The first architectural response is global. When every stage of the profile is over budget, the problem is not one bad layer; the model is scaled incorrectly for the deployment envelope. The design task is then to distribute capacity across depth, width, and input resolution rather than choose a single parameter count: depth adds sequential stages and activation storage, whereas width exposes more parallel work within each stage at the cost of larger weight and activation tensors, and higher input resolution sharpens spatial detail by multiplying the positions every convolution must visit. Which dimension to grow therefore depends on the machine, since a wide parallel accelerator can absorb extra channels while a small edge device is limited first by memory capacity and energy per access.

Mathematically, the total FLOPs for a convolutional model can be approximated as:

$$O \propto N_L \cdot w_{\text{mult}}^2 \cdot r^2,$$

where N_L is depth (number of layers), w_{mult} is the width multiplier (channel count relative to a base model), and r is the input resolution. This expression shows why naive scaling fails. Increasing width and resolution together multiplies work quickly, and the resulting model may exceed the memory bandwidth or power budget even when the parameter count appears reasonable.

The camera pipeline's own architecture exposes one of these knobs directly. MobileNetV2's width multiplier scales every layer's channel count, and at a width of 0.75 the network shrinks from 3.5M to 2.6M parameters and from 600 MFLOP to 418 MFLOP per frame, keeping about 70 percent of the arithmetic. The square law predicts a larger cut, because depthwise layers cost in proportion to the width rather than its square, and the network's final convolution keeps its full width at reduced multipliers. A width setting is therefore a trade the phone can measure directly, in milliseconds per frame, against the accuracy the narrower network loses.

Compound scaling turns this balancing act into a controlled design rule. Instead of adjusting depth, width, and resolution independently, compound scaling grows all three dimensions by fixed ratios (α, β, γ) relative to a base model:

$$N_L = \alpha^{\phi} N_{L,0}, \quad w_{\text{mult}} = \beta^{\phi} w_{\text{mult},0}, \quad r = \gamma^{\phi} r_0$$

Here, ϕ is a scaling coefficient, and α, β, and γ (as in the original EfficientNet paper) are scaling factors determined from empirical accuracy and efficiency measurements. The rule matters because it prevents one dimension from consuming the budget before the others can contribute useful accuracy.

EfficientNet (section 10.2.5) validated this principle by using search to find a baseline architecture and then scaling it with balanced depth, width, and resolution coefficients (Tan and Le 2019). The lesson is not that every deployment should use EfficientNet. The systems lesson is that scaling is a resource-allocation decision, because the same accuracy target can imply different depth-width-resolution trade-offs depending on which resource the target platform makes scarce. Chapter 12 formalizes how to measure those trade-offs; the design principle here is to scale the dimensions against the binding resource.

The same logic extends beyond convolutional models. Transformer layers, attention heads, sequence length, and embedding width play roles analogous to depth, width, and resolution. Each increases capacity, but each stresses compute, memory bandwidth, or activation storage differently. Hardware-aware scaling keeps those dimensions tied to the measured bottleneck instead of treating model size as a single scalar.

10.2.4.3 Computation reduction

If the profile shows that a small set of convolutional operators dominates arithmetic, reducing the whole model uniformly is wasteful. The better response is to change the expensive operator. Modern efficient architectures do this by factorizing dense computations into cheaper pieces that preserve the representation needed for accuracy.

Depthwise separable convolutions, the factorization behind the MobileNetV2 and KWS lighthouses (Howard et al. 2017; Sandler et al. 2018), are the standard example. They split a standard convolution into a depthwise stage that filters each input channel separately and a pointwise 1×1 stage that mixes channels, which cuts the arithmetic to about $1/d_{\text{out}} + 1/K^2$ of a standard layer with d_{out} output channels and kernel width K, roughly one-ninth for 3×3 kernels and many output channels. What this chapter adds to that result is the deployment condition. The wall-clock benefit depends on kernel support and memory behavior. A mobile runtime with optimized depthwise kernels can convert much of this arithmetic reduction into latency savings, while a poorly supported backend may expose the factorized operations as many small, memory-bound kernels.

↩ Depthwise separable convolution and its cost reduction relative to a standard convolution are established in section 6.3.5.

Other factorization patterns follow the same logic: ResNeXt's grouped convolutions split feature maps into independent channel groups before merging them, whereas ResNet's bottleneck blocks and SqueezeNet's fire modules use 1×1 convolutions to narrow the channel dimension before an expensive spatial convolution so that both arithmetic and parameter storage fall. Because all of these rewrites help only when the spatial convolution they shrink actually dominates the trace, they yield much smaller gains once memory traffic, launch overhead, or unsupported kernels become the binding cost.

Arithmetic reduction is only one possible response. When profiling instead identifies memory capacity or data movement as the binding resource on the target device, the architecture must address that memory bottleneck directly.

10.2.4.4 Memory optimization

When the profile points to memory rather than arithmetic, the architecture must reduce the working set or the number of expensive memory accesses. Activations, feature maps, and parameters can exceed cache, SRAM, accelerator memory, or edge-device storage even when the FLOP count is acceptable. Memory-efficient architectures therefore try to preserve useful information while storing or moving less data.

DenseNet illustrates the feature-reuse response (Huang et al. 2017). In a traditional convolutional network, each layer computes a new set of feature maps, increasing the activation footprint as the network deepens. DenseNet connects layers so later computations can reuse earlier feature maps instead of relearning similar representations. In DenseNet with N_L layers and growth rate g, each layer generates g new feature maps concatenated with prior layers, causing the total number of feature maps to grow linearly:

$$\mathcal{O}(N_L g)$$

DenseNet reduces parameter redundancy through feature reuse, but concatenating retained features can increase activation storage and memory traffic. The resulting working set and runtime must be measured on the target hardware.

Parameter reduction applies the same reasoning to storage. SqueezeNet uses 1×1 convolutions to reduce the number of input channels before applying standard convolutions, making the expensive layer operate on a smaller representation (Iandola et al. 2016). The number of parameters in a standard convolutional layer is:

$$\mathcal{O}(d_{\text{in}} d_{\text{out}} K^2)$$

By reducing d_{in} using 1×1 convolutions, SqueezeNet reduces parameter count, achieving the paper's AlexNet-level accuracy target with far fewer parameters than AlexNet. That trade is attractive when the deployment constraint is flash storage, model download size, or parameter bandwidth; it is less decisive when activation memory or operator overhead dominates.

Feature reuse and parameter reduction are therefore not interchangeable recipes: reused features cut redundant representations, whereas 1×1 bottlenecks cut parameter movement at deployment, so the profile's binding memory term decides between them. Each of these manual motifs fixes one operator pattern at a time, leaving open how to choose kernel sizes, expansion ratios, and channel widths jointly across an entire network.

10.2.5 Neural architecture search

Hand-tuning kernel sizes, expansion ratios, and channel widths across twenty or more layers can explore only a handful of the billions of valid configurations that fit a phone's latency budget, leaving significant accuracy or speed on the table. **Neural architecture search (NAS)** automates this structural design by systematically traversing a bounded space of operations, topologies, and compound scaling rules prior to training (Elsken et al. 2019). Early reinforcement-learning formulations maximized task accuracy without hardware constraints (Zoph and Le 2016); subsequent weight-sharing methods amortized evaluation overhead (Pham et al. 2018); and hardware-aware NAS explicitly incorporated measured device latency and energy into the multi-objective search (Tan et al. 2019). For the camera pipeline, architecture search is already part of the model's lineage, since MnasNet and MobileNetV3, MobileNetV2's successors, came from searches that measured candidate latency on phones (Tan et al. 2019; Howard et al. 2019).

[12] **Hardware-aware NAS**: Optimizes measured latency rather than FLOPs, which can diverge by 3–5× when memory access or operator support dominates. Tan et al. (2019) fed device latency into search and found architectures 1.8× faster than MobileNetV2 at higher accuracy.

[13] **Bi-level optimization**: A formulation where one optimization problem sits inside another. In NAS, the outer level selects an architecture while the inner level trains that candidate's weights, so early methods paid a full training cost for every architecture evaluated. Weight-sharing methods such as Efficient Neural Architecture Search (ENAS) amortize one training run across many candidates, reducing search cost by roughly 1,000× (Pham et al. 2018).

Discovery runs as a closed loop. The search strategy samples candidate architectures $a \in \mathcal{A}$ from the defined search space, and the performance estimation engine evaluates their latency or accuracy and feeds the result back to refine subsequent proposals (figure 10.13). NAS[12] returns graphs that sit on the Pareto frontier under explicit resource bounds.

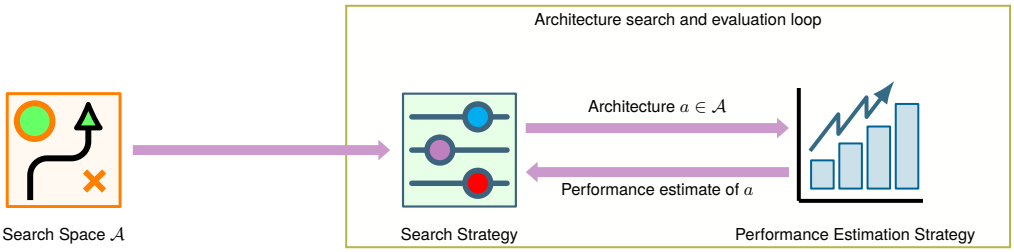

Figure 10.13: Neural Architecture Search Flow: An automated optimization loop for architecture discovery. The search strategy samples candidate subnetworks from a predefined search space, while the performance estimation engine evaluates candidates against target accuracy and hardware constraints (such as latency or energy), feeding reward signals back to steer subsequent exploration toward Pareto-optimal designs.

10.2.5.1 The NAS optimization problem (optional depth)

NAS rests on three design decisions: the search space, the search strategy, and how each candidate is evaluated. An architecture's quality cannot be known until it is trained, and training is expensive, which creates two nested decisions: which operations to include (the architecture) and which parameters work best for them (the weights).

NAS is therefore a **bi-level optimization problem**.[13] The outer loop searches the architecture space $\mathcal{A}$, while the inner loop trains candidate architectures to evaluate performance. Formally, the objective seeks the optimal architecture a^* that minimizes validation loss $\mathcal{L}_{\text{val}}$ under constraints C (latency, memory):

$$a^* = \arg\min_{a \in \mathcal{A}} \mathcal{L}_{\text{val}}(\theta^*(a), a) \quad \text{subject to} \quad C(a) \leq C_{\max}$$

where $\theta^*(a)$ represents the optimal model parameters for architecture a, obtained by minimizing training loss:

$$\theta^*(a) = \arg\min_{\theta} \mathcal{L}_{\text{train}}(\theta, a)$$

The computational bottleneck lies in this inner loop. If evaluating every candidate requires independent training from scratch, a modest search space of 10 operation choices across 20 layers yields 10^{20} possible architectures, making exhaustive enumeration impossible. Practical NAS methods overcome this combinatorial explosion through three mechanisms: restricting the search space to reusable cells, amortizing evaluation through weight sharing, or relaxing discrete choices into continuous, differentiable formulations.

10.2.5.2 Search space design (optional depth)

Many NAS systems search for reusable cells that are stacked to form complete networks, rather than searching whole architectures. A convolutional cell might choose among 3×3 convolution, 5×5 convolution, depthwise separable convolution, max pooling, or identity connections. A simplified cell with four nodes and two operations per edge yields roughly 10,000 possible cell designs, far more tractable than searching full architectures. NASNet discovered reusable normal and reduction cells this way.

Search spaces also encode hardware constraints by restricting candidate operations to primitives with efficient kernels on the target platform. Mobile search spaces, for example, prioritize depth-wise separable convolutions with bounded kernel sizes and channel counts (Zhang et al. 2020). MobileNetV3 paired this structured block-level search space with NetAdapt to prune layer channels against measured mobile CPU latency (Howard et al. 2019).

10.2.5.3 Search strategies (optional depth)

Search strategies trade search cost against architectural diversity (table 10.6). Reinforcement learning treats search as a sequential decision in which a controller proposes architectures and receives an accuracy reward. It discovered NASNet, but every reward requires training a candidate; Zoph and Le (2016) evaluated roughly 12,800 architectures on 800 GPUs for 28 days, a total of 22,400 GPU-days, a cost that pushed practical NAS toward weight sharing and cheaper performance predictors. Evolutionary algorithms instead mutate and recombine a population of candidates and keep the fittest; AmoebaNet reached ImageNet accuracy competitive with top human-designed models after 3,150 GPU-days (Real et al. 2019), a cost that needs proxy tasks, weight sharing, or massive parallelism to control. Gradient-based methods such as DARTS (Differentiable Architecture Search) (Liu et al. 2019) relax the search space into weighted combinations of all operations and optimize architecture weights and model weights jointly by gradient descent, reducing search cost from hundreds of GPU-days to one to four, though the relaxation may miss discrete patterns that discrete search finds.

Table 10.6: NAS Search Strategy Comparison: Representative trade-offs between search efficiency, use cases, and limitations for different NAS approaches. The costs are method-specific results from early reinforcement-learning and evolutionary searches and from DARTS, not universal ranges for each strategy (Zoph and Le 2016; Real et al. 2019; Liu et al. 2019).

Strategy	Search Efficiency	When to Use	Key Challenge
Reinforcement Learning	22,400 GPU-days	Novel domains, unconstrained search	High computational cost
Evolutionary Algorithms	3,150 GPU-days	Parallel infrastructure available	Requires large populations
Gradient-Based (DARTS)	1–4 GPU-days	Limited compute budget	May converge to suboptimal local minima

Hardware-aware NAS optimizes execution metrics on target silicon rather than FLOP counts, which correlate poorly with latency when memory bandwidth or launch overheads dominate. Under the arithmetic intensity law (principle 6), an operation with few FLOPs but low arithmetic intensity can run slower than a higher-FLOP operation that saturates compute. MnasNet addresses this divergence by measuring each candidate's latency directly on a mobile phone and folding it into the reward, which combines accuracy and latency through a weighted product:

$$\text{Reward}(a) = \text{Accuracy}(a) \times \left(\frac{L_{\text{lat,target}}}{L_{\text{lat,infer}}(a)} \right)^{\beta_{\text{lat}}}$$

where $L_{\text{lat,infer}}(a)$ is the measured on-device inference latency of architecture a, $L_{\text{lat,target}}$ is the latency constraint, and the exponent β_{lat} controls the accuracy-latency trade-off. Architectures that exceed the latency target are penalized. In the reported MnasNet search space, varying inverted-residual expansion ratios produced a stronger accuracy-latency trade-off than uniform expansion.

10.2.5.4 When to use NAS

Neural architecture search can discover architectures that outperform hand-designed alternatives, but its cost demands a check on whether the investment is justified. NAS can be worthwhile for novel hardware platforms with unusual constraints, such as new accelerator architectures or highly constrained edge devices, where existing architectures are poorly optimized. It can also make sense at deployment scales where small efficiency improvements justify the upfront search cost, or when architecture families for cloud, edge, and mobile deployments can amortize one search across many variants.

Conversely, custom NAS is difficult to justify when standard deployment constraints already have well-optimized architecture families. If the compute budget is only a few GPU-days, large reinforcement-learning or evolutionary searches are impractical; differentiable or weight-sharing methods such as DARTS may remain feasible, but still require deployment-scale and validation-cost justification. Rapidly changing requirements also weaken the case because the target can move before search and validation finish.

For most practitioners, existing NAS-discovered or NAS-assisted architectures provide strong baselines before funding a search from scratch. EfficientNet jointly scales depth, width, and resolution with compound coefficients (Tan and Le 2019), MobileNetV3 combines hardware-aware search with NetAdapt for phone latency targets (Howard et al. 2019), MnasNet folds measured phone latency into its reward (Tan et al. 2019), and FBNet puts device-specific latency into a mobile-CPU search objective (Wu et al. 2019). NAS has also been applied to compact transformer models under compute or memory constraints. These results show what search found under particular spaces, objectives, and measurements, not that search universally beats careful manual design. When latency, memory, or energy enters the objective and is measured on the target platform, the search evaluates candidates against the resource deployment actually constrains, yet the transfer quality of the resulting architectures still depends on task and hardware. Reserve custom NAS for unusual constraints or deployment scales that can amortize the search and validation investment. Even a searched architecture, however, still executes the same fixed graph on every input, spending as much compute on a blank background frame as on a crowded street scene.

10.2.6 Adaptive computation methods

A static 24-layer transformer executes identical multiply-accumulate (MAC) operations and streams its entire parameter footprint from HBM or off-chip DRAM for an obvious, easily classified sample as it does for an ambiguous one. Because pruning, distillation, factorization, and architecture search all produce a fixed execution graph, every input follows the same scheduled path regardless of difficulty. **Adaptive inference** replaces this open-loop pipeline with an input-dependent control loop, in which intermediate representations or runtime budgets decide whether to terminate execution early or which specialized subnetwork receives the activations. While dynamic paths can reduce average arithmetic operations and memory traffic, they introduce runtime overheads in routing logic, batch management, confidence calibration, and latency variance. The camera pipeline is a natural candidate, because many frames are easy and the phone processes one frame at a time. Dynamic pruning applies the idea at the granularity of channels and filters; early exits, conditional layers, and expert subnetworks apply it at coarser grain, where the savings per decision are larger and so is the cost of a wrong one.

10.2.6.1 Dynamic pruning

Traditional pruning methods, whether unstructured or structured, produce a **static pruning** mask or subnetwork that remains fixed during deployment, even if the mask was learned gradually during training. **Dynamic pruning** instead decides at inference time, from each input, which computation is active, so the executed subnetwork changes from one input to the next.

Dynamic pruning can therefore allocate different amounts of work to different inputs and can use, for a hard input, capacity that a static deployment mask would remove permanently. Activation-conditioned pruning, for example, deactivates neurons or channels for particular inputs (Hu et al. 2023). On a simple image with mostly uniform regions, some convolutional filters produce negligible activations, and a dynamic policy can exclude them for that frame. The exclusion reduces nominal work, but the controller sits on the critical path, input-dependent routing fragments execution across SIMD vector lanes, and any quality change remains part of the result. Training may also need routing losses or regularization so that the policy actually uses its cheaper paths. Dynamic pruning is therefore a candidate when input complexity varies enough to repay the controller and batching overhead, not a default substitute for static pruning, and its gain must be measured as latency and accuracy together across the full input distribution.

↪ Joint evaluation of compressed models on accuracy and target efficiency metrics such as latency, plotted as an efficiency-quality frontier, is measured in section 12.9.1.4.

Methods that change the mask during training are sometimes also called dynamic, but they solve a different problem. Gradual magnitude pruning progressively increases the fraction of pruned parameters while fine-tuning the survivors, which is the iterative schedule of section 10.2.1.5 run inside training, and dynamic sparse training additionally regrows connections that prove important later. Both end in a static mask for deployment, so this chapter reserves *dynamic pruning* for input-dependent execution.

10.2.6.2 Dynamic schemes

Because input samples vary widely in difficulty, spending the same compute budget on every input wastes memory bandwidth and execution cycles on simple cases. Dynamic schemes modulate

execution paths to lower amortized computation while preserving the deep network for worst-case inputs. This architectural flexibility spans four primary control variables: network depth (early exit), structural routing (conditional layer skipping), expert subnetworks (mixture-of-experts), and continuous computational allocation.

To control execution depth, **early exit** architectures attach auxiliary classification heads to intermediate layers, terminating execution when intermediate representations yield sufficient prediction confidence (Teerapittayanon, McDanel, and H. T. Kung 2017). BranchyNet implements this mechanism across convolutional backbones using shallow exit branches, whereas multi-exit vision transformers attach linear probes and entropy estimators between transformer blocks (Xin et al. 2021). When an input satisfies an exit criterion, such as softmax prediction entropy dropping below a pre-tuned threshold, the runtime halts evaluation and returns the intermediate prediction. The net operational benefit requires that the arithmetic operations and memory transfers avoided in subsequent layers exceed the computational overhead of evaluating the intermediate classifiers and gating thresholds.

The systems trade-off diverges sharply across hardware deployment targets. On single-sample edge processors (batch size $B = 1$, typical of microcontrollers and mobile NPUs), early exit immediately terminates the execution thread (Hu et al. 2020). Skipping remaining layers eliminates both the arithmetic operations and the off-chip DRAM transactions required to load subsequent layer weights into on-chip SRAM cache. Conversely, on parallel throughput accelerators (GPUs and TPUs) processing batched workloads ($B > 1$), early exit introduces severe batch fragmentation (Chen et al. 2024). If only a subset of samples in a batch reaches the exit threshold, the remaining samples must still traverse deeper layers. Unless the runtime executes dynamic batch compaction (gathering unresolved activation tensors into a contiguous memory buffer through memory copies and kernel synchronizations), inactive samples remain allocated in memory, or the accelerator must mask inactive SIMD or single instruction, multiple threads (SIMT) lanes. Consequently, tail latency for the batch remains dictated by the deepest traversing sample. Along a transformer backbone, each block taps its intermediate representation into an auxiliary classifier and a learned confidence estimator (learning to exit, LTE) that can trigger an early exit, while unresolved inputs continue to deeper layers (figure 10.14).

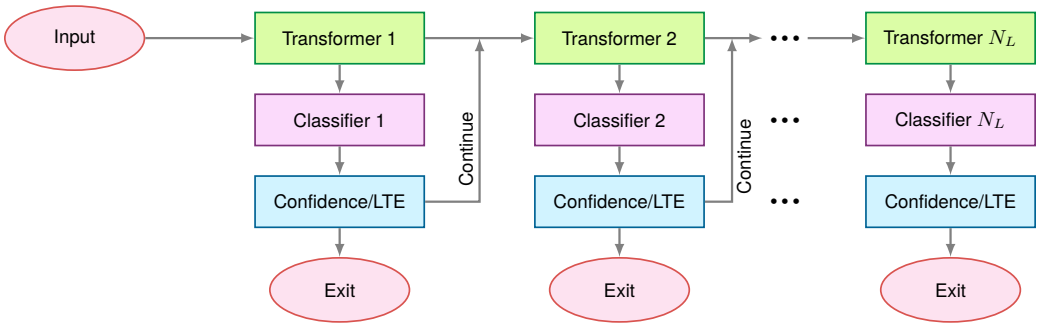

Figure 10.14: Early Exit Architecture: Transformer layers dynamically adjust computation by classifying each layer's output and enabling early termination if sufficient confidence is reached, reducing average latency and power when many inputs can exit before the final layer. Source: (Xin et al. 2021).

↪ The latency-throughput trade-offs of batching under production request streams, including service-level objective (SLO) violations, are developed in section 13.5.4.

Where early exit truncates depth along a single linear pipeline, **conditional computation** dynamically modulates the topological routing of activations through the network graph (Bengio et al. 2015). Instead of executing every block in a predefined sequence, gating functions evaluate activation tensors to bypass residual layers, alter operator kernels, or select specialized functional blocks. This converts a static directed acyclic graph (DAG) into an input-dependent dynamic graph.

SkipNet illustrates the pattern at the granularity of whole blocks. It uses lightweight recurrent or feedforward gating controllers to conditionally bypass residual blocks in convolutional networks, preserving full network depth only for computationally difficult inputs (X. Wang et al. 2018). From a hardware systems perspective, conditional routing achieves wall-clock speedups only when the cycles saved by bypassing operators surpass the latency of evaluating the gating network, executing host-device control synchronization, and managing uncoalesced memory accesses.

In a dense transformer, every token computes against every weight matrix, so parameter capacity and per-token compute grow together. The **mixture-of-experts (MoE)** architecture decouples them by replacing dense feedforward network (FFN) layers with a bank of parallel expert subnetworks coordinated by a parameterized router (Shazeer et al. 2017). Google's Switch Transformer[14] steers each token to a single expert ($k_{\text{experts}} = 1$), which reduces communication overhead relative to routing to $k_{\text{experts}} > 1$ experts (Fedus et al. 2022).

Sparse activation trades compute for memory. A token routed to one of N_{experts} experts executes arithmetic against only $1/N_{\text{experts}}$ of the expert parameters, yet an all-resident deployment keeps all N_{experts} expert matrices in device memory. In a Switch Transformer block, a Switching FFN layer sits inside the standard transformer stack, and its gating router dispatches individual tokens ("More" with $p_{\text{gate}} = 0.65$, "Parameters" with $p_{\text{gate}} = 0.8$) to distinct expert sub-blocks (FFN 2 and FFN 1) while unselected experts stay idle (figure 10.15). Because the router lies on the critical path, the runtime must gather tokens assigned to the same expert into contiguous tiles (Lepikhin et al. 2021); at low batch sizes or under a skewed routing distribution, divergent routing leaves some experts with too few tokens to keep matrix units busy and overloads others, forcing the runtime either to truncate tokens or to launch kernels that leave lanes idle.

[14] **Switch Transformer**: Fedus et al. (2022) scales to roughly 1.6 trillion total parameters while routing each token to one expert; in a compute-matched experiment, Switch-Base with 64 experts reached the T5-Base quality target in about one-seventh the training time; the trillion-parameter comparison reported roughly 4× speedup over T5-XXL. Routing each token to one expert reduces communication relative to routing to $k_{\text{experts}} > 1$ experts, but load imbalance requires auxiliary losses and capacity factors, which cap how many tokens each expert accepts per batch. This trade-off, massive parameter capacity at low per-token compute cost in exchange for complex load-balancing engineering, defines the MoE design space.

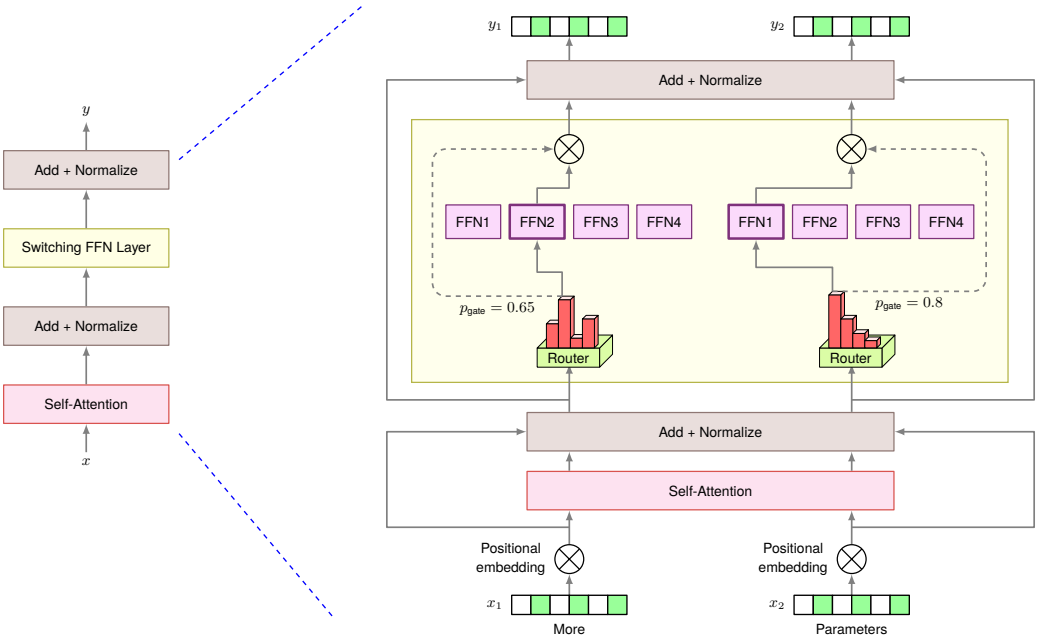

Figure 10.15: Switch Transformer Architecture: Replacing dense feedforward layers with a Switching FFN layer (left) enables sparse conditional routing. A gating network routes each token to a single expert (right) out of a large pool, decoupling total model capacity (parameters) from per-token compute cost (FLOPs). Source: (Fedus et al. 2022).

↪ How runtimes execute tensors whose shapes vary, by matching precompiled shape profiles, padding, splitting the batch, or falling back to a general kernel, is developed in section 11.8.3.2.

Early exit and MoE routing make discrete branch selections, but adaptive inference can also modulate depth or iteration counts continuously according to task difficulty (Yang et al. 2020). BlockDrop adjusts the number of active layers with a runtime policy network (Wu et al. 2018), and dynamic layer scaling adds computation until output uncertainty drops below a calibrated threshold. In an embedded vision system, high-contrast frames with clear road geometry resolve through a minimal prefix of layers, whereas degraded frames with occluded obstacles trigger deeper processing. The gain materializes only if the control evaluation remains computationally lightweight and the runtime schedules frames with matched execution depths concurrently to maintain high hardware utilization.

10.2.6.3 Implementation challenges

Realizing the efficiency gains of adaptive computation requires overcoming challenges across optimization, runtime orchestration, and hardware execution. During training, discrete routing decisions

(such as non-differentiable argmax branch selections) break standard gradient-based backpropagation. Practitioners overcome this with continuous relaxations such as the Gumbel-Softmax estimator, which replaces hard selections with smooth approximations so gradients flow, with policy gradients that reinforce routing choices that earn a reward, or with auxiliary load-balancing losses that keep routers from collapsing onto a single favored expert (Shazeer et al. 2017).

At runtime, control-flow branching conflicts with the lockstep execution of modern accelerators, where the threads of a warp execute the same instruction. When threads within a GPU warp take divergent branches, the hardware may serialize them and mask inactive threads, which erodes the theoretical FLOP savings. Gating also introduces control dependencies that can limit fusion, require token-permutation buffers, or trigger host-device synchronization. If these dispatch overheads exceed the compute time saved by skipping layers, the dynamic model has higher end-to-end latency than a dense baseline. Runtime strategies such as ragged batching and dynamic kernel launch queues manage these patterns, and they belong to the accelerator runtime rather than to the model.

Dynamic control also adds quality and security failure modes. Poorly calibrated gates underallocate computation to rare inputs, which degrades accuracy on safety-critical edge cases, and adversarial perturbations can push the gates toward truncated early exits or maximally deep paths. Evaluating adaptive models therefore cannot rely on average FLOP counts alone. Rigorous system profiling must report path distribution histograms, tail latency (p99), accuracy stratified by input difficulty, and throughput stability under dynamic batching, and a production deployment keeps monitoring route frequency and quality by route after launch.

The structural techniques covered so far (pruning, low-rank factorization, distillation, efficient architecture design, NAS, and adaptive computation) all optimize *what* computations the model performs, including which parameters exist, which connections remain, how the architecture is structured, and which paths a given input executes. These techniques can substantially reduce parameter counts and theoretical FLOPs. Regardless of structural efficiency, every surviving weight and activation must still be stored and processed at some numerical precision.

↪ Infrastructure telemetry that tracks latency distributions in deployed systems, alongside the model-quality signals production monitoring pairs with it, is developed in section 14.5.1.

Checkpoint 10.1: Choosing a structural method

Structural methods relocate deployment cost in different ways.

- ☐ **Structured vs. unstructured pruning**: compare how each pattern interacts with GPU and TPU execution.
- ☐ **Distillation vs. pruning**: explain why a dense student may preserve accuracy better than aggressive pruning while requiring additional training.
- ☐ **NAS selection**: identify when hardware-specific constraints and deployment scale justify architecture search rather than manual design.
- ☐ **Factorization cost**: explain why fewer stored parameters and MACs may not reduce latency when two factor operations add launches and an intermediate tensor.
- ☐ **Adaptive computation**: explain why early exit can cut latency at batch size one yet fragment batched execution on a GPU.

Structural optimizations alter what a model computes, but the surviving graph must still execute within the physical memory bandwidth, register files, and cache hierarchies of the target silicon. When structural pruning and distillation have carved away unnecessary parameters and layers, every remaining operation continues to incur a memory-movement and arithmetic cost determined entirely by its bit representation. Optimizing this numerical representation forms the second tier of the optimization stack, and its clearest case is a workload whose time is set by bytes rather than by arithmetic.

10.3 Numerical Precision: Changing How Values Are Stored

GPT-2 XL decoding on the phone shows what structural changes leave untouched. Its FP16 weights fit in the phone's memory, yet every generated token streams all 3 GB of them across a 51.2 GB/s bus, about 59 ms per token before any arithmetic (table 10.1). Pruning or factorizing its layers would

change which weights exist; the complementary optimization leaves the network topology unaltered and reduces the bit width of every surviving tensor. Quantization trades numerical precision for a smaller memory footprint, higher cache utilization, and higher arithmetic throughput on hardware with integer datapaths.

Definition 10.4: Quantization

Quantization is a model-compression technique that reduces information fidelity by mapping high-precision continuous values to a lower-precision discrete set.

1. **Significance**: FP32-to-INT8 conversion reduces the raw payload per quantized value by 4×. Real artifact size, traffic, and latency also depend on scales, metadata, packing, operator coverage, and the target kernels.
2. **Distinction**: Unlike pruning, which reduces the count of parameters, quantization reduces the bit depth of selected weights and/or activations.
3. **Common pitfall**: A frequent misconception is that quantization is just "rounding." In reality, it is a lossy mapping that requires careful range estimation and, often, quantization-aware training (QAT) to minimize its impact on accuracy.

Quantization[15] concerns every neural network weight and activation stored at some numerical precision: FP32 (32 bits), FP16 (16 bits), INT8 (8 bits), or lower. Bit width sets how many bytes each value occupies, how much cache it uses, and how fast specialized matrix engines can run.

Quantization transforms three physical terms of execution. First, converting FP32 to INT8 reduces raw weight payload by 4× before scale and packing metadata, allowing models to fit within constrained device memories. Second, when tensors remain packed across memory buses, memory traffic drops proportionally, directly reducing token latency in bandwidth-bound autoregressive decoding. Third, fixed-point integer arithmetic units occupy smaller silicon area and consume significantly less energy per operation than floating-point units, enabling higher compute density on supported hardware (Gupta et al. 2015; Y. E. Wang et al. 2019).

The accuracy cost varies by model, task, quantizer, calibration data, and bit width. Many convolutional neural network (CNN) inference models tolerate INT8 well; transformers, speech models, and outlier-heavy layers may need different granularity, mixed precision, or training-aware methods. The main approaches are **post-training quantization** (PTQ), **quantization-aware training** (QAT), and mixed-precision or **extreme quantization** for lower-bit deployment. They differ in training cost and control, not in a guaranteed ordering of accuracy.

The viability of each approach depends on how much precision a given model architecture can shed before quality degrades. Across precision formats from FP32 down to INT2, both CNN and transformer curves follow a low-loss plateau where INT8 quantization closely matches full-precision performance, followed by a steep accuracy cliff at lower bit widths where representational capacity breaks down. Because tolerable accuracy degradation depends on end-to-end application constraints, engineering teams must evaluate these cliff boundaries for each target workload and range-calibration recipe (figure 10.16).

10.3.1 Numerical formats

Cutting a tensor from 32 bits to 16 or 8 bits can still overflow on large activation outliers if the format lacks exponent range, or stall in software unpacking if the target processor lacks a native datapath for that bit width. How a format divides its bits between exponent range and fraction precision decides which values survive conversion, and whether the silicon provides a matching execution unit decides whether narrower values run any faster. Because neither property follows from bit count alone, selecting a numerical format requires balancing dynamic range and hardware execution support against memory traffic rather than minimizing bit width blindly. The formats commonly deployed across accelerator architectures differ in raw storage, peak arithmetic rate, and hardware support, each measured against standard 32-bit floating point (FP32) (table 10.7).

[15] **Quantization**: Rooted in Shannon's theory of representing continuous signals with discrete values (Shannon 1948), reducing FP32 to INT8 collapses over four billion representable values to just 256. Neural networks often tolerate this because trained weights concentrate information in relative magnitudes, not absolute precision: INT8 inference can stay close to the full-precision baseline with appropriate calibration or quantization-aware training, while INT4 and lower-bit methods become more architecture- and method-dependent (Jacob et al. 2018; Gholami et al. 2022; Shen et al. 2020; Lin et al. 2024). The systems consequence is that quantization viability must be validated per-model and per-task, not assumed from aggregate benchmarks.

↪ How accelerators trade precision and dynamic range for matrix-engine throughput, pairing low-precision inputs with higher-precision accumulation, is developed in section 11.4.5.

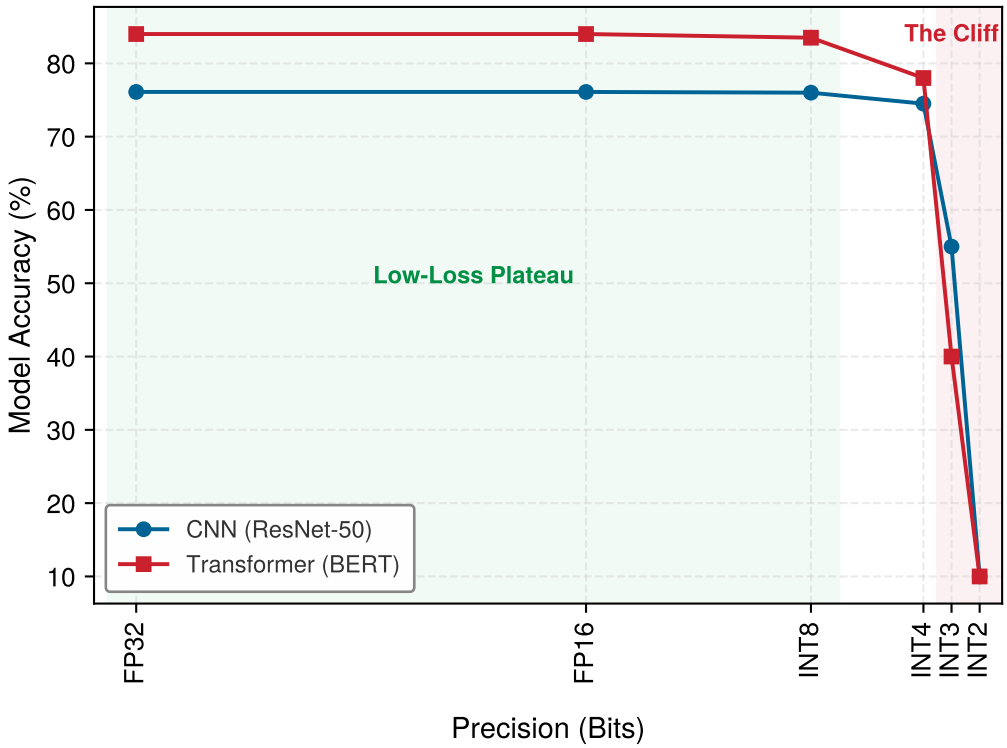

Figure 10.16: Illustrative Quantization Regimes: The curves depict a qualitative plateau followed by an accuracy cliff as bit width falls. Their breakpoints are illustrative; actual boundaries depend on the model, layer distributions, quantizer, calibration or training method, and evaluation task.

Table 10.7: Numerical Precision Formats: Storage ratios reflect raw value width; compute speed and power effects depend on hardware support and workload behavior.

