime change, and in scheduler logs for an allocation policy change—rather than in an isolated microbenchmark. Doubling the speed of a single kernel saves at most half of that kernel's share of the step, and saves zero wall-clock time if the kernel already ran hidden behind an exposed collective. Because an optimization at one layer can degrade another factor, all three goodput factors are re-measured under the contract before promotion. Even a change that appears purely local can exhaust a shared hardware resource when deployed across thousands of nodes simultaneously, which is why production fleets gate infrastructure changes behind staged rollouts (section 12.5.5). One of the clearest postmortems of a local cost turning into a fleet-wide outage comes from edge networking rather than ML training.

War Story 9.1: The regex that saturated the edge (2019)

Context: Cloudflare's web application firewall evaluates rules on HTTP/HTTPS traffic across its global edge (Cloudflare 2019).

Mechanism: A rule deployed on July 2, 2019 caused excessive regular-expression backtracking and drove the CPUs serving HTTP/HTTPS traffic to nearly 100 percent utilization across the network. A previously removed CPU-use protection, missing performance tests, and a global rollout allowed the local computational cost to become a fleet-wide failure.

Impact: The resulting 27-minute outage disrupted proxying, content delivery, and firewall service. Traffic through the network dropped by about 82 percent, and users received 502 errors.

Fix: Disabling the firewall globally restored traffic; the offending change was then removed and the firewall re-enabled after testing. The postmortem reported restoring CPU-use protection and plans for performance tests, staged rule deployment, and a regular-expression engine with runtime guarantees.

Systems lesson: Correct outputs do not establish acceptable execution cost. A change that leaves every result correct can still lower goodput across the whole fleet at once. Performance-sensitive changes to an ML fleet, such as a compiler upgrade, a kernel library, or a new input shape, are therefore measured under the contract, staged on a small share of the fleet, and promoted only when the factors they touch hold.

A measurement contract that locks down each factor's window, a three-rung telemetry ladder that localizes losses from the cheapest record downward, and continuous baselines that catch regressions together make each goodput boundary observable in production. The first boundary a workload encounters is the formation of a complete allocation, where fleet capacity can be lost before a single step begins.

9.4 Scheduling Goodput

Partially assembled gangs, scattered node fragments, and draining reservations waste accelerator hours *before* any workload holds a complete allocation, whereas zombie jobs, input starvation, exposed collectives, and fragmented key-value caches waste capacity inside an allocation a job already holds. A cluster orchestrator's general health dashboards surface both classes of waste together, but scheduling goodput counts only the pre-allocation losses; fixing the post-allocation losses leaves scheduling goodput unchanged. Separating pre-allocation losses from post-allocation losses, and quantifying the pre-allocation share, is what scheduling goodput adds to the orchestrator's own view. The policy levers that recover those scheduling losses (atomic gang admission, backfill, bin packing, topology-aware placement, quota lending, and preemption policy) are developed in chapter 8.

9.4.1 What scheduling goodput counts

A rigid distributed training job holding half of its requested accelerators while waiting for the rest completes zero steps, not half as many, yet a naive utilization counter credits every assigned device as busy. Scheduling goodput eliminates that distortion by taking the ratio of two capacity-time integrals over the same calendar window. The denominator is the in-service capacity-time offered by the pool: its allocatable accelerators multiplied by the window duration. The numerator is the all-allocated capacity-time held by complete allocations, summed across jobs as each job's device count multiplied by the interval from the moment its minimum gang became complete until release. A complete allocation corresponds to the minimum viable execution group of section 8.4.3—every accelerator, interconnect domain, and co-scheduled host resource required to execute one synchronous step. For a rigid job, that group is the full requested gang; for an elastic job, it is the

active gang size between two reconfiguration boundaries, and any accelerators the job relinquishes re-enter the numerator only when another complete allocation claims them. Because nothing inside the allocation enters this ratio, a wedged job that holds a complete gang without running a step achieves the same scheduling goodput as a job executing at peak FLOP/s.

Every device-hour of in-service capacity outside a complete allocation is a scheduling loss, regardless of its operational cause. Capacity sits unassigned when offered demand falls below pool size, when waiting jobs have exhausted their team quotas, or when free accelerators are scattered across racks in fragments too small for any queued gang. Capacity is assigned yet incomplete when a gang holds an initial subset of nodes while waiting for the remainder, when two partial gangs deadlock over the last free nodes, when freed accelerators sit idle in a reservation draining for the head-of-line gang, or during brief container teardown and setup transitions between tenants. Because an incomplete gang cannot advance synchronous training, section 9.2.3 restricted the orchestrator's allocated tier to complete allocations alone.

Accelerators removed from service for hardware repair or scheduled maintenance are excluded from the scheduling goodput denominator because no scheduling policy can place work on broken nodes. Those out-of-service hours are tracked alongside MPG as cluster availability, keeping hardware downtime visible without blaming the scheduler. If a report instead divides by total installed silicon, hardware unreliability is folded into scheduling goodput. The measurement contract (section 9.3.1) therefore requires stating whether the denominator is in-service or installed capacity so that two fleet reports are never compared on mismatched baselines.

When scheduling goodput is low, scheduler logs distinguish between two fundamentally different causes that call for opposite remedies. If accelerators sat unallocated while the job queue was empty, the pool exceeds current demand—a capacity-planning and quota-lending problem. If accelerators sat unallocated or trapped in partial gangs while runnable jobs waited in the queue, placement constraints, rigid quotas, or fragmentation stranded the hardware—a scheduling-policy problem. Recording queue depth alongside every interval of unheld capacity separates the two immediately.

Because unallocated fragments, partial gangs, and draining reservations belong to the shared pool rather than to any single workload, scheduling goodput is a property of the resource pool. Our running Llama 2 70B job inherits the scheduling goodput of the pool from which it draws its nodes. A job's own time spent waiting in the queue is a separate metric. Queue wait reduces scheduling goodput only during intervals when pool accelerators actually sat outside complete allocations. While other complete jobs occupy the cluster, a queued job's wait costs zero fleet goodput and instead lengthens that job's time to result, a trade-off priced in section 9.9. As the queueing analysis in section 8.3 demonstrated, driving pool utilization and scheduling goodput toward one causes queue waiting times to rise steeply.

↪ Sizing a fleet against forecast demand, the remedy for capacity that no queued work wants, is developed in section 12.9.5.

9.4.2 Attributing scheduler losses

Defining scheduling goodput strictly at the complete-allocation boundary means that not every failure mode managed by the orchestration team is a scheduling loss. If a zombie job were subtracted from scheduling goodput simply because orchestrator lease timeouts clean it up, those wasted hours would be deducted from capacity that the scheduling numerator already counted as a complete allocation, penalizing the same hours twice. Attributing a capacity loss to whichever team owns the remediation lever therefore breaks the multiplicative goodput identity. Whereas the operational debugging workflow in section 8.12 groups utilization anti-patterns by their observable symptoms, goodput accounting classifies each loss pattern by the *first boundary its capacity fails to cross*. Capacity outside a complete allocation reduces scheduling goodput; capacity inside a complete allocation that produces no checkpointed step reduces runtime goodput; and capacity in retained steps that execute below the hardware ideal reduces program goodput. Because each lost interval stops at the first boundary it fails, every device-hour is charged once. Applying that boundary test to the orchestration anti-patterns shows that the system layer responsible for fixing a loss often differs from the goodput factor that records it (table 9.5).

↩ The utilization anti-patterns and the evidence that diagnoses each one are established in section 8.12.3.

Table 9.5: Attributing Orchestration Losses to Goodput Factors: Each utilization loss pattern of fleet orchestration is charged to the first accounting boundary its capacity fails to cross. Scheduling goodput receives only the losses that occur before a complete allocation exists, and a topology mismatch lands in scheduling or program goodput depending on whether the job waited or ran. The factor a loss lowers and the layer that removes it are recorded separately.

Loss pattern	What the capacity is doing	First boundary missed	Charged to	Layer that removes it
Partial-gang hold, including hold-and-wait deadlock	Assigned to a rigid job still waiting for members, so no step can run	Complete allocation	Scheduling goodput	Orchestration (atomic group admission)
Reservation for a waiting gang	Freed devices kept idle so the gang at the head of the queue can assemble	Complete allocation	Scheduling goodput	Orchestration (backfill under enforced runtime bounds)
Fragmentation and capability mismatch	Free devices scattered so that no queued gang fits, or of a type no queued job requests	Complete allocation	Scheduling goodput	Orchestration (bin packing, capability matching)
Topology mismatch, waiting	Held free while a compact placement assembles	Complete allocation	Scheduling goodput	Orchestration (placement policy)
Topology mismatch, running	Running across slower links than a compact placement would use	Ideal rate	Program goodput	Collectives and parallel layout; orchestration (placement policy)

Loss pattern	What the capacity is doing	First boundary missed	Charged to	Layer that removes it
Idle reservation	Reserved block held as an allocation while no job takes steps	Retained step	Runtime goodput	Orchestration (quota reclamation and lending)
Zombie job	Complete allocation kept after execution has stopped	Retained step	Runtime goodput	Fault tolerance (failure propagation); orchestration (leases, progress monitoring)
Preemption	Steps since the last checkpoint discarded; state reloaded and warmed up	Retained step	Runtime goodput	Orchestration (preemption budgets); fault tolerance (checkpoint cadence)
Data starvation	Steps waiting for their next input batch	Retained step	Runtime goodput	Data storage (input pipeline)
Communication bottleneck, including noisy neighbors	Retained steps expose collectives that computation does not hide, or that a co-located job's traffic slows	Ideal rate	Program goodput	Collectives and parallel layout; orchestration (isolation)
Cache fragmentation limiting admission (serving)	A ready replica admits fewer concurrent requests than its node could serve	Ideal rate	Program goodput	Serving (paged cache allocation)

Idle accelerators appear in two different goodput factors, depending on their allocation state. When a partial gang, a stranded fragment, or a draining head-of-line reservation leaves accelerators idle *outside* any complete allocation, the loss belongs to scheduling goodput. By contrast, when a team holds a static capacity reservation (section 8.11.4) as a complete allocation while running no steps on it, that capacity crosses the scheduling boundary and fails at the runtime boundary, registering as a runtime goodput loss. Reclaiming an idle quota block and returning it to the shared pool therefore shifts the accounting before it improves fleet output. Whatever fraction of the reclaimed block a borrowing team puts to work is recovered, while any fraction that finds no borrower sits free in the pool and converts from a runtime loss into a scheduling loss. An orchestration policy can shift waste from one boundary to another without increasing useful work; only the product $\eta_{\text{scheduling}} \times \eta_{\text{runtime}} \times \eta_{\text{program}}$ reveals whether the fleet came out ahead.

In every row of table 9.5, the accounting charges the specific time interval that exhibits the loss pattern rather than tainting a job's entire run. A zombie job wastes

its complete allocation from the moment progress halts until the lease expires and releases the nodes (section 8.4.4). An input-starved job's data-loader stalls are charged to runtime goodput from the job timeline's input-wait counter, while the active execution intervals between stalls pass into retained step time and are judged on their program goodput.

Finally, a communication or placement bottleneck on a running job lies entirely past the first two boundaries. The first-order diagnostic bound from section 8.12.3 compares total step duration against compute-only step time. Because ideal hardware step time cannot exceed compute-only time, the ratio of compute-only time to actual step time provides an immediate upper bound on program goodput before any trace is collected. A targeted step trace then isolates the exposed collective in the Fleet Law's communication term (section 9.6.2). Once those post-allocation rows are routed to runtime and program goodput, the pre-allocation rows that remain can be measured directly from the scheduler's logs.

9.4.3 Evidence, size, and the serving replica

Enforcing the complete-allocation boundary in production hinges on a single timestamp in the scheduler logs, the top rung of section 9.3.2. The cluster scheduler must explicitly record the instant a gang allocation becomes complete, as Kubernetes `PodGroup` admission does in section 8.5.2, rather than inferring completion from the job's first training step. Inferring gang completion from the first step would sweep process launch and compilation into the pre-allocation window, misclassifying a runtime startup loss as a scheduling loss. Likewise, if a scheduler logs only individual node bindings without a gang-complete event, analysts can reconstruct completeness for rigid jobs from their requested gang size, but cannot do so reliably for elastic jobs whose valid size changes over time. When that gang-complete timestamp is present, scheduler logs provide everything needed to compute scheduling goodput: summing each job's device count over the interval from gang completion to release yields the numerator, summing partially assigned gangs from first device assignment to gang completion quantifies partial-hold waste, and tracking unallocated devices alongside queue state accounts for the remainder. The utilization breakdown from section 8.13 (the pitfall of treating all allocated GPU-hours as productive) illustrates how these boundaries partition a shared cluster pool of the kind that hosts our running Llama 2 70B job.

Napkin Math 9.2: Scheduling goodput of a shared pool

Problem: In a shared fleet's snapshot, 80 percent of in-service capacity is assigned to jobs, 15 percent is held by groups still waiting for their remaining members, and another 5 percent sits in complete allocations waiting for input. What is the pool's scheduling goodput, and how far can atomic group admission alone raise it?

Variables:

- Assigned share 0.80, which includes the incomplete-group share 0.15.

- Input-wait share 0.05, which lies inside complete allocations and is therefore a runtime loss, sized in section 9.5.

Math:

- Scheduling goodput: $\eta_{\text{scheduling}} = 0.80 - 0.15 = 0.65$.
- Scheduling loss: $1 - 0.65 = 0.35$, the 0.20 no job holds plus the 0.15 held by incomplete groups.
- Ceiling for removing partial holds: group admission returns the 0.15 to the pool as free capacity, so $\eta_{\text{scheduling}}$ rises at most to $0.65 + 0.15 = 0.80$, and only if other jobs' complete allocations take every freed device.

Result: The pool's scheduling goodput is 0.65, so 35 percent of its capacity is lost before any step runs, and removing partial holds alone can raise it no higher than 0.80.

Systems insight: The scheduling loss of 0.35 is more than three times the at most 0.10 of held capacity that Llama 3 405B lost to all its interruptions on a dedicated cluster. Because the factors multiply, every later gain in a job's runtime or program goodput reaches this pool at 0.65 of its value on a dedicated cluster.

This constructed pool snapshot—which also anchors the whole-fleet synthesis in section 9.8—shows why atomic group admission is necessary but not sufficient. Releasing partial-gang holds raises scheduling goodput only insofar as backfill and bin packing refill the freed accelerators with complete gangs, and pushing past the 0.80 ceiling requires runnable demand for the remaining unallocated devices. Queue logs distinguish whether that unheld capacity is stranded by fragmentation and rigid quotas, which scheduling policy can recover, or lacks runnable demand altogether, which only quota lending or capacity planning can address.

A single fleet-wide average also conceals how scheduling policy distributes goodput across job sizes, which is why production fleets track scheduling goodput by size cohort. Across Google's TPU fleet, scheduling goodput exceeds 95 percent for every size cohort, peaking at the smallest and largest jobs while dipping for medium-sized jobs (Wongpanich et al. 2025). Preemption policy explains that U-shaped curve. Evicting a multi-pod training run would discard a long initialization and significant post-checkpoint work, so the scheduler shields the largest gangs from preemption. At the other extreme, single-node jobs finish quickly and pack easily into small gaps when preempted, so the scheduler uses them to defragment the pool and concentrates evictions on medium-sized gangs instead. Raising the scheduling guarantee for one size class therefore lowers it for another—a policy trade-off that a single fleet-wide average hides.