Precision Format	Bit-Width	Storage Reduction (vs. FP32)	Compute Speed (vs. FP32)	Power Effect	Use Cases
FP32	32-bit	Baseline (1×)	Baseline (1×)	Baseline	Training & inference (general-purpose)
FP16	16-bit	2× smaller	Up to 2× peak on selected supported hardware	Hardware- and workload-dependent	Accelerated training, inference (NVIDIA Tensor Cores, TPUs)
BF16 (Brain Floating Point)	16-bit	2× smaller	Hardware- and workload-dependent	Hardware- and workload-dependent	Training on TPUs, transformer-based models
TF32 (TensorFloat-32)	19-bit	None (stored as FP32)	Up to 8× peak on NVIDIA Ampere Tensor Cores	Hardware- and workload-dependent	Training on NVIDIA GPUs
FP8 (E4M3, E5M2)	8-bit	4× smaller	2× the dense FP16 peak on the H100	Hardware- and workload-dependent	Inference and training on recent data-center accelerators
INT8 (8-bit Integer)	8-bit	4× smaller	Hardware- and workload-dependent	Hardware- and workload-dependent	Quantized inference (Edge AI, mobile AI, NPUs)
INT4 (4-bit Integer)	4-bit	8× smaller	Hardware- and workload-dependent	Hardware- and workload-dependent	Ultra-low-power AI, experimental quantization

Precision Format	Bit-Width	Storage Reduction (vs. FP32)	Compute Speed (vs. FP32)	Power Effect	Use Cases
Binary/Ternary (1-bit/2-bit)	1–2-bit	16–32× smaller	Hardware- and workload-dependent	Hardware- and workload-dependent	Extreme efficiency (binary/ternary neural networks)

At 16 bits, FP16 and BF16 halve memory storage relative to FP32 while targeting dedicated matrix execution units (such as NVIDIA Tensor Cores and Google TPUs) to accelerate arithmetic throughput. The range-versus-precision trade between them is established with mixed-precision training in section 8.6.3, and figure 10.17 shows the bit layouts that set it. BF16 keeps FP32's 8-bit exponent and therefore its dynamic range, whereas FP16 spends more bits on the fraction and caps finite values at 65,504, which is why FP16 training needs loss scaling and BF16 training does not. For inference, the same range limits decide whether activations with large outliers survive the narrower format. TensorFloat-32 (TF32) adopts a hybrid compromise. It retains the 8-bit exponent of FP32 and the 10-bit fraction of FP16, executing on Tensor Cores to accelerate matrix multiplication while storing values in standard 32-bit memory.

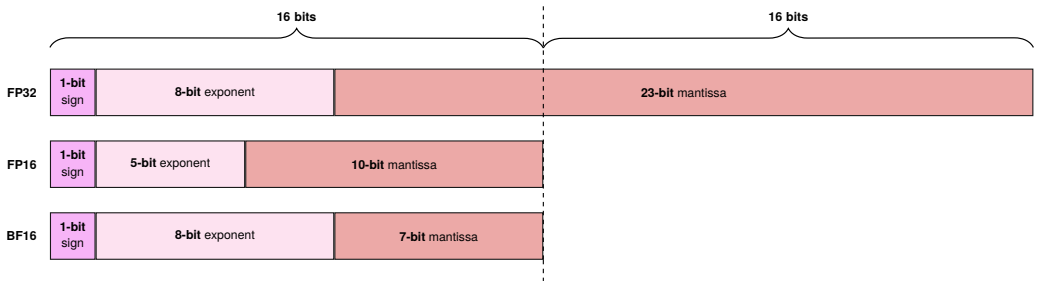

Figure 10.17: Floating-Point Bit Layouts: Bit allocation trades dynamic range against significand precision. FP32 uses 8 exponent and 23 fraction bits. BF16 retains FP32's 8-bit exponent and therefore a similar numerical range, but reduces the fraction to 7 bits. FP16 uses 5 exponent and 10 fraction bits, providing more significand precision than BF16 but a narrower range that can require loss scaling during training.

For inference workloads, INT8 precision provides a fourfold reduction in raw storage relative to FP32 when the chosen quantizer preserves acceptable prediction accuracy. Inference avoids the gradient backpropagation pass, eliminating the small-magnitude, high-dynamic-range updates that cause underflow during training. Activations and weights can still contain outliers or sensitive values, so range calibration or QAT must validate mapping them onto signed 8-bit integers ($[-128, 127]$) using uniform affine or symmetric quantization scales. In bandwidth-limited inference regimes, such as autoregressive language model token generation, this $4\times$ footprint reduction relieves memory bus contention by cutting DRAM and cache traffic. On compute-bound operators, dedicated INT8 vector and tensor units provide higher arithmetic operation density per clock cycle and per unit of silicon area than equivalent floating-point units.

FP8 gets its own row because it is the first 8-bit format that keeps an exponent. It comes in two layouts, each with one sign bit: E4M3, with four exponent and three mantissa bits, for weights and activations, and E5M2, with five exponent and two mantissa bits, for the wider range of gradients (Micikevicius et al. 2022). Like INT8, it halves the bytes of FP16, and on the reference H100 its peak matrix rate equals the INT8 rate, 2× the dense FP16 peak. Unlike INT8, it needs no zero-point, and its exponent absorbs the outliers that force an integer format to choose between clipping and resolution, so a model often converts to FP8 with less range-calibration effort than to INT8. FP8 as the default serving precision on such accelerators is developed in chapter 13. Microscaling formats carry the same idea below eight bits (Rouhani et al. 2023). A block of values, typically 32, shares one 8-bit power-of-two scale, so the elements of an MXFP8, MXFP6, or MXFP4 block borrow their range from the shared exponent and spend their few bits on precision. They are an awareness item here, because their payoff depends on accelerators with native support.

Binary and ternary formats occupy the far end of table 10.7, constraining values to $\{-1, +1\}$ or $\{-1, 0, +1\}$ so that multiplication collapses into bitwise logic or a conditional add. They promise

the largest storage ratio in the table, but byte-addressed memory and training stability make them a special case that section 10.3.4 develops in full. The keyword-spotting lighthouse shows why such formats are considered at all. Under the strict ~512 KB SRAM budget, INT8 is the baseline target, and INT4, binary, or ternary representations trade additional dynamic range to meet stricter memory and power bounds. Whereas table 10.7 counts bytes and peak rates, what each format saves in joules depends on where its bits travel, which is the subject of the energy comparison that follows.

10.3.2 Precision and energy

In silicon, energy dissipation scales directly with wire capacitance ($E \propto CV^2$), so shuttling bits across long memory buses costs orders of magnitude more joules than toggling logic gates inside an arithmetic logic unit. Because physical data movement so often dominates a workload's power budget, choosing a numerical precision is an energy decision governed by the number and location of memory accesses alongside the arithmetic performed. Reducing numerical precision directly shrinks the byte volume traversing the memory hierarchy (D_{vol}) and lowers the switching energy per ALU operation (E_{compute}), relaxing memory bandwidth and thermal bottlenecks across the hardware stack.

↪ Accelerator designs that keep operands in registers and on-chip SRAM, away from costly off-chip DRAM, are developed in section 11.2.3.

10.3.2.1 Where precision saves energy

Precision saves energy in two places, and the larger one is usually movement. The energy-movement principle (7), $E_{\text{move}} \gg E_{\text{compute}}$, says that moving an operand costs far more than operating on it (Horowitz 2014). In the reference technology model, a 32-bit read from off-chip DRAM costs about 640 pJ, roughly 2,100× the energy of the INT8 multiply-accumulate that consumes it, and the cost keeps rising as data leaves the chip for storage or the network (table 4.6). A packed INT8 stream carries one quarter of the raw value bits of an FP32 stream, so each weight or activation that crosses the memory bus costs about a quarter of the movement energy, provided transactions stay full; caches, metadata, alignment, and transaction size set the realized saving. The reference measurements predate FP8, but an FP8 value moves the same eight bits as an INT8 value, so the movement saving applies to it unchanged.

Arithmetic supplies the second saving (table 10.8). An FP32 addition costs 0.9 pJ/op and an INT8 addition 0.03 pJ/op, a ratio of 30×; an FP32 multiply costs 3.7 pJ/op and an INT8 multiply 0.2 pJ/op, a ratio of 18.5×. Every multiply-accumulate a matrix unit performs combines the two, so the figure that governs a format decision is their combination. Because INT8 products accumulate in INT32, a full INT8 multiply-accumulate uses roughly 15× less energy than its FP32 equivalent, on top of the 4× cut in bytes moved. Section D.1 collects the reference energy ratios, and section D.4 compares numerical format trade-offs.

Table 10.8: INT8 versus FP32 Energy per Operation: Reference 45 nm energy for one add, one multiply, and one multiply-accumulate at each precision. The INT8 multiply-accumulate sums its products in INT32, so its cost is an INT8 multiply plus an INT32 add, which is why its ratio is the smallest of the three. A 32-bit DRAM read, at 640 pJ, costs more than every row here combined. Total inference energy also depends on operation counts, access counts, and where operands reside (Horowitz 2014).

Operation	FP32 (pJ)	INT8 (pJ)	FP32 / INT8
Add	0.90	0.03	30×
Multiply	3.70	0.20	18.5×
Multiply-accumulate	4.60	0.30	15×

Accelerators equipped with native low-precision units (such as NVIDIA Tensor Cores, Google TPUs, or mobile NPUs) compound these arithmetic savings with reduced memory traffic. In contrast, general-purpose processors lacking native low-precision execution pipelines lose much of this benefit to the runtime overhead of bit unpacking, format conversion, and scalar fallback. Precision is therefore a model-hardware decision, not a software configuration flag.

Which saving matters depends on where the workload sits. Under the iron law of ML systems (principle 3), reducing bit width changes the data-movement (D_{vol}/BW) and compute ($O/(R_{\text{peak}} \cdot \eta_{\text{hw}})$) terms only through the execution path that uses the new representation. Workloads with little

The machine's memory capacity, not arithmetic, now sets the constraint.

arithmetic per byte are memory bound, so shrinking data movement dominates; workloads with more arithmetic per byte are compute bound, so arithmetic savings matter more, a distinction the roofline model in section 11.6.1 formalizes. Neither ratio predicts battery life on its own, because end-to-end energy also includes control, sensors, and idle power. When memory capacity binds, the more immediate benefit is placement, because smaller values may let the model reside in a memory tier that the uncompressed model cannot fit.

Recommendation models convert the energy argument into a placement problem, in which quantization must shrink the dominant memory structures enough to reside in the host machine's physical memory. When an embedding table outgrows a single accelerator's HBM, reducing bytes per entry determines whether the table fits on the node at all.

Lighthouse 10.1: DLRM and embedding quantization

The DLRM lighthouse presents a compression challenge where memory capacity, rather than compute throughput or memory bandwidth, is the binding constraint (Naumov et al. 2019). Even the reference configuration in table 10.1 needs 100 GB of weights, more than one accelerator's memory, and production embedding tables can grow to terabytes that must be sharded across many devices.

For DLRM, quantization targets storage density rather than arithmetic throughput. Reducing embedding-table precision from FP32 to INT8 (or lower) shrinks the memory footprint by 4–8×, allowing larger tables to fit on fewer GPUs when accuracy and lookup kernels tolerate the lower precision. Compressing the lookup tables ensures that physical device memory can accommodate the algorithmic model.

Lighthouse 10.2: Keyword spotting and the SRAM budget

The KWS lighthouse, DS-CNN, operates at the opposite extreme of the iron law from DLRM (Y. Zhang et al. 2017). Consider a deployment that keeps weights in roughly 512 KB of SRAM. Even the purpose-built DS-CNN keyword spotter overshoots that budget in FP32, where its weights occupy 800 KB. Quantized to INT8, its weights shrink to 200 KB, leaving space whose sufficiency must be checked against peak activation and runtime-buffer use. A device that reads weights directly from flash has a separate weight-storage budget; its SRAM feasibility still depends on the working set. A stricter smart-doorbell microcontroller with 256 KB SRAM leaves closer to 100 KB for model weights after runtime buffers, audio windows, and feature extraction state, motivating more aggressive INT4 or binary compression.

In FP32, even the compact DS-CNN architecture moves 4× more raw weight bytes than in INT8, and the arithmetic path can also cost more on hardware with efficient integer units. For an always-on coin-cell device, that reduction contributes to longer battery life, but sensor, wake-up, feature-extraction, and idle-power costs may dominate. Here, quantization reduces the model's data-movement term and can improve its compute term $(O/(R_{\text{peak}} \cdot \eta_{\text{hw}}))$ when the integer path is supported.

Together, DLRM and the TinyML lighthouse (10.2) illustrate the two operational extremes of this memory constraint. DLRM uses lower precision to fit embedding tables that can reach terabytes into host memory; TinyML uses lower precision to keep every inference within a tiny energy envelope and a few hundred kilobytes of on-chip SRAM. Across both extremes, reducing numerical precision attacks physical execution costs on two fronts, arithmetic energy and latency in the ALU and byte traffic across the memory bus. Both savings assume that the low-precision values still represent the model faithfully, and producing such values is the job of the quantization methods.

10.3.3 Quantization methods

Casting trained FP32 weights and activations straight to narrow integers without fitting their range clips outlier channels and rounds small values to zero, so practical quantization methods differ in

how much calibration or retraining they spend to keep that error small. Post-training quantization, quantization-aware training, and extreme low-bit formats differ chiefly in the training and validation cost they require. Representation choices, such as selecting INT8 versus INT4, mixing bit widths across sensitive layers, or choosing per-tensor versus per-channel ranges, are orthogonal options evaluated *within* these workflows rather than separate maturity levels. Ordered by the engineering effort each requires, the deployment sequence moves from fast post-training range calibration through quantization-aware retraining to custom low-bit pipelines (figure 10.18).

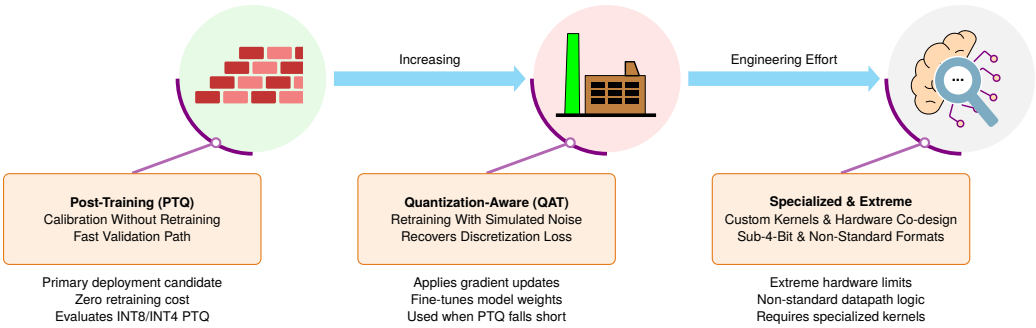

Figure 10.18: Quantization Engineering Workflow: The tiers order deployment paths by engineering and validation effort, not by format or guaranteed accuracy. PTQ serves as the initial candidate because it operates over frozen weights with zero retraining cost; QAT introduces simulated quantization into the training loop when quality recovery demands backpropagation; specialized sub-4-bit and binary formats require custom kernel execution and extensive hardware-specific validation. Representation choices such as INT8 versus INT4, per-channel scaling, and mixed precision apply across these stages rather than defining separate maturity levels.

Post-training quantization is evaluated first, because it changes representations with minimal compute and pipeline overhead. When PTQ satisfies the application's latency, energy, and quality thresholds, the optimization process stops. When post-training calibration introduces unacceptable accuracy degradation, quantization-aware training lets the weights adapt to discretization noise during backpropagation, and extreme sub-4-bit or ternary representations are reserved for targets that INT8 and INT4 cannot meet and whose hardware has kernels for them.

10.3.3.1 Post-training quantization

Retraining a large model checkpoint solely to adapt its weights to 8-bit arithmetic can cost hundreds of accelerator hours, and in many deployment pipelines the original training dataset or training cluster is not even available. **Post-training quantization (PTQ)** avoids that retraining loop altogether by converting weights and activation tensors from floating-point to fixed-point formats directly on a frozen checkpoint (Choukroun et al. 2019). Weight-only quantization requires only a single pass over static parameter tensors, while full integer quantization calibrates activation dynamic ranges using a small, unlabelled sample of representative inputs.

The principal constraint in PTQ is unmodeled discretization noise. Rounding introduces numerical error that cannot be compensated by gradient updates. While redundant architectures absorb 8-bit rounding noise with negligible accuracy loss, sensitive models or lower bit widths (such as INT4) experience degradation unless scaling granularities are refined or quantization-aware training is applied. Production runtimes such as TensorFlow Lite, Open Neural Network Exchange (ONNX) Runtime, and TensorRT provide automated calibration pipelines to profile tensor ranges and apply this conversion.

The core mechanism of PTQ is **uniform quantization**, which maps floating-point values to discrete integer levels using a consistent scaling factor. Because the interval between each quantized value is constant, uniform quantization simplifies implementation and enables efficient hardware execution. For the symmetric form shown here, s is chosen from the maximum absolute value so that the resulting integers stay within the target range. The quantized value x_q is computed as:

$$x_q = \text{round}\left(\frac{x}{s}\right)$$

where:

- x_q is the quantized integer representation,
- x is the original floating-point value,
- s is a scaling factor that maps the floating-point range to the available integer range.

Uniform quantization from FP32 to INT8 reduces the raw value payload from 32 to 8 bits per weight at the cost of a measurable quantization error, with scale metadata and packing overhead excluded (listing 10.2). Once a model is quantized, the runtime can use integer arithmetic where supported (Gholami et al. 2022).

Listing 10.2: Uniform Quantization: Converts FP32 weights to INT8, reducing raw per-weight payload from 32 to 8 bits while measuring quantization error; scale metadata and packing overhead are excluded.

```
import torch

# Original FP32 weights
weights_fp32 = torch.tensor(
    [0.127, -0.084, 0.392, -0.203], dtype=torch.float32
)
print(f"Original FP32: {weights_fp32}")
print(f"Memory per weight: 32 bits")

# Simple uniform quantization to INT8 (-128 to 127)
# Step 1: Find scale factor
max_val = weights_fp32.abs().max()
scale = max_val / 127  # 127 is max positive INT8 value

# Step 2: Quantize using our formula x_q = round(x/s)
weights_int8 = torch.round(weights_fp32 / scale).to(torch.int8)
print(f"Quantized INT8: {weights_int8}")
print(f"Memory per weight: 8 bits (reduced from 32)")

# Step 3: Dequantize to verify
weights_dequantized = weights_int8.float() * scale
print(f"Dequantized: {weights_dequantized}")
print(
    f"Quantization error: "
    f"{(weights_fp32 - weights_dequantized).abs().mean():.6f}"
)
```

Rounding to a uniform grid introduces an error with a precise bound. A uniform quantizer maps each value to the nearest of evenly spaced levels separated by a step size s (range calibration derives s from the tensor's clipping range in equation 10.1, later in this section). For any value inside the clipping range, rounding to the nearest level misses by at most half a step, so within-range error is bounded by $[-s/2, s/2]$. Aggregated across many tensors, most error concentrates inside that bound, while the tails carry the larger distortion that comes from saturation clipping and from mixing tensors that use different step sizes (figure 10.19). Many CNNs tolerate INT8 well, whereas large transformers often need outlier-aware or mixed-precision schemes because a few activation channels carry extreme values. Selecting the appropriate numerical precision therefore requires balancing accuracy constraints, hardware support, and efficiency gains.

An alternative, nonuniform quantization, assigns finer-grained precision to numerical ranges that are more densely populated, which can preserve accuracy for models whose weight distributions concentrate around specific values. Nonuniform schemes require more complex calibration and are less common in production, but they can be effective for models particularly sensitive to precision changes. More generally, sensitivity to PTQ varies by architecture, layer, and distribution. When a uniform configuration misses the quality target, the next options include finer granularity, mixed precision, weight-only methods, better calibration, or QAT.

Range calibration Mapping a tensor onto 8-bit or 4-bit integers with an ill-fitting range either saturates critical values through clipping or squanders available integer levels on sparse outliers. Quantization-range calibration prevents both failures by estimating the real-valued clipping range

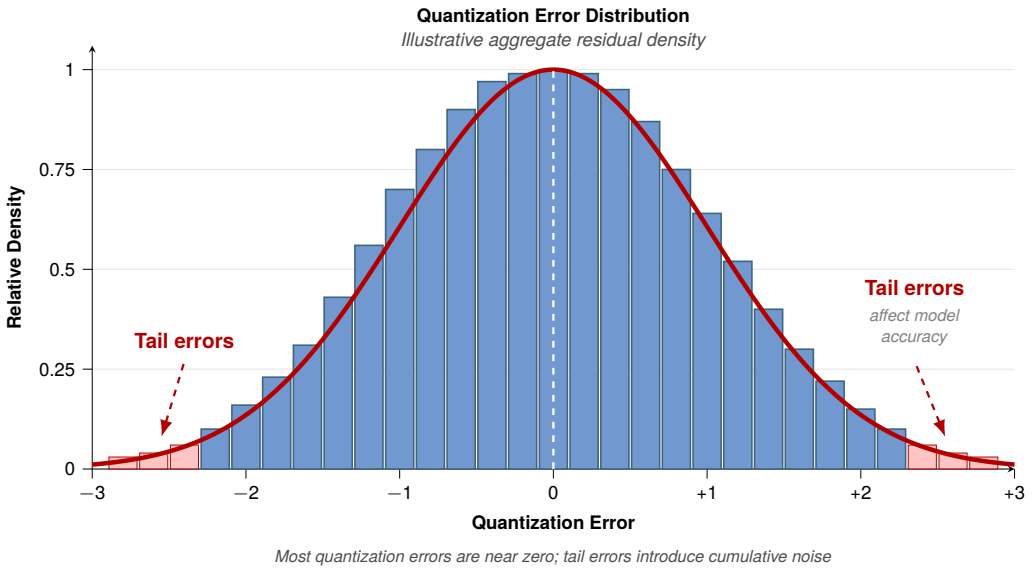

Figure 10.19: Illustrative Aggregate Quantization Residuals: Illustrative aggregate residual distribution across heterogeneous scales and clipped values. Within one unclipped uniform quantizer, rounding error is bounded by $[-s/2, s/2]$ for step size s; the displayed tails represent clipping or aggregation across different step sizes.

$[\alpha, \beta]$ for each tensor (from here on, α and β denote its lower and upper bounds). Calibration minimizes representation error over the sampled distribution, although it does not guarantee bounds on out-of-distribution deployment inputs.

Because activation tensors vary with input data, profiling requires running an unlabelled calibration dataset through the forward pass to capture dynamic ranges. In the offline conversion pipeline, the pretrained model and a representative calibration dataset pass through a profiling stage that establishes dynamic ranges, and those ranges parameterize the quantization step that yields the final quantized model (figure 10.20). Layer by layer, activation observers record value distributions from which the scale and zero-point metadata are computed (algorithm 10.1). Range calibration in this sense is distinct from the confidence calibration that asks whether a model's predicted probabilities match its observed accuracy, which returns in section 10.6.

Algorithm 10.1 Post-training quantization calibration

Require: pretrained model f_θ; representative calibration set $\mathcal{C}_{\text{cal}}$; bit width b; granularity (layer/group/channel); method (max, entropy, percentile)
Ensure: quantized weights and per-group range metadata $\{(\alpha_g, \beta_g, s_g, z_g)\}$

```
attach observers to weights and selected activation tensors, at the chosen granularity
for each batch in C_cal do ▷ calibration pass
    run f_θ in inference; record per-group value distributions
end for
for each quantization group g do
    select clipping range [α_g, β_g] by the chosen method
    derive scale s_g, zero-point z_g mapping [α_g, β_g] into the b-bit integer range
end for
quantize static weights; export activation range metadata for inference
if accuracy falls below the production threshold, widen ranges, change granularity, or move to QAT
```

The single calibration pass over $\mathcal{C}_{\text{cal}}$ avoids retraining, and FP32-to-INT8 weight quantization cuts raw stored weight values by 4× before scale, zero-point, and packing metadata. The price is

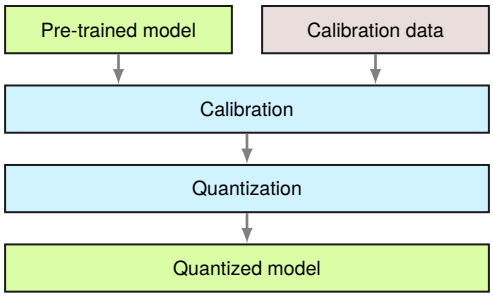

Figure 10.20: Post-Training Quantization Pipeline: PTQ converts a trained FP32 model directly to INT8 without retraining. Representative calibration data passes through the model to record activation ranges $[\alpha, \beta]$, computing scale factor s and zero-point z parameters to quantize parameters before deployment.

that the static activation ranges fixed in the loop risk saturation or wasted integer levels when the calibration data misses deployment tails. The quantization step then converts model parameters to the lower-precision format, producing the final quantized model.

Mapping an unnecessarily wide real-valued interval to the 256 discrete bins of an 8-bit integer wastes numerical resolution on empty range, whereas clipping too aggressively truncates signal. Three calibration methods balance this clipping-versus-resolution trade-off: **max** sets bounds to the absolute extremum (preserving extreme values at the cost of vulnerability to outliers), **entropy** selects bounds by minimizing the Kullback–Leibler (KL) divergence between original and quantized distributions, and **percentile** retains a chosen fraction (such as 99.9 percent) and clips the remaining tail. In one ResNet-50 layer, the dense bulk of activations clusters below 1.1, while a sparse outlier tail stretching past 2.0 motivates testing a candidate clipping boundary near 1.1 to allocate more INT8 bins to the bulk (figure 10.21). Choosing a percentile boundary requires cumulative activation counts; the illustrated boundary is not assigned a percentile rank. Task validation must establish whether clipping that tail preserves important rare cases.

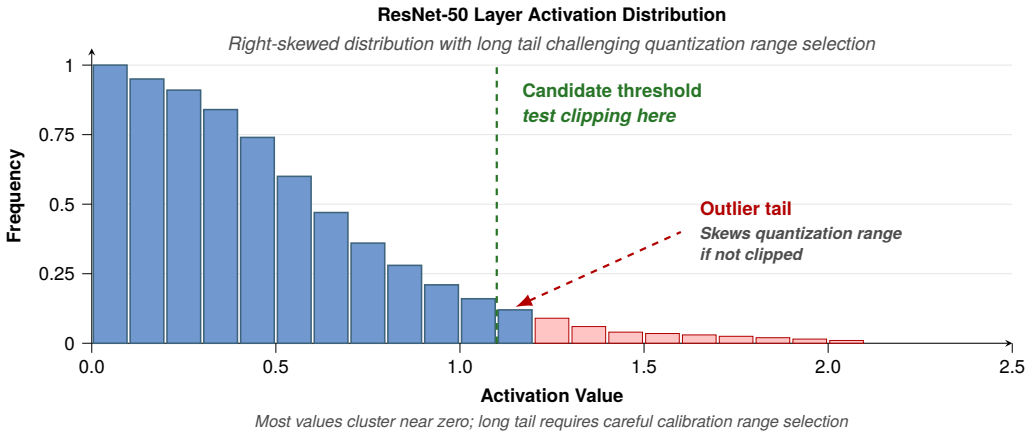

Figure 10.21: Activation Distribution: ResNet-50 layer activations have a long tail, with outlier values that can lead to inefficient precision use if not handled carefully. Source: (Wu et al. 2020).

Tuning quantization ranges Once calibration identifies clipping boundaries $[\alpha, \beta]$, the range must be mapped onto integer endpoints, and two mapping schemes dominate (figure 10.22). A **symmetric** mapping uses a zero-centered range with zero-point zero, forcing real zero to integer zero by mapping $[-1, 1]$ directly onto $[-127, 127]$. An **asymmetric** mapping keeps one scale but a generally nonzero zero-point z, which accommodates skewed activation intervals such as $[-0.5, 1.5]$ across $[-128, 127]$.

Symmetric quantization simplifies integer matrix multiplication kernels because the zero-point is zero ($z = 0$), eliminating cross-term additions during hardware accumulation. However, for

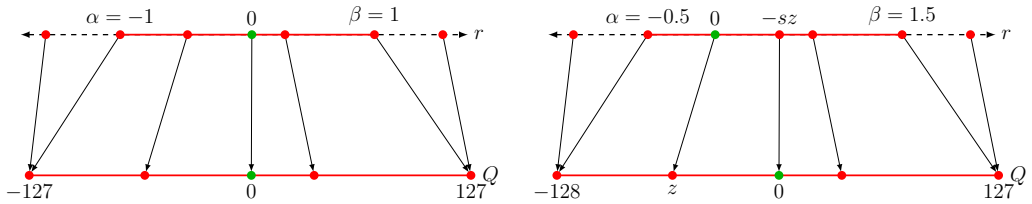

Figure 10.22: Calibration Range Selection: Symmetric vs. asymmetric affine quantization mappings. Symmetric quantization (left) forces real zero to map to integer zero, using equal-magnitude negative and positive clipping bounds at the expense of wasted dynamic range for skewed activation distributions; asymmetric quantization (right) uses an explicit zero-point offset z to map non-centered ranges $[\alpha, \beta]$ efficiently.

activations following asymmetric distributions (such as post-ReLU feature maps where all values are non-negative), symmetric quantization wastes roughly half of the integer dynamic range on unused negative values. Asymmetric quantization recovers this dynamic range by mapping $[\alpha, \beta]$ to $[0, 2^b - 1]$, but requires runtime hardware to compute offset corrections ($z \sum_k W_{ik}$ for output row i) during multiply-accumulate operations. Either mapping is fully specified by two numbers per range, a scale and a zero-point, and the uniform quantizer introduced for PTQ is the special case whose zero-point is zero.

Napkin Math 10.1: Calculating scale and zero-point

The affine quantization formula: An affine map sends a floating-point range $[\alpha, \beta]$ that includes zero to an integer range $[0, 2^b - 1]$ (for example, UINT8) via the following construction.

Analysis: Affine quantization establishes a linear mapping $x \approx s(x_q - z)$, where s is the **scale** (step size) and z is the **zero-point** (integer value corresponding to real zero). The mapping involves three computational steps:

1. **Calculate scale** (s): Divide the real range by the integer range using equation 10.1.

$$s = \frac{\beta - \alpha}{2^b - 1} \tag{10.1}$$

2. **Calculate zero-point** (z): Shift the range so that real zero maps to an integer using equation 10.2.

$$z = \text{round}\left(\frac{-\alpha}{s}\right) \tag{10.2}$$

3. **Quantize** $(x \to x_q)$: Divide by the scale, add the zero-point, then round and clamp to the integer range using equation 10.3.

$$x_q = \text{clamp}\left(\text{round}\left(\frac{x}{s} + z\right), 0, 2^b - 1\right) \tag{10.3}$$

Scenario: Consider quantizing a 2×2 activation matrix with values ranging from $\alpha = -1$ to $\beta = 3$, and the target precision is UINT8 $(b = 8)$:

$$\mathbf{X} = \begin{pmatrix} -1 & 1 \\ 0 & 3 \end{pmatrix}$$

- **Range**: $\beta - \alpha = 4$.
- **Steps**: $2^8 - 1 = 255$.
- **Scale**: $s = \frac{4}{255} \approx 0.0157$.
- **Zero-point**: $z = \text{round}(-(\alpha)/s) = \text{round}\left(-(-1)/\frac{4}{255}\right) = \text{round}(63.75) = 64$.

Applying equation 10.3 element-wise maps each floating-point entry to an integer bin:

$$\mathbf{X}_q = \begin{pmatrix} 0 & 128 \\ 64 & 255 \end{pmatrix}$$

Systems insight: The real value 0.0 is represented exactly by the integer 64. This is critical because it ensures that zero-padding (common in CNNs) is represented exactly, preventing "quantization drift" where padding introduces nonzero noise.

Granularity In convolutional filters or transformer projection matrices, weight magnitudes often vary widely from one channel to the next, so sharing a single scale factor across an entire tensor can collapse small-magnitude channels to zero or clip wider channels. Quantization granularity governs how broadly scale factors and zero-points are shared across a tensor, balancing representation resolution against metadata overhead and kernel complexity: across convolutional channels (filters 1 through d_{out}), a global layerwise threshold spans the widest distribution at the cost of resolution in narrower filters, whereas per-channel clipping boundaries adapt tightly to each filter's dynamic range at the cost of tracking additional scale vectors during matrix multiplication (figure 10.23).

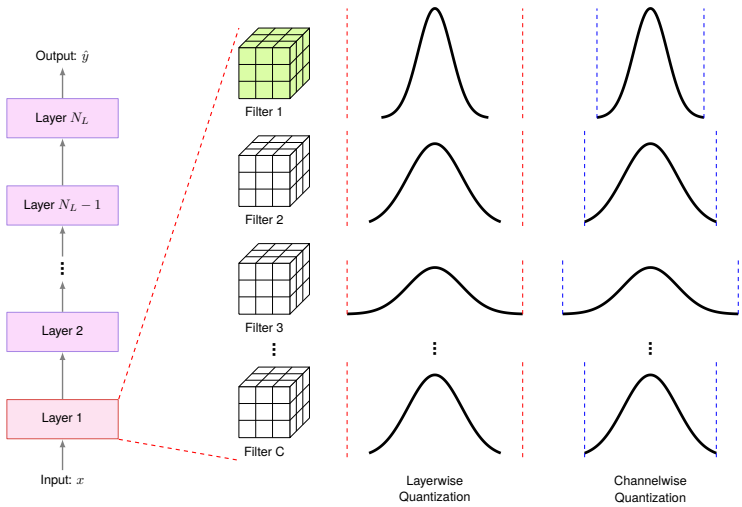

Figure 10.23: Quantization Range Variation: Different convolutional filters can have different weight ranges, motivating per-filter quantization to reduce quantization error. The differing clipping scales illustrate the choice between one layerwise range and separate channelwise ranges. Source: (Gholami et al. 2022).

Quantization granularity trades calibration and metadata overhead against representation error. More local ranges can preserve information when channels differ, but they do not improve accuracy automatically and may lack an efficient kernel path. Each additional scale also has to be stored, loaded, and applied at the granularity supported by the backend. Four levels are common, from one shared layer range to local ranges within a filter (table 10.9).

Table 10.9: Quantization Granularity Levels: Granularity trades calibration and metadata overhead against representation error, from a single per-layer range to per-filter sub-ranges.

Level	Range sharing	Trade-off
Layerwise	One range per layer	Simple but suboptimal when filter ranges vary widely
Groupwise	Filters grouped with shared ranges	Used in Q-BERT (Shen et al. 2020) for transformer attention layers
Channelwise	One range per filter	Common default; balances quantization error against scale metadata and implementation overhead

Level	Range sharing	Trade-off
Sub-channelwise	Ranges within each filter	More local ranges can reduce quantization error but increase metadata and implementation overhead

Channelwise quantization preserves accuracy over layerwise quantization when channel dynamic ranges differ, at the cost of storing additional scale vectors and executing per-channel rescaling in the kernel pipeline. Beyond scale granularity, execution efficiency depends on the distinction between static weights and dynamic activations, which impose fundamentally different memory and latency constraints on the deployment system.

Weights vs. activations Executing low-precision inference requires transforming floating-point inputs before kernel execution and requantizing intermediate accumulator outputs. During integer matrix multiplication, multiplying two 8-bit integers produces a 16-bit product. Summing these products across an inner dimension of length K causes bit-growth that quickly overflows 8-bit registers; hardware therefore accumulates into 32-bit integer registers (`INT32`). Before feeding the result into subsequent layers, requantization rescales the 32-bit accumulated sum by the layer's effective scale factor ($s_{\text{eff}} = \frac{s_W \cdot s_X}{s_Y}$) and clamps the values back into the 8-bit integer range. The full pipeline therefore has four stages (figure 10.24): quantizers convert floating-point activations and weights into INT8 operands, an integer core executes the matrix multiplication, a 32-bit accumulator holds the sum, and a requantization stage returns the result to INT8 before the nonlinear activation.

↪ How a single Tensor Core matrix instruction takes low-precision input tiles into higher-precision accumulator registers is developed in section 11.4.2.

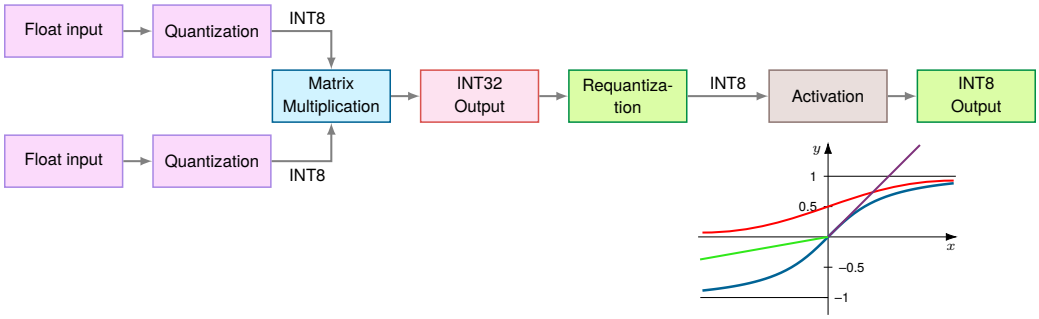

Figure 10.24: Quantized Matrix Multiplication Pipeline: Floating-point weights and activation inputs are quantized to INT8 (violet), fed into integer SIMD/Tensor Core matrix multiplication (blue), accumulated in 32-bit registers (red), and requantized back to INT8 (green) before non-linear activation. From the HarvardX TinyML course.

Activation quantization maps layer outputs to a lower-precision representation during inference. It reduces intermediate payloads and can reduce arithmetic cost on hardware with an efficient integer path, but it also introduces error between layers. For example, a CNN may convert FP32 feature maps to INT8 before later convolutions. The benefit is greatest when consecutive operators remain on the integer path; isolated quantized operators may pay conversion cost without reducing enough work. Whether activation quantization improves latency therefore depends on supported kernels, scale handling, tensor lifetimes, and any quantize or dequantize boundaries that remain in the exported graph.

Static vs. dynamic quantization The clipping range also depends on *when* activation ranges are computed, which divides activation quantization into two primary execution models: static quantization and dynamic quantization. In **static quantization**, the clipping range is precalculated during offline calibration and remains fixed during inference. This approach introduces zero runtime range-estimation overhead, because inputs are scaled by fixed factors and directly fed to integer execution units. However, static ranges risk saturation or underflow whenever production inputs deviate from the calibration distribution (Jacob et al. 2018; Yao et al. 2021).

Dynamic quantization instead calculates scaling factors and zero-points dynamically from runtime activation tensors. Adapting the clipping window to each input reduces mismatch with a fixed calibration range. Outliers can still consume resolution, and a policy that clips tails can still saturate values. The trade-off is runtime memory and latency overhead, because the hardware must perform

reduction passes over intermediate activation tensors to extract minimum and maximum values before integer arithmetic can begin. On memory-bandwidth-bound operators, this reduction pass can erode the execution advantage of lower precision.

Checkpoint 10.2: Calibration and range choices

Quantization succeeds only when the range policy matches deployment data and runtime constraints.

Range design

- ☐ **Calibration data**: explain how an unrepresentative calibration set creates clipping or wastes integer levels.
- ☐ **Granularity**: compare per-tensor and per-channel ranges by the error and metadata trade-off each creates.
- ☐ **Static vs. dynamic ranges**: select a range policy when activation distributions shift across inputs and runtime overhead is constrained.

PTQ in practice Post-training quantization balances deployment turnaround against accuracy control. PTQ requires no gradient backpropagation or retraining. Whether offline calibration is sufficient depends on the architecture, calibration data distribution, numerical quantizer design, and target hardware constraints.

The primary limitation is that PTQ freezes model parameters, preventing compensation for accuracy loss. When a quantized model falls below the production threshold, mitigations include recalibrating, refining scale granularity, adopting mixed precision, or escalating to quantization-aware training. QAT integrates precision constraints directly into the training graph using a **straight-through estimator (STE)** (section 10.3.3.2) to pass gradients through nondifferentiable rounding operators. This enables weights to adapt to low-bit representations during retraining, recovering accuracy at the cost of additional training compute (O_{train}) and hyperparameter tuning.

10.3.3.2 Quantization-aware training

When post-training quantization drops a sensitive model or a 4-bit target below its accuracy floor because frozen weights cannot adjust to coarse rounding steps, only gradient updates can recover the lost quality. Quantization-aware training incorporates numerical rounding noise directly into the optimization graph, retraining or fine-tuning a quantized checkpoint on the training dataset so its parameters adapt to low-precision discretization error (figure 10.25).

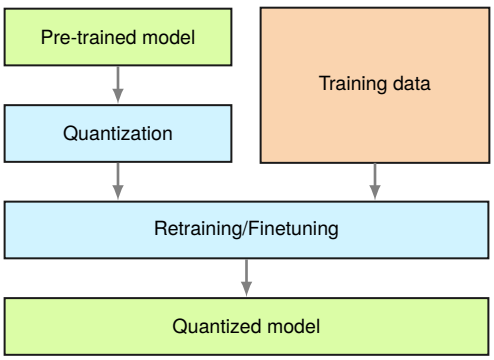

Figure 10.25: Quantization-Aware Training Pipeline: QAT inserts fake-quantization nodes into the forward graph to simulate low-precision clipping and rounding errors during training. Backpropagation updates floating-point master weights using straight-through estimators (STE), allowing network parameters to adapt to numerical noise before exporting fixed integer scales for inference.

Rather than training from scratch or cold-starting scale parameters, production workflows frequently initialize QAT using scale factors derived during an initial PTQ calibration pass. In this

two-phase pipeline, a PTQ phase feeds calibration data into the pretrained model to establish initial scale metadata, and the resulting PTQ checkpoint enters a QAT phase in which the full training data drives fine-tuning (figure 10.26).

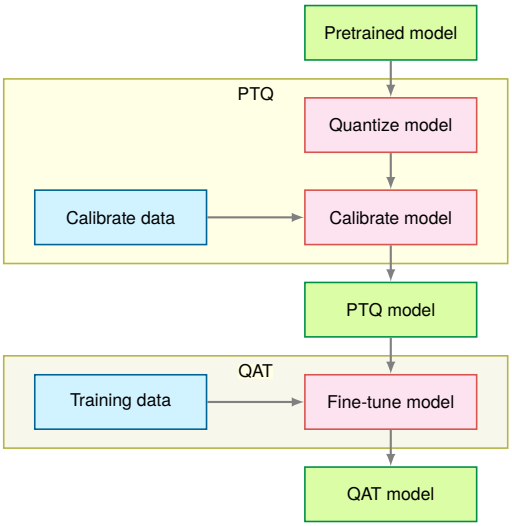

Figure 10.26: PTQ-to-QAT Pipeline: PTQ calibration can initialize ranges and scales before QAT fine-tunes the pretrained weights with simulated quantization. Calibration data feeds the PTQ stage, and training data feeds QAT.

Training mathematics During forward propagation, weights and activations are quantized and dequantized to mimic reduced precision. Let x be a full-precision value, s the scaling factor that maps floating-point values into a lower-precision range, and x_{fake} the simulated (quantized, then dequantized) value. Ignoring clipping and the zero-point for this simplified expression, the process is represented as:

$$x_{\text{fake}} = \text{round}\left(\frac{x}{s}\right) \times s$$

Although the forward pass executes with simulated quantization, computing gradients requires backpropagating through the rounding operator $\text{round}(\cdot)$. Because rounding is a piecewise-constant step function, its mathematical derivative is zero almost everywhere and undefined at step transitions, which would zero out gradients and halt gradient descent. The Straight-Through Estimator (STE) resolves this bottleneck by substituting the identity function for the rounding operator during backpropagation (Bengio, Léonard, et al. 2013).[16]

Integrating quantization effects during training lets the model adapt its weights and activation ranges to simulated low-precision error. QAT can recover quality that a post-training route loses, particularly at aggressive bit widths, but the advantage depends on the model, quantizer, calibration, and training procedure (Krishnamoorthi 2018).

Fake quantization nodes and implementation QAT implementation relies on fake quantization operations that simulate quantization during forward propagation while maintaining full precision for gradient computation. These operations insert quantize-dequantize pairs into the computational graph, creating a training-time simulation of inference-time behavior.

A fake quantization node must preserve the same errors the inference runtime will see, so its three operations model the deployment path during training:

1. **Quantization**: Map floating-point value to discrete quantization level
2. **Clipping**: Enforce range constraints based on bit width
3. **Dequantization**: Convert back to floating-point for subsequent operations

[16] **Straight-through estimator (STE)**: Proposed by Bengio, Léonard, et al. (2013), the common identity STE copies the upstream gradient through the quantizer unchanged. Because that identity is not the derivative of rounding, the estimate is biased, so QAT descends an approximation of the quantized model's loss surface rather than the surface itself.

Mathematically, for symmetric quantization with bit width b, given a floating-point input value x:

$$x_q = \text{clip}\left(\text{round}\left(\frac{x}{s}\right), -2^{b-1}, 2^{b-1}-1\right)$$
$$x_{\text{fake}} = x_q \times s$$

where x_q is the quantized integer level, $s = \frac{\max(|x|)}{2^{b-1}-1}$ is the scale factor computed from the input distribution, and x_{fake} represents the fake-quantized output that mimics INT8 values but remains in floating-point format.

For asymmetric quantization supporting unsigned integers, the node applies the scale, zero-point, and quantize steps of equation 10.1, equation 10.2, and equation 10.3 to the observed range (extended to include zero) and then dequantizes:

$$s = \frac{\max(x) - \min(x)}{2^b - 1}$$
$$z = \text{round}\left(-\frac{\min(x)}{s}\right)$$
$$x_q = \text{clip}\left(\text{round}\left(\frac{x}{s} + z\right), 0, 2^b - 1\right)$$
$$x_{\text{fake}} = (x_q - z) \times s$$

where z is the zero-point offset enabling asymmetric range representation and the observed range $[\min(x), \max(x)]$ serves as the clipping range $[\alpha, \beta]$.

In the QAT forward path, fake quantization is applied to inputs and weights before convolution, simulating INT8 numerics while retaining floating-point tensors for training (listing 10.3).

Listing 10.3: QAT Convolution Forward Pass: Fake-quantizes activations and weights before convolution to simulate deployment numerics during training.

```
# Forward pass with fake quantization
def qat_conv_forward(x, weight):
    # Fake quantize input activations
    x_scale = compute_scale(x, bits=8, symmetric=False)
    x_zero = compute_zero_point(x, x_scale, bits=8)
    x_quant = fake_quantize(x, x_scale, x_zero, bits=8)

    # Fake quantize weights (typically symmetric)
    w_scale = compute_scale(weight, bits=8, symmetric=True)
    w_quant = fake_quantize(weight, w_scale, zero=0, bits=8)

    # Convolution with fake-quantized values
    output = conv2d(x_quant, w_quant)
    return output
```

During backpropagation, fake quantization nodes approximate gradients through a clipping-aware straight-through estimator:

$$\frac{\partial x_{\text{fake}}}{\partial x} = \begin{cases} 1 & \text{if } x \in [\alpha, \beta] \\ 0 & \text{otherwise} \end{cases}$$

Within the clipping range $[\alpha, \beta]$, the estimator treats quantization as an identity mapping, passing the upstream gradient $\frac{\partial \mathcal{L}}{\partial x_{\text{fake}}}$ unchanged to master weight x. Beyond clipping boundaries, the derivative evaluates to zero, blocking gradients from saturated outliers that would otherwise destabilize optimizer updates.

In practice, frameworks like PyTorch and TensorFlow implement fake quantization as custom autograd operators whose forward pass performs the quantize-dequantize round trip while the backward pass applies an STE. Scale handling depends on the method, since observers may track distributions

and later freeze, or scales may be learned. Batch normalization also requires deployment-consistent handling. Workflows freeze batch-normalization statistics and fold them into the preceding convolution before export (section 10.4.1). Freezing running statistics before export allows fake-quantization scales to match the static fused parameters executed during inference.

QAT trade-offs QAT's[17] primary advantage is additional control over quality at low precision. By incorporating simulated quantization noise during training or fine-tuning, the model can adapt to the deployed numerical path. Processors with dedicated integer units can then exploit INT8 arithmetic for faster or lower-energy inference when the exported operators are supported (Wu et al. 2020; Gholami et al. 2022). The benefit must be measured against PTQ for the same model and target, including the extra training cost and any difference in calibration, graph coverage, or kernel selection.

The cost is additional engineering complexity. QAT inserts simulated quantization into training, so teams must validate quantization schemes, scale behavior, and accuracy recovery on the target model. For very large models whose training budgets are already constrained, that overhead can make QAT impractical, and post-training routes avoid retraining altogether (Choukroun et al. 2019). QAT is therefore warranted only when the exported PTQ model misses its quality or deployment targets and training resources permit. A hybrid approach, starting with PTQ calibration and applying QAT fine-tuning only to accuracy-critical layers, often provides a useful balance.

The choice among PTQ, QAT, and dynamic quantization comes down to engineering budget, accuracy threshold, and input variability (table 10.10). Dynamic range computation is a timing choice orthogonal to PTQ versus QAT (dynamic PTQ is common), but it belongs in the comparison because it answers the third of those questions.

[17] **Quantization-aware training (QAT)**: QAT simulates low-precision behavior during training or fine-tuning so weight updates can adapt to clipping and rounding error. BERT studies report that training-aware or Hessian-aware methods can remain closer to full-precision General Language Understanding Evaluation (GLUE) baselines than simpler post-training routes in their evaluated settings (Zafrir et al. 2019; Shen et al. 2020). The exact gap depends on model, task, quantizer, bit width, training budget, and evaluation distribution; a closer benchmark result is evidence for trying QAT, not a guarantee that its added training cost or exported runtime will meet a production target.

Table 10.10: Quantization Method Comparison: The choice turns on three binding questions, namely engineering budget, accuracy threshold, and input variability, rather than on a feature checklist.

Method	Engineering effort	Accuracy preservation	Input adaptability	Reach for it when
Static PTQ	Low: no retraining	Model-dependent; parameters do not adapt	Fixed calibration range	a calibrated model meets the measured accuracy and performance targets
Static QAT	High: additional training with quantization simulation	Often stronger when PTQ falls short	Fixed calibration range	PTQ misses the accuracy target and the training budget allows
Dynamic quantization	Moderate: ranges recomputed at runtime	Model-dependent; range fits each input	Per-input range	activation ranges vary widely across inputs and runtime overhead is acceptable

PTQ serves as the low-effort baseline; QAT spends training cycles when PTQ degrades task accuracy, while dynamic quantization expends runtime memory traffic and compute to track input-dependent dynamic ranges. In practice, PTQ and QAT commonly target 8-bit or 4-bit precision, where retained accuracy depends on the model, task, and quantizer. Some deployment scenarios, however, demand even more aggressive compression, pushing precision to the absolute limits of what neural networks can tolerate.

10.3.4 Extreme quantization

On a microcontroller whose runtime buffers and audio feature extraction leave barely 100 KB of SRAM for weights, or on an energy-harvesting sensor whose power envelope cannot afford hardware multipliers, even 8-bit and 4-bit integers exceed the deployment budget. Extreme quantization pushes numerical precision down to 1 or 2 bits per value for those targets (Courbariaux et al. 2015; Zhu et al. 2017). Binarization constrains weights and activations to two values, typically encoded as $\{-1, +1\}$. In digital logic, mapping -1 to binary 0 and $+1$ to binary 1 renders scalar multiplication isomorphic to the bitwise `XNOR` operation, replacing floating-point or integer MAC units with bitwise logic and population count (`popcount`) instructions (Rastegari et al. 2016). Because a 64-bit register packs 64 binary values, a single 64-bit `XNOR` instruction computes 64 binary products in parallel

and a hardware `popcount` instruction counts the matching bits to accumulate the dot product $(2 \times \text{popcount}(\mathbf{w} \text{ XNOR } \mathbf{a}) - 64)$, eliminating hardware multipliers altogether. That efficiency comes at a steep cost in expressiveness, since 1-bit representations degrade accuracy sharply on complex perceptual and language tasks (Hubara et al. 2018).

Ternarization mitigates this capacity loss by allowing three values: $\{-1, 0, +1\}$ (Zhu et al. 2017). The zero state introduces sparsity and simplifies arithmetic. Multiplying an activation by $+1$ requires an addition, multiplying by -1 requires a subtraction, and multiplying by 0 is skipped entirely. This eliminates general-purpose multipliers, reducing the arithmetic unit to a conditional adder-subtractor accumulator. However, ternary values cannot be packed at one bit per value. They require at least two bits per weight in standard byte-aligned memory (wasting one of four possible 2-bit states) or multi-trit encoding (such as packing five trits into a single byte, since $3^5 = 243 < 256$) that introduces runtime decoding overhead. The arithmetic gains of multiplier-free execution must outweigh the instruction overhead required to decode and unpack the weights on the target architecture.

Both binary and ternary quantization introduce step functions whose derivative is zero almost everywhere ($\frac{d}{dx}\text{sign}(x) = 0$ for $x \neq 0$), causing backpropagation gradients to vanish. To train these representations, quantization-aware training again relies on the straight-through estimator (Bengio, Léonard, et al. 2013; Choi et al. 2018) of section 10.3.3.2, whose gradients reach full-precision latent weights that accumulate small optimizer steps until they cross the quantization thresholds.

10.3.4.1 Challenges and limitations

Translating sub-byte precision into actual wall-clock speedups is constrained by standard processor architectures. Native support for binary or two-bit matrix operations varies across processors and kernel libraries. On a target without a matching sub-byte path, executing these representations requires bit-shifting, masking, or unpacking routines. The instruction overhead of this bit manipulation frequently offsets memory-bandwidth savings unless workloads run on custom bit-serial accelerators, field-programmable gate arrays (FPGAs), or specialized hardware with native bitwise execution units (Umuroglu et al. 2017).

Model quality is the second barrier. Extreme quantization sharply reduces the representational capacity of a network. While low-entropy workloads such as KWS on a microcontroller SRAM budget may tolerate binary or ternary weights, complex perceptual and generative models suffer steep accuracy degradation. Binary and ternary quantization become viable candidates only when higher-precision alternatives such as INT8 or INT4 fail to satisfy physical memory or energy budgets, and when the deployment hardware can execute bit-packed operations natively (Rastegari et al. 2016; Hubara et al. 2018; Zhu et al. 2017; Umuroglu et al. 2017). Production deployment requires evaluating binary and ternary baselines against INT8, INT4, structured pruning, and compact architectural redesigns on the identical workload, measuring total binary artifact size, end-to-end latency, energy per inference, and task accuracy on target hardware. Whether a narrower format actually runs faster is the last question the precision tier must answer.

10.3.5 When fewer bits run faster

Shrinking weights from 16 bits to 8 bits fails to speed up a compute-bound matrix multiplication if the processor lacks a faster 8-bit datapath, just as faster integer ALUs fail to speed up autoregressive decoding when latency is stalled on memory-bus transfers. Every byte that quantization removes is a byte the memory system no longer moves, so whether a quantized model runs faster depends on which hardware resource binds: a compute-bound matrix multiplication speeds up only when the hardware provides a higher-throughput datapath for the narrower format, whereas a bandwidth-bound decode speeds up in proportion to the bytes removed from each token's traffic. The worked examples below bracket the payoff, first on the reference H100 for a compute-bound layer and then on the running case's phone for GPT-2 XL decoding.

Napkin Math 10.2: The quantization speedup (compute bound)

Problem: A compute-bound matrix multiplication (for example, in a transformer multilayer perceptron block at a large batch) switches from FP16 to INT8 on the reference H100. What throughput speedup can the integer matrix units deliver?

Math: On hardware with dedicated INT8 units:

1. **Integer throughput path**: The H100 rates its INT8 matrix path at 1979 TOPS against 989 TFLOP/s on the dense FP16 path (NVIDIA Corporation 2022; Choquette 2023). The peak throughput increase is that spec ratio, about 2×.
2. **Memory bandwidth**: Packed INT8 weights carry half the raw weight bytes of FP16. Their streaming time can approach half at the same achieved bandwidth, before metadata and conversion costs.
3. **Combined effect**: For compute-bound operations, the ideal throughput factor is about 2× at comparable utilization of the two arithmetic paths.

Systems insight: The speedup from quantization depends on the bottleneck. Compute-bound operations (large batch sizes, high arithmetic intensity I) can approach about 2× at comparable utilization of supported INT8 units, where the gain comes from the integer matrix path rather than reduced memory traffic. The bandwidth-bound case inverts this. Halving the bytes moved (FP16 to INT8) yields up to 2×, and larger bit-width reductions scale the gain further, as the decode example below traces.

Processors without dedicated matrix units see the same compute-bound effect through data-level parallelism in their registers, the path a phone's CPU takes before a model moves to its integer accelerator. Fixed-width vector execution units (SIMD) and systolic arrays process more operands per cycle when each operand occupies fewer bits.

Napkin Math 10.3: The SIMD multiplier

Problem: A compute-bound layer executes using INT8 rather than FP32 on the same processor. Determine the architectural source of arithmetic speedup under fixed register width.

Mechanism: SIMD execution. A CPU or GPU core processes data in fixed-width vector registers (for example, AVX-512 is 512 bits wide).

Math:

1. **Register width**: 512 bits.
2. **FP32 capacity**: 512/32 = 16 elements per vector instruction.
3. **INT8 capacity**: 512/8 = 64 elements per vector instruction.

Result: Switching to INT8 packs 4× more elements into the same register. Throughput Gain = INT8 elements/inst/FP32 elements/inst = 64/16 = 4×

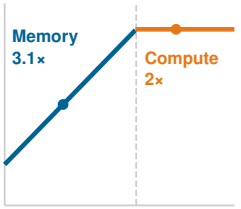
Systems insight: The packing ratio gives an ideal 4× throughput factor, assuming comparable vector-instruction throughput, occupied lanes, and supported operators. It is a candidate bound for compute-bound layers, not a measured layer speedup; memory traffic and conversion overhead still affect execution.

When an operation is bandwidth bound, speedup tracks the reduction in bytes transferred per token rather than peak arithmetic throughput. In autoregressive token generation with small batch sizes, memory bus traffic dominates latency.

Napkin Math 10.4: The quantization speedup (bandwidth bound)

Problem: The running case's phone decodes GPT-2 XL (1.5B parameters) at batch size one with a full 1,024-token context. Its memory bus delivers 51.2 GB/s, and each token must read every weight and the whole KV cache. How much faster does decoding run with INT4 weights than with FP16 weights?

Math (FP16 weights):



1. **Weights**: 3 GB at two bytes per parameter.
2. **KV cache**: Keys and values across 48 layers, 25 heads, and 64 dimensions per head, stored in FP16 for 1,024 tokens, occupy 0.31 GB.
3. **Total per token**: 3.3 GB, which fits the phone's 8 GB but takes 65 ms to stream, or about 15 tokens/s.

Fix (INT4 weights):

1. **Weights**: 0.75 GB at half a byte per parameter, for 1.06 GB per token with the unchanged FP16 KV cache.
2. **Speed**: Streaming that total takes 21 ms, or about 48 tokens/s.

Systems insight: INT4 weights yield a 3.1× speedup in this traffic model, below the 4× weight reduction because the FP16 KV-cache traffic is unchanged. The model already fit in memory at FP16; quantization bought speed, not feasibility. The realized speedup still depends on a kernel that unpacks INT4 weights inside the matrix multiplication rather than in a separate pass.

Across three vision networks (Inception v3, MobileNet v1, and ResNet v2), INT8 conversion contracts weight storage by exactly 4× (135 MB to 33.75 MB for the illustrative Inception bar), while the latency change varies with the architecture and its kernels (figure 10.27).

Quantization speedup depends on whether memory bandwidth or compute throughput is binding.

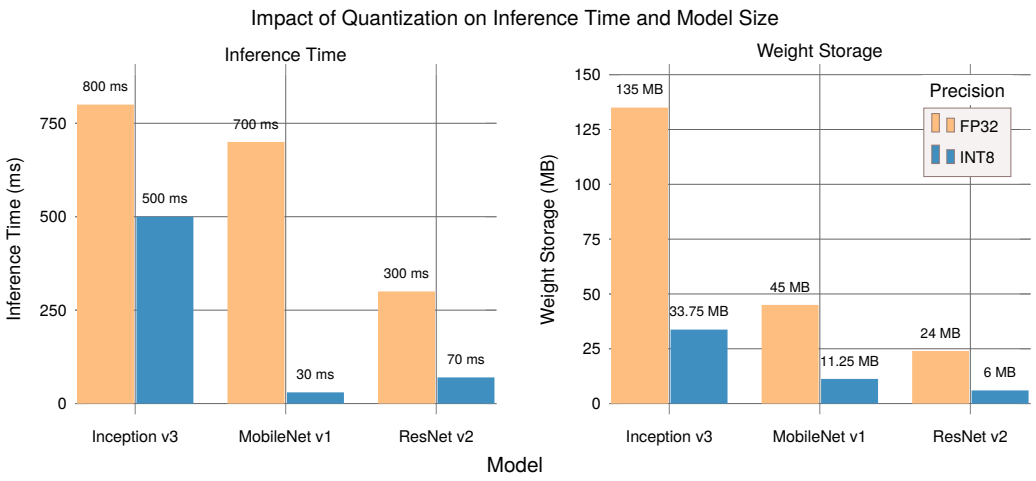


Figure 10.27: Illustrative Quantization Scenario: Paired bars separate FP32 and INT8 alternatives. The right panel shows illustrative weight storage, where reducing each weight from 32 to 8 bits produces an exact fourfold decrease; the left panel shows illustrative, architecture-dependent latency changes.

Activation-aware methods such as **activation-aware weight quantization (AWQ)**[18] target weight traffic in large language model (LLM) inference. This approach serves exactly the regime of GPT-2 XL decoding on the phone, where loading model weights limits the token rate. By protecting a small fraction of salient weight channels based on activation magnitude, AWQ supports INT4-class weight quantization while controlling task degradation. Packed low-bit weights can reduce the memory

[18] **Activation-aware weight quantization (AWQ)**: Salience is determined by activation magnitude, not weight magnitude, a distinction that matters because a small weight multiplied by a large activation produces a large output contribution. AWQ protects about 1 percent of salient weight channels through activation-aware scaling while quantizing most weights to low-bit formats, so GPT-2 XL's 3 GB of FP16 weights can move toward an INT4-class footprint of about 0.75 GB before metadata, scales, and kernel-specific packing overheads (Lin et al. 2024).

traffic required during token generation when the runtime provides a matching kernel (Lin et al. 2024).

Checkpoint 10.3: Quantization and precision checkpoint

Quantization design review criteria:

- ☐ **INT8 memory vs. energy**: Explain why INT8's per-operation energy saving can exceed 4× while its end-to-end energy saving is usually smaller.
- ☐ **QAT vs. PTQ**: Evaluate the architectural advantages of quantization-aware training over post-training quantization, identifying the accuracy and retraining cost trade-offs that justify auxiliary optimization.
- ☐ **Bit-width speedup**: For GPT-2 XL decoding on the phone, estimate FP16 versus INT4 weight bytes and the ideal weight-traffic speedup bound. Identify the conditions under which weight-traffic reduction approaches a proportional latency gain, and explain how KV traffic or a separate dequantization pass can limit that gain.
- ☐ **Compute versus bandwidth**: Explain why the same FP16-to-INT8 change can roughly double throughput on a compute-bound layer and halve time on a bandwidth-bound one for different reasons.

These speedups are bounds computed from bytes and peak rates. Whether a deployed model reaches them depends on how its compressed operations are lowered onto kernels, which is the third tier of the stack.

10.4 Hardware Implementation: Changing How the Model Executes

Pruning a model structurally to half its weights and quantizing the survivors from FP32 to INT8 cuts stored weight bytes by 2× and 4×, or 8× in all, yet in production such a model can easily run only 1.5× faster—roughly 18.8 percent of the paper projection. Profiling reveals where the missing speedup vanishes: sparse tensors continue to stream through dense kernels that cannot skip unindexed zeros, reduced-precision operators trigger unfused type conversions that flood the memory bus, and small layers spend more time launching kernels and moving intermediates than doing arithmetic. Paper metrics—parameter counts, theoretical FLOPs, and nominal bit depths—establish upper bounds that hold only when a workload is limited purely by weight traffic and every kernel exploits the new representation. Bridging the divide between paper reduction and measured hardware speedup is the job of the third tier of the stack, efficient **hardware implementation**.

The measured bottleneck selects the implementation technique. Kernel fusion consolidates memory-bound operator chains, custom dequantization loops keep packed low-precision weights inside cache, and hardware sparsity engines align with tensor layouts to bypass zeroed arithmetic.

10.4.1 Compression-specific fusion

In the camera pipeline's MobileNetV2, every inverted residual block chains a convolution, a batch normalization, and a rectified linear unit (ReLU); executed as separate kernels, each operator writes its output to accelerator global memory and the next reads that output back, paying three memory round-trips for work that could stay in on-chip registers. **Kernel fusion** (or operator fusion) eliminates those redundant memory transactions by combining adjacent operators into a single kernel (Chen et al. 2018; NVIDIA 2024c), and model compression introduces fusion requirements of its own. Folding batch normalization into a pruned convolution, keeping a dequantize step inside the matrix-multiplication kernel that consumes it, and choosing which adjacent operators of a rewritten graph can share one kernel are all fusion decisions that arise once the graph has been compressed.

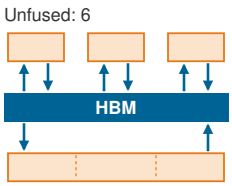
That read-compute-write cycle creates memory bandwidth bottlenecks for operations with low arithmetic intensity (FLOP/byte). The traffic rule for a fused chain, established in section 7.3.2, bounds what fusion can recover. Fusing a chain of n_{ops} operations over an intermediate tensor of M_{tensor} bytes cuts idealized read-and-write traffic from $2\,n_{\text{ops}}M_{\text{tensor}}$ to $2M_{\text{tensor}}$ bytes, because the fused kernel reads its input once and writes its final output once. Weights, auxiliary inputs, cache effects, and register spills are outside this simple bound, and data dependencies, tensor shapes,

and register pressure limit how much can legally be fused. Several inference patterns nevertheless approximate the bound closely enough for fusion to matter.

Convolution-BatchNorm-ReLU fusion

The common Conv-BN-ReLU pattern can replace three launches and intermediate round-trips with one fused path when the compiler can legally fold batch normalization and combine the activation (listing 10.4). Folding is compression-specific because it must happen after the convolution's channels and scales are final. Workflows fold batch normalization into preceding convolution weights ($\mathbf{W}_{\text{fused}} = \frac{\gamma}{\sigma_{\mathcal{B}}}\mathbf{W}$) where $\sigma_{\mathcal{B}}$ is the square root of the sum of running variance and the numerical stabilizer. Folding also adjusts the convolution bias, $\mathbf{b}_{\text{fused}} = \frac{\gamma}{\sigma_{\mathcal{B}}}(\mathbf{b} - \mu_{\mathcal{B}}) + \beta$, where $\mu_{\mathcal{B}}$ is the per-channel running mean and γ and β are the learned batch-normalization scale and shift. Batch normalization's per-channel scale thus multiplies into the surviving filters, and its shift becomes the convolution's bias, so a pruned or quantized network is folded once its structure stops changing.

Listing 10.4: Conv-BN-ReLU Fusion: Combining three operations into a single kernel reduces the idealized intermediate-tensor stream from 6 transfers to 2; weights, auxiliary inputs, and spills are outside this count.



```
# Pseudocode: runtime APIs and fusion legality are
# implementation-dependent.
# === UNFUSED: 3 kernel launches, 6 memory transfers ===
conv_out = conv2d(input, weight)
bn_out = batch_norm(conv_out, ...)
relu_out = relu(bn_out)

# === FUSED: 1 kernel launch, 2 memory transfers ===
def conv_bn_relu_fused(input, weight, gamma, beta, mean, var):
    # Read input and weight once
    conv = conv2d(input, weight)

    # Apply batch norm in registers (no memory write)
    bn = gamma * (conv - mean) / sqrt(var + eps) + beta

    # Apply ReLU in registers (no memory write)
    output = relu(bn)

    # Write final result once
    return output
```

The idealized intermediate stream falls from six transfers to two.

↩ IO-aware attention tiling and its HBM-traffic accounting are established in section 8.6.4.

↪ The register pressure and accelerator-specific constraints that bound how far kernels can be fused on GPUs and TPUs are developed in section 11.7.7.1.

The intended function is preserved, although batch-normalization folding changes the arithmetic sequence, and the intermediate traffic falls by 3×. Generic bias-activation and attention fusion, by contrast, do not depend on compression and belong to the general fusion toolkit of chapter 7.

A ResNet-50 layer with 256 channels and a 28×28 spatial size puts numbers on this. Its feature map occupies 802.8 KB, so the four intermediate transfers that fusion removes amount to $4 \times 256 \times 28 \times 28 \times 4$ bytes $\approx$ 3.2 MB per layer. The full accounting also counts weights and parameters. Without fusion, each operation performs its own memory round-trip: Conv reads input (802.8 KB) plus weights (2.4 MB) and writes output (802.8 KB), totaling 4 MB. BN then reads that output, adds its parameters (2 KB), and writes again, for 1.6 MB. ReLU repeats the pattern for another 1.6 MB. The total unfused memory traffic is 7.2 MB. With fusion, the entire sequence reads input and weights once and writes the final output once, requiring only 4 MB, a 44.8 percent bandwidth reduction.

At the reference H100's 3,350 GB/s HBM bandwidth, these traffic volumes imply ideal lower bounds of 2 microseconds before fusion and 1.2 microseconds after fusion, a 1.81× ratio for the traffic component alone. These are not full layer latencies because convolution compute, cache effects, and launch overhead must also be included. Furthermore, fusion needs the computation captured as a graph, and dynamic control flow, in-place mutation, or unsupported operations can block the rewrite, so the exported plan must be inspected rather than assumed (graph capture is developed in section 7.3.6).

Quantization adds a fusion of its own. A weight-only INT8 or INT4 kernel must turn each packed integer code x_q back into a real value x before multiplying it, using the scale s and zero-point z of equation 10.1 and equation 10.2:

$$x = s(x_q - z) \tag{10.4}$$

Executed as a separate kernel, dequantization writes the full-precision weights back to memory and reads them again, restoring the traffic that quantization removed. Fused into the matrix-multiplication kernel, the dequantize step runs in registers on each tile as it arrives, so only the packed bytes cross the memory bus. That fusion is what lets GPT-2 XL's INT4 weights deliver the decode speedup computed in section 10.3.5. When a runtime cannot fuse it, the quantized model can run slower than its FP16 baseline, a failure section 10.5.4.2 examines. Fusion removes intermediate traffic between operations that must all run, leaving the complementary hardware question of how to skip operands that pruning has already set to zero.

10.4.2 Sparsity exploitation

Replacing pruned weights with zeros inside a standard dense matrix still fetches every zero from memory and multiplies it in the ALU, yielding no wall-clock speedup. Sparsity exploitation designs the storage layouts and kernels that translate **sparsity**[19]—tensors where a substantial fraction of entries are zero—into reduced memory traffic and execution time.

Formally, for a sparse weight matrix $\mathbf{W}_{\text{sparse}} \in \mathbb{R}^{m \times n}$, the nominal sparsity ratio ρ_{sparse} is:

$$\rho_{\text{sparse}} = \frac{\|\mathbf{1}_{\{(\mathbf{W}_{\text{sparse}})_{ij}=0\}}\|_0}{m \times n}$$

where $\mathbf{1}_{\{(\mathbf{W}_{\text{sparse}})_{ij}=0\}}$ is an indicator function that yields 1 if entry (i, j) is zero and 0 otherwise, and $\|\cdot\|_0$ counts nonzero entries. When magnitude pruning treats entries below δ_{prune} as removable, the thresholded sparsity ratio becomes:

$$\rho_{\text{sparse},\delta} = \frac{\|\mathbf{1}_{\{|(\mathbf{W}_{\text{sparse}})_{ij}| \leq \delta_{\text{prune}}\}}\|_0}{m \times n}$$

where δ_{prune} defines the pruning boundary. Zeros yield wall-clock acceleration only when the execution pipeline skips both the arithmetic and the associated memory traffic.

From an execution standpoint, the spatial pattern of zeros determines memory transaction efficiency. As established in section 10.2.1.2, unstructured sparsity zeroes arbitrary scalar connections, requiring pointer arrays and non-unit-stride gathers that degrade bandwidth on SIMD and systolic units. Conversely, structured patterns, such as channel pruning or $N{:}M$ constraints, preserve predictable memory layouts, aligning with standard dense kernels or dedicated hardware datapaths.

[19] **Sparsity**: From Latin *sparsus* (scattered), past participle of *spargere* (to scatter); in ML, ℓ_1 regularization such as the lasso can induce exact zeros rather than merely small values (Tibshirani 1996). Software can represent arbitrary sparsity patterns, while efficient hardware execution generally requires a supported format or structured pattern (for example, NVIDIA's 2:4 sparsity). The gap between representable and executable sparsity separates theoretical compression from realized speedup.

10.4.2.1 Sparsity utilization methods

Translating zeros into runtime speedup requires a representation that encodes nonzero positions and a kernel that decodes those coordinates to bypass unneeded computation (Hoefler et al. 2021). In a matrix-vector product, a dense $4{\times}4$ operator executes 16 multiply-accumulate operations, whereas a sparse execution path computes only the six nonzero products alongside the necessary metadata lookups:

$$\begin{bmatrix} 2 & 0 & 0 & 1 \\ 0 & 3 & 0 & 0 \\ 4 & 0 & 5 & 0 \\ 0 & 0 & 0 & 6 \end{bmatrix} \begin{bmatrix} v_1 \\ v_2 \\ v_3 \\ v_4 \end{bmatrix} = \begin{bmatrix} 2v_1 + v_4 \\ 3v_2 \\ 4v_1 + 5v_3 \\ 6v_4 \end{bmatrix}$$

The runtime benefit depends entirely on whether the latency eliminated by skipping 10 multiply-accumulate operations exceeds the latency added by coordinate decoding and non-contiguous activation loads. For unstructured sparsity, that trade has a computable answer in bytes and a measurable one in time.

10.4.2.2 Storage and execution break-even

A variant of the running case makes the byte side concrete. Suppose the camera team must also ship its MobileNetV2 to a wearable companion device whose microcontroller offers only 2 MB of flash memory, against the model's 14 MB of FP32 weights. Retraining a smaller architecture from scratch would require weeks of data collection and validation that the product schedule does not allow. Suppose profiling shows that about 85.7 percent of the model's weights are near zero and contribute little on the validation set. Removing those weights and fine-tuning the remainder for a few epochs leaves surviving weight values that total 2 MB with an acceptable accuracy loss. Whether the stored artifact also fits in 2 MB depends on how the surviving weights are stored. The numbers are a labeled scenario that anchors the engineering trade-off, not a universal MobileNet benchmark.

Storing only the surviving values requires an indexed sparse encoding such as **Compressed Sparse Row (CSR)** or coordinate list (COO). Because these formats must store positional metadata (such as column indices and row pointers) alongside the nonzero values, metadata overhead offsets savings at low sparsity. For example, storing a 16-bit floating-point weight with a 16-bit column index doubles the per-element byte footprint, requiring over 50 percent sparsity just to break even on artifact size (D_{vol}). Storing a dense tensor with zeroed entries saves zero memory. The wearable variant shows the consequence. Its surviving weights total 2 MB only if they cost nothing to locate. A 16-bit index beside each value adds half again to 32-bit values and doubles 16-bit ones, so the stored artifact misses the 2 MB flash budget. A denser position encoding, such as a bitmap, reduces the metadata overhead but cannot fit unchanged values that already consume the entire budget. Fitting requires further pruning or lower-precision values with room reserved for metadata, or structured removal of whole channels so that the remaining tensors can be stored without per-value indices.

↪ The memory footprint and index-pointer layouts for compressed sparse row (CSR) representations are collected for reference in section C.1.4.

Nor does unstructured sparsity translate directly to inference acceleration on modern hardware. Commodity accelerators achieve peak throughput (R_{peak}) through dense systolic arrays and wide SIMD execution units that rely on *memory coalescing*. Memory transfers use device-dependent transaction granularity, and caches store data in *cache lines*. Coalescing nearby, aligned accesses lets parallel threads share transactions more efficiently. A dense masked tensor still moves its zero entries. An indexed sparse encoding instead packs nonzero values, but Sparse Matrix-Dense Matrix Multiplication (SpMM) kernels must decode metadata and gather the matching activations. Irregular activation accesses, load imbalance, and kernel overhead can offset the skipped arithmetic even when stored weight values are contiguous. The performance break-even point depends on shape, format, batch size, and the available sparse kernel, so artifact reduction alone does not establish a speedup.

10.4.2.3 Structured patterns

Structured patterns resolve the break-even problem by constraining where zeros occur, and achieving actual speedups from them requires hardware that can efficiently skip zero-valued computations. Processor architectures differ in which patterns they exploit. Ampere-generation and later Sparse Tensor Cores exploit fine-grained 2:4 structured patterns, while systolic arrays require dense block structures. Libraries such as cuSPARSE reformulate sparse computations into patterns the hardware handles well, and MegaBlocks (Gale et al. 2022) recasts sparse mixture-of-experts training as block-sparse operations on dense tiles.

A sparse pattern earns hardware speedup only when it is regular enough for kernels to predict. Two formats make that regularity explicit: block sparse matrices and N:M sparsity patterns. Block sparse matrices group nonzeros into dense submatrices, so operations on the large sparse matrix become a smaller number of dense operations on submatrices. In the illustrated representation, 3×3 dense sub-blocks are indexed by an auxiliary coordinate array, so sub-block kernels can bypass the empty tiles (figure 10.28) (NVIDIA 2020a). The block size is a teaching choice. Actual speedup requires a block shape, layout, datatype, and kernel supported by the target library and hardware; regular blocks alone do not guarantee aligned memory transactions or Tensor Core execution.