The eight-GPU serving replica crosses the scheduling boundary as a single indivisible gang: one full node across which tensor parallelism partitions the model weights. Because each replica requires a whole node, serving pools are sensitive to the intra-node fragmentation that small training or evaluation jobs

leave behind. A pool can have dozens of free GPUs scattered across partial nodes and still have zero whole nodes available. Both a replica waiting in the queue for an unfragmented node and dedicated serving nodes sitting without a placed replica count as scheduling losses. Once placed on a node, however, the replica holds a complete allocation even before it can answer requests: weight loading, warmup, and graph compilation are runtime losses, while spare capacity held on a ready replica for traffic bursts is a program loss. Placement records, replica lifecycle logs, and decode traces separate the three, turning the analysis to how much of a complete allocation's held time actually produces durable progress.

9.5 Runtime Goodput

A training job that loses held time to input stalls, synchronous checkpoint pauses, hardware failures, and forced preemptions encounters each loss in a different unit. Chapter 4 expresses input stalls as a fraction of step time, chapter 7 expresses checkpointing and recovery overhead against fault-free training time, and chapter 8 prices preemption in wasted minutes per eviction event. Runtime goodput—the fraction of a job's all-allocated held time that becomes retained progress—places all of those losses on a single common denominator. Expressed as shares of held time, every interruption can be compared directly so that engineers attack the largest loss measured on the job timeline rather than whichever subsystem they inspected most recently, while the mechanisms that shorten each loss remain with their owning chapters.

9.5.1 What runtime goodput counts

Holding a complete gang for an hour does not guarantee an hour of retained training steps: the job can spend much of that hour launching processes, waiting on a starved data pipeline, pausing for synchronous checkpoint commits, or re-executing steps erased by a node failure. Runtime goodput measures the fraction of all-allocated time that survives those interruptions as a ratio of two durations over the same calendar window. The denominator is the job's held time from the gang-complete timestamp to release, taken directly from scheduler logs (section 9.4.3). The numerator is productive time: the count of retained steps multiplied by the job's fault-free step duration. A step counts as retained once a committed checkpoint records its state update (or when the job finishes and commits its final weights). The fault-free step duration is the job's steady-state step time with input batches ready and no recovery in progress on that same allocation.

Normalizing the numerator to the job's own fault-free step duration keeps the runtime boundary cleanly separated from the program boundary. Because the fault-free step duration already includes exposed collectives, pipeline bubbles, memory bandwidth stalls, and persistent stragglers, those per-step inefficiencies pass through the runtime boundary unchanged and are evaluated in program goodput. Steps immediately following a restart are handled differently. While instruction caches warm up, just-in-time kernels compile, and data-loader queues refill, any excess step duration above the steady-state fault-free baseline belongs to the recovery event that triggered the restart and is charged to runtime goodput.

The fault-free baseline duration of each completed step, by contrast, counts as retained progress. Consequently, a degraded node that slows every step across a multi-day run registers as a program goodput loss, whereas a temporary slowdown confined to the warmup minutes after a restart registers as a runtime goodput loss.

Every other interval of held time that fails to produce retained steps is a runtime loss, ordered chronologically across a job's lifecycle:

- *Startup* spans the interval from gang completion to the first training step while processes launch, libraries load, collective communicators initialize, checkpoint weights load, and compilers warm up. Because scheduler logs timestamp gang completion and the job timeline timestamps the first step, startup is measured directly between those two records—which is why section 9.4.3 requires the scheduler, rather than the first step, to mark allocation completion.
- *Input waits* capture the time a retained step spends blocked on the data pipeline for its next batch, carved out of step duration per section 9.2.3.
- *Synchronous checkpoint pauses* capture the intervals during which training halts while accelerators or hosts flush state to persistent storage.
- *Failure recovery and rework* cover both the downtime from a fault through detection, relaunch, state reload, and warmup, and the held time spent earlier on post-checkpoint steps that the failure erased and the job had to repeat.
- *Forced preemption and planned reconfiguration* charge the post-checkpoint work discarded by an eviction, the subsequent reload after readmission, and the warmup before steady-state step times return, along with planned maintenance drains or elastic resizes. All of these belong to runtime goodput because the job held a complete allocation while the discarded or non-step hours were spent.

Three adjacent delays fall outside runtime goodput. Time a preempted job spends waiting in the scheduler queue before readmission is not held time and affects only time to result (section 9.4.1). Background bandwidth contention from asynchronous checkpoint writes and the steady-state execution speed of compiled kernels both lengthen retained steps and belong to program goodput, whereas ahead-of-time compilation before the first step belongs to runtime startup. Keeping cold-start compilation and warmup in runtime goodput matches the measurement contract of table 9.2, which excludes warmup trials from the steady-state step rate used for program goodput.

Finally, the measurement window for runtime goodput must span many interruption cycles (section 9.3.1) and requires a clean closing rule: steps executed after the last checkpoint committed inside the window are neither durably retained nor lost yet. Closing the measurement window at a checkpoint commit avoids that ambiguity; if a window closes between commits, those trailing steps count as retained only once the next checkpoint succeeds.

9.5.2 Composing runtime loss from its owners

A team whose job loses a tenth of its held time cannot tell from the aggregate runtime goodput alone whether to add storage bandwidth for input stalls, shorten checkpoint writes, or negotiate a tighter preemption budget. Because every non-productive interval of held time falls into exactly one of the five runtime-loss categories, those categories partition the gap between held time and productive time without overlap. Dividing each category's duration by total held time expresses it as a fractional loss share, and the five shares add directly. Earlier chapters already derived each individual share:

1. The *startup share* is the launch and compilation duration T_{startup} from gang completion to first step, divided by the held duration T_{wall} of that allocation.
2. The *input-stall share* is the data stall ratio f_{stall} of equation 4.4, which section 4.4 derives from the bottleneck stage of the storage pipeline.
3. The *checkpoint share* is the Young-Daly checkpoint waste $W(T_{\text{ckpt}})$ of equation 7.8 evaluated at the job's checkpoint interval T_{ckpt}, combining synchronous write pauses with expected post-checkpoint rework after failures.
4. The *failure-recovery share* is the per-fault recovery duration T_{recovery} from section 7.9.2 (detection, relaunch, checkpoint load, and warmup) divided by the cluster's mean time between failures $\text{MTBF}_{\text{system}}$.
5. The *preemption share* is the forced-preemption rate λ_{preempt} multiplied by the per-eviction overhead T_{preempt} from section 8.8.1.

Equation 9.4 sums the five shares to give total runtime goodput loss:

$$1-\eta_{\text{runtime}} \approx \frac{T_{\text{startup}}}{T_{\text{wall}}} + f_{\text{stall}} + W(T_{\text{ckpt}}) + \frac{T_{\text{recovery}}}{\text{MTBF}_{\text{system}}} + \lambda_{\text{preempt}} T_{\text{preempt}} \tag{9.4}$$

Writing runtime loss as an explicit sum turns optimization into a quantitative triage problem for a specific workload: which of the five terms dominates *this* job at *this* scale under *this* cluster policy. Each term carries the modeling assumptions of its owning chapter, so whenever a workload violates one of those assumptions, engineers refine that specific term using the owning chapter's full model while keeping the additive boundary accounting intact.

↩ The checkpoint waste equation, its optimal interval, and the four-term recovery budget are established in chapter 7.

Equation 9.4 is a first-order sum because the individual models normalize their losses against slightly different baselines—step time for data stalls, fault-free compute time for Young-Daly waste, and arrival rates times event durations for recovery and preemption. When every individual loss share is small, those baseline differences alter the sum only to second order (fractions of a percent). Whenever a single term grows large enough to consume a major fraction of held time, the first-order approximation has already served its diagnostic purpose, and engineers measure the exact shares directly from the job timeline.

Summing the five terms is valid only when no lost minute is counted in two terms at once. Four boundary junctions require care so that the owning chapters' formulas do not overlap:

- *Rework is counted once per interruption cause.* Because the checkpoint waste term $W(T_{\text{ckpt}})$ already includes the expected steps lost after a hardware failure, the failure-recovery term $T_{\text{recovery}}/\text{MTBF}_{\text{system}}$ includes only detection, relaunch, reload, and warmup. Conversely, steps erased by a scheduler eviction belong to T_{preempt} and must not be folded into $\text{MTBF}_{\text{system}}$ unless the two terms are solved jointly.
- *Warmup is charged to the event that triggered it.* Both the failure-recovery budget T_{recovery} and the preemption tax T_{preempt} already include post-restart warmup, so the initial startup term $T_{\text{startup}}/T_{\text{wall}}$ counts only cold launches that were not triggered by an in-run failure or preemption.
- *The data stall ratio f_{stall} is measured in steady state.* Pipeline refill immediately after a restart is part of post-restart warmup; averaging f_{stall} across restart warmup windows would charge that refill delay twice.
- *Only synchronous checkpoint pauses enter $W(T_{ckpt})$.* When checkpoints are written asynchronously in the background, any memory or fabric contention they inflict on running steps lengthens retained step time and is charged to program goodput instead.

At the 10,000-GPU scale analyzed in section 7.8.1, checkpoint waste (about 5.9 percent) and failure recovery (about 2.8 percent) together consume nearly a tenth of held time. Because both shares are evaluated here at the full component failure rate that governs the Young-Daly interval, the recovery fraction exceeds that section's GPU-only figure. Both failure-driven terms grow with device count, whereas startup, input stalls, and preemption do not. Consequently, jobs of different sizes lose runtime goodput to entirely different mechanisms. Because our running example is much smaller than that frontier reference, its loss terms rank in a different order.

Napkin Math 9.3: Runtime loss of the Llama 2 70B job

Problem: The Llama 2 70B training job holds 128 GPUs on a shared fleet for a week, under a per-job budget of 1 forced preemption a day. With each owner's model applied to the job's own configuration, what runtime goodput does it keep, and which term costs it the most?

Variables:

- Mean time between failures $\text{MTBF}_{\text{system}}$ is about 302 hours, from the component failure rates of section 7.8.1.
- The resumable checkpoint takes about 9.8 seconds to write at the 100 GB/s of the recovery budget in section 7.9.2, the job's tenth of a parallel file system shared by ten jobs (section 4.6), so the Young-Daly interval T_{ckpt} is about 77 minutes.
- Recovery T_{recovery} is about 6.2 minutes per failure, and startup T_{startup} is about 5.2 minutes per launch, the same steps without detection.

- The data stall ratio f_{stall} is 7.7 percent of held time, the snapshot's 5 percent of in-service capacity divided by its scheduling goodput of 0.65 (section 9.4.3).
- The preemption overhead T_{preempt} is about 20.2 minutes per forced event, the 15 minutes of lost work that section 8.8.1 assumes plus one startup.

Math (one line per term of equation 9.4):

- Startup: 5.2 minutes ÷ 7 days ≈ 0.05 percent.
- Input waits: 7.7 percent.
- Checkpoint: 9.8 seconds ÷ 77 minutes for writes, plus 77 minutes ÷ (2 × 302 hours) for rework, ≈ 0.2 percent + 0.2 percent ≈ 0.4 percent.
- Recovery: 6.2 minutes ÷ 302 hours ≈ 0.03 percent.
- Preemption: 1 per day × 20.2 minutes ≈ 1.4 percent.

Result: The five terms add to a runtime loss of about 10 percent, a runtime goodput of about 0.90. Input waits and preemption account for 9.1 percent of it, and checkpoint waste and recovery together for under half a percent.

Systems insight: On a mid-sized job that shares its fleet, the terms that grow with device count are the smallest, so the lever that reaches the most held time belongs to the input pipeline and the preemption budget rather than to the reliability layer.

Because the overall runtime goodput is already close to what a well-run job achieves, the engineering lesson lies in how the loss is divided. A team consulting only chapter 7 might invest in faster checkpoint writes and warm restarts, yet on this 128-GPU job those levers can recover at most the 0.4 percent and 0.03 percent shares assigned to them by the composition. Meanwhile, the input pipeline sized in section 4.4 governs roughly 17× as much held time. Without a preemption cap, the 12 forced preemptions per day that section 8.8.1 models for a low-priority run would consume 16.8 percent of held time—exceeding every other term and breaking the small-loss regime of the first-order sum.

Both job size and job duration reorder these terms. As device count grows, checkpoint waste and failure recovery expand until their combined loss overtakes input waits near 13,000 GPUs (figure 9.5). Similarly, the same 5.2 minutes startup cost that is negligible over a week consumes about 9 percent of an evaluation job that holds its allocation for only an hour. The composition does not pick a universal winner among these levers; rather, it shows each subsystem owner how much held time their lever can actually reach—a comparison no single subsystem can make in isolation.

Composing the terms also exposes a cross-layer coupling that no single owner sees alone. Because a forced preemption discards all work since the last committed checkpoint just as a hardware failure does, it acts as an additional interruption when choosing the checkpoint cadence. Our running example's 77 minutes interval was derived from hardware failures alone; counting its budgeted preemptions as

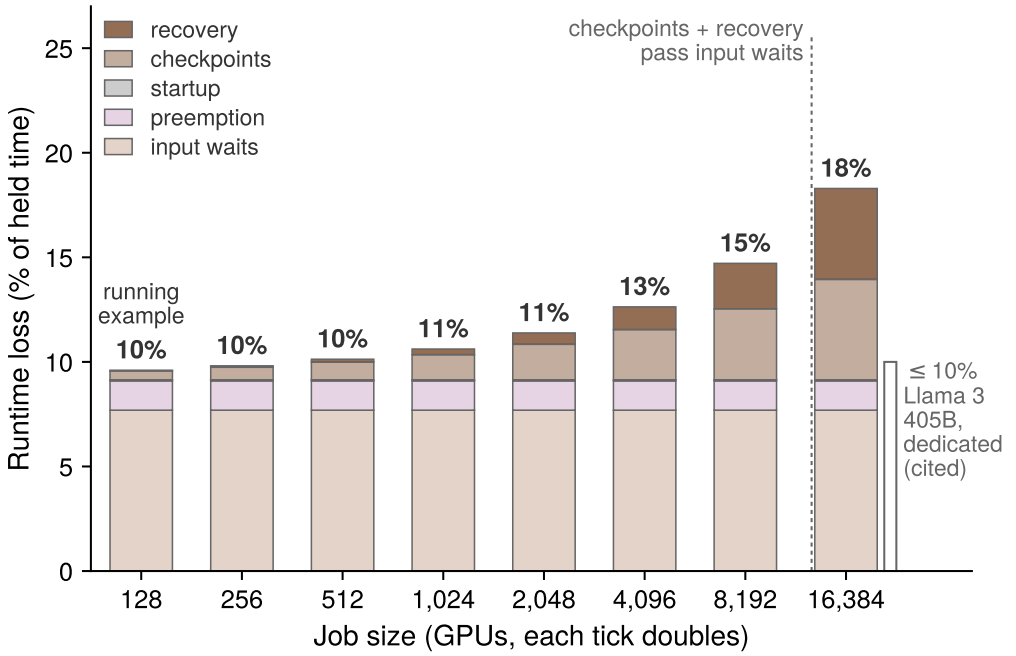

Figure 9.5: Runtime Loss versus Job Size: Each bar recomputes the five terms of equation 9.4 for the running example at one job size, from 128 to 16,384 GPUs, holding the 70B checkpoint, the recovery budget, the data stall ratio, the preemption budget, and the week of held time at the running example's values and recomputing the Young-Daly interval at each size. Input waits and preemption stay flat and dominate small jobs, while checkpoint waste and recovery grow with device count, pass input waits near 13,000 GPUs (dotted line), and lift the loss from 10 percent to 18 percent, above the loss of at most 10 percent implied by the effective training time Llama 3 405B reported on its dedicated cluster (hollow bar) (Dubey et al. 2024).

interruptions in equation 7.7 shortens the optimal interval to about 21 minutes. Although the checkpoint cadence belongs to section 7.8.1 and the preemption budget belongs to section 8.8.1, composing runtime goodput reveals that the two parameters are coupled parts of a single decision.[5]

While equation 9.4 describes an individual job, a pool's aggregate runtime goodput is also lowered by idle reserved blocks and by zombie allocations that continue to hold devices after execution has stalled. Because section 9.4.2 charges both intervals to runtime goodput, they appear only when the pool's total held time is compared against the sum of its active jobs' timelines.