Similarly, N:M sparsity retains at most n_{keep} nonzeros in each group of m_{group} consecutive elements; hardware-oriented pruning often enforces exactly n_{keep} retained values so every group has the same representation (Zhou et al. 2021). The deterministic format lets a supported kernel predict the value and metadata layout while retaining more capacity than removing whole channels or blocks. That

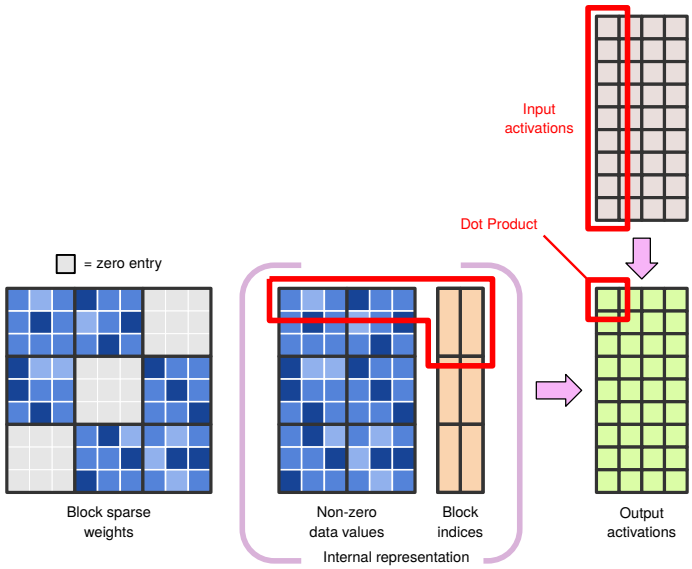


Figure 10.28: Block Sparse Representation: Grouping non-zero weights into dense sub-blocks and storing an auxiliary index array lets matching kernels skip empty blocks. The 3×3 tiles illustrate the representation; efficient GPU execution depends on supported block shapes, layouts, and kernels. Adapted from NVIDIA cuSPARSE documentation (NVIDIA 2020a).

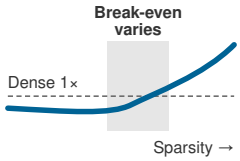
regularity creates an executable compromise between arbitrary masks and dense computation, but only for targets with the matching path.



On hardware with a sparse matrix path, the 2:4 pattern of section 10.2.1.3 turns into execution savings, since its 2-bit position indices cost far less than the pointer arrays of general CSR or COO formats (NVIDIA Corporation 2020a). The sparse datapath that consumes those indices and skips the zeroed multiplies is developed in section 11.4.5.3. Learned masks need not stop at 2:4; STEP, for example, learns more general N:M masks for inference (Lu et al. 2023).

Unstructured pruning zeroes arbitrary individual weights. Those irregular locations can disrupt memory coalescing and lane utilization, while Compressed Sparse Row (CSR) or Coordinate (COO) metadata adds storage and non-unit-stride accesses. An unstructured sparse model can therefore run slower than its dense counterpart when metadata and underutilization outweigh skipped arithmetic. TPUs are useful contrast cases for dense systolic-array acceleration (Jouppi et al. 2021), but sparse acceleration still depends on a specific hardware and software path rather than accepting arbitrary masks. Field-programmable gate arrays can implement application-specific sparse formats, yet their efficiency depends on the chosen dataflow and resource budget; programmability is not a universal sparse-speedup guarantee.

Across all platforms, sparse operations can reduce memory bandwidth requirements and energy consumption when the sparse representation and kernels actually skip data movement rather than only arithmetic. This benefit compounds with quantization, since a sparse INT8 model can require less memory traffic than either technique alone when the format overhead is small enough (Hoefler et al. 2021; Gale et al. 2020).

10.4.2.4 Challenges and limitations

The dependence of every sparse speedup on a matching format and kernel explains why nominal sparsity often fails to deliver speedups in practice. First, the performance break-even point varies with tensor dimensions, sparse format, kernel implementation, and hardware architecture. When coordinate metadata and irregular activation gathers saturate cache lines, an unstructured sparse kernel can run slower than an optimized dense baseline until sparsity exceeds 80 to 90 percent. Second, the accuracy-efficiency trade-off is nonlinear, because models often tolerate moderate pruning before task quality degrades abruptly past a critical density threshold. Finally, energy savings do not scale linearly with skipped operations; irregular memory access and index decoding can consume more power on edge devices than the arithmetic they eliminate. Fusion and sparse

Unstructured sparsity pays off only after crossing a hardware- and kernel-specific break-even point.

kernels thus decide whether each technique's paper savings survive contact with the hardware. Most deployments apply several techniques at once, and choosing and ordering them is the next decision.

10.5 Choosing and Combining Techniques

When the chapter's phone decodes GPT-2 XL, its FP16 weights and KV cache claim 3.3 GB of the 8 GB that the operating system and other applications also share, each generated token waits about 65 ms while every weight streams over the 51.2 GB/s bus, and the handset sustains only 3–5 W before thermal throttling. Choosing among compression techniques—and ordering them—starts from whichever of those physical limits binds first, alongside the allowable task accuracy loss and the available training budget.

The three primary optimization levers target different levels of the system stack. Distillation alters the algorithmic architecture by training a compact dense student to emulate a larger teacher, executing efficiently on standard hardware without specialized runtime support. Pruning modifies tensor topology and operation patterns, but yields wall-clock acceleration only when the resulting sparsity aligns with hardware execution units, such as 2:4 structured sparse matrix cores or channel-aligned sub-matrices. Quantization alters data representation by reducing numerical bit width, directly lowering memory bus traffic and cache footprint while engaging higher-throughput integer datapaths. Their first-order trade-offs, with representative ranges for common choices, sit side by side in table 10.11.

Table 10.11: Optimization Trade-Offs: Systems gain, quality impact, training cost, and hardware dependency for common compression choices. Region 1 marks little or no quality loss, region 2 a moderate trade, and region 3 steep quality loss. The ranges are representative engineering values synthesized from published work on inference runtimes, quantization, pruning, low-bit LLM quantization, and distillation (NVIDIA 2024c; Jacob et al. 2018; Han et al. 2015; Lin et al. 2024; Hinton et al. 2015); actual results vary with architecture, task, range-calibration data, and implementation quality. The rows identify first-order candidates, not guaranteed outcomes, and the hardware dependency decides whether pruning or quantization changes latency at all.

Technique	Systems gain	Typical impact	Training cost	Hardware dependency	Region
Kernel fusion	10–30% latency reduction	No accuracy loss	None	The compiler must recognize the pattern	1
FP32 → BF16	2× memory, ~2× throughput	$< 0.1\%$ accuracy drop	None for inference	A native BF16 path	1
FP16 → INT8	2× memory, 2–4× throughput	Quantization error, 0.5–1% accuracy drop	Low for PTQ; higher for QAT	INT8 kernels for a runtime speedup	2
50% pruning	~2× smaller model	Capacity loss, 0.5–1% accuracy drop	Usually includes fine-tuning	Structured shapes or supported sparse kernels	2
Knowledge distillation	2–10× smaller student	Capability ceiling, 1–3% accuracy drop	Teacher inference and a student run	Low; the student is an ordinary dense model	2
4-bit quantization	4× memory reduction	Significant error, 2–5% accuracy drop	Low for PTQ; higher for QAT	Low-bit kernels with fused dequantization	2–3
90% pruning	~10× smaller model	Severe capacity loss, 5–15% accuracy drop	Iterative fine-tuning	Sparse kernels past the break-even point	3

10.5.1 The accuracy-efficiency frontier

Pushing a single compression knob too far—such as pruning 90 percent of a network's weights or quantizing sensitive layers to 4 bits without retraining—crosses a cliff where a modest extra byte saving costs 5 to 15 percentage points of task accuracy (table 10.11). Every lever in the table moves the model along this **accuracy-efficiency trade-off**: additional model capacity can improve predictive accuracy while demanding larger weight payloads, expanded activation working sets, and higher memory bandwidth during inference. On hardware with strict memory or power limits, engineers first eliminate avoidable implementation costs, then choose among feasible operating points on the Pareto frontier (principle 5).

Systems Perspective 10.2: The compression-accuracy trade-off curve

The measured trade-off is not uniform. A structure-preserving implementation improvement can move a dominated model toward the frontier with little or no accuracy loss. Once on an efficient frontier, improving one objective trades against another; aggressive structural changes can enter regions with steep quality penalties.

The engineering decision is where to stop. The "knee" of the curve marks a region where further resource savings incur a sharper quality penalty. It is a useful visual diagnostic, but accuracy points cannot be compared directly with milliseconds, bytes, or joules. Stop at an operating point that meets the deployment's quality and resource thresholds, using explicit objective weights if a further trade must be ranked.

Techniques that preserve model structure, such as kernel fusion and modest precision reduction (FP32 to BF16), can yield latency or memory gains with little quality loss when the model and execution path support them. In contrast, techniques that alter network structure, such as pruning and distillation, yield larger reductions in memory and arithmetic volume but risk significant quality degradation without careful retraining. Optimization therefore begins by identifying the binding hardware constraint—memory capacity on mobile devices, frame latency in interactive pipelines, or energy per inference on battery-powered sensors—so each tier can target the resource that actually binds: structural methods cut parameter and operation counts, quantization shrinks memory traffic and raises arithmetic intensity, and compiler-level fusion eliminates intermediate memory round-trips. The regions in table 10.11 mark where each choice typically lands on that curve, and a structured decision framework maps each binding hardware constraint to the specific levers worth testing first.

Checkpoint 10.4: The efficiency frontier

Optimization can remove avoidable costs or trade among efficient operating points.

Trade-offs

- ☐ **Accuracy vs. cost**: compare a structure-preserving optimization and a structure-altering one by naming which resource each saves and which quality risk it introduces.
- ☐ **Dominated operating points**: explain how an implementation improvement can move a dominated operating point toward the frontier without reducing accuracy.
- ☐ **The knee**: explain how a sharp change in the measured trade-off informs a decision, and state the quality and resource thresholds needed to choose an operating point.

10.5.2 Decision framework

Applying a compression technique that targets the wrong hardware bottleneck wastes engineering cycles and task accuracy: pruning FLOPs from a layer stalled on off-chip weight streaming leaves memory-bus latency intact, whereas quantizing weights to 8 bits on a compute-bound processor that lacks an integer matrix unit leaves arithmetic throughput unchanged. Identifying the binding hardware constraint first narrows the search to the optimization tiers that can relieve it. Under the D·A·M taxonomy, compression methods redistribute resource demands across Algorithm (topology, pruning, distillation, and the numerical representation of weights) and Machine (execution units and memory hierarchies); range-calibration sets are the main Data-axis input. Each system constraint maps to the optimization tiers that can relieve it (table 10.12), where the marks identify mechanisms to investigate rather than guaranteed deployment gains.

Table 10.12: Optimization Tiers: System constraints drive optimization along three core tiers: model representation, numerical precision, and hardware implementation, each addressing different resource limitations and performance goals. ✓ marks a direct lever, while △ marks a workload- or hardware-dependent benefit; for example, low-precision arithmetic helps only when the accelerator and runtime provide a supported path.

System Constraint	Model Representation	Numerical Precision	Hardware Implementation
Computational Cost	✓	△	✓
Memory and Storage	✓	✓	△
Latency and Throughput	✓	△	✓
Energy Efficiency	✓	✓	✓
Scalability	✓	△	✓

One technique can move more than one term of the iron law. For example, quantizing weights from FP32 to INT8 directly relieves on-device storage capacity. A bandwidth-limited operator approaches proportional latency savings only when the affected traffic dominates and conversion overhead does not consume the gain. A compute-limited operator needs a faster supported execution path. Unstructured pruning likewise reduces executed arithmetic only when sparse kernels exploit the removed weights; indexing and irregular memory accesses can offset the saving. The changed representation therefore supplies a candidate improvement whose effect must be measured on the target.

When persistent storage or device memory capacity binds the deployment, as over-the-air package limits and microcontroller flash budgets do, quantization provides the most direct payload reduction. Relative to FP32 storage, INT8 post-training quantization (PTQ) cuts raw weight storage by $4\times$ without requiring retraining cycles. INT4 cuts raw payload by $8\times$, though aggressive bit-width reduction increases the risk of accuracy degradation. If uniform low-bit quantization causes unacceptable accuracy loss on sensitive layers, distilling knowledge into a smaller dense architecture followed by moderate quantization preserves fidelity while satisfying the storage budget.

When latency is compute-bound, the workload operates above the accelerator's ridge point, the arithmetic intensity at which its compute and memory-bandwidth limits meet, saturating execution units. Relieving this bottleneck requires reducing executed operations or increasing arithmetic throughput. Structured pruning removes channels, attention heads, or entire layers, yielding smaller dense matrices that execute on standard libraries without sparse runtime overhead; however, pruning to dimensions that misalign with hardware warp or tile sizes (such as channel counts not divisible by 8 or 16) degrades tensor core efficiency and curtails wall-clock gains. If the target platform provides dedicated integer execution units, INT8 quantization increases the instruction throughput rate, accelerating compute-bound kernels directly. Early-exit architectures provide an alternative algorithmic path by dynamically halting inference on simpler inputs, provided that routing and pipeline synchronization overhead do not disrupt batch processing.

↪ How the ridge point shifts across accelerators and precisions is developed in section 11.6.2.

Small-batch transformer generation often exposes a weight-bandwidth bottleneck, as GPT-2 XL decoding on the phone showed, because dense decoding streams large parameter matrices for matrix-vector operations with low arithmetic intensity. When fetched weights dominate latency, weight-only quantization (such as INT4 or INT8 weights paired with FP16 activations) can approach a speedup proportional to the reduction in those bytes. KV-cache traffic and dequantization overhead limit that gain without necessarily making execution compute-bound; larger batches can increase weight reuse and shift the limiting resource.

When energy or thermal dissipation binds, quantization provides substantial benefits because moving data across off-chip memory buses consumes orders of magnitude more energy per bit than on-chip arithmetic or local SRAM access. Reducing operand bit widths directly lowers bus capacitance charging energy, while integer ALUs consume less switching energy than floating-point datapaths. Structured pruning compounds these savings by eliminating operations and memory transactions entirely. Full-system power audits must still measure peripheral components (memory refresh, host bus communication, and static idle leakage) to ensure that kernel-level energy savings translate into extended operating life.

Selection also depends on the engineering and computational budget available. Calibrated PTQ needs only a small representative dataset, and QAT adds training cost only when PTQ misses

the accuracy threshold. Knowledge distillation costs more, requiring teacher forward passes and substantial training cycles to optimize a smaller student model. Hardware-aware NAS occupies the highest cost tier, justified only when high-volume deployment amortizes the extensive compute needed to explore the architectural search space.

Applied to GPT-2 XL decoding on the phone, this framework makes INT4 weight-only quantization the first candidate, not a completed solution. It cuts the weight bytes to a quarter of FP16, but each token also streams the unchanged KV cache, and the gain holds only when dequantization is fused into the matrix multiplication (section 10.3.5). Distillation to a smaller model is another candidate if the remaining gap justifies its training cost. Each candidate must pass task-quality, latency, peak-memory, and sustained-power checks against the phone's 3–5 W envelope.

Choosing an individual technique addresses a single binding bottleneck, but production deployment budgets frequently require compounding gains across multiple dimensions. When memory capacity, bandwidth, and compute throughput are all constrained simultaneously, optimizing a system requires composing structural alterations, precision reductions, and custom execution kernels into an integrated transformation pipeline.

10.5.3 Combining and sequencing techniques

Quantizing a network to fixed 8-bit integer ranges before pruning its channels shifts the activation distributions that those ranges were calibrated to fit, while removing floating-point precision before distillation hinders gradient recovery. Because each tier changes the weight and activation distributions or tensor shapes that the next tier sees, the order in which compression techniques are applied governs both final accuracy and hardware utilization. On the camera pipeline, the sequence follows directly from those dependencies between the tiers. Channel pruning comes first, with pruned channel counts kept on a multiple of the hardware's tile width so the smaller layers still fill the phone's matrix tiles. Distillation from the ResNet-50 teacher then serves as the recovery training for the pruned network, the prune-then-distill order described in section 10.2.3. INT8 quantization comes last among the model changes, because range calibration must see the weight and activation distributions of the final structure, and because INT8 is what moves the model from the phone's CPU onto its integer accelerator. Batch-normalization folding and the remaining fusions are applied when the graph is compiled for the device. Each step is profiled on the phone before the next is taken, because each one changes the bottleneck that the next one faces. The steps also move different quantities, and most of the frame time comes off at the step that changes the processor (figure 10.29).

A modeled BERT-Base pipeline attaches numbers to the same staging. Pruning, distillation, and quantization together reduce its footprint from 440 MB to 28 MB (rounded), a 16× raw-footprint reduction. Each stage addresses a distinct bottleneck. Structural pruning removes redundant matrix multiplications, distillation supervises the compact student to recover representational capacity, and quantization packs weights and activations into lower-bit integers to relieve memory bandwidth pressure.

Example 10.2: BERT-Base mobile deployment pipeline

Scenario: A modeled deployment targets executing a 110M-parameter BERT-Base language model on resource-constrained mobile hardware. The compact graph is stipulated for this example; the figures are not reported DistilBERT results.

The FP32 teacher begins at 440 MB with assigned task accuracy 76.2 percent. Structural pruning produces a stipulated 27.5M-parameter graph, a 75 percent parameter reduction, with raw FP32 weights of 110 MB and assigned accuracy 75.1 percent.

That pruned graph is the distillation student. Teacher supervision recovers its assigned accuracy to 75.9 percent without another parameter-count reduction. Final INT8 quantization leaves the same parameter count, reduces raw weight storage to 27.5 MB, and has assigned accuracy 75.6 percent. The headline ratio uses this unrounded weight payload; scales, zero-points, packing, activations, and runtime workspace remain outside the calculation.

Diagnosis: In this modeled comparison, quantization before pruning has an assigned accuracy loss of 2.1 percent. One mechanism to investigate is whether structural changes invalidate

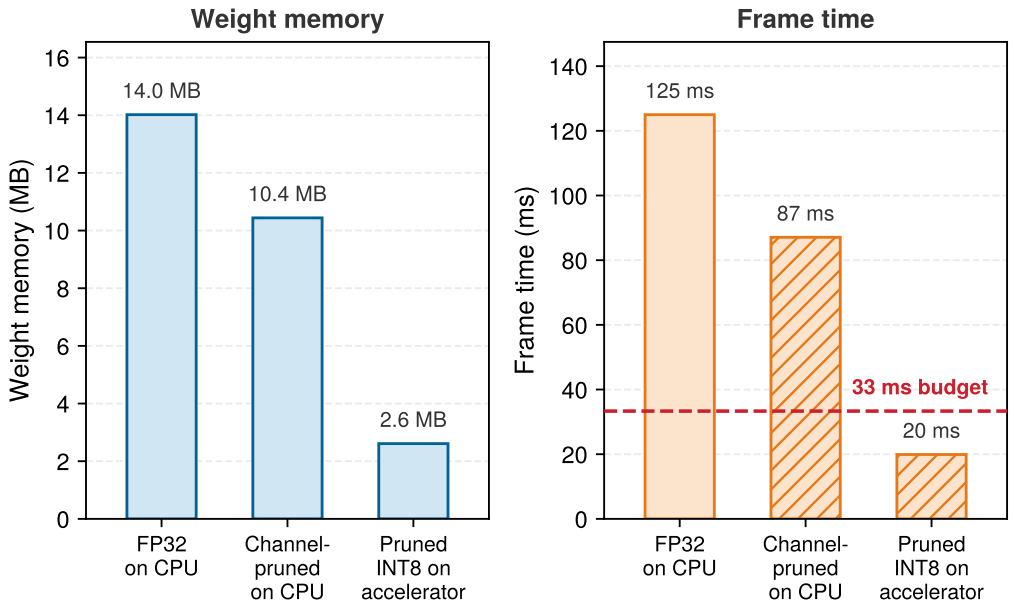


Figure 10.29: Compression Waterfall for the Camera Pipeline: MobileNetV2 weight memory (left) and frame time (right) after each model change, against the 33 ms budget of a 30 FPS camera. Weight memory follows from the parameter counts. The FP32 frame time is the running case's illustrative value, and the hatched bars scale the running case's frame times by the share of arithmetic the pruned network keeps. Channel pruning to width 0.75 keeps 70 percent of the arithmetic but leaves the frame near 87 ms on the CPU. INT8 cuts the weights by 4× and moves the model onto the integer accelerator, which brings the frame to about 20 ms. Folding and fusion, applied at compile time, are not modeled.

previously calibrated ranges. Pruning and distillation before quantization allow calibration to use the resulting distributions. These modeled values illustrate the mechanism and do not establish a universal ordering.

Systems lesson: In this modeled pipeline, pruning, then distillation, then post-training INT8 quantization produce a 16× footprint reduction (440 MB to 28 MB) while limiting task accuracy loss to 0.6 percent. Because tensor distributions and hardware kernel efficiencies vary across architectures, each intermediate artifact must be profiled on the target runtime.

Sequencing matters because these transformations interact through shared parameters and activation distributions. Structural pruning removes channels or attention heads, altering the dynamic range and variance of surviving weight tensors. Quantizing before pruning can leave ranges poorly matched to the resulting distributions, so recalibration or joint adaptation may be needed. In the staged candidate, floating-point recovery lets the pruned network adapt, and distillation supplies a teacher signal before final quantization. QAT itself updates floating-point master weights through approximate gradients; it does not require direct integer weight updates. Alternative schedules should be compared at matched recovery and calibration budgets.

Combining techniques also changes the size-quality trade-off itself (Han, Mao, et al. 2016). In one reported setting (figure 10.30), while individual SVD and pruning curves suffer steep accuracy cliffs below about 15 percent and 6 percent model size respectively, combining pruning with quantization extends the zero-loss plateau down to roughly 3 percent of original parameter footprint. This comparison does not isolate transformation order. The magnitude of these gains remains model- and runtime-specific, requiring engineers to validate each transformation stage independently.

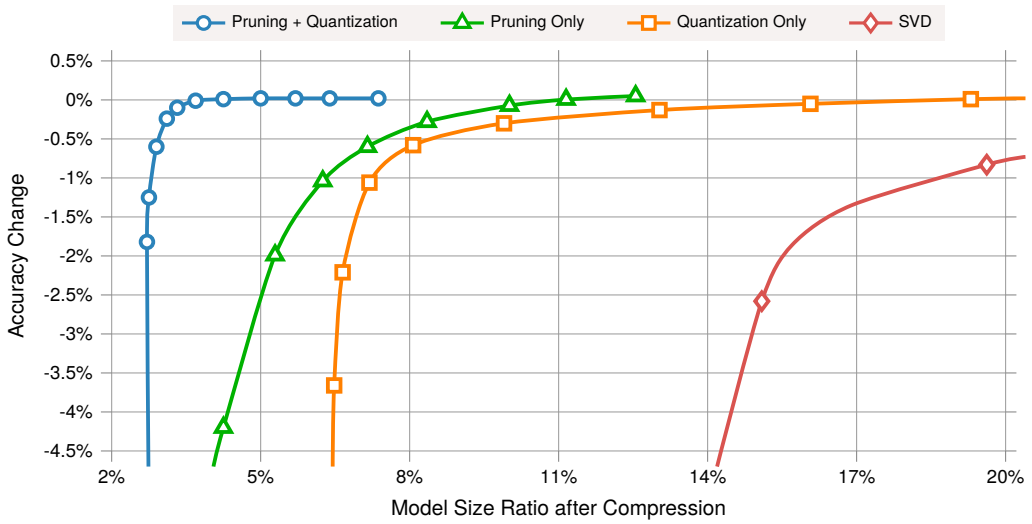

Figure 10.30: Compression Methods in One Reported Setting: The cited comparison plots accuracy change against model-size ratio for pruning, quantization, their combination, and SVD. In this setting, pruning plus quantization reaches the smallest ratio near baseline accuracy; the ordering is model- and implementation-specific. Source: (Han, Mao, et al. 2016).

> **Systems Perspective 10.3: The optimization composition problem**
>
> Optimization techniques interact through shared representations and physical resources rather than composing as independent functions. Pruning changes the surviving value distribution, tensor shapes, or sparse format; quantization adds scales and changes the available kernels; fusion changes which intermediates are materialized and can alter the profile that justified earlier choices. Composing pruning with quantization, as when 2:4 structured sparsity is paired with INT8 weights, leaves an executable that must carry both the sparsity metadata and the quantization scales, and a pruned shape that breaks the memory alignment a quantized kernel expects can erase the speedup of both (Hoefler et al. 2021). Effective optimization therefore treats the model-runtime-hardware combination as a coupled system, measures it after every transformation, and revisits the sequence when a new bottleneck appears. This makes compression a systems engineering problem as well as a machine learning problem.

A footprint reduction that compounds on paper therefore becomes a speedup only where the runtime supports every transformation in the sequence at once, which makes the toolchain that applies them part of the decision.

10.5.4 Compression toolchains

Quantizing a large model by hand would mean editing thousands of operator call sites to insert scale factors and track activation ranges. Manual graph surgery also cannot guarantee autograd consistency during retraining or the memory alignment that accelerator kernels require. Compression therefore runs through tooling, and the tool choice follows the layer of the software stack that owns the transformation. Framework APIs operate on the high-level computation graph during training and calibration, where the execution engine maintains visibility into weights, activations, and autograd state. At this stage, quantization is typically simulated, with fake-quantization nodes that clamp and round values within floating-point registers, modeling numerical precision loss while preserving differentiability.

Simulating quantization does not itself establish a physical speedup. A compiler or runtime must lower the graph into supported kernels; frameworks may integrate that stage or export to a separate deployment engine. The runtime compiler fuses scale factor arithmetic directly into matrix-multiplication compute tiles and packs sparse weights into hardware-specific metadata

layouts (such as 2:4 structured sparsity formats). This lowering eliminates round-trip memory transactions to HBM that would otherwise negate the benefits of reduced precision.

Reproducibility is the first requirement of a multi-stage pipeline. Compressing a model alters its numerical representations across both the algorithm and machine layers of the D·A·M taxonomy. Unrecorded calibration inputs or mismatched rounding modes can degrade accuracy silently without raising runtime errors, so every deployed artifact must remain traceable from its source training checkpoint, through the calibration data, pruning schedule, and fusions that produced it, to its compiled hardware execution graph.

↪ Versioned artifacts and the lineage graphs that keep deployed models traceable are developed in section 14.3.1.2.

10.5.4.1 Model optimization APIs and tools

At the model-development layer, compression algorithms require access to runtime state that downstream deployment compilers discard: gradient histories, optimizer state variables, and dynamic activation distributions. When post-training quantization or one-shot pruning degrades accuracy beyond acceptable operating thresholds, recovery requires retraining or iterative fine-tuning. Frameworks such as PyTorch and TensorFlow provide optimization APIs specifically to manage this graph-transformation boundary. These APIs inject quantization nodes and observers, reparameterize weight tensors with sparsity masks, and preserve calibration metadata alongside the trained parameters, which is what makes a compression recipe repeatable across many models.

Quantization-aware training demonstrates this graph-level intervention. Optimization APIs insert the fake-quantization operators of section 17 into the compute graph; these operators clamp and round in the forward pass and apply the straight-through estimator of section 10.3.3.2 in the backward pass. Producing a deployable low-precision artifact then takes a short sequence of graph transformations and metadata tracking (listing 10.5).

Listing 10.5: Quantization-Aware Training: Mechanism-level transformation that trains through simulated low-precision behavior and exports the calibration metadata needed for deployment.

```
choose target precision and calibration policy
insert quantize/dequantize boundaries around selected tensors
train with simulated low-precision values while keeping gradient flow intact
record scales, zero points, accumulator precision, and unsupported operations
export the calibrated graph and metadata as one reproducible artifact
```

Pruning tools implement the mask-then-export boundary of section 10.2.1.7. A mask-based API keeps the dense weight tensor $\mathbf{W}$ and a binary mask $\mathbf{M}$ of the same shape during recovery training, computing $\hat{\mathbf{W}} = \mathbf{M} \odot \mathbf{W}$ in the forward pass so the existing dense kernels and gradient updates keep working. An export pass then finalizes the transformation, either slicing away pruned channels or encoding the nonzeros in a sparse format the target's kernels accept. What must be recorded along the way, so that the compressed model can be reproduced, is short but not optional (listing 10.6).

Listing 10.6: Pruning Artifact Boundary: Applies unstructured or structured removal rules, then records the mask and fine-tuning context needed to reproduce the compressed model.

```
choose pruning granularity: individual weights, channels, blocks, or attention heads
score candidate parameters by magnitude, sensitivity, or validation loss impact
remove or mask the selected structure according to the hardware-compatible rule
fine-tune the compressed model against the original validation target
export weights, masks, sparsity pattern, and calibration evidence together
```

10.5.4.2 Hardware-specific optimization libraries

Exporting an optimized model from a training framework produces an intermediate graph representation, not an executable binary. Compilers and runtime engines such as TensorRT, Accelerated Linear Algebra (XLA), OpenVINO, and TVM own the final translation step: compiling a pruned, quantized, or fused graph into machine instructions tailored to the target accelerator. In D·A·M terms, algorithmic compression remains theoretical until the graph maps to kernels that physically exploit the target machine's memory hierarchy and execution units.

The compilation pass verifies whether nominal compression yields physical speedup. Pruning that leaves zeros in dense tensors still streams and multiplies those entries with a dense kernel. Compact sparse formats need matching kernels, such as a supported 2:4 path, while structured channel removal can produce smaller tensors for ordinary dense kernels. Quantization lowers bitwidth, but a weight-only path may unpack operands into floating-point registers before arithmetic. That unpacking adds instructions; its cost must be compared with the packed weight traffic saved.

The result can be the *runtime dequantization trap*. If an accelerator provides native INT8 matrix-multiplication kernels but lacks an INT8 implementation for an adjacent operation (such as LayerNorm, GeLU, or an attention softmax reduction), the runtime encounters a type boundary. An unfused execution path may allocate a temporary buffer, launch a dequantization kernel to recover floating-point values ($x = s(x_q - z)$, equation 10.4), execute the unsupported operator, and launch another kernel to re-quantize its output. The floating-point format and opportunities to fuse conversion depend on the runtime. These intermediate format conversions incur extra kernel launches, introduce synchronization barriers, and add temporary floating-point traffic that can make the quantized model slower than the FP16 baseline. A fused weight-only path instead unpacks values within the consuming kernel, the fusion of section 10.4.1, and retains a net memory-traffic benefit.

Low-precision kernels also require specialized tensor layouts, such as tiled or interleaved memory channels, to ensure coalesced loads into shared memory or register files. When an unsupported operator sequence blocks the fusions of section 10.4.1, the memory-bandwidth bottleneck remains intact. Whether integrated into a framework or supplied separately, the compiler and runtime determine which graph-level opportunities become an efficient machine execution plan. Whether that plan delivers the savings computed in the earlier sections is a question only measurement on the target hardware can answer.

10.6 Measuring Compression Gains

Shrinking a model's weights by $4\times$ with INT8 quantization rarely cuts end-to-end latency by $4\times$, because cache residency, memory bus contention, and kernel launch overhead absorb much of the theoretical gain. Every saving computed so far in this chapter is a paper bound, and only a measurement on the target device turns a bound into a result: profiling on the deployment hardware identifies which resource binds each layer, fixes an honest baseline, and separates model execution time from runtime and pipeline overhead.

10.6.1 Profiling and opportunity analysis

Compressing the layers with the most parameters or FLOPs can leave wall-clock latency barely changed when low-intensity operators—such as layer normalization or elementwise activations—contribute almost no FLOPs yet consume a large share of execution time by streaming whole activation tensors across memory. The top-down profiling method of section 8.5 tells compression where to act, and two of its measurements decide the technique. Static footprint (weight tensors and persistent buffers) decides whether parameters fit in fast memory or device DRAM without spilling across PCIe, while dynamic allocation (activation tensors and KV caches) sets peak residency and so bounds batch size and serving concurrency. Alongside memory residency, each operator's arithmetic intensity ($I = O/D_{\text{vol}}$) shows whether removing FLOPs or removing bytes will actually shorten it.

A profile of a Vision Transformer (ViT) on an edge accelerator illustrates this operational heterogeneity. Per token and layer, the multilayer perceptron (MLP) block costs about $8d^2$ multiply-accumulates against $4d^2$ for the query, key, value, and output projections. In a ViT-Base-sized model the MLP blocks therefore carry nearly two-thirds of FLOPs and the projections just under one-third, with the attention score and weighting products adding only a few percent at standard image resolution. Layer normalization inverts the picture, contributing almost no FLOPs yet can claim a visible share of wall-clock latency, because it streams whole activation tensors with little arithmetic per byte. The camera pipeline's MobileNetV2 splits the same way in convolutional form. Its 1×1 expansion and projection layers carry most of the multiply-accumulates (Sandler et al. 2018), while its depthwise layers, like layer normalization, do little arithmetic per byte moved and take a larger share of time than of work. Profiling isolates the governing physical bottleneck for each component, dictating targeted optimizations rather than uniform compression: structured pruning

of MLP hidden units relieves the compute-dominant blocks, kernel fusion eliminates intermediate global memory round-trips for memory-bound normalization layers, and INT8 quantization shrinks the static footprint that the MLP and projection weights dominate.

Non-model work dominates latency, so compression caps speedup at 1.25×.

Translating layer-level profiling metrics into end-to-end system speedup requires accounting for the complete serving pipeline. In production serving systems, model execution frequently represents only a fraction of total latency, with the remainder consumed by image decoding, tokenization, RPC deserialization, or network transfer. Optimizing the model in isolation encounters an Amdahl ceiling whenever non-model stages dominate the latency budget, a ceiling that section 12.3.4 measures end to end.

> **Systems Perspective 10.4: FLOPs reduction is not proportional speedup**
>
> Reducing a model's FLOPs by 50 percent does not guarantee 50 percent latency reduction. Memory-bound operations see little benefit from arithmetic reduction because data movement, not multiplication, sets their time. Amdahl's law (principle 8) applies at the system level. If model inference accounts for only 20 percent of end-to-end latency (with the remaining 80 percent spent on data loading, preprocessing, and postprocessing), then even perfect model optimization yields at most 1.25× overall speedup. Tokenization and network transfer can occupy the non-model fraction in language-model serving; image decoding, resizing, and normalization can do the same in vision pipelines. Profile the complete path on target hardware before estimating optimization benefits.

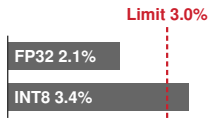
Complementing latency and throughput profiles, layer-wise sensitivity analysis quantifies how individual layers tolerate perturbation. In deep networks, different layers tolerate very different amounts of precision reduction or weight removal. Profiling accuracy degradation while systematically perturbing one layer at a time, with quantization noise or weight removal, identifies which components require high-precision representations and which can absorb aggressive 4-bit quantization or structured pruning without compromising task accuracy. Once opportunity and sensitivity profiles have guided a compression pass, the resulting candidate must be evaluated across both statistical quality and physical execution metrics.

10.6.2 Measuring optimization effectiveness

Judging a compressed model by a single scalar metric—such as top-1 accuracy or parameter count—can approve a candidate whose batch-one latency barely budges under kernel-launch overhead or whose confidence calibration drifts past safety limits on rare subgroups. Evaluating compression requires balancing statistical quality against physical execution costs across the Data, Algorithm, and Machine (D·A·M) axes. Quality baselines must capture aggregate accuracy, confidence calibration (verifying that predicted probabilities reflect empirical correctness), and performance across underrepresented input slices. Simultaneously, efficiency baselines must record peak memory residency, latency distributions (including p99 tail latency), memory bus saturation, and per-inference energy.

ResNet-50, the camera pipeline's teacher and the book's compute-bound lighthouse, shows how one compression decision ripples across physical and statistical dimensions. Quantizing it from FP32 to INT8 on the reference H100 changes latency, throughput, artifact size, energy, accuracy, and confidence calibration at once, and a deployment profile must report all six rather than an isolated accuracy number (table 10.13).

Table 10.13: ResNet-50 INT8 Deployment Profile on the Reference H100: Latency and FP32 throughput come from the modeled H100 engine profile, INT8 throughput is the MLPerf Inference measurement, and the accuracy and calibration values are illustrative. A real profile must measure all six on the target system.



Metric	FP32 baseline	INT8 result	Deployment reading
Top-1 accuracy	76.1%	75.8% (0.3 pp drop)	Aggregate accuracy mostly holds, but subgroup checks still matter.
Batch-one latency	0.38 ms	0.30 ms (1.3×)	Fixed per-request costs dilute the gain for one image.

Metric	FP32 baseline	INT8 result	Deployment reading
Large-batch throughput	15,200 img/s	89,470 img/s (5.9×)	INT8 Tensor Cores pay off once arithmetic dominates.
Model size	102.4 MB	25.6 MB (4×)	The artifact becomes easier to cache, transmit, and deploy on edge.
Energy/inference	46.1 mJ	7.8 mJ (5.9×)	Assumes full board power at large batch; measure it directly.
Confidence-calibration error	2.1%	3.4%	Confidence calibration can drift even when accuracy looks acceptable.

Converting weights to INT8 shrinks the artifact by 4× (from 102.4 MB to 25.6 MB), but the speed gain depends on how the model is served. At batch one, a compiled INT8 engine is only 1.3× faster than its FP32 counterpart (0.30 ms against 0.38 ms), because launch overhead, per-kernel floors, and the weight read form most of a single image's time and shrink little with precision. At large batch the arithmetic dominates, and INT8 throughput of 89,470 img/s, as MLPerf Inference measured it, is 5.9× the modeled FP32 rate, a ratio between a measured rate and a modeled one from different software stacks. Energy per image follows throughput only if the board draws its full 700 W in both precisions; the 5.9× energy figure is that assumption, not a separate measurement. The runtime comparison in section 13.6 derives both latency figures from the same engine profile. While aggregate top-1 accuracy drops by only 0.3 percentage points (from 76.1 percent to 75.8 percent), confidence-calibration error (the gap between predicted probability and observed accuracy, distinct from the range calibration of quantization) increases from 2.1 percent to 3.4 percent. Post-quantization probability distributions drift, which can compromise safety-critical confidence thresholds even when top-1 classification accuracy appears preserved. Production deployment decisions require corresponding quality, latency, and energy measurements using a supported execution path on target hardware.

Suppose the application requires at least 75.5 percent top-1 accuracy and no more than 3.0 percent confidence-calibration error, measured with the same validation data and calibration metric as the profile. The INT8 candidate passes the accuracy limit but fails the calibration limit. Its modeled resource savings therefore do not justify acceptance. Retain the baseline for comparison, try confidence recalibration or a less aggressive quantization configuration, and repeat the quality checks before validating resource gains on the target runtime.

A deployment profile shows whether a compressed model meets its limits but not why it misses one. Explaining a failure such as the calibration miss above requires looking inside the model, at where clipping, rounding, and pruning masks have changed its internal values.

The INT8 candidate fails the calibration limit despite holding accuracy.