9.5.3 Evidence, size, and the serving replica

A job that hangs inside a collective past its detection timeout, warms up much more slowly than its recovery budget assumed, or compiles longer after each software release loses held time that no analytical model predicts. Measuring runtime goodput directly from the job timeline—the second rung of section 9.3.2—captures both the modeled terms and any unmodeled residual because the timeline's events map directly onto the loss categories. Startup runs from the scheduler's gang-complete event to the first step; input stalls come from the per-step input-wait field of each retained step; and checkpoint pauses appear as the intervals at each commit. Every failure or preemption contributes its detection, relaunch, and

warmup intervals together with the steps it forced the job to repeat, while excluding any queue wait after an eviction. Finally, the retained-checkpoint markers establish which steps count toward progress, and the steady-state step times fix the fault-free rate.

Under this workflow, equation 9.4 serves as an analytical check on the job timeline rather than a substitute for it. When prediction and measurement agree, the largest modeled term identifies the subsystem owner to call. When the measured loss exceeds the prediction, the unexplained residual represents held time lost to unmodeled hangs, slow warmups, or creeping initialization overheads. A residual that widens across many jobs after a deployment is precisely the regression caught by the runtime row of table 9.4.

The Llama 3 405B training run provides the benchmark for a well-run frontier job. Meta reported more than 90 percent effective training time, corresponding to a runtime goodput of at least 0.90 (Dubey et al. 2024)—a demanding standard given the hardware failure cadence analyzed in section 7.1.

Although our running example's runtime goodput of 0.90 matches that frontier figure to two decimal places, the agreement masks a difference in mechanism. Running on a dedicated cluster across 128× as many devices, the Llama 3 job had to fight for its runtime goodput against failure-driven checkpoint and recovery overheads. Our 128-GPU job loses almost nothing to hardware failures and nearly all of its lost tenth to input stalls and preemption. Because the same aggregate factor can point to entirely different owners, a fleet report must record the constituent loss terms alongside their sum.

By contrast, a standard benchmark run is short, dedicated, and timed only after initialization completes,[6] so of the five runtime loss terms it experiences at most the steady-state input stall (perspective 9.1). Any capacity plan extrapolated from a benchmark rate must therefore restore the remaining terms of this composition.

For a serving replica, the same boundary separates held time from ready time, so its runtime goodput is the ratio of ready time to held time in the replica's lifecycle log. Provisioning precedes the complete allocation and belongs to scheduling goodput, whereas the weight fetch, model load, and warmup that follow—requiring about 5.7 minutes in the cold-start budget of section 10.13—are runtime losses. How heavily those minutes weigh on runtime goodput depends on the replica's lifetime: a replica recycled once a day spends about 0.4 percent of its held time becoming ready, whereas a replica spun up for a single burst hour loses about 9 percent. Maintaining a warm pool of loaded, idle replicas does not eliminate this cost; it shifts the idle capacity from runtime goodput into program goodput as serving headroom.

Whether measured as a ready replica or a retained training step, crossing this boundary means that held time has become retained work. How fast that retained work executes relative to its hardware ideal is the domain of the third factor: program goodput.

[5] **Effective training time ratio (ETTR)**: Kokolis et al. (2025) define a job's ETTR as productive runtime over wallclock time, including time spent queued, and derive its expected value from the failure rate, checkpoint interval, checkpoint write cost, restart overhead, and queue time; they use it to estimate how much large jobs on Meta's research clusters lose to failures. It is the closest published counterpart to this composition for the failure-driven terms. Because its denominator includes queueing, ETTR also spans part of scheduling goodput, so an ETTR and a runtime goodput for the same job are not directly comparable.

[6] **MLPerf Training timing**: The rules as first published start the clock when the system first touches training or validation data, leave system initialization untimed, and exclude up to 20 minutes of model creation as well as one-time data reformatting (Mattson et al. 2020). Startup, compilation, and data preparation therefore never enter a benchmark's time to train, although every production launch pays them in the startup term.

Checkpoint 9.1: Charging losses to factors

Every lost interval is charged once, at the first boundary it fails to cross, and each factor is read from the record that can see its boundary.

- ☐ **Which factor**: For a gang that holds half its devices while it waits, a zombie job, an input wait inside a retained step, and a straggling rank, can you name the factor each lowers and the layer whose lever removes it?
- ☐ **Which record**: A job retains fewer steps than planned. Can you explain why the scheduler records and the job timeline are read before any step trace, and what each can and cannot establish?
- ☐ **Which window**: Why can a one-day measurement report a runtime goodput near one for a job that loses a tenth of its held time over a month?
- ☐ **Composing runtime loss**: Given a data stall ratio, a checkpoint interval, a failure rate with its recovery time, and a preemption budget, can you add the runtime loss terms and name the interval that must not be counted twice?

↪ Cold-start latency, its decomposition into provisioning, loading, and warmup, and the pre-warming that hides it are developed in section 10.13.

9.6 Program Goodput

Even when a job holds a complete allocation and retains every step it executes, it can still waste most of its capacity if each retained step runs far below the speed its hardware allows. Within the held time of our Llama 2 70B training job, program goodput is the single largest source of loss—even though scheduling losses consume a larger share of the shared pool as a whole (section 9.8.1). Because the job's retained steps run at a fleet MFU of 48 percent, its program goodput is about 0.48, meaning that 52 percent of the time spent inside retained steps produces no progress at the ideal rate.

Program goodput is also the only factor whose losses this chapter both diagnoses and recovers directly by changing how the step executes. Diagnosing a program goodput loss requires two complementary instruments: the iron law and the Fleet Law identify which analytical term of a step a loss lengthens, while a hierarchical step trace—read from the fleet metric down to individual hardware counters—shows which term is actually exposed on the critical path.

9.6.1 The iron law and the Fleet Law terms

↩ Partitioning layouts and their communication patterns, which set most of a large job's step structure, are established in chapter 6.

Speeding up a kernel on a single accelerator often yields much less benefit—or none at all—once a job scales across a fleet, because the step also spends time moving data across memory hierarchies, waiting at synchronization barriers, and exchanging tensors over the network fabric. Separating what a local kernel change can reach from what requires a fleet-level change starts with the single-machine iron law (equation 9.5). The iron law decomposes the local execution of each

device into the data volume crossing a chosen memory boundary, the arithmetic operations performed, and the latency overhead that neither term explains:

$$T = \frac{D_{\text{vol}}}{\text{BW}} + \frac{O}{R_{\text{peak}} \cdot \eta_{\text{hw}}} + L_{\text{lat}} \tag{9.5}$$

Here D_{vol} is the data volume crossing the chosen memory boundary, BW is that boundary's bandwidth, O is the operation count, and $R_{\text{peak}} \cdot \eta_{\text{hw}}$ is the realized compute rate. At fleet scale, the overhead term L_{lat} splits into two parts with distinct owners: host dispatch (the kernel launches that keep each accelerator fed) belongs to single-device execution, whereas exposed communication and synchronization exist only because the step spans multiple devices. Section A.2 reviews these terms and their overlapped form.

The single-machine iron law connects to the fleet through the terms of the Fleet Law (equation 1.3). The data-movement and compute terms, together with the host-dispatch portion of L_{lat}, constitute local execution, whose unsharded reference time is T_{compute} and whose per-device share across N devices is T_{compute}/N. Meanwhile, the communication component of L_{lat} becomes the Fleet Law's $T_{\text{comm}}(N)$, the synchronization component becomes $T_{\text{sync}}(N)$, and any communication or synchronization hidden behind useful computation is credited back through T_{overlap}. When we measure an already-partitioned device shard, partitioning has already divided the local workload, so its measured execution time must not be divided by N a second time. Throughout the remainder of this chapter, "overhead" refers to host dispatch unless communication is named explicitly. A local kernel optimization therefore improves fleet performance only through the specific term it shortens, and it shortens the overall step only by the portion of that term that was exposed on the critical path.

Every program goodput loss cataloged in table 9.1 lengthens one of these Fleet Law terms. Memory stalls, sub-peak arithmetic, and slow host dispatch all lengthen local execution, whereas exposed collectives lengthen $T_{\text{comm}}(N) - T_{\text{overlap}}$. Stragglers and pipeline bubbles both manifest in $T_{\text{sync}}(N)$ as healthy devices wait at a barrier or stage boundary for upstream work to finish, whereas activation recomputation inflates O beyond the work required by the model itself. Each mechanism leaves a distinct signature in a step trace and answers to its own engineering lever (table 9.6).

Table 9.6: Program Goodput Losses by Fleet Law Term: Each loss inside a retained step lengthens one term of the iron law or the Fleet Law, and a step trace shows it as a characteristic interval. Only barrier and stage waits of the Fleet Law's coordination term are charged here.

Program goodput loss	Term it lengthens	Evidence in a step trace	Lever owner
Memory stalls	D_{vol}/BW in local execution	Kernels near the bandwidth ceiling; achieved HBM bandwidth close to peak while arithmetic is low	This chapter (fusion, tiling, compilation)

Program goodput loss	Term it lengthens	Evidence in a step trace	Lever owner
Arithmetic below peak	$O/(R_{\text{peak}} \cdot \eta_{\text{hw}})$ in local execution	Kernels far below both roofline ceilings; low occupancy or poor instruction mix	This chapter (kernel selection, compilation)
Recomputation	Added O beyond the model's required work	Hardware FLOPs utilization above MFU	chapter 6 (memory feasibility)
Host dispatch	Dispatch part of L_{lat} in local execution	Idle gaps between short kernels; long host-side launch intervals	This chapter (graph replay, compilation)
Exposed communication	$T_{\text{comm}}(N) - T_{\text{overlap}}$	Collective intervals with no concurrent computation on any rank	This chapter and chapter 5
Stragglers	$T_{\text{sync}}(N)$	All ranks but one waiting at the same barrier	chapter 7 (replacement)
Pipeline bubbles	$T_{\text{sync}}(N)$	Stages idle at the start and end of each step	chapter 6 (schedule)

Although the coordination term of the Fleet Law also encompasses checkpoint writes, failure detection, and failure recovery, those intervals occur *between* retained steps and are charged to runtime goodput (section 9.5). The Fleet Law's coordination term therefore straddles two goodput factors: only the barrier and pipeline-stage waits *inside* a retained step lower program goodput. Put simply, the Fleet Law term identifies the physical mechanism and its engineering lever, while the goodput boundary identifies which factor pays the cost.

This mapping also bounds how much a single-device speedup can help at scale. Because a kernel optimization shortens only T_{compute}/N, its share of the total step shrinks as N grows and T_{compute} is divided across more devices, while communication and synchronization do not shrink in proportion. Consequently, the very same kernel speedup delivers a smaller end-to-end gain on a larger job. Optimizations can also shift cost from one term to another rather than eliminating it: recomputing activations to free HBM capacity adds floating-point operations to O, illustrating that the conservation and displacement of overhead (principle 14) operates within a single step just as it does across the C^3 dimensions.

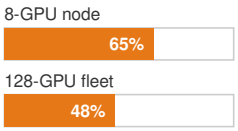
The serving replica applies the exact same decomposition to a single decode step. Because each of its eight devices holds one shard of the 70B model's weights, a small-batch decode step must stream its entire weight shard from HBM to perform only a handful of operations per weight, making the data-movement term D_{vol}/BW dominant. Meanwhile, the tensor-parallel activation exchange in every transformer layer forms its communication term. The replica's program goodput is therefore governed by how closely its decode step approaches the minimum time required to stream its weights—a relationship that the roofline model makes concrete in section 9.6.3.

CL
D

In the replica's small-batch decode step, the data-movement term dominates the iron law.

Checkpoint 9.2: The iron law and the Fleet Law terms

Program goodput falls only through the terms of a step, and a change helps only through the term it shortens.



- ☐ **Iron-law estimate**: For a step that is 60 percent data movement, 30 percent compute, and 10 percent overhead, can you estimate which single change buys the most wall-clock time, and what the iron law predicts once that dominant term is halved?
- ☐ **Fleet Law term**: Can you name the Fleet Law term a fused kernel shortens, and explain why its fleet gain shrinks as N grows?
- ☐ **Barrier waits**: Can you explain why a rank that waits at a barrier for a slow peer is charged to program goodput, while a job that waits for a failed node to be replaced is charged to runtime goodput?

9.6.2 Exposed communication at fleet scale

A job distributed across many nodes must exchange data over the inter-node network fabric, which is slower than intra-node links, shared with competing jobs, and traversed by collectives whose volume and latency grow with participant count. Whatever portion of that exchange the execution schedule cannot hide behind useful computation lengthens every retained step. That exposed communication interval is what separates a multi-node fleet job from the same workload on a single node, and because the job holds a complete allocation and retains every slowed step, the loss belongs entirely to program goodput.

↩ How much communication a schedule can hide, and why the hidden fraction falls as collectives grow relative to the compute window, are established in section 5.10.4.

Our running example measures this multi-node penalty directly. Because its single-node baseline and its 128-GPU fleet configuration train the same model with the same per-device workload, the ratio of their MFUs isolates what scaling across the fabric costs the program.

Fleet MFU falls below the single-node baseline.

Napkin Math 9.4: From one node to 128 GPUs

Problem: The 70B parameter training job of the running example achieves a node baseline of 65 percent MFU on one 8 GPUs node, with optimizer state offloaded to host memory because the full training state of a 70B model exceeds one node's HBM. Scaled to 128 GPUs with the same work on each device, its step time rises from 180 ms to 245 ms. What program goodput does the job keep at fleet scale, and how much of the node's efficiency does scale cost?

Math: Both MFU figures apply equation 9.3, the useful FLOPs of a step divided by the FLOPs the devices could execute at peak in that step's wall time.

Step 1: Fleet MFU. A step performs 14.9 PFLOP of useful work, while 128 GPUs $\times$ 989 TFLOP/s per GPU $\times$ 245 ms could execute 31 PFLOP at peak, so

fleet MFU is 14.9 PFLOP ÷ 31 PFLOP ≈ 48 percent. The same substitution on the node gives 65 percent.

Step 2: Efficiency relative to the node. Because each device does the same work in both configurations, the ratio of the two MFUs is the ratio of the two step times, 180 ms ÷ 245 ms ≈ 74 percent.

Step 3: Time beyond the node. Each fleet step spends 180 ms on the node's work plus 65 ms that the node step did not, about 27 percent of the fleet step.

Result: The job keeps program goodput of about 0.48 and 74 percent of the node's efficiency, losing 26 percent of it to scale.

Systems insight: The 65 ms per step beyond the node baseline bounds what exposed communication and synchronization can claim, but it does not by itself isolate the fabric, since offload, kernel shapes, and barrier waits can also change between the two configurations. The bound becomes an attribution only when a step trace shows which intervals fill the added time.

The ratio computed in the notebook is the scaling efficiency of equation 6.1—referenced here to a single node rather than to a single device as in section 6.4.2—and it completes the metric reconciliation begun in section 9.2.2. A job's fleet MFU equals its single-node baseline MFU multiplied by its scaling efficiency from that node (65 percent $\times$ 0.74 $\approx$ 48 percent), and that product, evaluated over retained steps, is its program goodput. An engineering report may quote the fleet MFU directly, or it may quote the single-node MFU alongside the scaling efficiency, but it must never multiply the fleet MFU by the scaling efficiency a second time, which would double-count the multi-node penalty. Because the single-node baseline already includes intra-node NVLink collectives and host-offload traffic, factoring fleet MFU at the node boundary isolates the cross-node scaling tax against a baseline that engineers can easily reproduce.

In the language of the Fleet Law, the additional 65 ms per step reflects growth in $T_{\text{comm}}(N) + T_{\text{sync}}(N) - T_{\text{overlap}}$ alongside any configuration difference in local execution, and only a step trace can separate those contributions. When section 9.3.2 localized the loss on our running example, it found no rank consistently lagging its peers, but it did find cross-node gradient reductions running exposed after backward computation had finished. Had the trace instead shown fifteen nodes waiting at a barrier for one slow node, the very same step-time increase would have belonged to $T_{\text{sync}}(N)$—yielding the same program goodput, but pointing to node replacement rather than communication overlap as the remedy.

The Llama 3 405B training run provides a production reference point: it sustained an MFU of about 41 percent across 16,384 GPUs[7] under a 4D parallelism layout tuned by the team that built the cluster (Dubey et al. 2024). Our 128-GPU running example achieves a slightly higher program goodput because it spans far fewer devices, so its cross-node collectives occupy a smaller fraction of each step, not because of superior kernel engineering. Both runs surrender roughly half of their retained step time relative to the peak arithmetic ceiling; the task of performance diagnosis is to determine which specific Fleet Law terms hold that lost half.

[7] **MFU across Llama 3 configurations**: The report's scaling table gives 43 percent BF16 MFU on 8,192 GPUs and 41 percent on 16,384 GPUs, with the same tensor and pipeline layout and twice the data parallelism (Dubey et al. 2024). The report attributes the drop to the smaller batch per data-parallel group needed to hold the global batch constant, so doubling the devices cost program goodput with no change to the model or its kernels.

9.6.3 Drilling into the step

Inspecting hardware counters on an arbitrary kernel before knowing which rank or stream delayed the step wastes engineering effort on operations that may not even lie on the critical path. Once a loss has been localized to program goodput, the step trace becomes the primary evidence, and it must be read from the top down. The step-trace rung of section 9.3.2 expands into four hierarchical levels (figure 9.6):

1. **Job and fleet metrics** (step time against plan, MFU of retained steps, and per-rank step timers) detect that a program goodput loss exists.
2. **Framework and distributed traces** correlate step time with model operations across ranks, revealing whether a lagging rank or an exposed collective is lengthening the step.
3. **Kernel timelines** expose host launch gaps and the stream-level overlap between computation and communication on a single rank.
4. **Hardware performance counters** measure achieved memory bandwidth, SM occupancy, and instruction mix for an individual kernel.

Each lower level is collected only for the specific ranks and time windows flagged by the level above it. Section A.8 maps the single-device profiling tools used at each rung.

Diagnosing our running example required descending three of the four levels. First, distributed traces across a data-parallel group showed that no rank lagged consistently behind its peers—ruling out a hardware straggler—while revealing collective intervals that widened with device count. Next, a kernel timeline on a representative rank showed those collectives executing on the communication stream with no concurrent kernels on the compute stream during the latter part of the backward pass. That timeline proved that the bottleneck stemmed from collective scheduling rather than fabric bandwidth. Hardware counters at Level 1 were unnecessary because the compute kernels flanking the exposed collective were already running at their expected rates; the descent stopped as soon as the responsible Fleet Law term was identified.

Systems Perspective 9.2: The cost of tracing a step

Tracing adds work to the step it measures. Recording every kernel launch, memory allocation, and collective consumes host cycles and memory and can add synchronization, so a traced step can run slower, or with a different overlap between communication and computation, than the untraced steps it is meant to explain. The perturbation grows with the events and options collected. A trace is therefore evidence about the structure of a step, while the step's duration is measured from the untraced job timeline, and comparing an instrumented with an uninstrumented window of the same job shows how much the trace changed.

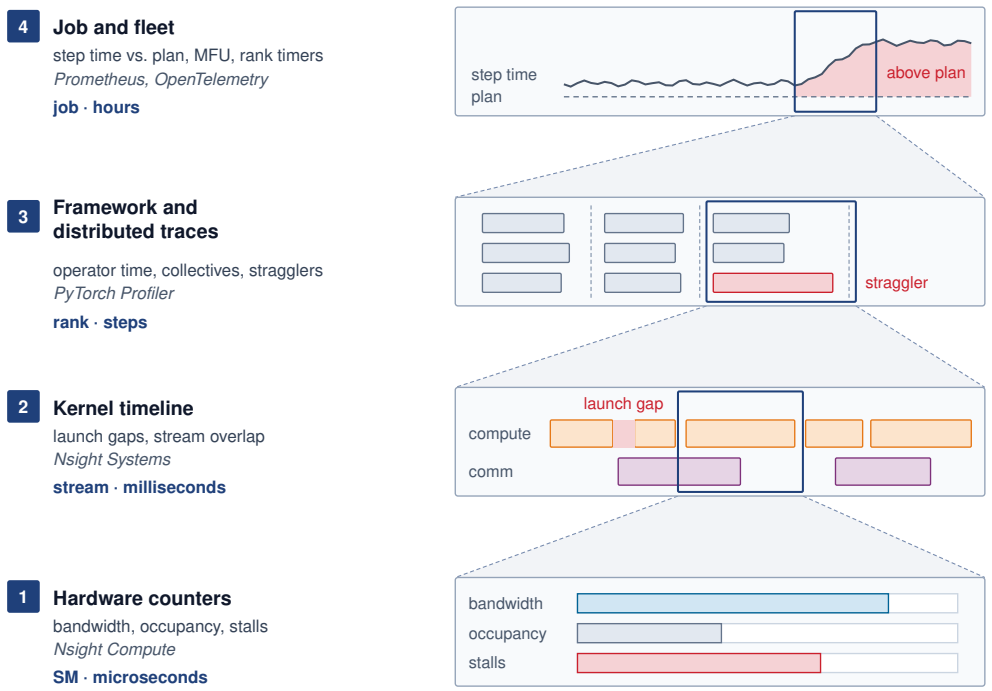


Figure 9.6: The Profiling Hierarchy: Diagnosis of a program goodput loss descends from the fleet measure that detected it to the hardware root cause. Each rung names the evidence that level exposes and a representative tool; the navy label under each tool gives the scope and time scale one sample covers, and each highlighted window expands into the trace below it. Each lower level trades breadth for the detail needed to isolate a root cause, and the three lower levels together are the step-trace rung of factor localization.

> The window must also describe the job's steady state. A profiler's own warmup steps let the profiler start up before it records, but they do not ensure that the application has finished compiling, allocating memory, and initializing its devices, so the window is chosen from step times that have stopped changing. Startup that falls inside the trace belongs to runtime goodput and is measured from the timeline, not from the trace.

Systematic triage of a slow step begins outside the accelerator kernels. If a step misses its duration target while accelerator utilization is low, the bottleneck lies in input stalls, host preprocessing, or exposed communication—because optimizing a kernel cannot speed up a device that is waiting for work to arrive. Only when the accelerator is actively executing kernels does diagnosis turn to whether those kernels are bound by arithmetic throughput or memory bandwidth, evaluated against the roofline's ridge point (the operational intensity where the memory-bandwidth slope meets the compute ceiling). Organized in order of application, these checks form a diagnostic decision tree (figure 9.7) whose initial branches exit program goodput altogether. A device waiting for its next batch or for host-side preprocessing is losing runtime goodput at the input boundary, which returns the investigation to section 9.5.

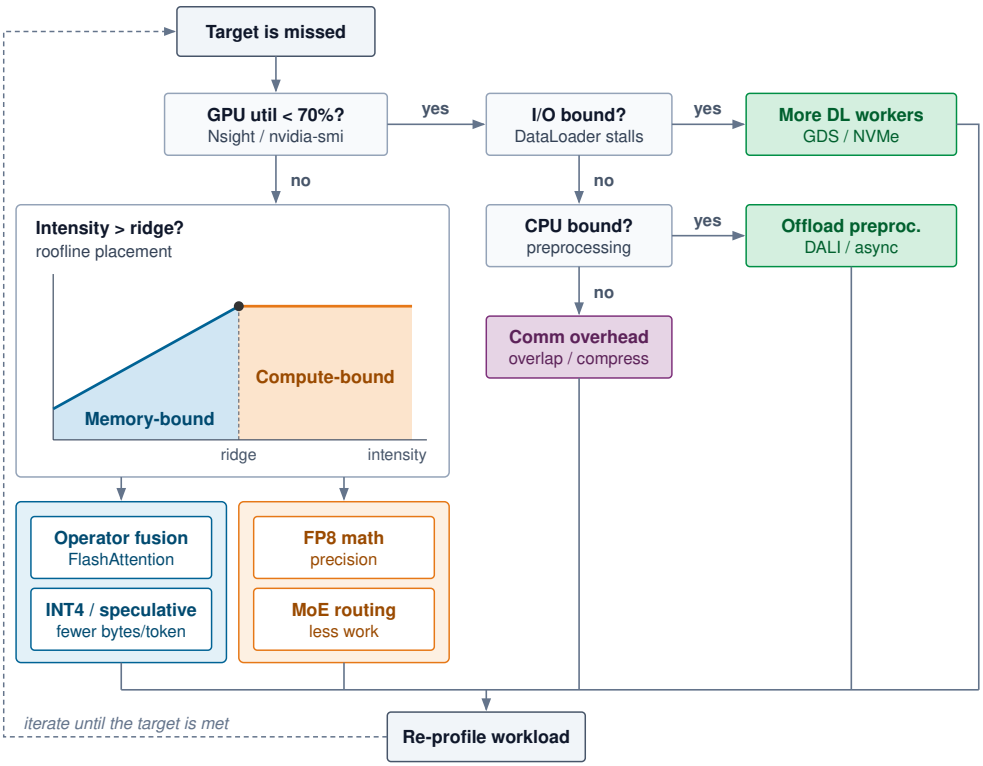

Figure 9.7: Iron Law Diagnostic Flowchart: A triage flow for a job or replica whose retained steps miss their step-time target. Low accelerator activity sends the diagnosis right, toward waits, and high activity sends it down to the roofline. The I/O and CPU branches identify input waits and host preprocessing, which are runtime goodput losses at the input boundary, so a yes on either sends the reader back to section 9.5 rather than to the program. The communication-overhead leaf is exposed communication, a program goodput loss in the Fleet Law's communication term. Only a busy device reaches the roofline panel, whose memory-bound and compute-bound leaves are candidate levers to test, not prescriptions. Fusion and tiling are developed in section 9.7, serving precision and speculative decoding in chapter 10, and expert routing in section 6.5.5. Every path returns to re-profiling.

Every path in the flowchart concludes by re-profiling the workload, because an optimization counts only if the measured step becomes shorter under the contract of section 9.3.1. Removing one exposed interval frequently uncovers the next, shifting the critical path and restarting the diagnostic cycle.

Once the flowchart confirms that an accelerator is busy, its kernels are evaluated against the roofline model. A kernel with arithmetic intensity I can achieve at most $\min(R_{\text{peak}}, I \times \text{BW})$, and the ridge point $I_{\text{ridge}} = R_{\text{peak}}/\text{BW}$ divides the memory-bound slope of that envelope from its compute-bound plateau (Williams et al. 2009). Whereas section 2.3.2 introduced the Roofline Model from hardware specifications and algorithmic bounds, performance engineering places each kernel on the roofline using the operations and memory traffic measured during the actual step that lost program goodput.

Definition 9.4: Measured arithmetic intensity

Measured arithmetic intensity is the ratio of the floating-point operations a kernel actually executes to the bytes observed crossing a named memory boundary, such as HBM, during that execution (FLOP per byte).

1. **Significance**: It places a profiled kernel on the same roofline as the bandwidth (BW) and compute (R_{peak}) ceilings, so its distance below the algorithmic estimate exposes traffic the algorithm did not require.
2. **Distinction**: Unlike *algorithmic intensity*, which counts the data movement an idealized algorithm requires, measured intensity includes tiling, cache behavior, fusion, padding, and redundant transfers.
3. **Common pitfall**: A roofline point is interpretable only when its FLOP convention and memory boundary match the ceilings on the same plot.

Placing a profiled kernel on the roofline proceeds in three steps. First, hardware counters for the kernel report its achieved FLOP rate and its achieved bandwidth across a named memory boundary. Second, dividing the achieved FLOP rate by the achieved bandwidth yields the kernel's measured arithmetic intensity, which reveals excess memory traffic whenever it falls below the algorithmic estimate. Third, comparing the achieved FLOP rate against the roofline ceiling at that measured intensity classifies the kernel into one of three regimes:

1. **Far below both ceilings.** The kernel suffers from an execution inefficiency rather than a hardware resource limit—such as serial dependencies, poor instruction mix, or insufficient parallelism—and the remedy lies in how the kernel is written or selected.
2. **Near the bandwidth ceiling.** The kernel is saturating memory bandwidth; only transferring fewer bytes (through operator fusion, tiling, or a narrower numeric representation) can speed it up.
3. **Near the compute ceiling.** The kernel is saturating the arithmetic units; only performing fewer operations or switching to a faster supported numeric format or accelerator can reduce its duration.

Whereas the roofline narrows the set of candidate levers for an individual kernel, the step trace determines whether that kernel occupies enough of the critical path to warrant optimization.

A normalization kernel illustrates this three-step placement. Suppose hardware counters for a LayerNorm kernel on an H100 report 5 TFLOP/s of achieved compute and 2.8 TB/s of achieved HBM bandwidth. Its measured arithmetic intensity is 5 TFLOP/s ÷ 2.8 TB/s ≈ 1.8 FLOP/byte—more than two orders of magnitude below the H100's FP16 ridge point of about 295 FLOP/byte. The kernel therefore sits squarely on the memory-bandwidth slope, and its achieved bandwidth is already 83.6 percent of the 3.35 TB/s hardware peak. Faster arithmetic units cannot speed it up at all, and tuning its memory access pattern can recover at most the remaining sixth of headroom to the ceiling. Any substantial speedup must come

from reducing D_{vol}: either by fusing the normalization into the preceding operator so the intermediate tensor never round-trips through HBM, or by adopting a narrower numeric format.

The kernels of our 70B training job divide along the same line. Large matrix multiplications in the attention projections and feed-forward blocks operate above the ridge point near the compute ceiling. By contrast, normalization, activation functions, softmax, residual additions, and the optimizer update sit far down the memory-bandwidth slope just like LayerNorm, executing a tiny fraction of the step's useful FLOPs while consuming a disproportionate share of local execution time. Comparing the time spent in matrix multiplications against the time spent in all other kernels therefore provides a rapid check on local program goodput losses. A step dominated by fast matrix multiplications loses its program goodput primarily to exposed communication and synchronization (as in our running example). A step spending substantial time in non-GEMM kernels, by contrast, has a local memory-traffic loss that operator fusion can recover.

The serving replica's decode step sits even farther down the bandwidth slope. At batch size one, each of its eight accelerators must stream its entire weight shard from HBM to emit a single token. That minimum streaming time, about 5.2 ms per token (section 2.3.1.3), serves as the named ideal for the replica's program goodput. Even at that ideal floor, the H100 tensor cores run at only 0.3 percent of their FP16 peak, rendering MFU uninformative. Instead, the replica's program goodput is measured by MBU: the ratio of the weight-streaming floor time to the measured step time (section 9.2.2).

Because the weight-streaming floor counts only model parameters, a measured decode step always takes longer. Reading the key-value cache, executing the per-layer tensor-parallel AllReduce, and dispatching dozens of small kernels per layer all lengthen the step and lower MBU, appearing as program goodput losses of the replica. How large a batch the replica can accumulate to climb the roofline slope toward the ridge point is governed by its latency service-level objective in chapter 10.