10.6.3 Diagnostic visualization

When an exported model fails a quality or latency gate—like the ResNet-50 candidate whose confidence calibration drifted to 3.4 percent—summary metrics cannot tell whether the culprit is a single activation channel saturating its clipping bounds, a pruning mask erasing an active feature detector, or an unsupported operator falling back to floating point. Diagnostic inspection looks inside the compressed graph to verify numerical integrity after framework APIs calibrate the model and hardware optimization libraries lower it to the execution substrate (section 10.5.4). While system-scale validation and artifact monitoring belong to downstream deployment infrastructure, the immediate diagnostic task is verifying that quantization clipping, pruning masks, or sparsity patterns have not perturbed internal feature distributions beyond acceptable task error tolerances.

Quantization error histograms show whether error is broadly distributed or concentrated in outliers. Activation visualizations help detect clipping, overflow, and saturation. In a grid of first-layer convolutional filters, the top rows show distinct edge, color, and frequency detectors, while the bottom row shows uniform-looking filters that appear redundant at a glance but require measured activation tracing before they can be pruned safely (figure 10.31). Framework observers and debuggers can expose quantization ranges and tensor error, while compiler or runtime inspectors can show the graph and kernels that the exported model actually executes.

Sparsity diagnostics identify candidate layers for sparse execution. The layer-wise schematic in figure 10.32 spans convolutional, fully connected, and transformer layer types and is not a

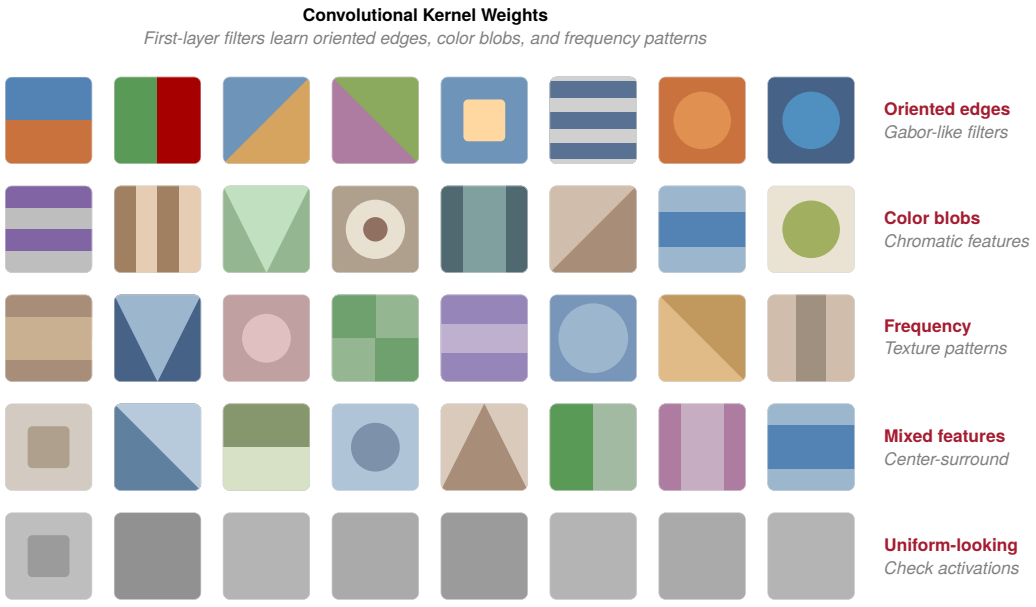


Figure 10.31: First-Layer Convolutional Filter Patterns: An 8×5 grid groups stylized kernels into edge, color, frequency, mixed, and uniform-looking patterns. Appearance alone does not establish inactivity; pruning requires measured activation or importance evidence in addition to low weight variance.

measurement from one model or pruning run. Its rows illustrate how a pruning policy might distribute zeros unevenly across architectural blocks. A real diagnostic would pair each layer's density with its storage format and target-kernel profile to determine whether those zeros reduce memory traffic or execution time. Graph viewers and sparsity inspection tools help locate the affected tensors; profiling establishes the deployment benefit.

The diagnostic value is the nonuniformity, not the exact shade of any one cell. Greater sparsity in later layers shows where the policy removed weights; it does not establish that those representations were redundant. Compare task quality after removing weights from a candidate layer and after recovery training, including performance on important input slices. Early-layer sparsity warrants the same checks because damaging feature extraction can propagate through subsequent layers. Only those comparisons can establish whether the observed removal pattern preserves required behavior. Each density also has a machine reading, because a layer whose zeros never cross the storage and execution break-even of section 10.4.2.2 saves neither bytes nor time, however dark its tile.

Checkpoint 10.5: From compression claim to deployment evidence

A compressed artifact must pass the same application requirements as its baseline.

- ☐ **Footprint and feasibility**: distinguish raw weight size from peak runtime memory, including activations, caches, metadata, and workspace.
- ☐ **Modeled and measured gains**: identify which claims in the ResNet-50 profile require target-hardware measurements, and explain why fewer FLOPs or bytes alone cannot establish latency.
- ☐ **Quality and operating limits**: specify the accuracy, confidence calibration, tail-latency, sustained-power, and energy checks needed before accepting a candidate.

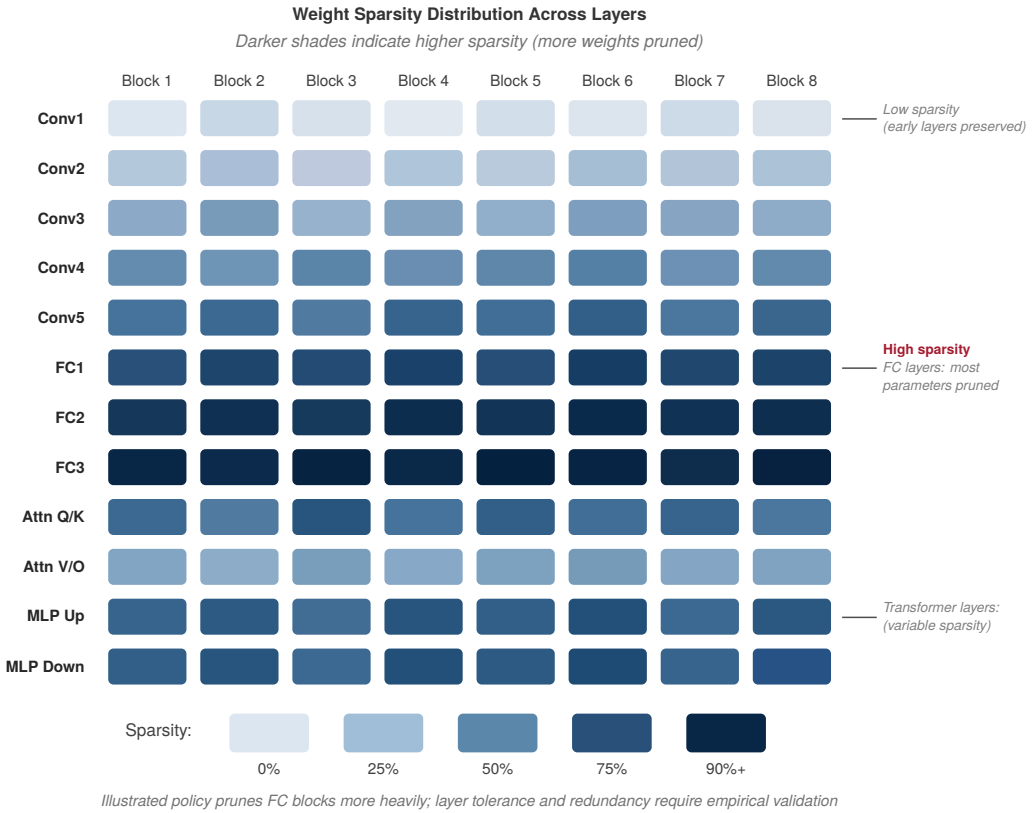

Figure 10.32: Illustrative Layer-Wise Sparsity Distribution: This schematic combines several layer types to illustrate non-uniform parameter removal. Darker tiles indicate more zero-valued weights; their shade establishes neither task redundancy nor a runtime benefit.

Implementation tools make compression repeatable, but they do not make the trade-offs disappear. Pruning alters model structure or parameter count, quantization changes numerical representation, and distillation trains the smaller artifact against a teacher's output distribution, and composing them unmeasured can produce latency regressions or silent accuracy collapse on target hardware. The methodology that makes a measured gain trustworthy, from benchmark design to the statistics of repeated runs, is developed in chapter 12. The fallacies that follow collect the places where intuitive compression assumptions fail.

10.7 Fallacies and Pitfalls

A team deploying GPT-2 XL on a phone might find that an uncalibrated 4-bit quantization cuts weight memory by 4× while generation quality collapses. Conversely, a vision team might achieve 70 percent weight sparsity through unstructured pruning only to find inference latency increases because commodity GPU kernels cannot execute irregular sparse indexing. Model compression presents numerous counterintuitive traps where theoretical parameter or FLOP reductions fail to produce wall-clock speedups. The following fallacies and pitfalls examine where standard engineering assumptions break down across the model-runtime interface.

Fallacy: *Optimization techniques can be applied independently without considering their interactions.*

Engineers assume optimization strategies compose additively: 50 percent pruning plus 4× quantization yields combined benefits. In reality, techniques interact nonlinearly and compound losses. In a representative BERT-style compression scenario, pruning to 70 percent sparsity may preserve most task performance, but applying INT8 quantization afterward can lose more accuracy than QAT on the pruned model. Knowledge distillation from heavily pruned teachers can also transfer

degenerate attention patterns that reduce student accuracy compared with distilling from dense teachers. As section 10.5.3 demonstrates, successful optimization requires coordinated application where techniques are sequenced together.

Pitfall: *Assuming theoretical metrics or compression ratios translate directly into proportional deployment speedup.*

Teams frequently reduce FLOPs or parameter counts substantially without realizing proportional latency gains on physical hardware. In one representative trace, a pruned model with 40 percent fewer parameters achieves only a 12 percent latency reduction because irregular sparsity prevents efficient execution. Similarly, reducing a transformer from 440 MB to 110 MB through INT8 quantization yields a 4× raw weight-payload reduction, yet format conversion and scalar fallback on hardware without a native low-precision datapath erode the latency gain. In the chapter's illustrative composed pipeline combining 50 percent structured pruning and INT8 quantization, the realized speedup reaches only 1.5× against an 8× paper target. Measure wall-clock latency on the target execution units rather than extrapolating from nominal compression ratios.

Fallacy: *Aggressive quantization maintains model performance with minimal accuracy loss.*

Engineers assume quantization error scales uniformly with bit width. In practice, precision reduction can show threshold effects, and the threshold depends on the model, layer, quantizer, calibration, and training method. The ResNet and BERT values in this chapter are illustrative rather than universal degradation bands. Even operations such as LayerNorm and Softmax can be implemented with integer approximations, so they do not universally require FP16; whether a low-precision implementation preserves task quality must be measured. As section 10.3.3 demonstrates, mixed-precision approaches can retain higher precision where uniform quantization fails.

Pitfall: *Defaulting to FP32 everywhere to avoid quantization risk.*

FP32 uses twice the raw storage and bandwidth of BF16, but lower-precision execution does not automatically preserve convergence or accuracy. Mixed-precision training often retains FP32 accumulators or master weights and may require loss scaling, while inference precision must be validated per model and operator. The right question is what lowest precision preserves quality on the evaluation distribution and maps efficiently to the target hardware.

Fallacy: *Post-training optimization is always enough.*

Teams often begin with post-training quantization (PTQ) because it avoids retraining, and move to quantization-aware training (QAT) only when the PTQ artifact misses its thresholds. Post-training pruning and post-hoc distillation can likewise underperform training-aware schedules at aggressive sparsity or bit width. As detailed in section 10.3.3, the production threshold, not a presumption that either path is universally superior, governs the decision.

Fallacy: *Sparse matrix representations always save memory and accelerate inference.*

Sparse formats introduce coordinate metadata that erodes storage savings at moderate densities, as the 16-bit case of section 10.4.2.2 showed; 32-bit indices make the penalty larger. To represent n_{nz} nonzero values across n_{rows} rows, a coordinate list (COO) stores explicit coordinate tuples `(row_idx, col_idx, value)`. For 32-bit floats and 32-bit integer indices, each nonzero element consumes 12 bytes (3× a dense 4-byte FP32 entry), requiring greater than 66.7 percent sparsity just to break even on memory footprint. Compressed sparse row (CSR) eliminates redundant row coordinates by storing three arrays: `values` ($n_{\text{nz}} \times 4$ B), `col_indices` ($n_{\text{nz}} \times 4$ B), and `row_pointers` ($(n_{\text{rows}} + 1) \times 4$ B). Each nonzero entry costs 8 bytes (2× a dense FP32 entry), requiring over 50 percent sparsity before the sparse structure consumes less memory than the original dense tensor; below 50 percent sparsity, CSR metadata expands the model's memory footprint.

Execution faces similar break-even constraints. Converting tensors to sparse storage as soon as pruning creates zeros degrades latency if metadata decoding, irregular gather operations, and poor cache locality outweigh the saved arithmetic. No universal sparsity threshold exists, because tensor dimensions, sparse format, runtime kernel, batch size, and hardware architecture jointly govern whether sparse execution outperforms dense execution. Specialized formats such as 2:4 structured sparsity eliminate index arrays in favor of fixed 2-bit multiplexer metadata, providing an accelerator

datapath that nearly halves weight traffic with minimal indexing overhead (section 10.2.1.3). Production workflows must therefore measure realized density and commit to a sparse representation only after verifying that the operational break-even threshold has been crossed on target hardware.

10.8 Summary

Model compression fits a trained model inside a deployment budget by working three tiers of one stack, the descent the chapter map laid out at the start (table 10.2). Structural optimization changes what the model computes, precision changes how each value is stored, and hardware implementation decides how efficiently the remaining operations execute. The running cases showed each tier where it matters most. The camera pipeline's MobileNetV2 spends its frame budget on arithmetic, so channel pruning, distillation from a ResNet-50 teacher, and an INT8 path onto the phone's integer accelerator are its levers. GPT-2 XL decoding spends its token on bytes, so INT4 weights raise its token rate by 3.1× on the same phone, and only when dequantization is fused into the matrix multiplication. The tiers can compound, but their gains do not multiply automatically. Pruning, distillation, and quantization together produce the illustrative pipeline's 16× footprint reduction from 440 MB to 28 MB; metadata, unsupported operators, and hardware mapping determine the realized deployment gain. A parameter reduction approaches the same latency reduction only when the affected work is on the critical path and the runtime can exploit the new representation. Profile on target hardware, not paper metrics.

Data selection and model compression divide the efficiency work along the D·A·M axes. Data selection acts on the Data axis and lowers the cost of producing a model by spending compute only on examples that carry signal. Compression acts where Algorithm meets Machine and lowers the cost of running the model by reshaping its structure and numerics for the target. Whether those deployment savings become real speedups still depends on the hardware and runtime that execute the compressed model. The need for them does not fade, because the bitter lesson keeps growing the models that win benchmarks while the envelopes of phones and microcontrollers stay fixed.

The counting rules developed across the chapter fit on one page (table 10.14). Together they let an engineer bound what a compression plan can save before a model is profiled on its target.

Table 10.14: Key Equations: The chapter's counting rules in the notation of the sections that derive them. Each gives a paper bound; the hardware tier explains why a measured gain can fall short of it.

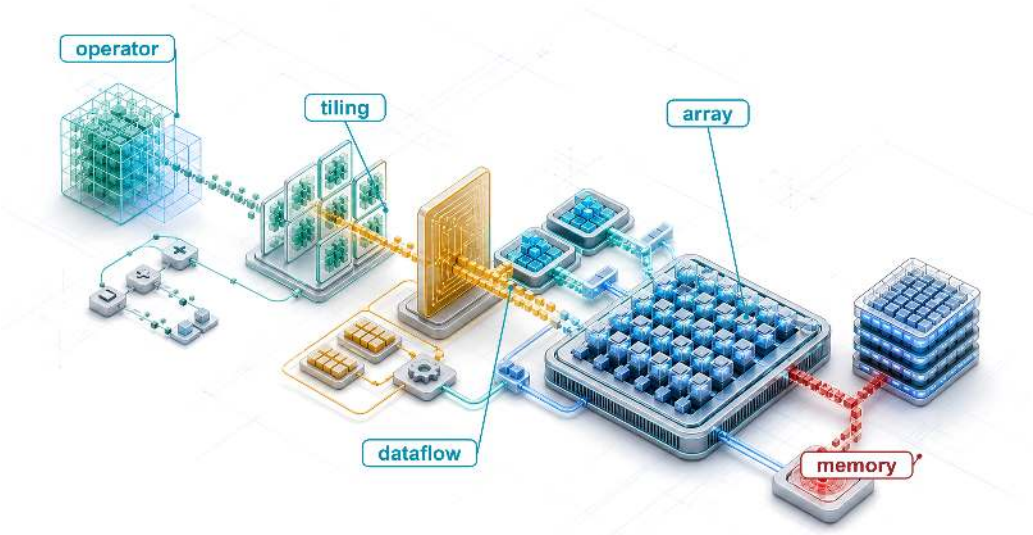
Quantity	Formula	Where derived
Nominal sparsity	$\rho_{\text{sparse}} = \frac{\|\mathbf{1}_{\{(\mathbf{W}_{\text{sparse}})_{ij}=0\}}\|_0}{m \times n}$	section 10.4.2
Low-rank storage	$mk + kn$ values in place of mn	section 10.2.2.1
Depthwise separable cost	$1/d_{\text{out}} + 1/K^2$ of a standard convolution's arithmetic	section 10.2.4.3
Convolutional model scaling	$O \propto N_L \cdot w_{\text{mult}}^2 \cdot r^2$	section 10.2.4.2
Affine scale and zero-point	$s = \frac{\beta - \alpha}{2^b - 1}$, $z = \text{round}\left(\frac{-\alpha}{s}\right)$	equation 10.1, equation 10.2
Dequantization	$x = s(x_q - z)$	equation 10.4
Requantization scale	$s_{\text{eff}} = \frac{s_W \cdot s_X}{s_Y}$	section 10.3.3.1
Fused chain traffic	$2\,n_{\text{ops}} M_{\text{tensor}}$ bytes unfused; $2M_{\text{tensor}}$ fused	section 10.4.1
Bandwidth-bound decode time	D_{vol}/BW per token, where D_{vol} counts the weight bytes plus the KV-cache bytes	section 10.3.5

Key Takeaways: From benchmark winner to production model

- **Compression spends surplus capacity**: Production models trade unused parameters, precision, and capacity for latency, memory, power, or cost limits the deployment cannot violate. The target is an artifact that meets the deployment objective and all required quality and resource constraints.

- **Savings multiply only when aligned**: Structural pruning, distillation, quantization, and architecture changes can compound raw footprint reductions, as the modeled BERT mobile pipeline's 16× ratio illustrates. The gain becomes real only when task quality holds and the resulting operators match the target runtime and accelerator.
- **Precision is a deployment decision**: Where the target runtime supports it, INT8 post-training quantization is a useful first experiment because it reduces raw FP32 weight payload by 4× without retraining. QAT, distillation, or mixed precision become candidates when range calibration or layer sensitivity exposes unacceptable error.
- **Hardware decides what a saving is worth**: Unstructured sparsity and theoretical FLOP cuts do not imply latency gains unless kernels and memory layouts can exploit them. The chapter's hypothetical 8× paper target vs. 1.5× realized outcome illustrates why target-hardware profiling is mandatory.
- **End-to-end latency caps model wins**: Compression reduces end-to-end latency only when it accelerates the critical path; capacity or energy savings can remain valuable elsewhere. When inference is 20 percent of total request latency, Amdahl's law (principle 8) caps even perfect model acceleration at 1.25×, so preprocessing, dispatch, and data movement may be the true optimization target.

The techniques in this chapter differ in almost every detail, yet one rule runs beneath all of them. Each obtains a smaller, faster, or cooler model by giving up something else. Pruning gives up capacity, quantization gives up numerical precision, and distillation consumes training compute. Where the model holds no surplus to give up, task quality degrades instead. Apart from removing genuinely avoidable work, such as an unfused intermediate round-trip, compression does not make the work disappear; it moves cost or risk from one part of the system to another, and the hardware decides how much each move saves. A technique that helps on a phone can therefore be worthless on a data-center GPU. This is the conservation-of-complexity heuristic at the level of a single model. A production artifact is a model whose structure, representation, and execution path have been engineered together until they fit the silicon and application constraints that govern deployment.



What's Next: From math to physics

These optimization techniques compress the model's logic, reducing the work the algorithm asks the machine to perform. Whether less work becomes less time depends on the silicon that executes it, and this chapter repeatedly ran into the memory wall, the regime where fetching a weight costs more than computing with it. Chapter 11 starts from that wall and from the ResNet-50 INT8 profile that closed this chapter, and explains how GPUs, TPUs, and NPUs organize tensor units, systolic arrays, and tiered SRAM/HBM hierarchies to keep arithmetic fed, which is what decides whether a quantized or sparse representation actually runs faster.

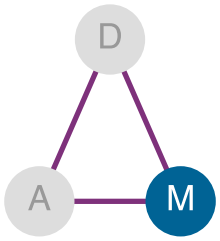
Purpose

Why does moving data cost more than computing it?



Arithmetic is inexpensive relative to data movement. In the time required to fetch a single scalar operand from off-chip DRAM, modern arithmetic units can execute dozens to hundreds of floating-point operations, and that DRAM access consumes on the order of a hundred times more energy than the computation itself. This fundamental imbalance, the memory wall, means specialized accelerators are not merely faster arithmetic engines. Rather, their microarchitectures are designed to stage, amortize, and hide data movement through wide spatial interconnects, deep on-chip memory hierarchies, and specialized execution pipelines. When general-purpose processor scaling faltered, hardware specialization enabled machine learning models to continue scaling by turning transistor budgets into high-throughput tensor datapaths. Delivered performance, however, depends on whether a model's tensor access patterns match the data paths of the underlying silicon. Hardware selection cannot be reduced to comparing peak FLOP/s: two accelerators with identical theoretical compute ratings often deliver radically different throughput on real workloads because one saturates its functional units while the other starves for data. A recommendation model dominated by sparse embedding lookups stresses memory bandwidth and interconnect latency, demanding a fundamentally different memory architecture than a dense transformer training run bounded by matrix multiply-accumulate throughput. If an operation is bandwidth bound, reducing theoretical operation count yields zero speedup because arithmetic is not the binding constraint. Matching workload characteristics to architectural dataflows determines whether an accelerator operates near its hardware ceiling or languishes at a fraction of its advertised peak. In D·A·M terms, the accelerator makes the machine constraint concrete, governing which algorithms and model architectures remain practical in production.

Learning Objectives

- Explain hardware acceleration as tensor-workload specialization and why Amdahl's law bounds its end-to-end speedup
- Compare Tensor Cores, systolic arrays, SIMD/SIMT units, and sparse execution for ML compute primitives
- Diagnose memory-wall bottlenecks using bandwidth, cache hierarchy, host-device transfer, and energy-movement costs
- Calculate arithmetic intensity and execution-path roofline ceilings, then use profiling to diagnose compute or memory limits
- Select dataflow, tiling, and mapping strategies that maximize reuse under memory-capacity constraints
- Analyze compiler and runtime optimizations that fuse kernels, plan memory, and schedule accelerators
- Evaluate accelerator choices across throughput, latency, power, cost, and deployment-context constraints

11.1 Anatomy of an Accelerator

Hardware acceleration turns on the machine axis.

Chapter 10 closed on a deployment profile for ResNet-50 quantized to INT8 (table 10.13): a model four times smaller whose large-batch throughput rises severalfold on the reference H100 while its batch-one latency barely moves. Data selection reduced the iron law's Data factor (Samples/Task) and compression reduced the Algorithm factor (FLOPs/Sample) and byte traffic (D_{vol}), but whether either saving reaches the wall clock is decided by the Machine factor (Seconds/FLOP). This chapter supplies the machine side of that profile. It explains why the same INT8 weights run faster on one execution path than on another, and why the hardware, not the model, determines how much of every compression saving survives execution. The explanation starts with the memory wall: arithmetic is cheap relative to data movement, so specialized hardware matters less because it raises compute throughput than because it organizes memory, dataflow, and parallelism so that its arithmetic units stay fed.

One workload runs through the chapter. ResNet-50 quantized to INT8 carries the book's compute-bound regime (table 1.4): its convolutions reuse each weight across many image positions, so on a data-center accelerator most of its time can go to arithmetic rather than to moving bytes. It reappears at every level of the machine, from the matrix units that execute its convolutions to the compiler that lowers its graph, and each time the question is what the INT8 path changes. GPT-2 XL decoding one token at a time supplies the single contrast. It carries the bandwidth-bound regime: every generated token streams all of the model's weights from memory for about two operations per parameter, so the machine that keeps ResNet-50 busy spends most of a decode step waiting for bytes. MobileNetV2, whose depthwise layers trade arithmetic for a small parameter footprint, and keyword spotting (KWS), the power-bound lighthouse, return where the chapter reaches phone-class and embedded chips. DLRM appears where its embedding lookups, the capacity-bound regime, break the regular access patterns that accelerators assume. The reference machine is the NVIDIA H100, the data-center accelerator this book uses for training and serving examples; its numbers are one generation's instance of limits that every generation obeys.

Definition 11.1: Hardware acceleration

Hardware acceleration is the practice of mapping work from general-purpose execution onto specialized processors or functional units optimized for a narrower operation class. For ML workloads, that specialization commonly trades some programmability for the compute density (R_{peak}) and performance-per-watt gains that regular tensor operations can exploit.

1. **Significance**: An H100 GPU delivers 989 TFLOP/s for dense FP16/BF16 matrix multiplication; against this chapter's illustrative 1–2 TFLOP/s reference-CPU baseline, this is a

490–990× gap. Its 80 billion transistors devote far more silicon to parallel arithmetic than to branch prediction, out-of-order scheduling, and large caches (Choquette 2023).

2. **Distinction**: A general-purpose CPU is designed for flexible execution, low-latency control, and varied workloads. An accelerator instead concentrates resources on a narrower operation class, so it achieves its gains only when the workload exposes the supported operations and enough parallel work to keep its arithmetic units busy.
3. **Common pitfall**: A frequent misconception is that an accelerator's advertised peak throughput is the throughput a workload receives. Delivered performance is bounded above by the lower of the compute ceiling and what memory bandwidth can feed (the roofline constraint, developed later in this chapter), so a low-arithmetic-intensity kernel can sit at a small fraction of peak FLOP/s no matter how fast the silicon is rated, because it starves for data rather than for arithmetic.

The anatomy of an accelerator is the arrangement of parts that every machine learning accelerator shares: arithmetic units built for tensor operations, on-chip memory that holds operands next to those units, a wide path to off-chip memory, and a host interface through which work arrives. Every inference and every training step on such a machine is a stream of operand movements that ends in multiply-accumulate operations, and the anatomy decides how far each operand travels before it is used. A matrix unit that can retire thousands of multiply-accumulates per cycle sits idle whenever its next operands are still in flight, and an off-chip access can take many processor cycles and cost orders of magnitude more energy than the low-precision operation it feeds. The arithmetic units are the easy part of the design; the rest of the anatomy exists to keep them fed.

The definition becomes concrete in the generic chip of figure 11.1, which serves as this chapter's map. External high-bandwidth memory (HBM) feeds shared on-chip storage (an L2 cache), which distributes operands into rows of processing elements, each equipped with a private scratchpad or cache, a matrix unit, a vector unit, and a special function unit. A host interface connects the chip to the CPU that issues its work.

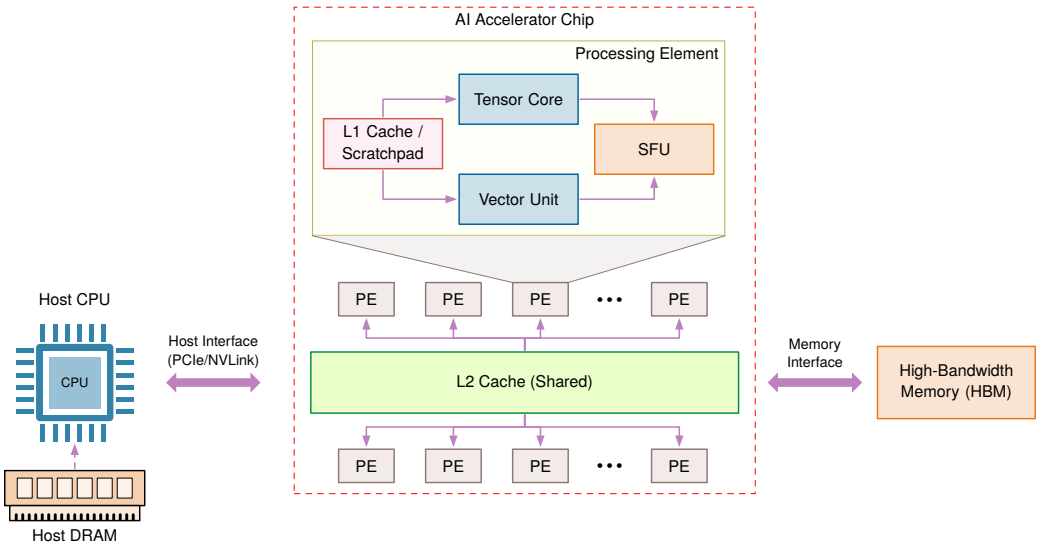


Figure 11.1: Anatomy of a Modern AI Accelerator: This generic schematic combines common components rather than depicting one product. A host interface connects the accelerator to a CPU, a high-bandwidth device-memory interface feeds shared on-chip storage, and processing elements contain matrix, vector, and special-function units with local memory. Real accelerators differ in which units they provide and whether storage is hardware-managed cache or software-managed scratchpad.

Within each processing element, specialized units partition execution across distinct mathematical primitives: dedicated matrix units (Tensor Cores) execute dense matrix multiplication, vector units

evaluate element-wise arithmetic, and special function units (SFUs) approximate transcendental operations such as activations and exponentials. Their number, grouping, and names vary by vendor; some designs arrange them into an explicit 2D systolic grid, and others distribute matrix engines among wide parallel cores.

The memory hierarchy amortizes the cost of data transport across tiers. High-bandwidth memory provides off-chip capacity and throughput, while shared on-chip storage and per-element caches or scratchpads cut off-chip traffic. Because moving a tensor tile across the package boundary costs orders of magnitude more energy than keeping it on chip, compilers and kernels must coordinate tile capacity, reuse, and prefetching to keep operands staged locally; more HBM bandwidth raises the off-chip ceiling, but without local reuse the execution units still stall. The system assumptions appendix (Appendix E) collects reference specifications for the accelerators this book uses, including the H100.

The host interface links the accelerator to the host CPU, which coordinates execution graphs, asynchronous I/O, and fallback operations while the accelerator executes dispatched kernels. Direct-memory-access engines can overlap host-device transfers with execution, but an operator unsupported by the accelerator backend may require a CPU round-trip. An operator outside the matrix-unit instruction set may instead use vector or other device kernels. These execution boundaries help set the effective speedup envelope. Kernel execution time matters little if transfers, launches, and synchronization dominate end-to-end latency. The three parts of the figure (the processing elements, the memory tiers, and the host link) are the parts this chapter takes apart in turn.

The anatomy embodies the chapter's central engineering trade-off. General-purpose processors allocate silicon area to complex control logic, speculative execution, branch prediction, and multi-level cache hierarchies to handle arbitrary control flow. An accelerator redirects that transistor budget toward dense arithmetic arrays, dedicated register files, and high-bandwidth memory paths tailored to a narrower workload class. When the software path exposes sufficient tensor parallelism, this specialization yields order-of-magnitude improvements in energy efficiency and throughput per watt. Silicon built for a narrow class of dense tensor operations pays off only because, as the bitter lesson predicts, the general methods that win by exploiting computation keep reducing to those same operations at ever larger scale. The dependence also runs the other way, because scale keeps winning only while accelerators keep lowering the time and energy of each additional operation, so the hardware this chapter studies is part of what sustains the bitter lesson itself.

↩ The bitter lesson, the observation that general methods exploiting computation win as computation grows, is established in section 1.4.

Hardware alone cannot achieve these gains. Algorithms must structure operations to expose data reuse and regular memory access, while silicon architectures must allocate physical units to the mathematical primitives and numeric precisions that algorithms actually execute. That mutual dependence motivates a complementary principle: hardware-software co-design.

Definition 11.2: Hardware-software co-design

Hardware-Software Co-design is an ML accelerator development method that crosses conventional abstraction boundaries, allowing algorithm constraints to inform silicon design and hardware capabilities to shape algorithm formulation.

1. **Significance**: On a supported tensor-core path, 8-bit integer (INT8) quantization can deliver multi-fold throughput gains because hardware executes lower-precision operations more densely and moves fewer bytes than an FP32 path; the exact gain depends on the architecture and workload (NVIDIA Corporation 2020a; Dally et al. 2021; Dally 2023).
2. **Distinction**: Unlike layered abstraction (where software calls a hardware API without knowing the silicon details), co-design exposes hardware constraints directly to algorithm and compiler authors: data alignment requirements, precision formats, and memory access patterns all become visible inputs to global cross-layer optimization.
3. **Common pitfall**: A frequent misconception is that co-design is a one-time hardware design choice. In practice, the supported features continue to evolve: NVIDIA Tensor Cores began with FP16 matrix multiplication, later generations added TF32 and broader integer support, and Ampere added acceleration for 2:4 structured sparsity (NVIDIA 2017; NVIDIA Corporation 2020a).

Co-design explains why model compression techniques deliver real speedups. Quantization shows why converting FP32 to INT8 accelerates execution on supported hardware: reduced precision cuts memory traffic, while specialized arithmetic units execute more low-precision operations per cycle than FP32 equivalents (NVIDIA Corporation 2020a). Structured pruning improves performance when it produces smaller dense shapes or a sparsity pattern recognized by silicon, whereas arbitrary unstructured sparsity incurs metadata handling and non-coalesced memory accesses that often erase theoretical gains. Evaluating accelerator performance requires tracing this path from workload to silicon: compute primitives, memory hierarchies, roofline diagnosis, mapping and dataflow, and compiler scheduling. The recurring question is why algorithmic improvements frequently fail to deliver proportional end-to-end speedups. Amdahl's law (principle 8) already answered it for model-side optimizations, since whatever an optimization leaves untouched caps the overall gain. The same bound governs hardware. The theorem below applies the principle to an accelerator, and the only new quantity is the gain, which becomes the accelerator's path gain G_{accel}.

↩ Quantization and its effect on weight payload, memory traffic, and compute cost are established in section 10.3.

Theorem 11.1: The fundamental limit of acceleration (Amdahl's law)

Hardware acceleration *does not speed up the entire system*; it speeds only the baseline-time fraction using the accelerated path. For that fraction f_{parallel} and path gain G_{accel}, **Amdahl's law** (Amdahl 1967) gives the bound in equation 11.1.

$$\text{Speedup} = \frac{1}{(1 - f_{\text{parallel}}) + \frac{f_{\text{parallel}}}{G_{\text{accel}}}} \tag{11.1}$$

- **Accelerated fraction** (f_{parallel}): Share of baseline time receiving the stated gain, often in matrix multiplication or another supported kernel.
- **Accelerator gain** (G_{accel}): The raw speed advantage of the GPU or Tensor Processing Unit (TPU) over the CPU for the accelerated portion of the workload.
- **Unaccelerated fraction** ($1 - f_{\text{parallel}}$): Work outside the chosen path, such as data loading, host overhead, unsupported operators, and kernel launch latency.

Pitfall: *Unaccelerated work caps total speedup.* If 10 percent of baseline time is unaffected ($f_{\text{parallel}} = 0.9$), even infinite path gain ($G_{\text{accel}} = \infty$) yields at most $10\times$ overall. Once the accelerated component is fast enough, unaffected work dominates.

Hardware acceleration targets specific terms in the iron law of ML systems, which decomposes end-to-end time into data movement (D_{vol}/BW), computation ($O/(R_{\text{peak}} \cdot \eta_{\text{hw}})$), and fixed latency ($L_{\text{lat}}$). While data selection reduced the number of samples processed (Samples/Task, shrinking both O and input traffic D_{vol}) and model compression reduced the operations and bytes per sample (FLOPs/Sample and weight traffic D_{vol}), hardware acceleration reduces the realized time per operation (Seconds/FLOP) by improving R_{peak}, η_{hw}, and BW. Which of these physical terms an upgrade actually improves determines its accelerated fraction under Amdahl's law.[1]

This dynamic explains why hardware upgrades frequently fail to produce proportional end-to-end speedups. Figure 11.2 maps system speedup across accelerator gain (G_{accel}) and accelerated fraction (f_{parallel}), charting where those returns diminish. Where the unaccelerated fraction $1 - f_{\text{parallel}}$ remains substantial, the white contour curves flatten horizontally into the unaccelerated-bound regime, bounding total speedup at the $1/(1 - f_{\text{parallel}})$ asymptote regardless of how far G_{accel} scales along the horizontal axis. Because f_{parallel} differs substantially across workload archetypes running on identical hardware, a workload's vertical position on this map determines whether an accelerator investment pays off or stalls on non-matrix operations.

[1] **Amdahl's law**: Maps onto the iron law only after the proposed change is specified. If a faster tensor unit reduces the computation term ($O/(R_{\text{peak}} \cdot \eta_{\text{hw}})$) but leaves data transfer and fixed latency unchanged, those unaffected terms bound total speedup. A different accelerator or memory system may improve bandwidth as well. The unaccelerated fraction is therefore defined by the intervention, not by a permanent classification of each term as serial.

↩ The decomposition of execution time into data, compute, and latency terms is established in section 1.7.

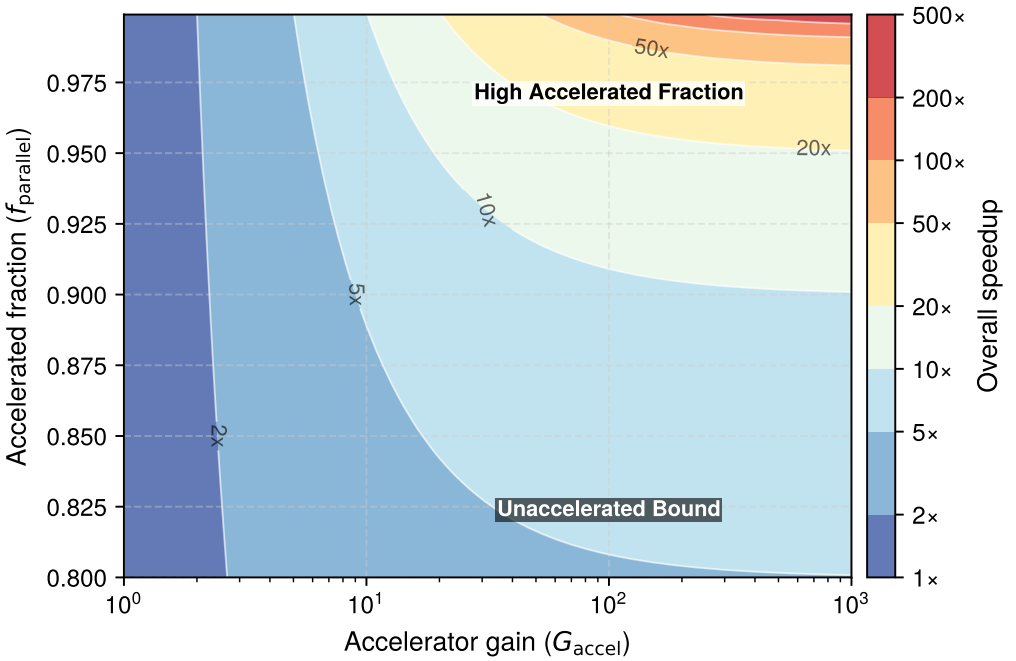

Figure 11.2: The Iron Law Heatmap: Total system speedup as a function of accelerator gain (G_{accel}) and accelerated fraction (f_{parallel}). High speedup appears only near the top-right corner, where both accelerator gain and accelerated fraction are high. At $f_{\text{parallel}} = 0.9$, for example, even an infinite gain on the accelerated path cannot exceed 10× end-to-end speedup. Contours span roughly 1×–200× speedup.

Checkpoint 11.1: The parallelism gate

These checks turn Amdahl's bound into a hardware-selection test.

Amdahl's reality

- ☐ **Serial bottlenecks**: use Amdahl's bound to explain why a 1,000× faster GPU may only speed up training by 5× when data loading is slow.
- ☐ **Speedup ceiling**: for $f_{\text{parallel}} = 0.95$ and $G_{\text{accel}} = 100$, estimate total speedup and compare it with the infinite-accelerator ceiling.
- ☐ **Workload variation**: what baseline profiling would establish the ResNet-50 and MobileNet accelerated fractions for a proposed hardware change? Explain how those fractions would determine which benefits more.

The serial bottleneck becomes concrete on real hardware, where the same accelerator that nears its parallel ceiling on one workload can stall on another. The comparison below uses the INT8 (8-bit integer) path, whose advantage over FP32 or FP16 has two sources. Each operand occupies a half or a quarter of the bytes, and an 8-bit multiplier occupies far less silicon area than a floating-point one, so the same die holds more multiply-accumulate (MAC) units. Evaluating an NVIDIA H100 on two workloads whose unaccelerated fractions differ illustrates how that fraction governs whether this peak INT8 advantage becomes realized speedup, and a second look at the decode case separates that limit from a different one, bandwidth-boundedness.

↪ Order-of-magnitude throughput, bandwidth, and capacity for each accelerator class are collected for reference in section D.3.3.

Lighthouse 11.1: An illustrative Amdahl budget on H100

Illustrative ResNet-50 inference on NVIDIA H100:

- Assume H100 provides $G_{\text{accel}} = 247\times$ on matrix multiplication relative to a server CPU without matrix extensions (1979 TOPS INT8 vs. ~8 TOPS) (Choquette 2023). The CPU's INT8 rate is a scenario assumption for this budget, not the FP32 peak of the reference CPU used elsewhere in the chapter.
- Assume $f_{\text{parallel}} = 0.95$: 95 percent of baseline time receives that gain, while 5 percent remains in data loading, preprocessing, postprocessing, and other work.

$$\text{Speedup} = \frac{1}{(1-0.95) + \frac{0.95}{247}} = \frac{1}{0.05 + 0.0038} \approx 18.6\times$$

The 247× path gain produces only 18.6× end-to-end speedup because the 5 percent unaffected fraction sets the ceiling.

Contrast with GPT-2 (autoregressive):

- For GPT-2 token generation, assume $f_{\text{parallel}} = 0.80$; the remaining 20 percent includes host overhead, sampling, and decoding work outside the accelerated matrix path.

$$\text{Speedup} = \frac{1}{(1-0.80) + \frac{0.80}{247}} = \frac{1}{0.20 + 0.0032} \approx 4.9\times$$

Less token-generation time receives the assumed gain, so even an infinite path gain yields at most $1/(1 - f_{\text{parallel}}) = 5\times$.

This calculation still overstates the decode path gain. Decode is bandwidth bound, so its accelerated path runs at the rate weights stream from memory rather than at the INT8 TOPS rate. The relevant ratio is the H100's memory bandwidth over the reference CPU socket's, 67× (a different path from the host-DRAM link used below), and INT8 helps decode on either machine by halving the bytes each weight occupies relative to FP16, not by multiplying faster. With that gain the bound falls from 4.9× to 4.7×, barely moving, because the unaccelerated fraction already dominates. Two distinct limits are at work. Bandwidth-boundedness shrinks G_{accel}, whereas the unaccelerated fraction caps what any G_{accel} can deliver. Serving optimizations attack both. Batching raises the work done per weight byte fetched, and speculative decoding, developed in chapter 13, lets a small draft model propose several tokens that the full model then verifies in one step, reducing the number of sequential full-model steps.

Whether an operation is limited by compute rate or by data movement dictates both hardware selection and software optimization. Under the arithmetic intensity law (principle 6), upgrading to an accelerator with $10\times$ higher peak compute yields negligible speedup if data delivery is the binding bottleneck. The roofline model, previewed in section 2.4.2, makes this diagnosis (Williams et al. 2009). It compares an operation's arithmetic intensity, the ratio of operations to bytes of memory traffic (FLOP/byte), with the hardware's ridge point. An operation below the ridge is bandwidth bound, the regime the roofline literature calls *memory bound*; an operation above it is compute bound. GPT-2 decode and ResNet-50 sit on opposite sides of that line, a difference the Amdahl budget above already registered in the decode path gain. Section 11.6 turns the classification into numbers once the compute units and memory systems that set the two ceilings have been examined.

The chapter builds the machine from the bottom up (table 11.1). Compute primitives and compute units supply the arithmetic side of the anatomy, ending with the INT8 and sparse paths that ResNet-50's profile depends on, and memory systems supply the other side, from registers to host memory. Performance bounds then combine the two into the roofline's ceilings and show which ResNet-50 layers clear the H100's ridge at FP16 and which fall below it at INT8; this is the chapter's midpoint, marked by a checkpoint. The second half asks how software reaches those ceilings, through hardware mapping and then the compilers and runtimes that make its choices automatically. Three shorter

↩ The arithmetic-intensity spectrum that separates the workload signatures of the major architectures is established in section 6.9.1.

sections widen the view to work beyond one accelerator, heterogeneous systems-on-chip, and the choice of an accelerator for a workload and a budget.

Table 11.1: Chapter Map: Each section supplies one part of the accelerator's anatomy and follows the chapter's INT8 ResNet-50 workload into it; the first five sections build the machine and its ceilings, and the remaining sections ask how software and system choices reach them.

Section	Part of the accelerator	Question it answers	ResNet-50 INT8 thread
Hardware Specialization	The whole chip	Why silicon is specialized for tensor work, and what a byte costs	Why its convolutions justify dedicated matrix silicon
Compute Primitives	Operations the hardware executes	Which operation classes earn dedicated units	Its convolutions lower to matrix multiplication
Compute Units	Vector, matrix, and special units	How each unit executes its primitive, including INT8 and sparse paths	The INT8 tensor path and its arithmetic floor
Memory Systems	Registers through host memory	Where operands live and what each tier costs	One activation tile's trip from HBM to registers
Performance Bounds	Compute and bandwidth ceilings	Which ceiling binds a given kernel	Which layers clear the FP16 and INT8 ridge points
Hardware Mapping	Placement, dataflow, and tiling	Which schedule captures the available reuse	Weight-stationary tiles and fused epilogues
Compilers and Runtimes	Software that lowers the graph	Who makes the mapping decisions, and when	Naive versus compiled latency
Beyond One Accelerator	Links between accelerators	What changes when one accelerator is not enough	Awareness only; ResNet-50 fits one accelerator
Heterogeneous SoC Design	Phone and embedded chips	How shared memory and power budgets change the mapping	MobileNetV2 and KWS take over
Choosing an Accelerator	The complete system	Which machine fits a workload, a latency target, and a budget	Energy and cost per request

Architectural design begins with the physical constraints that forced specialization: the breakdown of classical Dennard voltage scaling and the prohibitive energy cost of moving data across memory hierarchies. When general-purpose microarchitectures encountered these thermal and memory barriers, domain-specific hardware specialization emerged as the primary engineering path to sustain performance scaling.

11.2 Hardware Specialization

When Google deployed its first Tensor Processing Unit (TPUv1) into production data centers alongside NVIDIA K80 GPUs, the comparison showed a large efficiency gap (example 11.1). General-purpose processors dedicate substantial silicon area and power to instruction fetch, branch prediction, and cache coherence, machinery built for arbitrary code that yields poor arithmetic density on regular, dense linear algebra. When an algorithmic pattern becomes sufficiently dominant and structured, specialized hardware outperforms general-purpose platforms by replacing dynamic control machinery with dedicated arithmetic arrays and software-managed data movement.

Example 11.1: The TPUv1 vs. K80 efficiency gap

Scenario: In 2015, Google deployed its first Tensor Processing Unit (TPUv1) into production data centers, comparing its throughput and energy efficiency against general-purpose NVIDIA K80 GPUs (Jouppi et al. 2017).

Diagnosis: The K80 was a programmable GPU designed to support a broader mix of graphics and compute workloads. The TPUv1 domain-specific architecture (DSA) made a narrower, inference-focused design choice, pairing a large 8-bit systolic matrix unit with software-managed memory and simpler control.

Systems lesson: On the six Google inference workloads and contemporary CPU/GPU baselines evaluated in the TPU paper, tailoring silicon to the dominant matrix operations delivered

15–30× higher throughput and 30–80× better performance per watt (Jouppi et al. 2017). Those ratios describe the evaluated systems, not every workload.

In D·A·M terms, this efficiency gain stems from tailoring machine resources to algorithmic structure. The TPU[2] replaced hardware caches with software-managed buffers and routed data directly between neighboring arithmetic units, raising data reuse and cutting off-chip traffic. The cost is rigidity. Irregular memory access, dynamic control flow, or an unsupported numeric precision stalls a fixed-function data path and leaves expensive silicon idle. Every modern ML accelerator, from DianNao-class designs (Chen et al. 2014) to GPUs with Tensor Cores, strikes its own balance between specialization and flexibility, following a pattern that began decades before deep learning.

[2] **TPU (tensor processing unit)**: The first TPU made a deliberately narrow design choice, centering the design on a single 256×256 systolic array for 8-bit matrix multiplication and avoiding much of the control machinery required by a general-purpose core (Jouppi et al. 2017). That trade buys high compute density on dense matrix multiplication at the cost of flexibility. Irregular or branch-heavy code remains a poor fit, and compiler tiling, padding, and layer dimensions determine how fully the array is used.

11.2.1 Specialized computing

On a late-1970s microprocessor without floating-point hardware, a single 32-bit floating-point multiply required a software routine of dozens of integer shift-and-add instructions, turning scientific and signal-processing loops into an instruction-fetch bottleneck. Hardware specialization emerges whenever one computational pattern becomes a bottleneck that general-purpose processors cannot scale past. The Intel 8087 coprocessor (1980) executed floating-point operations directly in hardware (Palmer 1980), and the Intel 486DX (1989) later moved the floating-point unit onto the CPU die itself (Hennessy and Patterson 2017). That cycle—specializing silicon to relieve an acute bottleneck and integrating it once the capability proves universal—recurs in every later era, and so does its limit. Dedicated silicon removes the instruction overhead around a dominant operation, but the overall gain is bounded by how much of the run time that operation occupies.

Graphics supplied the second lesson, throughput over latency. A CPU spends most of its silicon on control logic, branch prediction, and caches that minimize the latency of a single instruction stream, which buys nothing when identical arithmetic must be applied to millions of independent pixels. GPUs reallocated that silicon to dense arrays of arithmetic units, and when unified shader architectures (2006) replaced separate vertex and pixel pipelines with arrays of identical programmable cores, the GPU became a general-purpose parallel processor (Owens et al. 2008). Digital signal processors such as Texas Instruments' TMS32010 (1983) contributed the memory organization. To meet hard real-time deadlines, they replaced caches, whose misses introduce variable latency, with software-managed scratchpads feeding dedicated MAC data paths (Lyons 2011). ML accelerators inherit both lessons.

The payoff arrived in 2012, when AlexNet (Krizhevsky et al. 2012) won the ImageNet competition after training on two consumer GPUs, the co-design result examined in section 1.3.3. Its dense 2D convolutions mapped directly onto thousands of GPU arithmetic lanes. In D·A·M terms, the machine constraint had dictated which algorithms were feasible, and aligning the algorithm's parallel structure with throughput-oriented hardware lifted it.

Across five eras from the 1980s to the 2020s (figure 11.3), specialization moved from discrete coprocessors such as the Intel 8087 FPU and TMS32010 DSP through graphics engines and dedicated media codecs to deep-learning tensor arrays and wafer-scale hardware. Each era's specialized unit targets a different bottleneck, yet the principles modern accelerators depend on (dedicating silicon to the dominant operation, staging operands in local memory, and minimizing off-chip data movement) were all in place before deep learning arrived.

11.2.2 Domain-specific architectures

A general-purpose CPU core spends most of its energy on instruction fetch and decode, branch prediction, speculative execution, and cache coherence rather than arithmetic: executing one scalar instruction can burn hundreds of picojoules of control overhead just to perform a floating-point operation that costs a few picojoules. For decades, Moore's law[3] (Moore 1998) and Dennard scaling (Dennard et al. 1974) hid that overhead by letting operating voltage fall as transistors shrank, so clock frequencies rose at constant power density. When leakage current halted voltage scaling in the mid-2000s, frequencies stalled against the power wall of section 2.2, and adding more general-purpose cores ran into Amdahl's law and **dark silicon**, the thermal limit under which only a fraction of a chip's transistors can switch at full speed simultaneously (Esmaeilzadeh et al. 2011). As Hennessy

[3] **Moore's law**: Gordon Moore's 1965 observation, revised in 1975, that the number of transistors per chip doubles roughly every two years (Moore 1998). It describes density, not performance; performance tracked density only while Dennard scaling held.

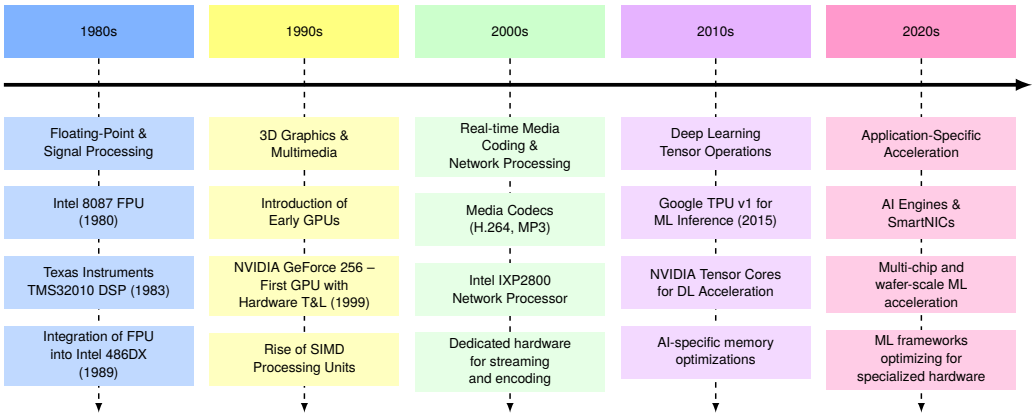

Figure 11.3: Hardware Specialization Timeline: Computing architectures evolve through recurring cycles of specialization and integration across five eras. Each era introduces domain-specific hardware to resolve an important memory or arithmetic bottleneck, from off-chip FPUs to GPUs, codecs, and TPU/Tensor Core array units. Many of these capabilities later appear alongside CPUs in broader systems, even when the specialized units remain distinct.

and Patterson (2019) argued in their Turing Lecture, the way past this wall is **domain-specific architectures (DSAs)**,[4] hardware that gives up general-purpose control machinery to spend its power budget directly on the operations a target domain performs.

A DSA wins by specializing every layer of the machine around the workload's invariants. Its data path is custom-built; matrix units in AI accelerators are often **systolic arrays**, grid-like networks of processing elements that compute and forward data directly to neighboring units, so a value fetched once from on-chip memory is reused across an entire row or column of multiply-accumulate operations instead of returning to a register file after each use. Its memory hierarchy follows the workload's reuse pattern, with software-managed scratchpads and prefetching replacing hardware-managed caches for deterministic tensor streams. Its instruction set encodes coarse tensor operations, so one macro-instruction configures thousands of arithmetic units. The same recipe produced smartphone video codecs, genomics aligners, and cryptographic application-specific integrated circuits (ASICs) wherever a kernel stabilized (Sullivan et al. 2012; Turakhia et al. 2018; Bedford Taylor 2017).

The pressure to specialize has grown because model demand has outrun single-device hardware scaling. The measured trend is the historical training-compute curve charted in chapter 1, whose fitted doubling time runs from 3.4 to about 6 months depending on the window, far faster than the roughly two-year doubling of transistor density (Amodei and Hernandez 2018a; Epoch AI 2024). No single chip closes a gap that compounds at that rate; parallelism and co-design must close the rest.

[4] **DSA (domain-specific architecture)**: A DSA that excels at dense matrix multiplication may perform worse than a CPU on irregular workloads such as graph traversal, so its gain on the target domain must justify the software, compiler, and ecosystem cost of a narrower machine (Hennessy and Patterson 2019, 2017).

↩ The measured growth of training compute and its doubling time are established in section 1.8.

11.2.3 Machine learning hardware specialization

When Google projected in 2013 that three minutes of daily voice search per user would require doubling its global CPU fleet just to run neural-network inference (example 11.2), the bottleneck was not a shortage of servers but a mismatch between neural networks and general-purpose cores. Many important neural-network workloads concentrate their work in regular tensor operations, such as dense matrix multiplications and convolutions, with substantial data parallelism, predictable reuse, and tolerance for reduced precision. Other ML operations remain irregular, bandwidth bound, or too small to fill a wide engine, so an accelerator need not speed up every part of a model; hardware built to exploit the regular portion forms the class of ML accelerators.

Example 11.2: The TPU capacity cliff

Scenario: Google projected in 2013 that user adoption of voice-search speech recognition (3 minutes/day/user) would require doubling global data center capacity to run CPU-based neural network inference (Jouppi et al. 2017).

Diagnosis: General-purpose CPU server capacity was economically unable to absorb the exponential growth in inference FLOPs, threatening a capital infrastructure bottleneck.

Systems lesson: Custom hardware acceleration becomes a candidate when workload volume makes the existing fleet uneconomical. Workload reuse, supported operations, development cost, and server total cost of ownership determine whether a custom ASIC is preferable to software changes or other hardware.

A general-purpose CPU is a poor host for this work. Take the chapter's reference CPU, the low end of the 1–2 TFLOP/s baseline used in the definition of hardware acceleration, and assume it sustains 5 percent–10 percent of its peak on a neural network workload. The upper endpoint then delivers approximately 100 GFLOP/s (billions of floating-point operations per second). CPUs optimize for single-thread performance and irregular memory access, whereas neural networks require massive parallelism and predictable data streams, and a single layer that touches gigabytes of parameters overwhelms cache hierarchies designed for smaller working sets.

The deeper mismatch is energy. Per event, accessing a 32-bit value from DRAM costs about 640 pJ in the 45 nm estimates of Horowitz (2014), roughly 173× the 3.7 pJ of one FP32 multiply, the same ratio table 4.6 reported for the data pipeline. The roughly 145-fold gap quoted with the iron law in section 1.7 comes from the same table but compared one DRAM byte, a quarter of this 32-bit access, with one FP16 operation. Exact values vary by technology node and design, but a gap of two orders of magnitude, the energy-movement principle (7), makes data movement a primary optimization target (Sze et al. 2017). Purpose-built accelerators such as TPUs sustain high utilization on dense kernels because systolic arrays and similar structures maximize data reuse while minimizing movement.

Data access can dominate the energy budget of a memory-intensive kernel.[5] On a logarithmic scale, representative 45 nm operation energies span more than four orders of magnitude, from an INT8 addition (0.03 pJ) and an FP32 multiply (3.7 pJ) to an off-chip DRAM fetch (640 pJ) (figure 11.4). This ladder is the chapter's single reference for what moving a value costs; later sections cite it rather than restate it.

Training and inference load an accelerator differently. Training computes gradients, typically in mixed precision with lower-precision tensor operations and higher-precision accumulation (Micikevicius et al. 2018), and backpropagation retains or recomputes activations, raising memory demand. Inference requires only the forward path and may use INT8 or INT4 when the model and kernels support it. The service objective, whether tail latency, throughput, cost, or energy, then decides which accelerator fits.

5 **Von Neumann bottleneck**: Separating storage from compute requires instructions and data to cross interfaces rather than remain in local registers. The exact cost of each crossing changes with technology and operation, but locality remains a first-order design concern.

↩ The activation memory that backpropagation must retain is established in section 8.3.3.1.

Definition 11.3: ML accelerator

Machine Learning Accelerators are processors or specialized units designed primarily for common neural-network tensor operations and dataflows. They pursue high R_{peak} and data reuse on matching workloads by devoting more resources to arithmetic and local data movement than a general-purpose execution path can.

1. **Significance**: An ML accelerator's defining feature is not raw arithmetic alone but a balanced path that supplies operands and retains reusable values nearby. The H100 provides 3.35 TB/s of device-memory bandwidth, about 16.8× the illustrative 200 GB/s host-DRAM path used here (Choquette 2023). This is a ceiling comparison, not a guarantee: sufficient arithmetic intensity, concurrency, and reuse are still required to approach its 989 TFLOP/s dense FP16/BF16 peak.
2. **Distinction**: The gains are conditional on operation support, parallel work, regular data access, and a software stack that selects the intended path. An ML accelerator can be orders of magnitude faster than a reference CPU on large dense matrix multiplication, yet lose much of that advantage on small, irregular, synchronization-heavy, or control-heavy workloads. Transfers and unsupported operators can dominate even when the accelerated kernel itself is fast.

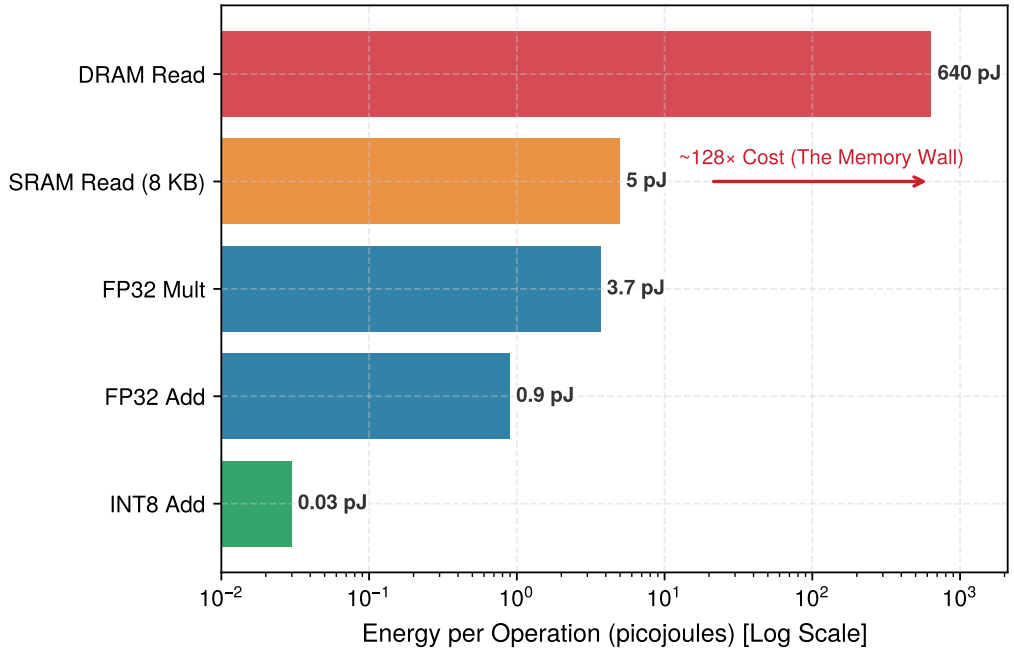

Figure 11.4: The Energy Hierarchy: Representative 45 nm energy estimates on a logarithmic scale from Horowitz (2014). An off-chip DRAM access costs about 173× an FP32 multiply and about 128× a read from an 8 KB SRAM array in this model; a small, register-adjacent L1 access (about 0.5 pJ in the registry used elsewhere in this chapter) is cheaper still. The values are not universal device specifications; they illustrate why reuse in registers and SRAM can matter more than reducing arithmetic count alone.

3. **Common pitfall**: A frequent misconception is that ML accelerators always accelerate ML. Approaching peak throughput requires a compatible precision, operation shape, layout, and enough parallel work to keep the relevant units busy, and memory and interconnect paths must sustain that work. A batch-1 autoregressive request may therefore use only a small fraction of a large training accelerator's arithmetic capacity even though the same device performs well on batched prefill or training.

Deployment context decides which constraint binds. In data centers it is often time-to-result for training large models. An NVIDIA H100 trades hundreds of watts of power for high throughput (Choquette 2023), and Google's TPUv4 makes a similar trade through systolic arrays and high-bandwidth memory (Jouppi et al. 2023); whether either lowers total cost depends on utilization, rental price, workload scaling, and the electricity rate.

At the edge, the priority shifts toward energy per inference and hard latency or power limits. A smartphone camera or always-on audio path inside a few-watt budget cannot adopt a data center memory system, so edge architectures reduce movement through local scratchpads, tight integration, and dynamic voltage and frequency scaling. Because the binding constraint differs by setting, no single architecture dominates, yet the memory wall governs both. Data center chips buy capacity and bandwidth with HBM, while edge chips depend on proximity and reuse.

Checkpoint 11.2: The accelerator gate

The energy hierarchy decides when specialization pays.

Energy hierarchy

- ☐ **Data movement cost**: explain why a DRAM access costs about two orders of magnitude more energy than the FP32 multiply that consumes its operand?
- ☐ **Architectural response**: why would keeping and reusing operands near arithmetic units reduce movement energy? Use this prediction when the following sections develop systolic arrays and Tensor Cores.

Selection logic

- ☐ **Training vs. inference**: how do training and inference objectives affect precision, memory capacity, bandwidth, and latency requirements? Explain why both phases can need high memory bandwidth.

11.2.4 The integration bottleneck

Packing thousands of multiply-accumulate units onto a die buys nothing if those units spend most cycles stalled waiting for operands to cross the memory hierarchy. From the 8087 onward, hardware has evolved to fit the algorithm's dominant bottleneck (Palmer 1980; Sze et al. 2017; Jouppi et al. 2017), and for dense matrix multiplications and convolutions the remaining difficulty is feeding the arithmetic units. The integration bottleneck is the memory wall seen from inside the accelerator: transporting operands and results through the memory hierarchy quickly and efficiently enough to keep thousands of parallel compute units busy. Specialized silicon delivers its performance-per-watt advantage only when the workload's demand concentrates into regular operations that align with the hardware's data paths.

Neural-network kernels make this integration bottleneck tractable because their arithmetic, dataflow, and numerical requirements reinforce one another. Large matrix multiplications and convolutions expose abundant data parallelism that dense processing-element arrays can execute concurrently, and because static or compiled tensor graphs move those operands along predictable paths, compilers can tile and stage transfers into local scratchpads[6] instead of relying exclusively on hardware-managed caches. Those staged operands also tolerate reduced precision, allowing supported 8-bit or 4-bit paths to pack more values into each scratchpad and multiply them more densely (Dally et al. 2021; Dally 2023). Workloads dominated by dynamic control flow, large embedding tables, small tensors, variable shapes, or strict precision requirements break these assumptions and remain bound by memory latency and irregular access.

Once arithmetic capacity is abundant, the central engineering challenge shifts to staging data close to compute. Given the 173× energy penalty of off-chip DRAM transfers, accelerator architects deliberately allocate silicon area and thermal budgets to stacked HBM, wide on-chip SRAM, and software-managed scratchpads rather than packing in additional floating-point logic.[7] Those are the memory tiers drawn in figure 11.1, and they occupy as much of the design as the arithmetic units they feed.

The specialization evident in processing elements, vector pipelines, and tiered scratchpads reflects the computational profile of neural networks, which repeatedly invoke a compact set of linear-algebraic and element-wise primitives. Within the D·A·M framework, an algorithmic change produces a wall-clock speedup only when its computational structure and memory access pattern map onto these primitives; one that cuts theoretical operations without aligning with the hardware's data paths leaves compute units starved. The next section identifies those primitives, beginning with the multiply-accumulate that carries nearly all of ResNet-50's arithmetic.

11.3 Compute Primitives

A single forward pass through a neural network layer can issue millions or billions of MAC operations, and executing them one scalar instruction at a time would swamp the processor in instruction-fetch and register-access overhead. Across fully connected, convolutional, and attention layers, learned linear transformations reduce to these repeated MACs, whose regular tensor structure exposes the parallel work and operand reuse that hardware specialization requires. MACs do not dominate every model or phase (normalization, routing, indexing, communication, and element-wise operations can become limiting), but they account for much of the peak arithmetic capacity in modern ML

6 **Scratchpad memory**: When a compiler can determine a tensor kernel's access pattern, it can explicitly stage tiles in fast, software-controlled local memory. This avoids some tag, replacement, and coherence machinery, but transfers, synchronization, banking, and capacity must be scheduled correctly. Scratchpads complement rather than universally replace caches because irregular or shared data may still benefit from hardware management. Google's TPU v1, for example, used a 24 MB software-managed Unified Buffer for intermediate activations, while weights and instructions used other paths (Jouppi et al. 2017).

7 **HBM**: The A100 and H100 generations provide 2.0–3.4 TB/s of device-memory bandwidth through stacked memory and wide interfaces, compared with 760 GB/s for the GDDR6X reference used here (NVIDIA Corporation 2020a; Choquette 2023). Raising the bandwidth ceiling can move some kernels toward the compute-bound side of the roofline, but only if their access pattern and arithmetic intensity can use it. HBM also increases packaging and system cost, so its value depends on the workload's bandwidth demand.

accelerators. Whether they dominate elapsed time still depends on tensor shape, data movement, and the surrounding operators.

The hardware units that exploit these patterns are **AI compute primitives**: specialized functional blocks, each optimized for a particular class of operation. Three primitives are especially common in accelerators, each targeting a distinct computational pattern found in neural networks; at the framework level, a single declarative statement encapsulates thousands of their arithmetic operations (listing 11.1).

Listing 11.1: Dense Layer Abstraction: High-level framework APIs encapsulate 131,072 MACs (256 inputs times 512 outputs) in a single function call, hiding the computational complexity from developers while enabling automatic hardware optimization.

```
# Framework abstracts compute-intensive operations
dense = Dense(512)(input_tensor)  # 256x512 MACs per sample
```

Beneath this API call, an autograd or compilation engine lowers the layer into a computational graph. Listing 11.2 exposes a bulk matrix multiplication and bias broadcast, followed by an optional element-wise activation; the activation is a separate stage rather than an implicit part of the shown `Dense` call.

Listing 11.2: Matrix Operation Expansion: Each dense layer decomposes into matrix multiplication and element-wise operations, exposing the dominant compute pattern that many neural-network kernels are built around.

```
# Linear transformation work scales with input_dim x output_dim x
# batch.
output = (
    matmul(input, weights) + bias
)  # Matrix multiply dominates cost
output = activation(
    output
)  # Element-wise: proportional to output_dim x batch
```

While graph representations group these steps into coarse tensor operators, execution on physical hardware requires scheduling individual scalar operations. Lowering the matrix multiplication to loop nests (listing 11.3) makes the execution structure explicit: three nested iterations traverse the batch, output feature, and reduction dimensions, establishing $\mathcal{O}(B \times d_{\text{in}} \times d_{\text{out}})$ arithmetic complexity.

Listing 11.3: Processor-Level Execution: Nested loops reveal the $\mathcal{O}(B \times d_{\text{in}} \times d_{\text{out}})$ multiply-accumulate operations that accelerators must execute, with 4.2M MACs for B=32, d_{in}=256, d_{out}=512 configurations.

```
# Total operations: batch_size × output_size × input_size MACs
for n in range(batch_size):  # Batch dimension: parallelizable
    for m in range(output_size):  # Output neurons: parallelizable
        sum = bias[m]  # Initialize accumulator
        for k in range(input_size):  # Reduction dimension: sequential
            sum += input[n, k] * weights[k, m]  # MAC operation
        output[n, m] = activation(sum)  # Nonlinear transformation
# Example work scales as batch_size × output_size ×
# input_size multiply-accumulate operations
```

These nested loops expose three recurring computational patterns: element-wise operations along vectors, matrix-level multiply-accumulate reductions, and nonlinear transformations. Their ubiquity justifies dedicated hardware execution paths: vector pipelines stream independent elements and reductions, matrix engines organize multiply-accumulate grids across spatial tiles, and special-function units approximate nonlinear math. The boundaries between these units are architectural rather than mathematical; an optimizing compiler frequently fuses operations across all three paths within a single kernel invocation to eliminate intermediate memory traffic.

11.3.1 Vector operations

In the scalar loop nest of listing 11.3, evaluating a batch of 32 samples through a 256-to-512 dense layer requires 4.2M MACs, and a scalar processor must fetch and decode separate instructions to load each input-weight pair, multiply-accumulate them, and advance the loop counters. Vector architectures eliminate this per-element control overhead by packing multiple data elements into wide register files (typically 128 to 512 bits) and applying a single decoded instruction across parallel execution lanes simultaneously.

RISC-V,[8] an open instruction-set architecture (ISA) with a standardized vector extension (Waterman et al. 2013), provides a concrete vehicle for this execution model. The contiguous loads in listing 11.4 assume that the selected weight column has been packed into a contiguous vector; the row-major `weights[k, m]` access in the scalar example is otherwise strided. In RISC-V vector assembly, code is decoupled from fixed hardware widths: the instruction `vsetvli` queries the hardware to determine how many elements fit into available registers, processes that chunk, and loops until all features are exhausted.

[8] **RISC-V (reduced instruction set computer V)**: The open ISA allows hardware teams to add custom ML instructions, including vector dot products, activation functions, and sparse tensor operations, without changing the base ISA. The trade-off is software ecosystem maturity: custom extensions require corresponding compiler, library, and runtime support, which can limit portability and increase integration work.

Listing 11.4: Vectorized Dot-Product Loop: This illustrative loop processes several element pairs per iteration and reduces them into one scalar dot product.

```
fmv.w.x fa0, zero          # Scalar dot-product accumulator
fmv.w.x ft1, zero          # Zero seed for vector reduction
loop_feature:
    vsetvli t0, feature_cnt, e32, m1, ta, ma
    vle32.v v1, (in_ptr)
    vle32.v v2, (wt_ptr)
    vfmul.vv v3, v1, v2
    vfmv.v.f v0, ft1
    vfredusum.vs v4, v3, v0
    vfmv.f.s ft0, v4
    fadd.s fa0, fa0, ft0
    slli t1, t0, 2         # Four bytes per FP32 element
    add in_ptr, in_ptr, t1
    add wt_ptr, wt_ptr, t1
    sub feature_cnt, feature_cnt, t0
    bnez feature_cnt, loop_feature
```

Each pass of the loop in listing 11.4 asks the hardware how many 32-bit elements fit in its vector registers (`vsetvli`), loads that many input and weight elements with two wide loads (`vle32.v`), multiplies them lane by lane (`vfmul.vv`), reduces the products into a partial sum (`vfredusum.vs`), and advances the pointers until no elements remain. One decoded instruction thus does the work of a whole chunk of scalar instructions.

Across iterations, the vector multiply instruction processes multiple data elements concurrently while wide loads amortize instruction decode and memory-request overhead. Because the runtime vector length dynamically adapts to the implementation's hardware width (`VLEN`), the identical binary executes correctly on both narrow embedded vector units and wide data-center pipelines. For this 256-feature workload, an 8-lane implementation breaks the reduction into approximately 524,288 vector chunks across the batch.

Beyond dense inner products, deep learning workloads rely on a broader set of vector instructions. Table 11.2 maps these primitive vector operations to the specific neural network layers that depend on them.

Table 11.2: Vector Operations: Core vector operations map directly to deep learning primitives: reductions implement pooling layers, gathers enable embedding lookups, scatters update embedding gradients, and masked operations handle attention masks. These mappings show how vector hardware supports common ML primitives.

Vector operation	Description	Neural network application
Reduction	Combines elements across a vector (for example, sum, max)	Pooling layers, attention score computation

Vector operation	Description	Neural network application
Gather	Loads multiple nonconsecutive memory elements	Embedding lookups, sparse operations
Scatter	Writes to multiple nonconsecutive memory locations	Gradient updates for embeddings
Masked operations	Selectively operates on vector elements	Attention masks, padding handling
Vector-scalar broadcast	Applies scalar to all vector elements	Bias addition, scaling operations

The benefit extends beyond instruction count. Contiguous vector loads can use memory interfaces efficiently, and control overhead is amortized across several data elements. Gather, scatter, masking, and short tails may use fewer lanes or require extra memory transactions, so vector width alone does not guarantee proportional speedup. The architectural pattern is not new. The Cray-1[9] used vector registers and pipelined functional units for scientific computing in the 1970s (Jordan 1982); modern ML processors apply related principles at much larger commercial scale. In ResNet-50 the vector path carries the ReLU after every convolution and the residual addition that closes every bottleneck block. Each touches every activation element once and performs about one operation per element, so on its own it is limited by how fast the activations stream past, not by lane count.

Vector operations excel at element-wise transformations such as activation functions, where each output depends only on *its corresponding input*. Neural networks, however, also require structured computations where each output depends on *all inputs*, the weighted sums that define layer transformations. These many-to-many operations naturally express themselves as matrix multiplications, the second compute primitive.

9 **Cray-1 vector legacy**: The Cray-1 (1975) used 64-element vector registers with pipelined functional units, allowing a stream of elements to advance through arithmetic operations without issuing one scalar instruction per element. Modern accelerators extend the same principles of wide registers, pipelined execution, and data reuse to vector and matrix tiles.

11.3.2 Matrix operations

Evaluating a dense layer one vector dot product at a time wastes reuse: each weight row is loaded for one sample and discarded before the next sample in the batch arrives, and each input vector is re-read for every output neuron. Matrix multiplication eliminates this redundant traffic by organizing work across two-dimensional tiles of weights, activations, and gradients, accounting for much of the arithmetic in dense neural networks (Goodfellow et al. 2016). Hardware and libraries tile those dimensions so blocks of weights and activations are reused across an entire tile while partial sums accumulate locally, though small or irregular matrices can still leave tile capacity unused.

11.3.2.1 Matrix operations in neural networks

Neural network computations decompose into hierarchical matrix operations. Listing 11.5 captures this hierarchy through a linear layer that transforms input features into output neurons over a batch. Its expanded mathematics uses a column-batch convention and adds an optional ReLU; this illustrates the arithmetic rather than the framework API's internal tensor layout or an activation implicit in `nn.Linear`.