9.6.4 Common bottleneck patterns

An accelerator that idles *between* steps waiting for its next input batch shows the same drop in utilization as an accelerator that idles *within* a step waiting for a collective to finish. Yet the first is losing runtime goodput and answers to the data pipeline, whereas the second is losing program goodput and answers to communication overlap. Recognizing recurring trace signatures provides fast diagnostic hypotheses (table 9.7), and identifying which goodput factor a signature lowers is just as important as identifying its mechanism, since not every slow-step symptom is a program loss.

Table 9.7: Common Bottleneck Trace Patterns: Each trace signature maps to a likely cause, the goodput factor and term the cause lengthens, a candidate lever, and the trade-off to check before applying it. Levers marked with a section reference are developed there.

Trace pattern	Likely cause	Factor and term	Candidate lever	Trade-off to check
Small gaps between many short kernels	Host dispatch of each kernel dominates	Program; dispatch part of L_{lat}	Graph replay, fusion, or compilation (section 9.7.3)	Compilation time, charged to runtime goodput; variants per input shape
Large memory spikes	Unfused operators materialize intermediates in HBM	Program; D_{vol}/BW and HBM capacity	Fusion, or tiled attention that never writes its score matrix (section 9.7.3)	Numerical validation and kernel maintenance
Low FLOP/s with high achieved bandwidth	Memory-bound operations dominate the step	Program; D_{vol}/BW	Fewer bytes per step, through fusion, a smaller representation, or a larger per-device batch where memory and convergence allow	Accuracy, cache pressure, and quality guardrails
Much of the step in non-GEMM kernels	Normalization, activation, softmax, and optimizer kernels sit on the bandwidth slope	Program; D_{vol}/BW and dispatch	Fuse non-GEMM work into neighboring kernels (section 9.7.3)	Fusion legality and kernel maintenance
Collective bars during device idle gaps	Communication serialized rather than overlapped	Program; $T_{\text{comm}}(N) - T_{\text{overlap}}$	Overlap collectives with independent work (section 9.7.2); compiler-chosen partitioning	Bucket size, contention for device resources, schedule complexity
All ranks but one wait at a barrier	Uneven work or a degrading device	Program; $T_{\text{sync}}(N)$	Even partitioning; expert capacity limits for MoE (section 6.5.5); node replacement by the reliability layer	Restart cost, charged to runtime goodput, against the recovered step time
Stages idle at the start and end of each step	Pipeline bubbles	Program; $T_{\text{sync}}(N)$	More microbatches or an interleaved schedule (section 6.5.2)	Activation memory and per-microbatch efficiency

Trace pattern	Likely cause	Factor and term	Candidate lever	Trade-off to check
Repeated large allocations	Buffers recreated rather than reused	Program; allocator time in L_{lat}	Memory planning by a compiler (section 9.7.3) or preallocated buffer pools	Allocator behavior; recomputation cost if activations are dropped instead
Periodic activity drops between steps	Input preparation not pipelined with the step	Runtime; input wait, not a program loss	More data workers, preprocessing services, or pretokenized data (chapter 4)	Storage cost and data freshness

The final row of table 9.7 is the most frequently misdiagnosed in practice; checking the per-step input-wait field in the job timeline distinguishes an input stall from an exposed collective before any profiler trace is opened. Once the hierarchical drill-down concludes, it hands off a specific Fleet Law term and its measured share of the step—exposed cross-node communication for our training job, and the gap above the weight-streaming floor for our serving replica—which section 9.7 now recovers through targeted engineering levers.

9.7 Recovering Program Goodput

Tuning a single-device kernel when a step is bound by cross-node gradient reductions, or overlapping collectives when the step is bound by host kernel launches, leaves the critical path untouched. Recovering program goodput requires changing how a retained step executes, and an optimization helps only to the extent that it shortens an exposed term of the step. Three families of levers target distinct Fleet Law terms:

1. **Compiler-derived partitioning** determines which collectives a step executes and across which physical links they travel ($T_{\text{comm}}(N)$).
2. **Communication overlap** hides a portion of those collectives behind independent computation, enlarging the overlap credit (T_{overlap}).
3. **Kernel-level optimizations** (fusion, tiling, graph replay, and compilation) compress single-device execution (T_{compute}/N).

Because the speedup from any one lever depends on what the others leave exposed on the critical path, engineers apply these levers one at a time and remeasure the step after each change.

9.7.1 Compiler-derived partitioning

A model whose tensor-parallel modules place AllReduce calls directly inside the forward and backward methods of each layer, and whose data-parallel wrapper hard-codes gradient reductions (chapter 6), cannot move to a different allocation size or node topology without modifying the model code itself. Because how a large training job is partitioned across devices determines most of the communication its

step performs, tying that layout to hand-written layer code makes every topology change or elastic resize a code change. Compiler-derived partitioning, pioneered in the Accelerated Linear Algebra (XLA) compiler's GSPMD partitioner (Xu et al. 2021), shifts the derivation of tensor layouts and the insertion of collective operations from the model author to the compiler.

Definition 9.5: Compiler-derived partitioning

Compiler-derived partitioning is the division of one program across a mesh of devices in which the programmer annotates how a few tensors are split along named mesh axes and the compiler derives the layout of every other tensor and inserts the collectives those layouts require.

1. **Significance**: The inserted collectives are the step's communication term, so the annotations and the mapping of mesh axes onto the fleet decide how much of each retained step a job spends communicating. Because the layout is stated apart from the model code, a different layout is a different set of annotations rather than a rewritten program.
2. **Distinction**: Unlike programmer-specified parallelism, in which the engineer writes or selects each collective through a data-parallel wrapper or a hand-partitioned layer, compiler-derived partitioning leaves the engineer only the key annotations and derives the rest. The partitioning strategies themselves, data, tensor, and pipeline parallelism, are unchanged; what changes is who writes their communication.
3. **Common pitfall**: A frequent mistake is to read the step's communication from the annotations. Where derived layouts disagree, the compiler inserts resharding collectives that no line of the program names, so the step trace, not the source, is the record of what the step communicates.

Under this model, the engineer specifies only two inputs. The first is a logical device mesh whose axes carry symbolic names. For our running example, which uses tensor parallelism within each node and data parallelism across the 16 nodes, the mesh has a `model` axis of 8 devices and a `data` axis spanning the sixteen nodes. The second input is a small set of sharding annotations on key tensors, declaring which tensor dimension is partitioned along which mesh axis. The input batch dimension is split along the `data` axis. Within each feed-forward block, the gate and up projection weights are split column-wise along the `model` axis while the output projection weight is split row-wise. The attention projections are split by head along the `model` axis. Every other intermediate tensor in the program remains unannotated.

From those few seeds, the compiler derives the rest of the parallel program through sharding propagation, walking the computation graph to infer the output layout of each operator from the layouts of its inputs. Multiplying an input activation by a column-split weight matrix yields an activation split along its feature dimension; the subsequent element-wise gated activation preserves that

layout without communication. Next, multiplying that feature-split activation by a row-split output weight produces a partial sum on each device, prompting the compiler to insert an AllReduce along the `model` axis to complete the projection. The backward pass mirrors this derivation. Each device's weight gradients cover only its local shard along the `model` axis but represent partial sums across the `data` axis, so the compiler automatically inserts a cross-node gradient reduction along the `data` axis (or a ReduceScatter paired with a forward AllGather when optimizer state is sharded). The resulting communication schedule matches the hand-partitioned Megatron-style layer of section 6.5.3, yet it is synthesized automatically from single-device model code that contains no explicit collective calls (figure 9.8). Wherever two incompatible tensor layouts meet in the graph, propagation resolves the mismatch by inserting an AllGather, ReduceScatter, AllToAll, or point-to-point permutation.

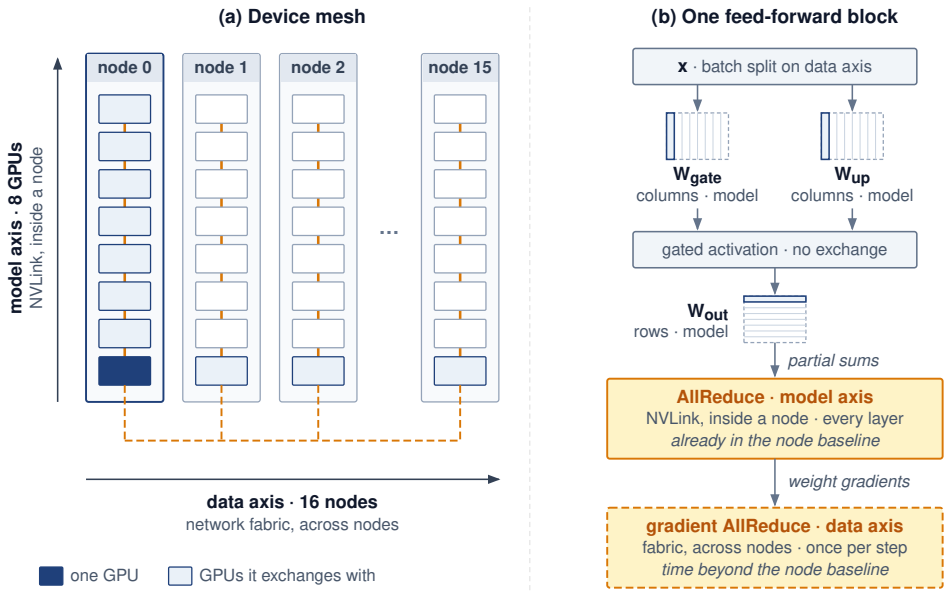

Figure 9.8: From Annotations to Collectives: The running example's mesh places the model axis of 8 GPUs inside each node and the data axis across the 16 nodes. In one feed-forward block, the column-split gate and up projections need no exchange, and the row-split output projection leaves partial sums that propagation completes with a model-axis AllReduce in every layer, over NVLink and already inside the node baseline. The weight gradients are reduced once per step along the data axis across the fabric (a ReduceScatter and an AllGather when the optimizer state is sharded), and that exchange is the time the fleet step spends beyond the node baseline. Schematic; representative nodes only.

↩ Which strategies a training job combines, and the feasibility of each combination, are established in section 6.6.

Every accelerator executes the same compiled binary, using its own mesh coordinates at runtime to index its local weight shard and select its collective peers—the single program, multiple data (SPMD) execution model from which GSPMD takes its name (Xu et al. 2021). Because a single compilation serves all ranks, compilation time scales with the size of the model graph rather than the number of devices in the fleet. Changing the mesh dimensions or sharding annotations still triggers a fresh compilation, whose runtime goodput cost is weighed against its program goodput gain in section 9.9.3.

Because the device mesh is a logical abstraction, the cluster scheduler's physical placement determines which hardware links carry each mesh axis. When an eight-device `model` axis maps onto a single node, its per-layer AllReduce collectives traverse high-bandwidth NVLink; if that same axis is scattered across nodes, those identical collectives traverse the inter-node fabric at a fraction of the bandwidth. Three distinct mechanisms therefore govern a step's communication cost: sharding annotations determine *which* collectives are synthesized, physical mesh placement determines *how fast* each collective runs, and stream scheduling determines *how much* of that duration remains exposed. In Fleet Law terms, compiler-derived partitioning sets $T_{\text{comm}}(N)$ and shapes the opportunity for T_{overlap}, while leaving single-device execution (T_{compute}/N) to the kernel levers of section 9.7.3.

Consequently, modifying a sharding annotation alters the step's communication pattern without changing a single line of mathematical model code, and its effect must be verified under the measurement contract of section 9.3.1. The step trace provides the necessary audit: counting the collectives in one step by operation type and mesh axis, and checking that count against the intended layout, confirms whether propagation behaved as expected. An unexpected AllGather appearing in every layer is the classic symptom of an annotation conflict—typically caused by an intermediate reshape or a single misannotated tensor that forces the compiler to reshard back and forth. Because a compiler's internal cost model can also pick a suboptimal propagation path, any compiler-derived layout should be treated as a hypothesis about $T_{\text{comm}}(N)$ until confirmed by the step trace.

At the fleet level, decoupling layout from model code allows the partitioning to adapt seamlessly to the allocation. When the fleet orchestrator resizes an elastic job (section 8.7.3), only the `data` axis length changes, and the compiler regenerates the executable from the existing annotations. Exploring layout trade-offs—such as sharding optimizer states or shifting communication onto intra-node links—likewise reduces to editing annotations rather than rewriting layers. At the same time, our running example illustrates the boundary of what partitioning alone can achieve. Its mesh already confines every `model`-axis collective within a single node, so the extra time its 128-GPU step spends beyond the single-node baseline comes from cross-node `data`-axis gradient reductions. Hiding those reductions is a problem of communication overlap.

9.7.2 Tensor-parallel collectives under contention

Once the partitioning layout fixes which collectives a step must execute, the exposed communication time is whatever fraction of those collectives the schedule fails to hide behind independent computation. Our running example executes two classes of collectives that differ in their data dependencies. Cross-node gradient reductions along the `data` axis have loose dependencies. As soon as the backward pass finishes computing the gradients for one bucket of layers, that bucket can be reduced across nodes while backward computation continues on earlier layers. This is the standard bucketed overlap implemented by `DistributedDataParallel`. The analytical limits on hiding such loosely coupled exchanges are established in

section 5.10.4; for our 128-GPU job, the unhidden remainder accounts for most of the 65 ms that each fleet step spends beyond the single-node baseline.

By contrast, intra-node collectives along the `model` axis have strict serial dependencies: each AllReduce completes an activation tensor that the very next operator in the same transformer layer consumes immediately, preventing subsequent operations in that layer from starting until the collective finishes. Because these `model`-axis exchanges never leave the node, their duration is already embedded inside the single-node baseline.

A bandwidth-floor estimate (excluding launch latency and activation recomputation) bounds how much of the single-node step those intra-node collectives can occupy. Each exchange point reduces roughly 36 MB of activations across the 8 GPUs of the node, and the 320 exchange points in a full forward-and-backward step require about 45 ms of NVLink transfer time. Even if none of that transfer were hidden, it would represent about 25 percent of the 180 ms single-node step—well within the 35 percent gap between the node's 65 percent MFU and the arithmetic ideal. Consequently, `model`-axis collectives represent a local, node-level program loss that does not grow with fleet size so long as the `model` axis remains confined to a single node. The cross-node `data`-axis reduction carries the scaling penalty, and a single-rank trace easily separates the two because they execute on distinct process groups.

Hiding a collective whose output is needed by the next operation requires finding independent computation to execute concurrently. One approach interleaves work from a second microbatch that has no dependency on the collective in flight. The alternative is fine-grained compute-communication decomposition. It splits both the matrix multiplication and the collective that consumes its output into smaller tiles, so that one tile's collective transfer runs concurrently with the next tile's matrix multiplication. A partitioning compiler can synthesize this transformation automatically (Wang et al. 2022). Neither strategy reduces the byte volume $T_{\text{comm}}(N)$; both work purely by enlarging the overlap credit T_{overlap}.

However, overlapping communication and computation on the same accelerator is never contention-free. On NVIDIA GPUs, concurrent execution is orchestrated through CUDA streams—ordered queues of kernels, memory copies, and collectives that execute sequentially within a stream but may run concurrently across distinct streams. A distributed training step typically assigns matrix multiplications and element-wise ops to a compute stream while dispatching NCCL collectives to a separate communication stream (listing 9.1).