Listing 11.5: Linear-Layer Operation Hierarchy: The example expands a linear layer into a matrix multiply and bias broadcast, then applies element-wise ReLU, separating the matrix and vector work that hardware must execute.

```
layer = nn.Linear(256, 512)  # Layer transforms 256 inputs to 512 outputs
output = layer(input_batch)  # Process a batch of 32 samples

# Framework Internal: Core operations (column-batch convention)
Z = matmul(weights, input)  # Matrix: transforms [256×32]
# input to [512×32] output
Z = Z + bias  # Vector: adds bias to each
# output independently
output = relu(Z)  # Vector: applies activation to
# each element independently
```

The scale of this matrix work follows from the layer dimensions. Each output neuron (512 total) must process all input features (256 total) for every sample in the batch (32 samples). The weight

matrix alone contains $256 \times 512 = 131{,}072$ parameters that define these transformations, illustrating why efficient matrix multiplication dominates performance considerations.

Neural networks employ matrix operations across architectural patterns beyond simple linear layers. Convolution operations transform into matrix multiplications through the im2col technique,[10] enabling efficient execution on matrix-optimized hardware. Listing 11.6 illustrates these applications.

Listing 11.6: Matrix Patterns Across Architectures: Linear layers, attention mechanisms, and convolutions all reduce key work to matrix multiplications, making matrix hardware the shared primitive across modern neural architectures.

```
hidden = matmul(weights, inputs)
# weights: [out_dim x in_dim], inputs: [in_dim x tokens]
# Result combines all inputs for each output

# Attention Mechanisms - Multiple matrix operations
Q = matmul(Wq, inputs)
# Project inputs to query space [query_dim x tokens]
K = matmul(Wk, inputs)
# Project inputs to key space [key_dim x tokens]
attention = matmul(Q.T, K)
# Compare all query tokens with all key tokens [tokens x tokens]

# Convolutions - Matrix multiply after reshaping
patches = im2col(input)
# Convert [H x W x C] image to matrix of patches
output = matmul(kernel, patches)
# Apply kernels to all patches simultaneously
```

[10] **Im2col (image-to-column)**: The im2col lowering of section 6.3.3 turns convolution into a matrix multiplication by unfolding each receptive-field patch into one row or column of a dense matrix. An explicit materialization can duplicate overlapping values and expand storage by up to roughly the kernel area before edge, stride, and channel effects are considered. Production libraries often use implicit-GEMM or direct-convolution kernels to obtain matrix-friendly execution without materializing the full expanded matrix.

These examples differ in tensor shape and reuse pattern, which determines how efficiently each multiplication occupies a matrix unit. Linear layers reuse one weight matrix across a batch; attention forms projections and then a token-to-token score matrix; convolution reuses each kernel across many image patches. Expressing all three as matrix multiplication exposes a common interface to hardware, but it does not make their execution costs identical. Batch size, sequence length, channel count, and tiling determine whether operands are reused locally or repeatedly fetched from memory. For ResNet-50 the lowering is nearly total: every convolution and the final fully connected layer become matrix multiplications, so almost all of its operations run on whatever matrix hardware the accelerator provides, and the INT8 profile of chapter 10 is in effect a statement about that hardware.

11.3.2.2 Matrix operations hardware acceleration

Accelerators therefore need units that handle whole tiles. Listing 11.7 demonstrates a representative dedicated matrix unit that processes an entire 16×16 block at once, illustrating why matrix instructions and Tensor Cores can deliver much higher throughput than scalar or vector-only execution paths (NVIDIA 2017; Intel Corporation 2021a).

Listing 11.7: Illustrative Matrix-Unit Operation: Representative load, matrix-multiply-accumulate, and store instructions operate on matrix blocks rather than individual scalar elements.

```
mload mr1, (weight_ptr)     # Load e.g., 16x16 block of
                            # weight matrix
mload mr2, (input_ptr)      # Load corresponding input block
matmul.mm mr3, mr1, mr2     # Multiply and accumulate entire
                            # blocks at once
mstore (output_ptr), mr3    # Store computed output block
```

The illustrative unit operates on matrix tiles rather than individual elements. A full $16 \times 16 \times 16$ tile product contains $16^3 = 4{,}096$ multiply-accumulate operations, but the cycles required depend on the actual instruction and architecture. Sustained throughput also depends on the number of matrix units, operand precision, issue rate, pipeline behavior, and whether memory can keep the units fed. Matrix units complement vector execution by accelerating structured many-to-many transformations.

Much like vector processing, matrix acceleration has deep historical roots; digital signal processors (DSPs) and graphics processors optimized matrix computations in the 1980s–1990s for image processing, scientific computing, and 3D rendering (Owens et al. 2008; Hwu 2011). Neural networks have made matrix multiplication commercially dominant, driving the integration of two-dimensional systolic arrays and matrix execution engines (such as NVIDIA Tensor Cores and Google TPUs) directly into processor datapaths.

Linear algebra constitutes only part of the neural network execution pipeline. Between linear transformations, neural networks introduce nonlinear activation functions and normalization layers. While piecewise-linear functions such as ReLU map to simple vector comparison instructions, transcendental computations (such as exponentials in softmax and GELU, or reciprocal square roots in normalization) cannot be computed directly on multiply-accumulate datapaths without incurring severe cycle penalties. Table 11.3 summarizes the execution characteristics of the three primary compute primitives and their mapping to neural network operations.

Table 11.3: Operation Characteristics: Matrix operations excel at many-to-many transformations, while vector units handle element-wise operations and reductions such as activation and normalization. Special-function paths handle transcendental arithmetic through architecture-specific approximation or dedicated logic. The operation structure determines which hardware primitive is appropriate.

Operation type	Best For	Examples	Key characteristic
Matrix Operations	Many-to-many transforms	Layer transformations, attention, convolutions	Each output depends on multiple inputs
Vector Operations	Vector and reduction work	Activation functions, layer normalization, element-wise gradients	Uses element-wise operations and vector reductions
Special-Function Paths	Transcendental arithmetic	Exponential, logarithm, reciprocal square root	Uses architecture-specific approximation or dedicated logic

11.3.3 Special function units

Evaluating an exponential in softmax, a hyperbolic tangent in GELU, or a reciprocal square root in layer normalization on standard multiply-accumulate hardware requires a multi-instruction polynomial approximation that can stall the pipeline between fast matrix kernels. Special Function Units (SFUs) and specialized instruction paths remove this bottleneck, completing the chapter's trio of processing primitives. The need is not new: floating-point coprocessors addressed scalar arithmetic bottlenecks (Palmer 1980), and digital signal processors added specialized arithmetic for signal-processing workloads (Smith 1997). An implementation may use a standalone unit, vector approximation instructions, or a library sequence, trading accuracy, latency, and throughput. In neural networks, activation, normalization, and softmax operations can become the limiting stage between matrix kernels when repeated memory passes or transcendental functions cap throughput.

11.3.3.1 Nonlinear functions

A common layer sequence illustrates how non-matrix operators enter the execution pipeline (Goodfellow et al. 2016). Listing 11.8 chains a linear transformation with ReLU activation and batch normalization, operations that appear trivial in Python framework code but impose distinct arithmetic and memory constraints on hardware.

Listing 11.8: Linear–Nonlinear Layer Sequence: A linear layer, ReLU, and BatchNorm combine matrix, element-wise, and normalization work in one common layer sequence.

```
layer = nn.Sequential(
    nn.Linear(256, 512), nn.ReLU(), nn.BatchNorm1d(512)
)
output = layer(input_tensor)
```

Listing 11.9 expands this sequence into its arithmetic primitives, isolating the element-wise thresholding of ReLU from the cross-batch reductions and reciprocal square root required by batch normalization. Here rows are samples and columns are features; `weights` has input features by output features, while `bias`, `gamma`, and `beta` contain one value per output feature. Keeping the reduced batch dimension permits those per-feature statistics to broadcast across samples.

Listing 11.9: Nonlinear Operation Expansion: Expanding the layer sequence exposes ReLU comparison, BatchNorm reductions, variance computation, and square-root normalization around the matrix multiply.

```
Z = matmul(input, weights) + bias  # Linear transformation
H = max(0, Z)  # ReLU activation
mean = reduce_mean(H, axis=0, keepdims=True)  # BatchNorm statistics
var = reduce_mean((H - mean) ** 2, axis=0, keepdims=True)  # Variance computation
output = gamma * (H - mean) / sqrt(var + eps) + beta  # Normalization
```

11.3.3.2 Hardware implementation of nonlinear functions

Translating these mathematical functions to silicon exposes sharp differences in memory traffic, instruction count, and pipeline utilization. For instance, batch normalization (Ioffe and Szegedy 2015) demands multi-pass statistics gathering across memory, variance accumulation, and a reciprocal square root, while softmax requires computing exponentials across an entire normalization dimension. While a rectified linear unit (ReLU) is mathematically simple, a naive scalar implementation incurs branch overhead or redundant memory round-trips unless fused into adjacent kernels. Listing 11.10 contrasts the memory and dependency overheads of pointwise activation against multi-pass normalization in an unfused loop model.

The label *nonlinear* hides three different execution patterns. Pointwise functions such as ReLU leave elements independent and therefore map naturally to vector lanes or parallel threads. Reductions such as the mean and variance in batch normalization introduce cross-element dependencies: partial results must be combined before later stages can proceed. Transcendental functions such as exponential, logarithm, and reciprocal square root add a numerical trade-off because their implementations balance latency, precision, and valid input range. The dependency pattern, not the mathematical label alone, determines whether vector arithmetic, a reduction tree, or a specialized approximation path is appropriate. A faster special-function path accelerates only the operation it implements; it does not remove surrounding tensor traffic or synchronization.

Listing 11.10 is intentionally dependency-explicit rather than a model of an optimized kernel. The loops expose three state lifetimes: per-element activations, per-feature accumulators, and the final normalized outputs. The normalization parameters cannot be applied until the required statistics are available, so implementations must either retain intermediate activations or recompute them. Training derives those statistics from the current batch, whereas inference can use stored statistics and reduce normalization to an element-wise affine transform. Compilers may fuse legal stages, but the data dependencies determine which transformations preserve the computation. Reading the listing as a dependency graph therefore reveals the durable hardware questions: how often each tensor crosses a memory interface, which intermediates remain local, and where reductions impose synchronization.

Listing 11.10: ReLU and BatchNorm Operations: Neural networks process input data through element-wise selections and multiple normalization passes, highlighting efficiency challenges in naive implementations.

```
for batch in range(32):
    for feature in range(512):
        # ReLU: Naive scalar compare/select; optimized kernels
        # usually implement this branchlessly.
        z = matmul_output[batch, feature]
        h = max(0.0, z)  # Conditional operation

        # BatchNorm: Multiple passes over data
        mean_sum[feature] += h  # First pass for mean
        var_sum[feature] += h * h  # Additional pass for variance

        temp[batch, feature] = h  # Extra memory storage needed

# Normalization requires complex arithmetic
for feature in range(512):
    mean = mean_sum[feature] / batch_size
    var = (var_sum[feature] / batch_size) - mean * mean

    # Square root computation: Multiple iterations
    scale = gamma[feature] / sqrt(var + eps)  # Iterative
    # approximation
    shift = beta[feature] - mean * scale

    # Additional pass over data for final computation
    for batch in range(32):
        output[batch, feature] = temp[batch, feature] * scale + shift
```

The dependency structure in listing 11.10 exposes two costs of naive execution. The pointwise ReLU and normalization scale-and-shift perform little arithmetic per accessed byte, so materializing each pass can place a low bandwidth ceiling on throughput. In this unfused loop model, `temp` is stored and reread after batch statistics are finalized; its physical traffic depends on cache residency and the chosen memory interface. Computing $1/\sqrt{\text{var}+\epsilon}$ also adds a dependent arithmetic path. The listing illustrates an iterative approximation, but actual kernels may use a reciprocal-square-root instruction and refinement, with device- and accuracy-dependent latency. Specialized function paths address this arithmetic cost, while legal fusion and local buffering reduce intermediate traffic. Neither removes the need to complete the reductions before normalization.

11.3.3.3 SFU hardware implementation

SFUs address arithmetic bottlenecks by implementing nonlinear and transcendental operations in specialized functional units rather than multi-instruction software routines. Accelerators deploy dedicated datapath circuits, such as quadratic polynomial interpolators and small lookup tables (LUTs), that evaluate functions like exponential, reciprocal square root, and logarithm within a few pipeline stages. Listing 11.11 illustrates how an instruction set exposes these operations alongside vector memory accesses.

Listing 11.11: Illustrative SFU Operations: Pseudocode shows vector nonlinear operations that may map to specialized execution paths; instruction names and latency are implementation dependent.

```
vld.v v1, (input_ptr)    # Load vector of values (pseudocode)
vrelu.v v2, v1           # Vector ReLU path
vsigm.v v3, v1           # Vector sigmoid path
vtanh.v v4, v1           # Vector tanh path
vrsqrt.v v5, v1          # Vector reciprocal-square-root path
```

Specialized function paths balance circuit area against mathematical precision. While piecewise linear activations such as ReLU require only single-cycle compare-and-select (maximum) datapath

logic, transcendental functions trade off lookup table size and polynomial interpolation degrees against approximation error. Representative mechanisms and their qualitative latencies differ by function (table 11.4).

Table 11.4: Special Function Units: Dedicated paths reduce instruction overhead for nonlinear and reduction primitives. Implementations and latency are architecture-dependent; the table describes mechanisms rather than universal cycle counts.

Function unit	Operation	Implementation strategy	Illustrative latency
Activation unit	ReLU	Compare-and-select or maximum	Low; architecture-dependent
Statistics unit	Mean, variance	Parallel reduction trees	Grows with reduction depth
Exponential unit	exp, log, sigmoid, tanh	Approximation, table lookup, and interpolation	Architecture-dependent
Root/power unit	sqrt, rsqrt	Iterative or approximation hardware	Architecture-dependent

The two lighthouses use this path very differently. ResNet-50 barely touches it: its only activation is ReLU, a comparison, and its only exponentials are the thousand in its final softmax. GPT-2 XL leans on it at every step, because each attention head applies softmax across the whole context and each feed-forward block applies GELU, so its special-function work grows with sequence length while ResNet-50's stays fixed.

Vector operations, matrix operations, and special-function paths establish the foundational arithmetic primitives of ML accelerators, but functional units alone do not dictate sustained throughput. These primitives govern *what* the silicon computes; the execution model and memory hierarchy govern *how* data feeds the datapath. A matrix unit rated for hundreds of teraFLOP/s will idle if memory bandwidth cannot sustain operand delivery, if tile dimensions mismatch register blocking, or if thread synchronization serializes execution. Peak assumes operands are always ready; the execution model decides how much of it a real workload achieves.

11.4 Compute Units

Applying ReLU to a 512-element vector shows why execution models matter: the operation is simple, but throughput depends on whether the hardware treats those 512 comparisons as scalar instructions, as lanes of a single instruction, multiple data (SIMD) unit, as GPU threads, or as tensor-program fragments. Modern AI processors package the three compute primitives into distinct execution units (vector units for vector work, matrix units such as Tensor Cores and systolic arrays for matrix work, and special function units for nonlinear functions) and then group those units into processing elements. That organization defines how computations are structured and exposed to programmers, and it explains why theoretical capability and delivered throughput diverge.

The packaging follows reuse per operand. For the reference low-precision operations, reading an operand from a register file and moving it across on-chip wires can cost more energy than the arithmetic itself, so each primitive goes to the unit whose dataflow supplies the reuse it offers. In D·A·M terms, this partition binds algorithmic primitives to machine execution paths. Routing dense matrix multiplications through vector pipelines saturates register-file read ports and collapses throughput to a small fraction of peak, while routing low-intensity elementwise work through matrix arrays leaves their lanes idle.

11.4.1 From SIMD lanes to SIMT threads

Even a wide CPU vector unit stalls when streaming through gigabytes of tensor data: cache misses freeze the pipeline for hundreds of cycles waiting on main memory, the instruction reorder buffer fills, and the SIMD lanes sit empty. The vector path of section 11.3.1 follows Flynn's SIMD execution model, which amortizes instruction fetch and decode by issuing a single decoded instruction across multiple data elements packed into wide vector registers (Flynn 1966). A 512-bit SIMD register processes sixteen 32-bit floating-point values per instruction—an idea carried into fixed-width CPU vector extensions, Arm's length-agnostic Scalable Vector Extension (SVE) (Stephens et al. 2017), and two-dimensional tile extensions such as Intel's Advanced Matrix Extensions (AMX) (Intel Corporation 2021a)—but those wide registers still live inside a CPU core built around branch

predictors, out-of-order execution logic, and deep cache hierarchies for a few sequential threads. Conditional branching within a vector also requires evaluating divergent paths under bitmasks, further cutting useful lane utilization.

Architectures built on **single instruction, multiple threads (SIMT)** execution resolve these bottlenecks by decoupling the logical programming abstraction from physical hardware execution (Lindholm et al. 2008; Nickolls et al. 2008). Instead of requiring the programmer to pack data into explicit vector registers, SIMT exposes an execution model of independent scalar threads. In GPU architectures, each Streaming Multiprocessor (SM)[11] coordinates thousands of concurrent threads. Hardware warp schedulers group these threads into warps, the 32-thread scheduling groups (wavefronts in AMD architectures) whose granularity already set lane utilization in training kernels, and every thread in a warp executes a common instruction in lockstep across parallel ALUs. This lockstep execution introduces a critical constraint known as **warp divergence**. When threads within a single warp take different paths through a conditional branch, the hardware must execute both required paths sequentially, masking off the inactive lanes during each path. This serialization reduces useful lane utilization and increases execution time, which is why performance-critical ML kernels avoid divergent branching in favor of uniform or predicated control flow.

Rather than relying on large caches to reduce memory latency, GPUs hide latency through massive thread-level concurrency. An SM statically partitions an on-chip register file across all active threads, eliminating context-saving overhead; when one warp stalls waiting hundreds of cycles for an off-chip memory fetch, the warp scheduler selects and issues instructions from another ready warp on the very next cycle. The baseline matrix multiplication kernel in listing 11.12 illustrates how this scalar thread model maps onto hardware. CUDA organizes a grid of threads into blocks: `blockIdx` locates a block in the grid, `blockDim` gives the block dimensions, and `threadIdx` locates a thread within that block. Multiplying a block coordinate by its dimension and adding the within-block coordinate gives the global row or column used by the listing.

11 | **SM (streaming multiprocessor)**: The physical hardware engine that implements the SIMT model by using warp schedulers to coordinate many parallel threads. Maintaining enough active warps can help hide instruction and memory latency, but occupancy alone does not identify the bottleneck. Low occupancy may result from register use, shared-memory use, block dimensions, or insufficient parallel work, while a memory-bound kernel can still have high occupancy.

↩ Warps as the 32-thread unit in which GPUs schedule tensor kernels are established in section 8.4.3.1.

Listing 11.12: SIMT Execution: Each thread processes a unique output element in parallel, demonstrating how SIMT enables efficient matrix multiplication on GPUs.

```
__global__ void matrix_multiply(float* C, float* A, float*
                                B, int N) {  // CUDA kernel
    // Each thread processes one output element
    int row = blockIdx.y * blockDim.y + threadIdx.y;
    int col = blockIdx.x * blockDim.x + threadIdx.x;

    float sum = 0.0f;
    for (int k = 0; k < N; k++) {
        // Threads in a warp execute in parallel
        sum += A[row * N + k] * B[k * N + col];
    }
    C[row * N + col] = sum;
}
```

In listing 11.12, the CUDA[12] kernel assigns one output element `C[row * N + col]` to each thread. Adjacent threads in a warp share the same row index while having consecutive column indices (`threadIdx.x`). When threads fetch `B[k * N + col]`, their memory requests target contiguous 4-byte floating-point addresses. The memory controller merges these 32 individual 4-byte loads into a single 128-byte coalesced memory transaction, maximizing DRAM bus efficiency. Concurrently, all threads in the warp read the identical element `A[row * N + k]`, allowing the hardware to broadcast that single fetched value across all 32 lanes. However, this naive kernel runs into the arithmetic intensity law (principle 6). Because each inner-loop iteration performs only two floating-point operations while reloading operands from global memory without on-chip SRAM staging, the kernel remains severely memory bound. Furthermore, executing dense matrix multiplication on scalar SIMT ALUs requires one instruction fetch, decode, and issue cycle for every multiply-accumulate, saturating register file read ports. Overcoming this machine bottleneck requires moving beyond vector-of-scalars execution to specialized two-dimensional matrix units.

12 | **CUDA (compute unified device architecture)**: Released by NVIDIA in 2006, CUDA eliminated the need to disguise general-purpose computations as graphics operations, opening GPUs to scientific and ML workloads through a C-like programming model. The ecosystem it created (cuBLAS, cuDNN, TensorRT) constitutes a software ecosystem whose switching cost can lock the ML training stack to NVIDIA hardware: migrating away requires rewriting or replacing thousands of GPU-optimized kernels, a cost that often exceeds the hardware savings of competing platforms. This software lock-in, not raw silicon performance alone, helps explain why many large ML training stacks remain CUDA-centered.

11.4.2 Tensor Cores

Computing the $\mathbf{Q} \times \mathbf{K}^T$ product for a single transformer attention head over a 2,048-token sequence with 64-dimensional embeddings multiplies a 2048×64 matrix by a 64×2048 matrix: roughly 268.4M MACs, or 536.9 MFLOP when the multiply and add are counted separately. On a scalar processor executing one FLOP per cycle at 2 GHz, that single attention head would take 268.4 ms, and even on GPU SIMT lanes, issuing a separate scalar fused multiply-add for every element pair saturates instruction-issue bandwidth and register-file read ports. Dedicated matrix engines remove both bottlenecks by organizing work around multidimensional tiles and reusing fetched operands across many multiply-accumulate operations on chip. NVIDIA GPUs expose Tensor Cores, the reduced-precision matrix units[13] that mixed-precision training was built to exploit, whereas Google TPUs use matrix units built around systolic arrays; both execute tiled matrix multiplication and accumulation.[14]

Assume, for illustration, that the Tensor Cores of a single streaming multiprocessor complete that 2,048-token attention head in 0.5 ms, an implied rate of about 1.1 TFLOP/s and a small slice of a full GPU's tensor peak. The tiled path is then roughly 536.9× faster than the scalar baseline, and that speedup comes not from a higher clock frequency but from hardwiring tile-level data reuse into the execution datapath. Whether a workload reaches that rate depends on tile reuse, matrix shape, numeric precision, and memory delivery.

In NVIDIA Parallel Thread Execution (PTX), Tensor Core operations are invoked through warp-synchronous matrix instructions (`mma.sync`).[15] The mnemonic encodes the tile geometry and data types: `.m16n8k16` gives the tile dimensions ($M = 16, N = 8, K = 16$), and the trailing types (`.f32.f16.f16.f32`) declare FP16 inputs accumulated into an FP32 destination. In listing 11.13, all 32 threads in a warp execute this single instruction collectively to compute the tile product $\mathbf{D} = \mathbf{AB} + \mathbf{C}$.

Listing 11.13: Tensor Core Operation: Matrix multiplications are performed in parallel across entire matrix blocks, optimizing computational efficiency for neural network training.

```
Tensor Core Operation (example GPU PTX):
mma.sync.aligned.m16n8k16.row.col.f32.f16.f16.f32
  {d0,d1,d2,d3},      // Destination registers
  {a0,a1,a2,a3},      // Source matrix A
  {b0,b1},            // Source matrix B
  {c0,c1,c2,c3};      // Accumulator
```

Here inputs **A** (16×16) and **B** (16×8) are FP16, while accumulator **C** and destination **D** (16×8) are FP32. A single instruction evaluates 2,048 multiply-accumulate operations that would otherwise take 64 separate scalar fused multiply-add (`fma`) instructions per thread, which relieves two bottlenecks of conventional SIMT execution: instruction issue bandwidth and register file read-port contention.

Design priorities determine how matrix engines appear in different processor families. GPU Tensor Cores preserve programmability while accelerating general-purpose deep learning kernels. TPU-style designs use large-scale matrix units arranged in systolic arrays to maximize sustained training throughput on dense tensor kernels. Mobile NPUs[16] shrink the same idea into low-power inference blocks, while server CPUs add matrix instruction extensions (AMX-class tiles) for inference and mixed workloads. Each version keeps a different amount of flexibility in exchange for removing a different amount of data movement.

Tensor Cores also changed how each accelerator generation states its peak. Successive generations combined more matrix units with narrower formats (FP16, then INT8, FP8, and FP4) and, from Ampere onward, a structured-sparsity path, so the headline rating rose by more than three orders of magnitude between 2012 and 2024 while measuring a different precision at almost every step (NVIDIA Corporation 2017, 2020a, 2024; Choquette 2023). A peak quoted without its precision and sparsity assumption therefore says little about a given workload. The generation-by-generation ratings, with their precision-specific peaks, bandwidths, and power limits, are collected with the other dated specifications in section E.2.1. Whatever the format, a Tensor Core retires a tile per

[13] **Reduced-precision ML**: Halving operand width halves the bytes per stored element and can support denser arithmetic, although realized throughput depends on the available datapath and kernel (Dally et al. 2021; Dally 2023). NVIDIA's transition from Pascal P100 vector arithmetic to mixed-precision Tensor Cores in Volta V100 increased advertised peak FP16 throughput from about 21.2 to 125 TFLOP/s, roughly 6× across those products (NVIDIA 2017). Precision selection must preserve numerical behavior and use an efficient supported path; the smallest format is not automatically the best one.

[14] **Tensor Core dimension alignment**: NVIDIA Tensor Cores are most efficient when matrix dimensions are aligned to precision- and architecture-specific multiples, such as multiples of 8 or 16 for common FP16/BF16/INT8 paths. Modern cuBLAS and cuDNN can still use Tensor Cores for many nonaligned dimensions, but poorly aligned shapes may trigger less efficient kernels, require padding, or reduce effective throughput (NVIDIA 2024a; NVIDIA Corporation 2021b). This is why model architects often choose embedding and channel dimensions such as 512 rather than 500 and why batch-size-1 inference may fail to reach peak Tensor Core utilization: alignment and arithmetic intensity jointly determine whether the hardware's matrix engines stay full.

[15] **Tensor Core**: A single Tensor Core instruction executes a complete matrix-multiply-accumulate operation on a small tile of data using a dedicated hardware block (NVIDIA 2017; NVIDIA Corporation 2020a). This approach bypasses the overhead of fetching and scheduling dozens of individual arithmetic instructions on general-purpose CUDA cores. Because these blocks constitute a large fraction of a modern accelerator's advertised tensor throughput, failing to use them can leave most of the chip's theoretical peak unavailable to the workload.

instruction only when its operands are already nearby, so accelerators never deploy matrix units on their own; the next level of the execution hierarchy exists to supply that proximity.

11.4.3 Processing elements

High-throughput matrix units cannot be fed directly from global memory: off-chip DRAM and even on-package HBM lack the bandwidth and low latency required to stream fresh operands into dense arithmetic arrays on every cycle. Accelerators resolve this bandwidth deficit by grouping Tensor Cores, vector units, and special function units alongside high-bandwidth register files and scratchpad SRAM inside modular processing elements (PEs). Staging operands inside the PE keeps data adjacent to the functional units, amortizing the latency and energy cost of external memory accesses across repeated arithmetic reuse. The term is used at two scales in this chapter. Here a PE is a tile or core that bundles several units with local memory, the role a streaming multiprocessor plays in a GPU and a core plays in a TPU; inside a systolic array (section 11.4.4), a PE is a single multiply-accumulate cell in the grid.

Processing element design varies because each architecture chooses a different balance between compute density, local memory capacity, and interconnect distance. Graphcore's Intelligence Processing Unit (IPU), for example, distributes computation across tiles backed by dedicated local SRAM (Graphcore 2020). Retaining an operand in one tile saves external traffic, but a consumer on another tile still requires an interconnect transfer. Local storage therefore shifts the mapping problem toward keeping repeated consumers close to their operands.

Across these designs, the binding physical constraint is compute density versus data locality: silicon area dedicated to arithmetic units cannot simultaneously house SRAM storage or routing wires. Packing more execution units raises peak theoretical FLOP/s, but those units idle if memory bandwidth and routing channels cannot deliver operands. A processing element's delivered efficiency therefore depends as much on its local memory hierarchy and interconnect strategy as on its raw arithmetic capability. Systolic arrays push this locality principle to its limit: rather than staging operands in a processing element's local memory and fetching them again for each operation, they pass operands directly from one processing element to its neighbor.

11.4.4 Systolic arrays

Even when operands sit in local SRAM or registers, reading two inputs and writing a partial sum back to a central register file on every multiply-accumulate burns wire energy and port bandwidth that limit how many arithmetic cells a chip can pack. While Tensor Cores amortize register access across instruction-driven micro-tiles, systolic arrays remove intermediate register-file round-trips altogether by wiring hundreds or thousands of processing elements into two-dimensional spatial grids. In a classic 2D systolic array, data streams rhythmically through adjacent cells on regular clock cycles: inputs march horizontally, partial sums accumulate vertically, and stationary weights remain anchored in place. Because every value passed from one processing element to its immediate neighbor participates in an arithmetic operation without returning to a register file or SRAM buffer, nearest-neighbor wires replace memory reads. An operand loaded once at the array edge contributes to N sequential multiply-accumulate steps across an $N \times N$ grid, driving memory traffic down by an order of magnitude. Counting DRAM accesses per multiply-accumulate with and without neighbor-to-neighbor passing makes the saving concrete.

16 **NPU (neural processing unit)**: Mobile NPUs achieve low-power inference by implementing common tensor operations in fixed-function or narrowly programmable hardware rather than as fully general GPU kernels. This architectural commitment can deliver large energy-efficiency gains for supported kernels, but it makes deployment dependent on operator coverage: unsupported functions must fall back to a CPU or GPU path that may be far less efficient for that workload (Sze et al. 2017).

Napkin Math 11.1: The energy advantage of pulsing data

Scenario: The systolic architecture improves energy efficiency by keeping operands local as work pulses through the array; the "Systolic" (heartbeat) metaphor reflects this benefit of reusing operands locally. This worked model compares systolic dataflow with a naive implementation that streams every operand through DRAM:

1. **DRAM-streaming baseline**: Loads **A**, **B**, and the running **C**, computes $\mathbf{A} \times \mathbf{B} + \mathbf{C}$, and writes **C** back without cache or register reuse.
   - **Data movement**: 3 loads + 1 write = 4 DRAM accesses (per operation).
   - **Energy**: $\approx 4 \times 640$ pJ + 1 pJ (compute) = 2561 pJ/op.

2. **Systolic array** (128 × 128): Loads **A** and **B** once at the edges. Data "pulses" through 128 processing elements.
   - **Data movement**: 2 loads per 128 operations = 0.016 DRAM accesses (per operation).
   - **Energy**: ≈ 0.016 × 640 pJ + 1 pJ (compute) ≈ 11 pJ/op.

Systems insight: Under this deliberately naive DRAM-streaming baseline, the worked model gives the systolic array a 232.8× energy advantage. The ratio measures locality, not an inherent gap between vector and systolic arithmetic.

- Concretely, a 128×128 array can sustain 16,384 MACs/cycle with a large energy saving by pulsing data through processing elements instead of repeatedly loading it from DRAM (Horowitz 2014; Jouppi et al. 2023).
- This locality lets dense arrays sustain many simultaneous MAC operations without paying a DRAM access for every operation.
- **Limitation**: The comparison assumes no effective reuse in the baseline and full reuse across the array. Caches, register blocking, array underutilization, and other dataflows change the ratio substantially.

Kung and Leiserson[17] (Kung and Leiserson 1979) first introduced systolic arrays, formalizing their use in parallel computing architectures for efficient matrix operations (Kung 1982). Unlike general-purpose execution units, systolic arrays exploit spatial and temporal locality by reusing operands as they propagate through the grid. Google's TPU exemplifies this architectural approach: in the TPUv4, a 128×128 systolic array of multiply-accumulate units processes matrix operations by streaming data through the array in a pipelined manner (Jouppi et al. 2023). Figure 11.5 traces this 2D pipelined dataflow: a control unit stages operands into input FIFO buffers that stream activation data horizontally across the processing grid, while partial sums accumulate vertically down columns into the bottom adder-accumulator chain. Each processing element performs one multiply-accumulate per cycle and passes its operands to its neighbors, so a value loaded once is reused across an entire row or column rather than refetched from memory.

[17] **Systolic array**: Kung and Leiserson used the term for arrays in which data advances through neighboring processing elements on a regular schedule (Kung and Leiserson 1979). Pipeline fill permits concurrent wavefronts and local reuse. The benefit depends on the stationary operand, tile, buffers, and utilization; it does not guarantee fixed DRAM savings. Irregular workloads and poorly aligned shapes remain a weaker fit because fill, drain, and idle elements consume capacity.

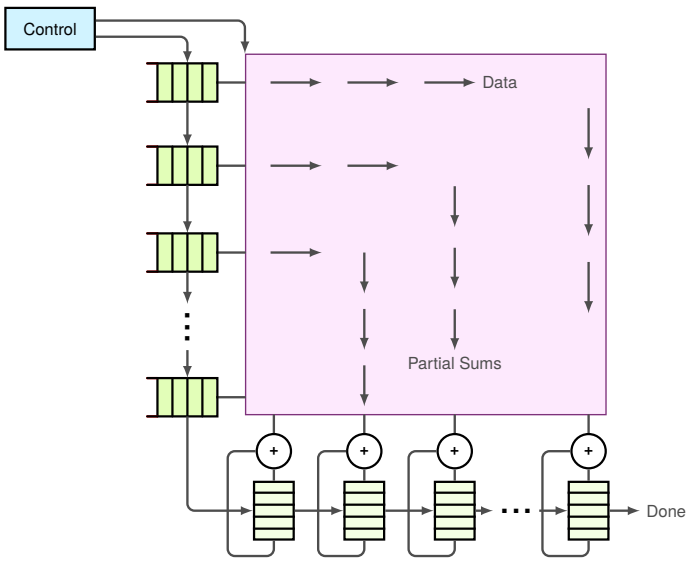

Figure 11.5: Systolic Array Dataflow Architecture: A pipelined grid of processing elements (PEs) passes operands and partial results between neighbors. The illustrated movement is one possible matrix-multiplication dataflow; designs choose which operand or partial sum remains stationary to match reuse, buffers, and tensor shape. Utilization depends on mapping and dimensions.

A 128 × 128 systolic array capable of 16,384 operations per cycle requires a continuous operand stream to maintain utilization. On-chip buffers feed activations and weights to the array edges and are replenished from off-chip memory as needed; reuse within the array avoids fetching every operand from HBM each cycle. The TPU v4's 1,200 GB/s HBM2 bandwidth helps sustain this stream, but off-chip bandwidth can still limit models whose working sets and reuse patterns exceed on-chip capacity.

> Systems Perspective 11.1: Matching architecture to workload
>
> **Challenge**: Systolic arrays must choose which operand to keep stationary in processing-element registers (weights, inputs, or partial sums), and that choice hard-codes the hardware's preference for certain model types. Section 11.7.3 develops the three options as a general mapping decision.
>
> No single accelerator architecture suits every workload. A chip optimized for weight-stationary dataflow (like early TPUs) excels at convolutional neural networks (CNNs), where filter weights are small and reused across many image patches. That same architecture stalls on large language model (LLM) autoregressive inference at batch size 1, where the entire weight matrix must be read from off-chip memory once per generated token with zero batch reuse. No choice of stationary operand recovers reuse that does not exist; the levers are batching, lower-precision weights, and memory bandwidth.

11.4.5 Numerics and sparsity on the datapath

Storing weights in INT8 or pruning half of them to zero shrinks a checkpoint on disk, but if the accelerator lacks a datapath that multiplies narrow integers or skips zero weights in silicon, the runtime must unpack those weights back to dense floating point and executes no faster than the baseline. Number formats and structured sparsity patterns were defined in chapter 10; what turns them into wall-clock speedups—including the ResNet-50 INT8 profile—is the hardware datapath that executes them. Systolic arrays and Tensor Cores often provision higher multiply-accumulate capacity for narrower formats such as FP16, BF16, INT8, and FP8, while halving or quartering the bytes moved per value relative to FP32. That speedup is not automatic: it requires a supported kernel, matching input and accumulation formats, and enough parallel work to keep the narrower datapath full without hitting another bottleneck.

11.4.5.1 Precision trade-offs

Lower precision is not free, for the range-and-precision reasons that forced loss scaling in mixed-precision training and that section 10.3.1 compared format by format. FP16 trades dynamic range for significand bits, BF16 keeps FP32's exponent range at the cost of precision, and INT8 has no exponent at all, so its usable range depends on scale, zero-point, and clipping choices. For the hardware designer, those numerical properties set the silicon cost of each datapath. A narrower format needs a smaller multiplier and moves fewer bytes, but accumulation usually stays wider, as the FP32 accumulator of the Tensor Core instruction in listing 11.13 shows, so part of the area saved in the multipliers is spent keeping sums accurate.

↩ The software side of mixed-precision training, including loss scaling, is established in section 8.6.3.

Precision support is integrated into execution units and memory paths. SIMD and SIMT lanes may support several scalar formats, while Tensor Cores (section 11.4.2) and systolic units (section 11.4.4) expose architecture-specific input and accumulation combinations. Changing storage alone may reduce bytes without producing the advertised arithmetic speedup, because the model must select a kernel that uses the efficient path. Converting FP32 weights to INT8 cuts weight traffic by 4×, but whether that moves a kernel from bandwidth bound to compute bound depends on the operation's original arithmetic intensity, the ridge point of the accelerator's INT8 path, and the overhead of quantization and dequantization (equation 10.4). Tiling and dataflow, not precision itself, determine reuse, while conversion, scaling, or fallback overhead can offset part of the gain. A format is useful only when the kernel and numerical policy can employ it safely.

11.4.5.2 Mixed-precision computing

Modern AI accelerators support mixed-precision execution, in which different stages of one computation use different numerical formats. The training recipe (FP16 or BF16 multiplications with FP32 accumulation) (Micikevicius et al. 2018; Mellempudi et al. 2019) is developed in section 8.6.3, and the inference recipe (INT8 or INT4 weights with selected activations kept wider) in section 10.3. The hardware's part is to execute several formats side by side, with an accumulator wide enough for each.

The shift toward precision diversity is evident in the evolution of AI hardware. Early architectures such as NVIDIA Volta provided Tensor Core support only for FP16, whereas later architectures, including Turing and Ampere, added integer formats and then TF32, a hybrid between FP32 and FP16, alongside BF16 (NVIDIA 2020b; NVIDIA Corporation 2017, 2018, 2020a). The generation-by-generation list of supported formats belongs with the other dated specifications in Appendix E; the durable observation is the direction of the trend, toward more formats, each narrower than the last.

The precision format used in hardware design has cascading implications across the entire system. Reducing an operand from FP32 to FP16 halves its value bytes. When those values dominate traffic, the reduction can substantially lower movement energy; the full energy budget still includes access counts, arithmetic, and other device activity (Horowitz 2014). Simultaneously, Tensor Cores and systolic arrays can pack more lower-precision multiply-accumulate units into the same silicon area, raising peak throughput (Dally et al. 2021; Dally 2023). Lower-precision integer arithmetic also consumes less energy than FP32 in representative technology studies (Horowitz 2014), and the inference-focused TPUv1 was built around 8-bit multiply units (Jouppi et al. 2017). Reduced precision can therefore cut value traffic *and* raise the supported compute ceiling at the same time.