Listing 9.1: Computation and a Collective on Separate Streams: Both streams first wait for the stream that produced their inputs, and each tensor is recorded on the stream that uses it so that its storage is not reused while that stream still needs it. The matrix multiplication and the AllReduce may then run concurrently. Concurrency on the timeline does not by itself establish a shorter step.

```
compute_stream = torch.cuda.Stream()
comm_stream = torch.cuda.Stream()
producer_stream = torch.cuda.current_stream()
# Inputs are ready on producer_stream; gradients do not alias A or B.
compute_stream.wait_stream(producer_stream)
comm_stream.wait_stream(producer_stream)
A.record_stream(compute_stream)
B.record_stream(compute_stream)
gradients.record_stream(comm_stream)

with torch.cuda.stream(compute_stream):
    output = torch.matmul(A, B)  # Non-blocking compute

with torch.cuda.stream(comm_stream):
    work = dist.all_reduce(gradients, async_op=True)
    work.wait()  # Establish completion on the communication stream

torch.cuda.synchronize()  # Wait for both to complete
```

Placing work on separate streams enables concurrency, but it does not partition the underlying hardware resources. Because collective libraries such as NCCL launch their own GPU kernels to copy, pack, and reduce buffers across NVLink and network interfaces, an overlapped collective competes directly with concurrent matrix multiplications for streaming multiprocessors (SMs), L2 cache, and HBM bandwidth (Pati et al. 2024). In a kernel timeline, successful stream overlap shifts the collective bar underneath the compute kernels, but resource contention stretches the duration of those compute kernels, causing the step to finish later than an idealized contention-free model would predict (figure 9.9). Overlapping a collective improves program goodput only if the communication time removed from the critical path exceeds the contention delay added to the concurrent computation—a net balance that only an end-to-end step measurement can verify.

When a program manages multi-stream overlap manually rather than relying on a tested wrapper, it must also enforce two correctness invariants. Data readiness uses `wait_stream` so that no consumer stream reads a tensor before its producer stream has finished writing it. Storage lifetime uses `record_stream` so that the caching allocator does not recycle a tensor's memory buffer while a side stream is still reading it. Because host kernel launches are asynchronous, a tensor's Python reference can go out of scope on the CPU before the side stream finishes using the buffer on the GPU, and the allocator tracks buffer liveness only on the allocating stream unless `record_stream` registers the side stream as well. Both invariants must be verified before crediting a shorter step time to communication overlap rather than to a data race that silently corrupted or skipped work.

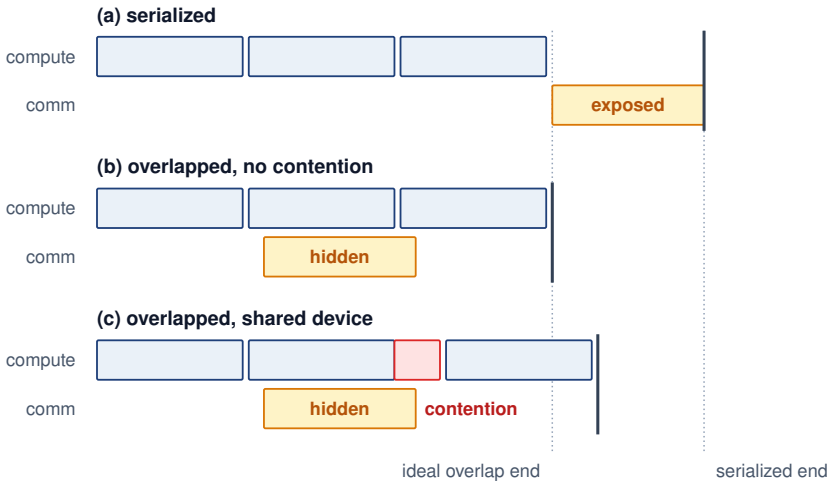

Figure 9.9: Overlap on a Shared Device: One step of three kernels and one collective on a compute stream and a communication stream. Serialized, the collective runs after the kernels and is exposed. Overlapped on a device with resources to spare, it hides completely behind the kernels. Overlapped on a real device, the collective's own kernels take streaming multiprocessors and memory bandwidth from the kernel beside it, which runs longer, so the step ends between the two. Only a measured step shows where between them it ends. Durations are schematic, not measured.

Our 8-GPU serving replica, partitioned purely along the `model` axis within a single node, illustrates the opposite regime. At batch size one, each per-layer AllReduce transfers only about 32.8 KB across the 8 GPUs—orders of magnitude below the message size required to exit the latency-bound regime of section 5.5. At this scale, fixed collective launch and protocol overhead (roughly 70× the wire transfer time itself) dominates the exchange, and stream overlap cannot hide it because the immediately following layer operator awaits the reduced activation. Shortening this term requires either reducing the number of exchanges through the partitioning layout or cutting per-launch overhead via CUDA Graph replay. How larger decode batches alter this balance is analyzed in section 10.10.2.

9.7.3 Kernel-level levers

Even when inter-device communication is well hidden, an accelerator can waste much of its local execution time writing short-lived intermediate tensors out to HBM and reading them immediately back, materializing quadratic attention score matrices, or sitting idle between thousands of small host-dispatched kernels. Four single-device optimization techniques—operator fusion, tiling, graph replay, and graph compilation—recover these local losses without altering the model's mathematical semantics. In the Fleet Law, all four techniques compress only the local execution term T_{compute}/N; because none of them directly reduces $T_{\text{comm}}(N)$ or $T_{\text{sync}}(N)$, their end-to-end fleet impact diminishes whenever exposed communication or barrier waits dominate the step.

↪ Fusion, tiling, graph replay, and compilation are collected for reference in section A.5.

Operator fusion merges a chain of consecutive operations into a single GPU kernel so that intermediate activations remain in registers or shared memory (SRAM) instead of round-tripping through HBM, while replacing multiple host

kernel launches with one. It therefore reduces both the memory traffic volume D_{vol} and the host-dispatch portion of L_{lat}. For a linear layer followed by an activation and normalization at the hidden dimension of Llama 2 70B and a batch of 2,048 tokens, eliminating the HBM write-and-read of the two intermediates cuts total modeled HBM traffic by a factor of about 1.7×. The hardware limit on fusion is register and SRAM pressure: keeping too many live intermediates per thread reduces SM occupancy and can eventually slow the kernel down. In a profile, successful fusion manifests as fewer kernel launches, fewer measured HBM bytes transferred, and a shorter step duration (section A.5.1).

The boundary comparison in figure 9.10 shows which intermediate transfers fusion can remove.

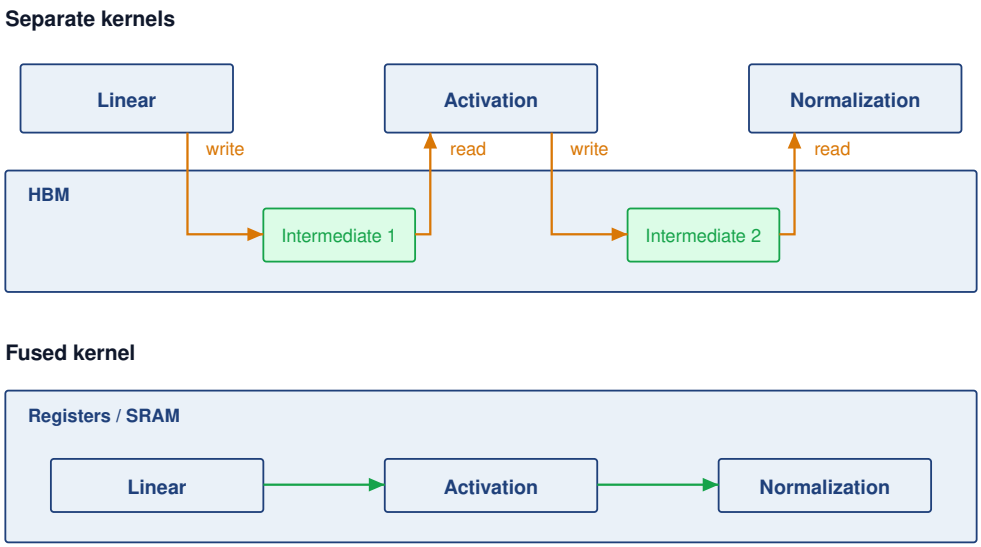

Figure 9.10: Fusion Across the HBM Boundary: Separate kernels write each intermediate tensor to HBM and read it back for the next operation. A fused kernel keeps these intermediates in registers or SRAM as it executes the same chain. The diagram isolates intermediate traffic; common input, weight, and final-output transfers remain outside the drawing. The fused schedule assumes compatible operations and enough on-chip storage for the live working set, including normalization state.

A profile must confirm that the intermediate transfers disappear. Fewer launches alone establish a dispatch change, not a reduction in HBM traffic.

Tiling partitions a computation into blocks sized to fit in on-chip SRAM so that each operand fetched from HBM is reused across many arithmetic operations before eviction. Applied to self-attention (as in FlashAttention (Dao et al. 2022)), tiling evaluates attention block by block using online softmax rescaling, avoiding ever materializing the quadratic sequence-by-sequence score matrix in HBM. For a single attention head of our 70B model at a sequence length of 8,192 tokens, an idealized traffic bound shows that eliminating the score and probability matrix round-trips reduces HBM traffic by roughly 65×. Beyond cutting D_{vol}, tiling frees substantial HBM capacity, which training jobs reinvest in longer context lengths or larger microbatches and serving replicas reinvest in larger key-value caches. The trade-off is extra arithmetic for online rescaling and, during backpropagation,

recomputing attention scores on the fly rather than storing them. Success is verified by the disappearance of quadratic score-matrix allocations and HBM traffic in the memory trace (section A.5.2).

The working set in figure 9.11 stays local while attention consumes successive key/value tiles.

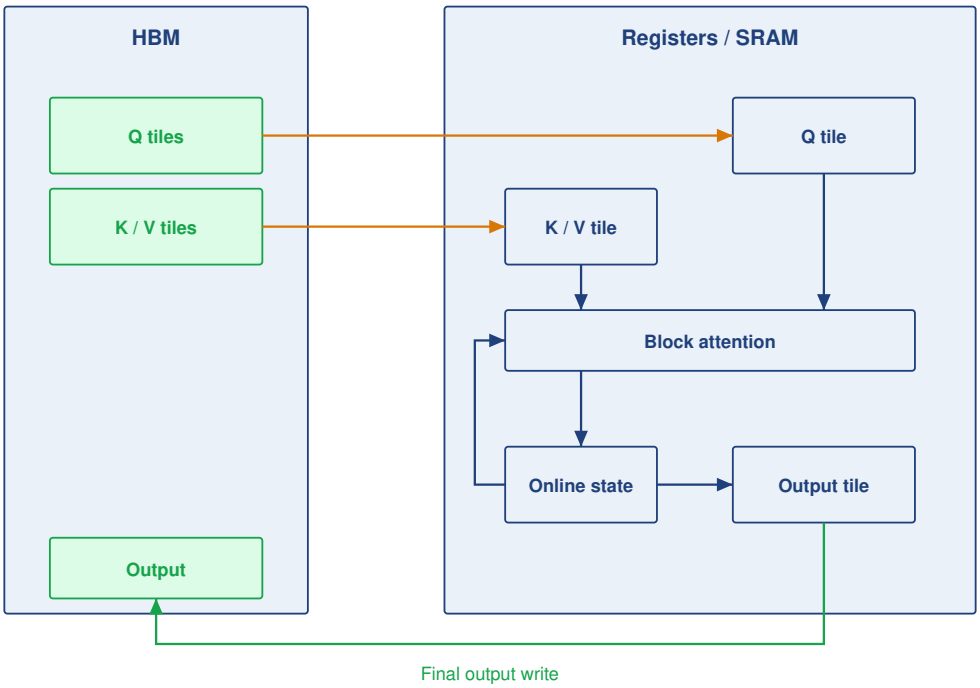

Figure 9.11: Tiled Attention and Online State: For one query tile, the kernel reads relevant key/value tiles from HBM and updates on-chip state after each block. This state contains running row maxima, normalization sums, and output accumulators; the feedback path carries it into the next block. After the last required block, the kernel normalizes and writes the output tile. Score tiles remain temporary on-chip values rather than a sequence-by-sequence HBM allocation. Another query tile can require reading the same key/value tiles again; the diagram does not imply one global read.

The memory saving comes from the allocation that never crosses the HBM boundary, not from omitting attention pairs. Tile size must leave room for the retained state as well as the operands.

Graph replay captures a fixed sequence of GPU kernel launches once and replays the entire subgraph with a single host API call, compressing the host-dispatch portion of L_{lat} while leaving kernel execution itself unchanged. In eager execution, dispatching the kernels of a single forward pass of our 70B model consumes roughly 12–24 ms of host CPU overhead—several times longer than the 5.2 ms weight-streaming floor of the serving replica's decode step (section 9.6.3). Eager small-batch decode therefore becomes host-dispatch bound long before it saturates HBM bandwidth. Distributed training encounters the same regime under strong scaling: when a job expands across more accelerators at a fixed global batch size, per-device kernel durations shrink while the number of kernel launches per step

stays constant. The constraint of graph replay is static structure: tensor shapes, memory addresses, and control flow must remain fixed across replays, requiring serving engines with dynamic batch sizes to capture and cache a separate graph for each padded shape bucket. Success is verified when inter-kernel launch gaps vanish from the kernel timeline (section A.5.3).

Graph compilation traces a region of the model into an intermediate computation graph, rewrites the graph, fuses compatible operators, plans static buffer reuse, and generates or autotunes specialized kernels for each fused subgraph—automating fusion, memory planning, and kernel selection in a single pass. Compilation reduces D_{vol} and host dispatch L_{lat}, and when autotuning selects superior tile shapes it increases hardware compute efficiency η_{hw} as well. Because compilation runs before the first retained step (and re-runs whenever dynamic shapes trigger a guard failure), its build duration is a runtime goodput cost that must be amortized across subsequent execution, a cross-factor trade-off quantified in section 9.9.3. Success is verified by fewer, larger kernels in the timeline and a shorter steady-state step measured after compilation completes (section A.5.4).

Numeric precision is the final lever acting on local execution. This book divides its mechanics between two domain chapters: reduced-precision training (such as FP8), which raises the compute ceiling R_{peak} and halves activation and weight traffic under the numerical stability contract of section 6.4.8, and post-training weight quantization for inference, which reduces weight-streaming bytes D_{vol} in section 10.9.

These single-device levers pay off very differently across our two running workloads. In the 128-GPU training job, large matrix multiplications already run near the H100 compute ceiling, so kernel-level levers can compress only the non-GEMM kernels on the bandwidth slope while leaving the job's primary program loss—exposed cross-node gradient communication—untouched. In the 8-GPU serving replica, by contrast, the program loss is overwhelmingly local (weight-streaming traffic and host kernel dispatch), allowing operator fusion, weight quantization, and CUDA Graph replay to close most of the gap to the bandwidth floor.

9.7.4 Composing program fixes

Applying several kernel and communication optimizations simultaneously—or adding their isolated microbenchmark speedups on a spreadsheet—almost always overpredicts the fleet gain, because speeding up backward compute kernels shrinks the execution window that previously hid gradient communication. Effective performance engineering therefore follows a disciplined, sequential loop that starts from the whole job rather than an individual kernel:

1. Measure the program goodput of retained steps under the measurement contract (section 9.3.1), and use factor localization (section 9.3.2) to confirm that the bottleneck lies in program goodput rather than scheduling or runtime goodput.
2. Descend the profiling hierarchy (section 9.6.3) to identify which Fleet Law term holds the exposed time on the critical path, and select the lowest-cost candidate lever targeting that term (table 9.7).

3. Apply a single lever, re-measure the end-to-end step under the exact same contract, and restart the drill-down from the new trace—because compressing one exposed term routinely exposes another.

For our 128-GPU training example, the hierarchical drill-down identified exposed cross-node gradient reductions along the `data` axis as the primary bottleneck. The first experiment therefore targets communication overlap—either by tuning gradient bucket sizes and launch order, or by sharding the optimizer state so that ReduceScatter overlaps with backpropagation and AllGather prefetches parameters ahead of the forward pass. Only after re-profiling that change does the second experiment target the remaining node-level losses (intra-node `model`-axis collectives and memory-bound non-GEMM kernels) via fine-grained compute-communication decomposition and operator fusion.

Isolated speedups fail to add linearly because every optimization alters the step's critical path. A lever shortens a single Fleet Law term, and end-to-end step time decreases only by the portion of that term that was exposed. Once the first lever takes effect, every term's share of the step shifts, invalidating isolated speedup estimates for subsequent levers. In practice, pairs of optimizations interact in three ways:

- **Reinforcing combinations.** Operator fusion and tiled attention free HBM activation memory; reinvesting that freed memory in a larger microbatch lengthens the compute window per step, which in turn hides a larger fraction of collective communication.
- **Redundant combinations.** Enabling a graph compiler that automatically fuses element-wise operator chains leaves nothing for a hand-written fused kernel on the same chain to recover.
- **Conflicting combinations.** Overlapping NCCL communication kernels steals SMs and HBM bandwidth from concurrent matrix multiplications, lengthening local compute. Conversely, speeding up backward compute kernels via FP8 or fusion shrinks the compute window that hid cross-node gradient reductions, exposing communication that was previously hidden for free.

Because of these interactions, an optimization validated on a single-node baseline must always be re-evaluated on the full fleet configuration. Only an end-to-end measurement under table 9.2 can establish whether a combination of levers is reinforcing, redundant, or conflicting—and whether a rise in program goodput came at the expense of scheduling or runtime goodput (section 9.9).

Checkpoint 9.3: Composing program fixes

A program fix recovers goodput only through the exposed term it shortens, and only a new measurement shows what it added.

Choosing the lever

- ☐ **Decode at low MBU**: The serving replica's decode step runs well above its bandwidth floor. Can you name the trace evidence that would separate a dispatch-bound step, a step that streams more bytes than the weights require, and a step that exposes its tensor-parallel exchanges, and the lever each points to?
- ☐ **FP8 on a communication-bound step**: Can you explain why faster lower-precision arithmetic alone may leave the running example's fleet step nearly unchanged, and identify what would have to be true of its exposed term for lower precision to help?
- ☐ **Annotation change**: After an annotation change, which collectives should a step trace show, on which mesh axis, and what does an unexpected AllGather in every layer indicate?

Composing and measuring

- ☐ **Non-additive speedups**: Two fixes each shorten the node step when measured alone. Can you describe how applying both could yield less than the sum of their savings, and one way it could yield more?

9.8 The Whole Fleet

The Llama 2 70B job keeps 0.90 of its held time as retained steps, runs those steps at 0.48 of the ideal rate, and draws its nodes from a pool that holds 0.65 of its capacity in complete allocations. Each figure is accurate on its own boundary, yet none states alone how much of the fleet's capacity becomes training progress or which engineering lever yields the largest return. Those answers emerge only from the product of equation 9.1, which also converts a fraction of fleet capacity into the unit cost of useful work.

9.8.1 Decomposing the running example

Evaluated solely by its runtime and program goodput inside its own allocation, the Llama 2 70B job appears nearly half efficient, yet the shared pool that supplies its nodes loses roughly another third of its capacity before any job holds a complete gang. Composing all three factors for one job on one fleet reveals where the entire efficiency gap goes across the cluster.

Napkin Math 9.5: Where the running example's fleet capacity went

Problem: The Llama 2 70B job holds 128 GPUs drawn from a shared pool. What share of the accelerator-hours the job holds becomes progress at the ideal rate, what share of the capacity the pool offers becomes progress, and at which boundary is the rest lost?

Variables:

- Scheduling goodput $\eta_{\text{scheduling}} = 0.65$, the pool's value from notebook 9.2.

- Runtime goodput $\eta_{\text{runtime}} = 0.90$, composed from five owners' terms in notebook 9.3.
- Program goodput $\eta_{\text{program}} = 0.48$, the fleet MFU of the retained steps from notebook 9.4.

Math:

- Job product, $\eta_{\text{runtime}}\eta_{\text{program}}$: $0.90 \times 0.48 \approx 0.43$.
- Pool product, MPG $= \eta_{\text{scheduling}}\eta_{\text{runtime}}\eta_{\text{program}}$: $0.65 \times 0.43 \approx 0.28$.
- Loss shares by equation 9.2: scheduling $1 - 0.65 = 0.35$; runtime $0.65 \times 0.10 \approx 0.06$; program $0.59 \times 0.52 \approx 0.31$, where 0.59 is $\eta_{\text{scheduling}}\eta_{\text{runtime}}$. With the 0.28 that became progress, the four parts add to one.
- Calibration: Llama 3 405B's product of about 0.37 on its dedicated cluster (notebook 9.1) becomes $0.65 \times 0.37 \approx 0.24$ on this pool.

Result: The job turns about 43 percent of the accelerator-hours it holds into ideal-rate progress, and the pool turns about 28 percent of its offered capacity into progress. Of that offered capacity, 35 percent is lost before any job holds it, 6 percent is held without producing a retained step, and 31 percent is spent on retained steps that run below the ideal rate.

Systems insight: The scheduling layer multiplies every job's product by the same 0.65, so even the best-documented large run on record, moved onto this pool, would deliver only about a quarter of the pool's capacity as progress. No engineering inside a job recovers a loss that occurs before the job holds its devices.

Both products are meaningful (table 9.8), and they answer different questions. The job's product ($\eta_{\text{runtime}} \times \eta_{\text{program}}$) measures what the team running the job can improve directly: runtime and program losses occur inside its allocation, and a higher job product means fewer held hours per retained step and an earlier result. The pool product (MPG) measures what the fleet's owner pays for: capacity that never forms a complete allocation is still powered, depreciated, and billed. Raising the pool's scheduling goodput does little for an individual job that already holds its allocation, because the capacity it recovers becomes complete allocations for other jobs waiting in the queue. Reporting only the job's product hides the pool's largest loss from the infrastructure team, whereas reporting only the pool's product charges the workload team for a scheduling loss it cannot control.

The pool product also rests on an assumption that the job product does not require. Because it multiplies the pool's scheduling goodput by this job's runtime and program goodput, it describes a pool in which every workload runs like the running example. The pool-level runtime losses identified in section 9.5.2—reserved blocks that no job uses and zombie allocations—lower the pool's effective runtime goodput further, making the pool figure an upper bound.

Table 9.8: Goodput Decomposition of the Running Example: The three factors of the Llama 2 70B job and the share of fleet capacity each boundary loses, computed by equation 9.2 in the order a job meets the losses. The scheduling layer comes from a constructed snapshot and is illustrative; the Llama 3 column multiplies factors reported over different measurement windows and is an estimate (Dubey et al. 2024). The pool product assumes every job in the pool runs like the running example, so it is an upper bound. The serving replica's program goodput divides by a bandwidth ideal rather than peak arithmetic, so a fleet report carries it as its own row and never averages it with the training job's.

Boundary	Factor value	Share of fleet capacity lost here	Llama 3 405B (cited)	Lever owner
Scheduling goodput (illustrative)	0.65	35%	1 (dedicated)	chapter 8
Runtime goodput	0.90	6%	at least 0.90	chapter 7, chapter 4, chapter 8
Program goodput	0.48	31%	about 0.41	section 9.7
Job product ($\eta_{\text{runtime}} \times \eta_{\text{program}}$)	0.43		about 0.37	
Pool product (MPG)	0.28	28% useful	about 0.24 on the same pool	
Serving replica (separate row)	Runtime from 0.996 (released daily) to about 0.91 (one burst hour); program goodput as MBU against a floor of 5.2 ms per token	Not added to training	Not applicable	chapter 10

Read as a map of where the fleet's capacity went, table 9.8 shows that two boundaries carry almost all of the loss. The capacity lost before allocation and the capacity lost inside slow steps are each several times larger than the capacity lost to startup, input waits, checkpoints, failures, and preemptions combined (figure 9.12). Those runtime interruptions are nevertheless the losses that operators see most directly in job logs and restart alerts.

Comparing the running example against the Llama 3 405B column highlights how cluster scale shifts the balance between factors. The running example's program goodput sits above the Llama 3 reference because a job on 16 nodes exposes less communication per step than a run across 16,384 H100 GPUs, whereas its runtime goodput matches the reference through the different mix of losses analyzed in section 9.5.3.

Ranked by the share of the pool's capacity lost at each boundary, scheduling comes first, program goodput comes second, and runtime goodput comes a distant third. However, a boundary's loss share is not what an engineering lever recovers, because capacity recovered at an early boundary must still survive the later boundaries.

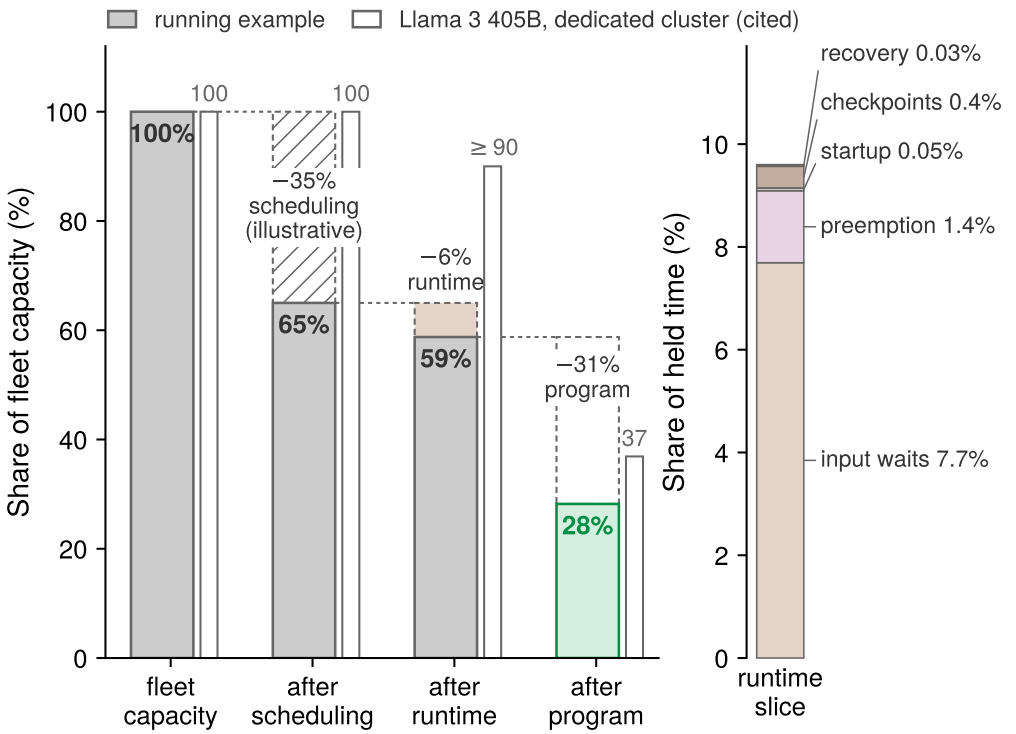

Figure 9.12: Where the Running Example's Fleet Capacity Goes: Each solid bar is the share of fleet capacity left after one boundary, and each dashed slice is the share lost at that boundary, so the three slices are the terms of equation 9.2: 35 percent lost to scheduling, 6 percent to runtime, and 31 percent to the program, leaving 28 percent as ideal-rate progress. The hatched scheduling slice comes from a constructed snapshot and is illustrative. The right panel opens the runtime slice into its five terms as shares of the time the job holds, which scheduling goodput scales down to the slice's share of fleet capacity; input waits and preemption carry almost all of it. The hollow bars place Llama 3 405B on its dedicated cluster beside the example, an estimate that multiplies factors reported over different measurement windows (Dubey et al. 2024).

Instead, the product equation gives the marginal value of a lever directly. One percentage point of any factor is worth the product of the other two factors, because raising one factor by a small increment increases the overall product by that increment times the remaining two factors. For the running example, one point of scheduling goodput is worth 0.43 of a point of MPG, one point of runtime goodput is worth 0.31, and one point of program goodput is worth 0.59. A point of program goodput is worth the most because its multiplier is the product of the two highest factors, whereas a point of runtime goodput is worth the least because its multiplier is the product of the two lowest factors. Consequently, every factor's lever is worth more on a fleet whose other two factors are already high.

The gains a lever can achieve are also bounded by its own structural ceiling, and those ceilings reinforce the ranking. Removing every partial-gang hold and filling every freed device raises scheduling goodput to at most 0.80 (section 9.4.3). Eliminating input waits—the largest runtime term in section 9.5.2—raises runtime goodput to 0.98. Eliminating every loss the fleet adds beyond a single node's baseline—mostly exposed communication (section 9.6.2)—raises program goodput to the single-node baseline of 0.65. Because each lever multiplies MPG by its factor's

relative gain,[8] reaching those ceilings raises MPG by 23 percent (to 0.35) for the scheduling lever, by 9 percent (to 0.31) for the input pipeline, and by 35 percent (to 0.38) for the program lever. For this workload, the program lever yields the largest gain even though scheduling loses a larger share of the pool's total capacity, and the input pipeline yields the smallest gain of the three. Although these ceilings are optimistic—no communication overlap hides all exposed transfers and no packer fills every freed device—the priority order holds unless one team's practical reach falls far short of the others'. Still, this ranking is a property of the workload's measured factors rather than a universal law of the accounting; a fleet running a different model archetype will arrive at a different priority order.

8 **Relative gains and boundary order**: Raising one factor multiplies MPG by the ratio of its new value to its old one, whatever the other two factors are, so the ranking of levers at their ceilings does not depend on the order in which the boundaries are drawn. The loss shares of equation 9.2 do depend on that order, because each later factor's loss is measured on what the earlier factors passed. A ranking by loss share can therefore differ from a ranking by relative gain, and only the second gives what a lever is worth.

Lighthouse 9.2: Archetype B (DLRM at Scale): Where a recommendation fleet loses goodput

A recommendation model stores embedding tables that far exceed accelerator memory in host DRAM or across remote shards (section 4.3.3). When the embedding rows required by a batch are fetched ahead of the training step, they belong to the input path; if that path cannot keep pace with the step rate, the accelerators stall waiting for their batch. The input-wait rule of section 9.2.3 charges that stall to runtime goodput, and the data stall ratio of section 4.4 sizes it. Inside a retained step, the gathered embedding vectors travel to their destination ranks through an AllToAll collective whose completion time is governed by the slowest destination under shard skew or fabric congestion (section 5.8). Whatever portion of that exchange is not hidden by dense computation lengthens the retained step and is charged to program goodput. Because a recommendation step is bounded more by memory and network bytes moved than by dense arithmetic, its program goodput must define its ideal denominator with the same care as a bandwidth-bound serving replica. The engineering levers shift accordingly: runtime goodput rises with prefetching and hot-row caching, whereas program goodput rises with shard load balancing and message coalescing (section 6.5.6). The marginal value of one point of any factor remains the product of the other two factors, but the lever ranking must be computed from the recommendation fleet's own measured numbers.

9.8.2 Cost per useful unit

An organization pays for fleet capacity by the accelerator-hour regardless of whether a complete allocation holds it, whether a retained step uses it, or whether that step runs at the ideal rate. Every factor of the goodput decomposition therefore divides directly into the cost of useful work. Specifically, the price of one accelerator-hour of ideal-rate progress equals the raw capacity price divided by MPG. With the capacity price per accelerator-hour $R_{\text{GPU/hr}}$ and the cost of one useful accelerator-hour C_{useful}, equation 9.6 states this relationship:

$$C_{\text{useful}} = \frac{R_{\text{GPU/hr}}}{\text{MPG}} = \frac{R_{\text{GPU/hr}}}{\eta_{\text{scheduling}} \times \eta_{\text{runtime}} \times \eta_{\text{program}}} \tag{9.6}$$

This relation turns each goodput factor into an inverse cost multiplier: a loss at any boundary raises the price of every unit of useful output in exact proportion. Using the internal fleet reference rate of $2/GPU-hour from section 12.9 as the cost of one in-service accelerator-hour, dividing by scheduling goodput charges the scheduling loss once, consistent with the in-service denominator defined in section 9.4.1. Under this accounting, the running example's pool pays roughly $7.09/GPU-hour for each accelerator-hour of ideal-rate progress, or 3.5× the raw capacity price. Because any unit of useful output—whether a training token or a served token—requires a fixed number of ideal-rate accelerator-hours, its unit cost carries the exact same multiplier. The spot-instance cost equation (equation 8.3) is the special case that divides the instance price by runtime goodput alone.

A chargeback policy that bills each workload team only for the accelerator-hours its jobs hold charges the running example 2.3× the raw rate per useful accelerator-hour and leaves the pool's scheduling loss unbilled. How an organization assigns that unallocated pool cost is a matter of cost-attribution policy (section 12.9.7.2).

Raising any goodput factor lowers the cost of every useful unit in proportion. Lifting the running example's program goodput to its single-node ceiling would reduce the cost of useful work by 26 percent without purchasing a single additional accelerator. However, the cost multiplier alone does not dictate which improvement to pursue, because levers that raise one factor frequently lower another; section 9.9 evaluates those cross-boundary trade-offs using the full goodput product.

↪ Lifecycle cost of ownership, chargeback, and utilization as the invariant beneath build-versus-buy are developed in section 12.9.

9.9 Trading Between Factors

Waiting for a compact node placement, running a longer autotuning compilation before the first step, and enforcing a tighter preemption policy each raise one goodput factor by shifting loss to another boundary. Evaluating any cross-boundary change on the single factor it was built to improve ignores the capacity lost at the boundary that paid for it, so the change must be judged by the goodput product it leaves behind. This trade-off is the fleet-level manifestation of the conservation of overhead (principle 14), in which an optimization relocates overhead among compute, communication, and coordination rather than eliminating it outright. Because every factor multiplies the same goodput product, and one point of any factor is worth the product of the other two (section 9.8.1), a loss displaced to one boundary can be weighed in a common currency against the gain it purchases at another.

9.9.1 Judging a trade by the product

When a compiler team enables an autotuning pass that speeds up steady-state steps while adding minutes to startup, the compiler team sees only the faster step trace and the reliability team sees only the longer launch in the job timeline. Deciding whether that trade helped the fleet requires combining both teams' measurements

without rebuilding the whole-fleet waterfall from scratch. A change that touches more than one boundary multiplies MPG (equation 9.1) by the product of each factor's before-and-after ratio, with every ratio measured on the same boundary and over the same time window. The change improves fleet efficiency only when that product of ratios exceeds one, regardless of which individual factor the lever was designed to raise. Expressing the rule in ratios allows separate engineering teams to evaluate a trade from their own telemetry: the reliability team measures what a restart policy does to runtime goodput, the compiler team measures what an autotuned build does to program goodput, and the two relative ratios multiply directly. Because a 1 percent relative gain in any factor produces a 1 percent gain in the overall product, small changes reduce to adding percentage gains and subtracting percentage losses. The marginal value of one absolute percentage point derived in section 9.8.1, the product of the other two factors, is the exact same rule expressed in percentage points. A point added to the lowest factor therefore represents the largest relative change and carries the highest marginal value.

Even so, every factor's ratio must be re-measured after the same change, because a lever aimed at one factor mechanically shifts the others across their shared boundaries. Productive step time is both the denominator of program goodput and the numerator of runtime goodput, while held allocation time is both the denominator of runtime goodput and the numerator of scheduling goodput. Shortening the time spent on one side of a boundary therefore alters the ratio on the other side. The fleet-goodput study measured this coupling on production clusters, and table 9.9 summarizes the directional effects (Wongpanich et al. 2025). A compiler optimization that shortens on-device execution per step raises program goodput, yet it simultaneously lowers runtime goodput because the job now spends fewer productive device hours relative to its fixed startup, checkpoint, and recovery durations. When the job is device-bound, total wall-clock step time falls and the run finishes earlier. Releasing the allocation sooner slightly reduces the pool's held-allocation numerator relative to fixed scheduling transitions between jobs, so scheduling goodput dips slightly even as total MPG rises. When the job is host-bound and paced by its input pipeline, faster on-device execution does not shorten wall-clock step time at all. Every millisecond saved on the device becomes an extra millisecond spent waiting for the next input batch, so the rise in program goodput and the drop in runtime goodput cancel out and leave MPG unchanged. Eliminating runtime waste likewise finishes the job earlier, raising runtime goodput while slightly lowering scheduling goodput, and only shortening partial-gang holding raises scheduling goodput in isolation. Consequently, a monitoring dashboard that shows one factor dipping after an optimization does not indicate a regression until the full product has been evaluated.

Table 9.9: How a Lever Moves All Three Factors: Each row is a change made at one layer of the fleet stack and each column a factor's direction afterward. Program and runtime goodput share the productive-time boundary, so a faster step that raises one lowers the other, and only the product says whether the fleet gained. Adapted from Wongpanich et al. (2025).

Lever	Program goodput	Runtime goodput	Scheduling goodput	MPG
Compiler shortens on-device step	Rises	Falls	Falls if device-bound; else no change	Rises if device-bound; else no change
Runtime removes idle or lost time	No change	Rises	Falls	Rises
Scheduler shortens partial holding	No change	No change	Rises	Rises

This ratio rule is strongly asymmetric when the factors start at different levels. A program optimization that lifted the running example's program goodput from 0.48 to its single-node ceiling of 0.65 would increase the product by 35 percent. It would therefore still yield a net gain even if it sacrificed up to 26 percent of the job's runtime goodput (figure 9.13). A runtime lever has no comparable margin to spend: even if every runtime loss were eliminated, a runtime goodput of 0.90 could rise by at most 11 percent. Because a factor already near one has little relative headroom left to offer, a trade that spends runtime goodput to purchase program goodput merits careful measurement, whereas a trade in the opposite direction warrants immediate skepticism.

Two conditions determine whose product and which measurement window the product rule requires. First, a lever confined to a single job's allocation—such as a compiler flag or a local checkpoint strategy—is measured on that job's own product ($\eta_{\text{runtime}} \times \eta_{\text{program}}$). By contrast, a lever that moves capacity between jobs—such as priority preemption, a placement wait, or an elastic resize that returns devices to the pool—also alters other jobs' factors. It must therefore be judged on the pool's MPG, the only quantity that captures both the urgent job's scheduling gain and the preempted victim's runtime loss. Second, one-time costs such as a compilation build, a mesh rescale, or a restart purchase gains across every subsequent step, so a ratio measured over one hour and the same ratio measured over one week can fall on opposite sides of unity. For that reason, the measurement contract of section 9.3.1 requires the observation window to be reported alongside the result.

The goodput product itself does not measure wall-clock completion time: two configurations with the exact same product can finish a job days apart. The product rule evaluates capacity efficiency for the fleet, whereas section 9.9.4 introduces the additional dimensions on which a job's owner chooses an operating point.

The elastic scaling decision analyzed in section 8.7.3 illustrates this trade-off across boundaries. Consider a job whose target batch is designed for 512 GPUs under three strategies. The first starts immediately on 128 GPUs and remains at that size. The second waits 4 hours in the queue for the full 512 GPUs allocation. The last starts immediately on 128 GPUs and steps up to 256 GPUs when capacity frees, leaving the remaining devices to queued jobs. Because the global batch size

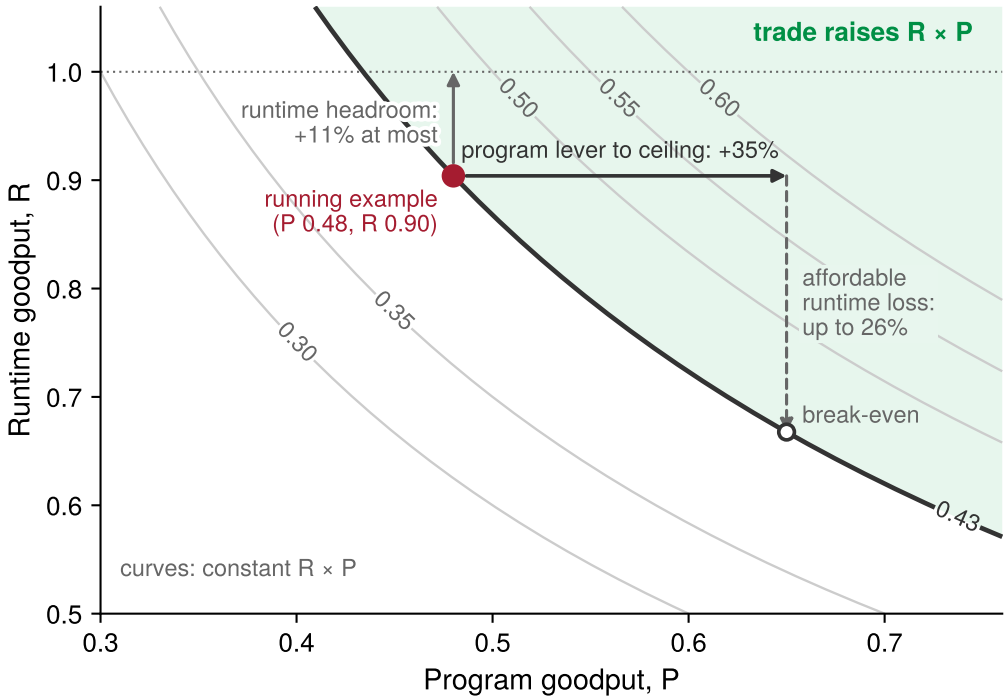

Figure 9.13: Iso-goodput Curves of the Product Rule: Program goodput against runtime goodput for the running example, with scheduling goodput held at 0.65, so each curve of constant $\eta_{\text{runtime}} \times \eta_{\text{program}}$ is also a curve of constant MPG. A program lever that lifts P from 0.48 to its ceiling of 0.65 can give up as much as 26 percent of runtime goodput before it falls back to the bold curve through the running example, while removing every runtime loss raises R by only 11 percent.

is held fixed across all three strategies, each epoch delivers identical statistical progress. Program goodput separates the three options most strongly: the scaling efficiencies—90 percent at 256 GPUs and 80 percent at 512 GPUs—are the exact ratios of each larger allocation's program goodput to that of the 128 GPUs baseline. Runtime goodput separates them by a single non-productive interval: the 10-minute pause required to checkpoint, reshard, and restart during the step-up transition (section 9.5.1). The step-up strategy retains its throughput advantage over the immediate small run unless that rescale pause exceeds roughly 9 hours.

Scheduling goodput—which belongs to the shared pool—determines which strategy serves the cluster best. The 256 GPUs that the step-up strategy leaves in the pool are worth whatever the queue can do with them. If waiting jobs form complete allocations on those devices immediately, the pool's MPG rises. If those devices sit in unallocated fragments that no queued gang can use, they become a scheduling loss, and giving the full allocation to the first job would have been more productive. Wall-clock completion time pulls in the opposite direction: the step-up strategy advances at nearly 1.7× the rate of the immediate small run yet still trails the full allocation by roughly 38 percent over the window. Consequently, a team facing a hard deadline prefers waiting for the full allocation, whereas a fleet operator managing a deep queue prefers the elastic step-up.

9.9.2 Cross-boundary trades across the fleet stack

Elastic resizing is one instance of a recurring pattern across the fleet stack: replacing a straggling node, preempting a low-priority job, lending idle quota, or staging checkpoints asynchronously in background memory each buys a gain at one goodput boundary by paying a cost at another. Earlier chapters in this book priced these mechanisms in the local units of their own subsystems, such as restart minutes, cascade multipliers, or storage bandwidth. Mapping those results onto the three goodput boundaries identifies which factor each lever raises and which factor it lowers, allowing cross-layer trade-offs to be compared on a single scale (table 9.10).

Table 9.10: Trades between Goodput Factors Priced in This Book: Each row reads an owning chapter's result onto the accounting boundaries, naming the factor the lever raises and the factor it lowers. The owners' results are not re-derived; the product rule of section 9.9.1 decides each trade from the measured ratios. The last row trades within one factor and is listed because it couples to the preemption rows.

Trade	Raises	Lowers	Priced in	What decides it
Straggler replacement	Program goodput: steps return to the healthy pace	Runtime goodput: restart, state reload, and replay of lost steps; any wait for spare capacity	section 7.9.5	How long the slowdown persists, against the restart and replay cost
Priority preemption	Scheduling goodput: the urgent gang forms without draining capacity for it	Runtime goodput of every victim, multiplied by the cascade	section 8.8.1	Preemption budget and requeue rule, against admission delay
Quota lending	Scheduling goodput: unused guaranteed capacity becomes a borrower's complete allocation	Runtime goodput of the borrower when the owner reclaims	section 8.11.2	How quickly a borrower can checkpoint or shrink
Placement wait	Program goodput: collectives stay on the fastest links	Scheduling goodput while capacity is held free to assemble the placement; otherwise only time to result	section 8.6.2	End-to-end completion time, including the wait

Trade	Raises	Lowers	Priced in	What decides it
Elastic resizing	Program goodput: a smaller allocation runs at higher scaling efficiency; scheduling goodput when freed devices form other jobs' allocations	Runtime goodput: each rescale pause; the job's own time to result	section 8.7.3; section 9.9.1	The pool's queue and fragmentation at the resize
Asynchronous checkpoint staging	Runtime goodput: no synchronous pause per save	Program goodput: background writes contend with steps; runtime goodput again if a failure lands before the new generation is durable	section 4.6.1; section 7.8.3.1	Not priced in this book; measured step time with writes in flight
Compilation build	Program goodput: faster compiled steps	Runtime goodput: build time in every startup that compiles	section 9.9.3	Number of executions that reuse the artifact
Checkpoint cadence (within one factor)	Runtime goodput: less rework per interruption	Runtime goodput: more frequent pauses	equation 7.8; section 7.8.1; section 9.5.2	Interruption rate, including preemptions

Three structural patterns recur across table 9.10. First, any lever that transfers capacity between jobs—such as priority preemption or quota lending—must be evaluated at the pool level because its gain lands on one job while its cost lands on another. The orchestrator's preemption budget sets the rate at which one is exchanged for the other. Second, waiting in the queue costs scheduling goodput only when capacity is held idle to assemble the target allocation. If other jobs run on those devices in the meantime, the wait costs only wall-clock time to result, which is why placement waits and elastic resizing depend on the state of the pool's queue rather than on the job alone. Third, an elastic resize changes the device mesh, forcing a compiler-partitioned program to recompile for the new topology (section 9.7.1) and adding that build time to the rescale pause.

Asynchronous checkpoint staging is the one trade in the table whose program-goodput cost must be measured empirically on the target system. Staging copies a state snapshot to host memory or local flash and flushes it to durable storage in the background while training continues (section 7.8.3.1), removing most of the synchronous pause counted by the checkpoint term of equation 9.4. However, the background flush still contends with active training steps for pinned host memory, PCIe transfers, network links, and storage bandwidth, so its overhead surfaces as