Each narrower format raises the arithmetic ceiling again. The H100 advertises 989 TFLOP/s on its dense FP16 tensor path and 1,979 TFLOP/s on its FP8 path, an 8-bit floating-point format introduced for training and inference (Choquette 2023; Kuzmin et al. 2022; Micikevicius et al. 2022). NVIDIA's Blackwell (B200) architecture extends this trajectory with an FP4 tensor datapath (a 4-bit floating-point format that, unlike INT4, spends some of its four bits on an exponent and so trades uniform spacing for range), rated at up to 9 PFLOP/s dense or 18 PFLOP/s sparse peak throughput per chip (NVIDIA Corporation 2024). Reaching those theoretical ceilings requires numerical representations, kernel implementations, and sparsity patterns that align exactly with the specialized hardware paths. Narrower numerical formats expand the available design space, but numerical stability and dynamic range requirements dictate whether a workload can safely use FP4.

11.4.5.3 N:M structured sparsity mechanics

The sparse rating in that comparison depends on one more datapath feature, one that skips zeros only when they follow a fixed pattern. While unstructured pruning reduces model parameter counts, it rarely translates to hardware speedup because arbitrary nonzero placements destroy memory locality. Hardware accelerators resolve this with N:M structured sparsity,[18] the pruning constraint from model compression that keeps exactly n_{keep} of every m_{group} contiguous values along the reduction dimension nonzero, so memory access stays uniform and indexing predictable across parallel execution units.

Parallel hardware needs this regularity because of how sparse matrices are encoded. Classical formats such as Compressed Sparse Row (CSR) and Block Compressed Sparse Row (BSR) rely on auxiliary index arrays to locate nonzero entries, and the corresponding activation gathers can touch scattered addresses, reducing useful bytes per memory transaction. Varying numbers of nonzeros across rows also create load imbalance and divergent execution. Block sparsity groups retained values into larger dense tiles to restore regularity, at the cost of a more restrictive pruning pattern. In the block formats, a short list of nonzero block indices tells the hardware which tiles to fetch, so zero blocks are never read. Whether an indexed format saves bytes or time at a given sparsity, its break-even point, is derived in section 10.4.2.2; the datapath question here is how regular the retained values must be for parallel hardware to use them.

NVIDIA's Sparse Tensor Cores implement the 2:4 instance of the N:M pattern (NVIDIA Corporation 2020a; NVIDIA 2020a). Their input is the compressed 2:4 encoding, the two retained values of each group plus a 4-bit metadata tag (2 bits per value) recording their original positions. During execution, the memory hierarchy transfers only the compressed weights and their metadata, halving

[18] **N:M structured sparsity**: The 2:4 ratio (50 percent density) used by NVIDIA's Ampere Sparse Tensor Cores is a hardware-friendly compromise: every contiguous four-value group retains two nonzero values, preserving regular indexing while halving the dense value payload (NVIDIA Corporation 2020a). At 2:4, the metadata overhead is compact enough to store alongside the weights without overwhelming the memory-traffic savings, which is the constraint that makes the advertised 2× tensor-math throughput path plausible when kernels and model weights satisfy the pattern.

↩ The N:M and 2:4 structured sparsity patterns and their compressed storage are established in section 10.2.1.3.

↪ The CSR storage format is collected for reference in section C.1.4.

the weight-value payload while adding metadata traffic; total transferred bytes therefore fall by less than half before other overheads. Inside the Sparse Tensor Core datapath, the 4-bit metadata steers an internal multiplexer network that selects the matching two values from an uncompressed four-element activation vector. These selected activations and the two nonzero weights are then routed into a half-sized dot-product multiplier tree. Because the hardware computes only on the nonzeros while streaming compressed weights, this design doubles the peak arithmetic instruction throughput, yielding an advertised 2× tensor-math speedup over dense operations when weights are fine-tuned to satisfy the pattern (figure 11.6).

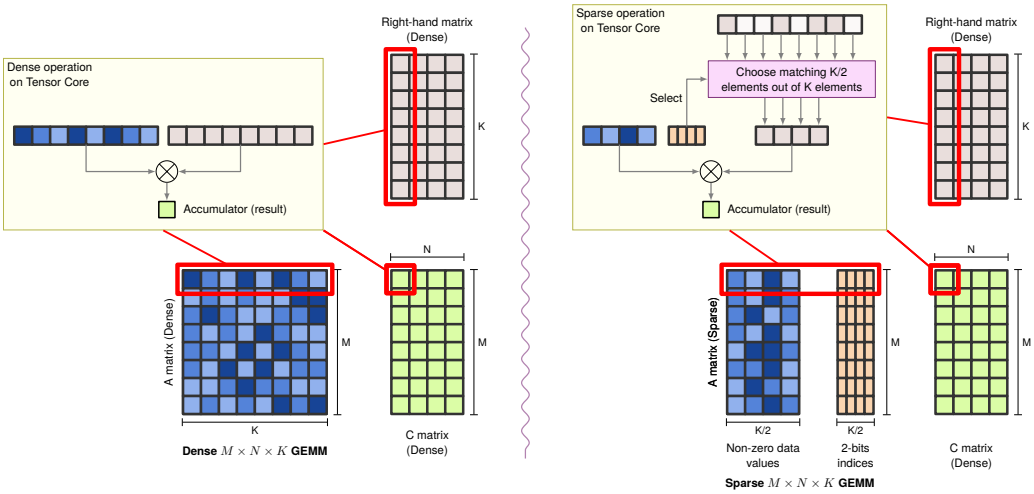

Figure 11.6: 2:4 Structured Sparsity GEMM: Left: standard dense matrix multiplication on Tensor Cores using full 8-element rows. Right: 2:4 sparse multiplication retains two nonzeros in every group of four and uses compact indices to select matching elements from the dense right-hand matrix. A supported sparse inner loop can halve the multiplied values, although metadata handling and the rest of the execution path determine end-to-end speedup. Source: PyTorch blog (PyTorch 2022).

The 2:4 pattern saves about half of the weight bytes and half of the multiplies, minus the metadata, so the reduced weight payload can lower traffic across HBM and on-chip SRAM. A roofline comparison must use consistent accounting: useful dense-equivalent operations can stay fixed while bytes decrease, whereas the count of physically executed sparse operations also decreases. Metadata and activation traffic remain in either traffic budget. Narrower values and skipped zeros therefore help when they reduce the bytes moved and keep the matrix engines fed, and the ResNet-50 INT8 profile collects that benefit only on an execution path that supports both its format and its shapes; how fast such a path can possibly run follows from one division.

Dividing a model's total operation count by peak arithmetic throughput produces an idealized lower bound on execution time, not a realistic inference latency. On the H100's INT8 tensor path, dividing ResNet-50's 8.2 GFLOP per inference by the 1,979 TOPS peak yields a floor of about 4 µs, against 8 µs at the FP16 peak. Real single-image ResNet-50 inference takes far longer than either floor. Part of that gap is kernel launch, synchronization, and host overhead that no roofline captures; part is memory traffic in low-intensity layers, because bandwidth has improved more slowly than tensor arithmetic throughput. That imbalance decides whether the advertised INT8 peak delivers high sustained utilization or sits largely idle on a given workload (Horowitz 2014; Gholami et al. 2024), and closing the gap requires the other half of the anatomy: the memory hierarchy that supplies the compute units.

11.5 Memory Systems

A neural network kernel starves whenever the memory subsystem cannot deliver operands and consume outputs fast enough to saturate arithmetic pipelines. Modern accelerators provide hundreds of teraflops (or even petaflops) on low-precision tensor datapaths (NVIDIA Corporation 2020a, 2024; Choquette 2023), yet their compute pipelines idle as soon as memory traffic saturates the bus. This

is the memory wall, the growing divergence between arithmetic capability and memory bandwidth, seen from inside the accelerator.

Because deep neural networks manipulate millions or billions of parameters across high-dimensional activation tensors, performance is frequently dictated by data movement rather than raw arithmetic capacity. Accelerators combat this memory wall through tiered storage hierarchies, software-managed scratchpads, high-bandwidth 3D stacked memory, and architectural dataflow strategies designed to maximize spatial and temporal reuse. For the chapter's ResNet-50 workload the question becomes where each activation tile lives between the moment one convolution writes it and the moment the next consumes it, and what each tier on that path costs in time and energy.

↩ The memory wall, the widening gap between compute growth and memory bandwidth growth, is established in section 2.2.

11.5.1 The AI memory wall

Upgrading to an accelerator with twice the peak FLOP/s yields zero speedup when a workload's weights and activations already saturate memory bandwidth, pinning execution time at $\frac{D_{\text{vol}}}{\text{BW}}$. On an accelerator the **AI memory wall** is chiefly this bandwidth ceiling, set by the parameter volumes and activation tensors of deep learning rather than by the single-access latency gap of the classic CPU formulation. Adding more memory capacity does not remove it either, because a model that fits comfortably in device memory still waits on the rate at which its bytes reach the compute units of section 11.4. The energy side of the wall was set out with the energy ladder in section 11.2.3: an off-chip DRAM access costs about 173× the energy of the FP32 multiply that consumes its operand (figure 11.4), and the memory wall adds the time side of the same imbalance, which grows with every hardware generation.

11.5.1.1 Quantifying the compute-memory performance gap

Over the past two decades, peak computational capabilities have grown substantially faster than DRAM bandwidth (Gholami et al. 2024). This divergence stems from physical scaling constraints: while transistor scaling and dense systolic arrays multiply arithmetic throughput, memory bandwidth remains bounded by pin counts, package-substrate routing density, and interface signaling power. Representative high-end accelerators can deliver on the order of 10^3 TFLOP/s of peak tensor throughput (for example, NVIDIA H100 delivering 989 TFLOP/s in FP16 or 1,979 TFLOP/s in dense FP8) while providing approximately 3.35 TB/s of memory bandwidth (Choquette 2023). This implies that on the order of 10^2 FLOP of work per byte moved is required to fully use the compute, a threshold section 11.6.2 calls the ridge point and that exceeds the arithmetic intensity of many practical neural network workloads.

When a workload's arithmetic intensity falls below this threshold, data transfer ($\frac{D_{\text{vol}}}{\text{BW}}$) sets the larger of the two modeled time bounds. Accelerators attempt to tolerate memory latency (typically hundreds of clock cycles for off-chip DRAM) by maintaining thousands of concurrent execution threads and switching between active warps while memory requests remain in flight. However, when memory bandwidth saturates or when register pressure limits occupancy, the scheduler runs out of independent instructions to issue. Compute pipelines then stall, leaving high-throughput tensor cores idle while waiting for operands. Simultaneously, driving wide off-chip memory buses across capacitive printed circuit board traces and PHY interfaces consumes a substantial fraction of the chip's thermal design power (TDP), directly constraining the energy budget available for arithmetic logic (Horowitz 2014; Sze et al. 2017).

The time gap and the energy ladder describe the same pressure from two sides: each byte fetched from DRAM costs more time relative to the arithmetic it feeds with every generation, on top of its energy cost. The TPUv1's performance-per-watt advantage (example 11.1) came largely from minimizing that off-chip movement through systolic arrays and large on-chip SRAM (Jouppi et al. 2017). Whether a model can exploit such a design depends on the pattern of its memory accesses, which differs sharply among parameters, activations, and optimizer state.

Hardware balance is the supply side of the memory wall; model size is the demand side. The structural widening between model footprints and available memory bandwidth is what turns the iron law's memory term into the binding constraint across generations. Parameter count is a capacity quantity. In low-batch dense decoding with weights streamed from device memory, weight traffic per generated token grows with the parameter count. Sparse expert models read selected experts rather than every stored parameter, so their total parameter counts do not directly specify per-token traffic.

Figure 11.7 plots this logarithmic divergence relative to 2014, contrasting the roughly 3,900× increase in dense model parameters (filled red points) against the 33× increase in per-device accelerator memory bandwidth (blue points) to isolate the widening shaded memory-wall gap (Krizhevsky et al. 2012; Simonyan and Zisserman 2015; Brown et al. 2020; Chowdhery et al. 2022; Dubey et al. 2024). DeepSeek-V3 appears as an open marker at its total parameter count and is left out of the trend for exactly that reason (DeepSeek-AI 2025). Even high-bandwidth accelerators such as NVIDIA B200 and AMD MI300X/MI325X cannot close this growth-rate gap through bandwidth scaling alone (NVIDIA Corporation 2024; AMD 2023). Parameter counts for proprietary systems such as GPT-4 and Gemini are not officially disclosed, so they are not plotted as factual data points.

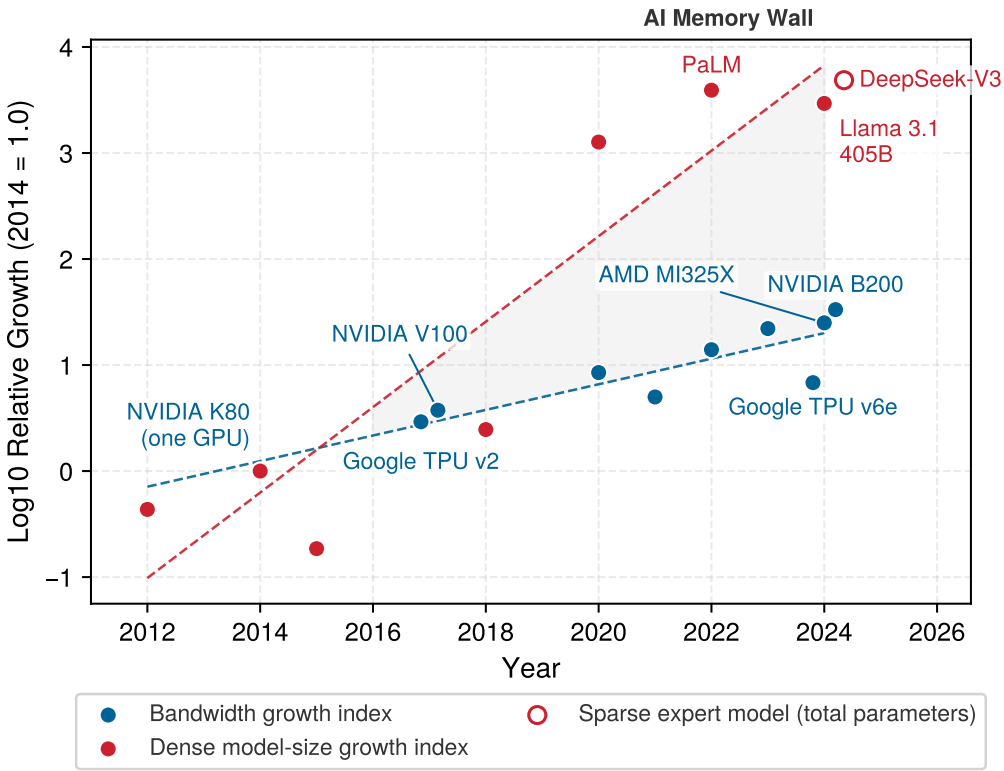

Figure 11.7: Model Size vs. Hardware Bandwidth: Both series are the base-10 logarithm of growth relative to 2014 (VGG-16 for parameters, one GPU of the dual-GPU K80 board for bandwidth), so each unit on the vertical axis is a tenfold increase. Over the plotted decade dense parameter counts grow roughly 3,900× against per-device bandwidth's 33×. The open marker is a sparse expert model plotted at total parameters and excluded from the fit. The shaded band is a gap between logarithms rather than a difference, so its width reads as a ratio, and the fitted trends describe the decade's average rates; the dense frontier has been flat since 2022. Method after Gholami et al. (2024).

11.5.2 Memory access patterns in ML workloads

In dense FP16 autoregressive generation at batch size 1, streaming a model's weights from device memory for each generated token yields roughly 1 FLOP/byte on the matrix-vector work, starving compute units before activations or gradients ever enter the picture. Across training and inference, parameters, activations, and optimizer states compete for that same memory bandwidth in distinct ways. Model parameters (weights and biases) can span hundreds of billions of values (Brown et al. 2020) that must stream from memory whenever batch reuse is low. Intermediate activations produced at each layer must also be buffered for subsequent operations, and during training those forward activations must either stay in memory until backpropagation consumes them or be recomputed on the backward pass. Training then compounds the traffic with gradients and optimizer state: backpropagation writes a gradient for every parameter, and adaptive optimizers such as Adaptive

Moment Estimation (Adam) read and write multi-word momentum states on every step, multiplying the bytes moved per parameter update (Narayanan et al. 2021; Kwon and Rhu 2018).

The physical cost of this data movement depends on where each tensor resides in the memory hierarchy. While an on-chip register access completes in a single clock cycle at sub-picojoule energy, a dependent off-chip DRAM fetch can expose hundreds of cycles of latency and expends orders of magnitude more energy. Independent requests can overlap that latency, subject to available concurrency and bandwidth. Tracing a single tensor of the chapter's ResNet-50 workload through the memory tiers during an inference pass makes this disparity concrete (lighthouse 11.2).

Lighthouse 11.2: Life of a tensor: A ResNet-50 activation map

Follow one activation map of the chapter's ResNet-50 workload, the output of a stage-2 convolution (56×56 positions by 64 channels), on its way to the next convolution's Tensor Cores on an H100:

1. **HBM**: The previous kernel wrote the map here.
   - **Size**: 201 KB per image at INT8 and 401 KB at FP16; a batch of 32 holds 6.4 MB at INT8.
   - **Latency**: A dependent off-chip request takes about 300 ns, while streaming one image's map at full bandwidth would take only about 60 ns, so the kernel must keep many requests in flight to approach the bandwidth ceiling.
   - **Energy**: About 160 pJ per byte in the 45 nm estimates used throughout the chapter, or about 32.1 µJ to read one image's map once.
2. **L2 cache**: The H100 shares 50 MB of L2 across its streaming multiprocessors (SMs), enough to hold the whole batch's map at INT8 if the next kernel consumes it soon after the previous one wrote it.
   - **Latency**: About 150 ns on Hopper.
3. **Shared memory**: One SM stages a tile of the map in its 228 KB of software-managed shared memory. A whole image's map fits at INT8 but not at FP16, so the INT8 format changes which tier can hold it.
   - **Latency**: About 17 ns on Hopper.
4. **Registers**: The Tensor Core reads its operands here.
   - **Latency**: A small number of cycles, depending on the instruction.
   - **Energy**: About 0.1 pJ per access, more than three orders of magnitude below an off-chip access.
   - **Device arithmetic peak**: 1,979 TOPS on the H100 INT8 tensor path, the rate these registers must sustain, not a register-transfer rate.

Systems insight: Latency and energy per access rise from registers to HBM. The working set's location, access count, reuse, and dependencies determine the memory contribution to time and energy; arithmetic adds its own cost. The bandwidth term of the roofline is whichever link of this ladder the working set must cross; HBM-to-L2 is one possible limiting link, not the only one.

The boundary between bandwidth-bound and compute-bound execution emerges directly from the balance between data transfer time and arithmetic execution time. For a workload requiring data volume D_{vol} (bytes) across available memory bandwidth BW (bytes/s), and executing O floating-

point operations on hardware with peak throughput R_{peak} (FLOP/s) at realized hardware utilization η_{hw}, the respective execution times are the iron law's data and compute terms:

$$T_{\text{memory}} = \frac{D_{\text{vol}}}{\text{BW}}$$
$$T_{\text{compute}} = \frac{O}{R_{\text{peak}} \cdot \eta_{\text{hw}}}$$

In a strictly sequential model without overlap, $T_{\text{memory}} > T_{\text{compute}}$ identifies bandwidth-bound execution. When hardware overlaps memory transfers with computation, the larger term sets the theoretical lower bound on execution time. In practice, however, data dependencies, memory controller queueing, and partial pipeline overlap dictate how much arithmetic hardware remains idle while waiting for operands.

11.5.2.1 Irregular memory access

Production machine learning workloads combine regular dense matrix kernels with irregular memory access patterns that defeat conventional caching and prefetching hardware. While dense operations like general matrix multiply (GEMM) and convolution stream contiguous blocks that map cleanly onto hardware caches and systolic arrays, irregular operations rely on indirect, sparse, or input-dependent memory addresses. Table 11.5 contrasts these two memory regimes across access geometry, cache locality, and hardware pressure.

Table 11.5: Regular and Irregular Memory Access: Regular dense kernels expose tileable reuse and predictable addresses, whereas irregular ML components rely more on indirect or input-dependent access, weakening caching and prefetching and adding metadata or load-balance overhead. A single model may contain both regimes.

Feature	**Regular dense kernels**	**Irregular ML components**
Access pattern	Contiguous or tiled	Indirect, scattered, or input-dependent
Cache locality	Often high after tiling	Often lower and workload-dependent
Data reuse	Structured across tiles or batches	Sparse or dynamic, depending on the operator
Dependencies	Static loop nests	Input-dependent routing or variable shapes
Examples	GEMM, convolution, dense attention	Embedding lookup, unstructured sparsity, MoE routing
Primary pressure	Compute or bandwidth, depending on arithmetic intensity	Latency, bandwidth, metadata, and load imbalance
Energy consequence	Depends on reuse and memory tier	Extra movement and metadata can increase energy

Within a single neural network, memory access behavior varies sharply across layer types. Convolutional layers have high spatial locality and register reuse as small weight kernels slide across input feature maps, whereas fully connected layers and dense attention execute regular matrix multiplications whose large parameter matrices or key-value caches can exceed on-chip SRAM capacity and become bandwidth bound when operational reuse is low. Variable sequence lengths complicate memory buffer allocation, yet the attention operations within each sequence remain regular, contiguous matrix multiplies.

True memory irregularity arises instead from unstructured sparsity,[19] embedding lookups, and dynamic token routing. Unstructured sparsity stores nonzero weights or activations in compressed formats (such as CSR or COO) that require pointer indirection to decode operand coordinates. Embedding tables break sequential transfers in a different way: sparse categorical IDs select arbitrary rows from tables spanning tens of gigabytes in DRAM, turning reads into uncoalesced, scattered fetches. DLRM, the book's capacity-bound lighthouse, is the extreme case, because its embedding tables exceed one accelerator's memory and each lookup fetches a short row from an address known only when the input arrives, defeating both caches and prefetchers. Mixture-of-Experts (MoE) models introduce a third irregularity at the routing layer, where gates direct tokens to different expert networks based on input context; although deterministic for a given input, token assignments vary across batches, disrupting prefetch pipelines and unbalancing execution queues across parallel cores.

[19] **Sparsity and memory irregularity**: Unstructured sparse formats commonly gather nonzero elements through indirect addressing, which can weaken sequential access and make metadata overhead significant. Structured sparsity preserves hardware-friendly blocks, so its access behavior differs from arbitrary pruning. Without suitable kernels or hardware support, an unstructured sparse model can run slower than its dense counterpart despite performing fewer arithmetic operations.

Irregularity degrades performance through distinct mechanisms, and treating them as one memory problem can point to the wrong optimization. Scattered addresses may turn one logical access into several memory transactions, so each fetched cache line carries few useful payload bytes. Indirection can also serialize address generation: the system must fetch an index or pointer before it knows which payload to request, limiting memory-level parallelism even when aggregate bandwidth remains available. Input-dependent routing creates a third failure mode when some processing elements receive longer queues than others; completion time follows the slowest queue while neighboring units idle. Variable-sized allocations may fragment capacity, but fragmentation is neither necessary nor sufficient for irregular access. A sequential stream can saturate bandwidth without being irregular, whereas a dependent lookup chain can stall far below peak bandwidth.

Diagnosis should therefore begin with the mechanism that prevents forward progress. A low ratio of useful payload bytes to transferred bytes indicates poor spatial utilization or coalescing. Long memory stalls alongside unused bandwidth indicate dependent misses or too few concurrent requests to hide latency. Uneven queue depths or per-route work reveal load imbalance rather than a cache-capacity problem. Cache hit rate alone cannot distinguish these cases because a miss can waste bandwidth, expose latency, or both. Each diagnosis implies a different remedy: packing or blocking improves spatial utilization, reordering and prefetching expose concurrent requests, structured sparse formats reduce indexing overhead, and routing or partitioning balances work. The memory hierarchy determines the cost of the remaining accesses, while dataflow and tensor-layout choices determine how much irregularity software can remove before execution reaches the hardware.

The optimization order follows that diagnosis. Representation comes first when the format is under system control because a block-structured sparse format or grouped routing can remove indirection before a kernel executes. Request organization comes next: accesses issued together should target adjacent addresses, and enough independent requests must remain in flight to hide unavoidable latency. Additional cache capacity or bandwidth helps only when profiling shows that the regularized request stream still exhausts that resource. More bandwidth cannot resolve a serial pointer dependency, and more capacity cannot rebalance skewed work. The objective is to expose as much regular structure as possible while confining unavoidable irregularity to the smallest portion of execution.

Software can mitigate irregular access by regularizing tensor layouts, enforcing structured sparsity, and sorting dynamic routes into uniform batches. Yet software restructuring cannot eliminate the physical penalty of data movement: whether a memory request is contiguous or scattered, every transferred byte must cross physical wires governed by finite bandwidth, propagation latency, and energy dissipation. Bounding these physical costs requires organizing storage into cascading hardware tiers. Rather than treating memory as a uniform pool, accelerator architectures deploy multilevel memory hierarchies that trade off capacity against latency and energy at every tier.

11.5.3 Memory hierarchy

No single storage technology can simultaneously satisfy the multi-terabyte-per-second bandwidth required by dense execution units and the tens of gigabytes of capacity required to hold modern model parameters. Accelerators resolve this tension through multilevel memory hierarchies. Rather than treating memory as a monolithic address space, the machine organizes storage into distinct physical tiers, each optimized for a specific balance of capacity, access latency, bandwidth, and energy dissipation.

At the apex of the hierarchy, register files and on-chip SRAM caches supply operands to arithmetic units with sub-nanosecond latency and single-digit picojoule energy costs, but their capacity is strictly limited by silicon die area. At the base, nonvolatile flash storage holds hundreds of gigabytes of model checkpoints and training datasets, but requires milliseconds or microseconds to access. Between these boundaries, software-managed scratchpads stage active tensor tiles, while device-local DRAM (such as HBM or GDDR) provides the primary working memory for parameters and activations.

This organization establishes an inverse relationship across tiers: as storage capacity expands and physical distance from arithmetic units grows, bandwidth falls, latency lengthens by orders of magnitude, and energy consumption per bit escalates. Table 11.6 compares these tiers across latency, bandwidth, capacity, and functional roles in deep learning workloads.

Table 11.6: Memory Hierarchy Trade-Offs: AI accelerators use a multilevel memory hierarchy to balance performance and capacity. Each level provides distinct latency, bandwidth, and capacity characteristics that dictate how neural network components (weights, activations, and intermediate results) should be allocated to minimize bottlenecks and maximize throughput. Relative labels describe the typical ordering; exact values depend on architecture. Section D.1.1 supplies registry-backed reference latencies.

Memory Level	**Relative latency**	Bandwidth	**Relative capacity**	**Example Use in Deep Learning**
Registers	Lowest	Highest	Tiny	Storing operands for immediate computation
L1/L2 Cache (SRAM)	Very low	High	Small	Caching frequently accessed activations and small weight blocks
Scratchpad memory	Very low	High	Small to medium	Software-managed storage for intermediate computations
Device DRAM (HBM, GDDR, or LPDDR)	High	Moderate–Very High	Large	Storing model parameters and activations that do not fit on-chip
Host DRAM (typically DDR)	High locally; transfer adds latency	Moderate	Large to very large	Staging or offloading data outside accelerator memory
Flash Storage (SSD/NVMe)	Very high	Low	Very large	Storing pretrained models and checkpoints for later loading

A recurring systems question is why accelerators cannot bypass on-chip SRAM entirely and stream all operands directly from high-capacity off-chip DRAM. A dependent DRAM request exposes the full access latency. Many independent requests can hide that latency, but their sustained operand supply remains limited by off-chip bandwidth; on-chip staging also enables reuse.

Napkin Math 11.2: Why HBM cannot feed the array directly

Problem: Why is on-chip SRAM necessary instead of fetching all data from HBM?

Math:

1. **Clock cycle**: At 2 GHz, $1/(2\ \text{GHz}) = 500$ ps.
2. **DRAM access**: Off-chip HBM sits millimeters away on the package, but row activation, DRAM-array latency, serialization, protocol traversal, and queuing add up to 100+ cycles per access.
3. **Distance, for comparison**: On an H100-class 814 mm² die, signals travel ~20 mm; at $\approx 0.5c$, $20\ \text{mm}/(0.5c) \approx 130$ ps, less than one cycle.

Systems insight: The propagation estimate alone does not explain the DRAM access cost, and it omits real interconnect delay from wiring and routing. Independent requests can overlap the 100-plus-cycle access path; a dependent request cannot. Registers and SRAM supply operands at the rate the array needs while reusing values that would otherwise cross HBM repeatedly. Transformer tiling addresses both operand supply and reuse, whereas streaming a growing KV cache can still limit inference when its required traffic exceeds the available bandwidth.

11.5.3.1 On-chip memory

The **on-chip memory** subsystem integrates registers, Static Random-Access Memory (SRAM) caches, and software-managed scratchpads directly on the accelerator die. Register files provide the immediate operand and accumulator storage needed by execution pipelines. Modern accelerators provision substantial register capacity in aggregate across the chip, but partition this pool dynamically among concurrent threads or warps. Increasing per-thread register allocation allows individual threads to retain larger matrix tiles, but limits the total number of concurrently scheduled warps, reducing the hardware's ability to hide memory latency. Conversely, underallocating registers forces the compiler to spill values to off-chip memory, converting single-cycle register accesses into multi-cycle stalls. Efficient kernel design balances register allocation to maintain maximum occupancy while keeping hot operands resident.

Hardware-managed L1 and L2 caches provide fast buffering for frequently referenced data using automatic tag checking and hardware eviction policies. However, automatic caches are poorly suited for streaming multi-gigabyte tensor operations: scanning through large activation tensors can evict reusable weight tiles before arithmetic units can reuse them. Furthermore, specialized execution pipelines impose strict layout and data-type constraints that general caches cannot satisfy automatically. As illustrated in example 11.3, hardware matrix engines require specific alignments and memory layouts; a mismatch may require padding, conversion, or a different kernel whose efficiency must be checked.

Example 11.3: Tensor Cores that never engage

Scenario: An engineering team migrates a transformer workload to NVIDIA A100 GPUs expecting automatic Tensor Core acceleration, but profiling reveals Tensor Cores remain idle (NVIDIA Corporation 2020a).

Diagnosis: The workload used shapes and data types that selected less efficient kernels rather than the intended Tensor Core path.

Systems lesson: Specialized paths have operator, precision, layout, and shape requirements. Libraries can often handle nonaligned dimensions through padding or alternative kernels, but reaching high utilization requires verifying which path was actually selected.

To avoid the eviction overhead and unpredictability of automatic caches, AI accelerators incorporate scratchpad memory. Unlike hardware caches, scratchpads are software-managed SRAM structures mapped directly into the core's address space without tag directories or hardware replacement logic. The compiler or programmer explicitly controls when tensor tiles are loaded from external DRAM, how long they reside on-chip, and when updated values are written back. In convolutional models, scratchpads retain input feature maps and weight kernels across sliding receptive windows, eliminating redundant DRAM reads (Chen et al. 2017). On NVIDIA GPUs, scratchpad memory is exposed as *shared memory*: a fast, programmer-controlled SRAM bank shared across all threads within a thread block. Custom kernels written in CUDA or Triton manage shared memory explicitly. FlashAttention demonstrates the power of this mechanism: rather than materializing the full $S \times S$ attention score matrix in off-chip HBM, the kernel tiles queries, keys, and values through shared memory and updates softmax statistics online (Dao et al. 2022). The speedup stems entirely from eliminating high-latency HBM round trips rather than reducing arithmetic operations; in fact, the algorithm recomputes intermediate attention values during the backward pass to avoid storing them to off-chip memory.

↩ FlashAttention as an IO-aware attention kernel for training is established in section 8.6.4.

11.5.3.2 Off-chip memory

When tensor working sets exceed on-chip SRAM capacity, operands and parameters reside in device-local DRAM. Rather than sequential hierarchy levels, HBM, Graphics DDR (GDDR), and Low-Power DDR (LPDDR) represent alternative memory architectures engineered for distinct cost, bandwidth, and power envelopes. High-performance accelerators use HBM, which stacks DRAM dies vertically using through-silicon vias (TSVs) and interfaces with the accelerator die across a wide silicon interposer (e.g., 1,024 to 8,192 bits). This wide bus delivers multi-terabyte-per-second bandwidth at lower clock frequencies and lower energy per bit than conventional DRAM, but requires complex 2.5D packaging. Where silicon interposers are cost-prohibitive, accelerators adopt GDDR, which uses narrower buses (e.g., 256 to 384 bits) driven at high pin speeds across standard circuit boards. Mobile and embedded accelerators use LPDDR, trading raw bandwidth for low operating voltage and reduced standby power.

When parameter and activation footprints exceed device-local DRAM capacity, the system must offload state to host DRAM (typically standard DDR). Accessing host memory requires crossing an I/O interconnect such as PCIe or a coherent fabric like NVLink or Compute Express Link (CXL). Because PCIe bandwidth (tens of gigabytes per second) is one to two orders of magnitude lower than accelerator DRAM bandwidth, unmanaged offloading stalls arithmetic execution. Efficient runtimes mitigate this penalty by overlapping asynchronous direct memory access (DMA) copies with kernel execution, prefetching upcoming layer parameters while current layers compute.

At the base of the hierarchy, nonvolatile flash storage and solid-state drives (SSDs) provide persistent, multi-terabyte capacity for datasets and training checkpoints (Narayanan et al. 2021). With read latencies measured in tens of microseconds and bus bandwidths capped at single-digit gigabytes per second, flash devices cannot participate directly in kernel execution. Checkpointing and data-loading pipelines treat flash storage as an asynchronous streaming source, staging batches through host DRAM into accelerator memory before computation begins.

The physical tiers of the memory hierarchy establish the latency floors and capacity ceilings of the accelerator, but advertised memory bandwidth is only a ceiling within them; achievable bandwidth depends on access pattern, batching, locality, and the host interface that feeds the accelerator. Peak figures assume continuous, stride-1 coalesced access across all memory channels. Real neural network workloads deviate substantially from this ideal: transformer attention, convolution, and fully connected layers realize distinct fractions of peak bandwidth because their memory access strides, tiling dimensions, and operational reuse differ. A sufficiently large, coalesced weight stream can approach peak bandwidth even at small batch size. Batching instead reuses each loaded weight across more samples, raising arithmetic intensity as analyzed under the roofline model in section 11.6. Small or irregular kernels may lack enough concurrent accesses to approach the bandwidth ceiling, making memory latency and available parallelism part of the diagnosis.

11.5.4 Host-accelerator communication

An accelerator rated for hundreds of teraflops sits idle if its input tensors are still crawling across a host PCIe bus an order of magnitude slower than its on-package HBM. In discrete accelerator systems, the host CPU and the accelerator operate as separate computational domains joined by a peripheral bus: the host manages storage I/O, network streams, and runtime orchestration in system DRAM, while the accelerator executes dense mathematical kernels over device memory (HBM or GDDR). Because those two memories occupy separate physical address spaces, computation cannot begin until tensors cross the host-accelerator interconnect, making peripheral bus bandwidth and launch latency a hard gate on end-to-end speedup.

Figure 11.8 sequences the four-stage execution trace across host and device lifelines: copying input data across PCIe to device memory via DMA (step 1), dispatching kernel instructions from the CPU (step 2), executing parallel core compute with local writeback (step 3), and copying results back to host memory (step 4). In a naive synchronous execution model, every transfer step sits directly on the critical path, stalling either the host or the accelerator until each memory transaction finishes.

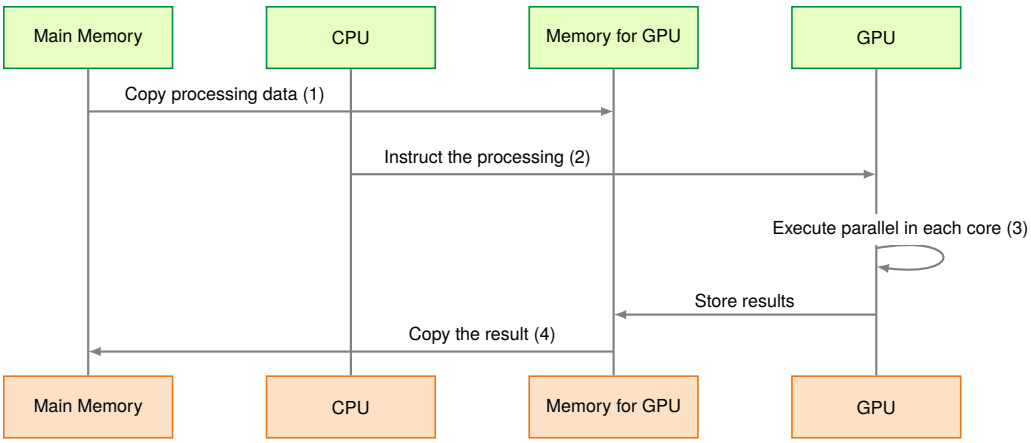

Figure 11.8: Host-Accelerator Data Transfer Sequence: Four-step execution flow between CPU host and GPU device: (1) copying input data over PCIe, (2) issuing kernel instructions, (3) GPU compute, and (4) transferring results back to host memory. Low PCIe bandwidth and host dispatch latencies can easily dominate runtime unless kernel compute time exceeds data transfer overhead.

The end-to-end latency of a kernel launch decomposes into transfer time, queue dispatch overhead, and arithmetic execution time. When tensor transfers are small or frequent, the fixed overhead of driver submission and bus round trips dominates runtime. When transfers are large, the low

bandwidth of PCIe relative to on-package HBM creates a sustained I/O bottleneck. In D·A·M terms, the Machine boundary between host and accelerator forces the Algorithm to maximize arithmetic reuse on the device once tensors arrive.

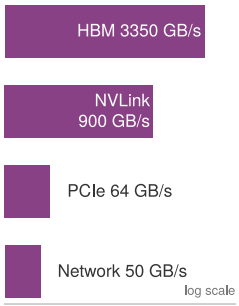
11.5.4.1 Node-level interconnect topology

Within a single machine, how bits move between GPUs and the CPU sets the next ceiling. In the 1–8 GPU regime, scaling is achieved through high-speed intra-node interconnects such as NVLink and host-to-device PCIe transfers that mitigate the memory wall. These links form a **bandwidth taper**: data-movement speed falls at each step away from the compute units, from on-package HBM through the GPU-to-GPU NVLink bridge down to the host PCIe link. The PCIe step is much slower than the accelerator-local memory and inter-GPU fabric, so any data path that touches the CPU can become a performance hazard, and keeping accelerator-to-accelerator traffic off that link is the reason NVLink exists (NVIDIA Corporation 2020c). A typical AI server is therefore not a flat mesh of connected devices, and optimizing data movement starts from its physical topology.

Within a multi-accelerator server node, two interconnect tiers define this bandwidth taper below device memory:

1. **Device-device interconnect (NVLink/Infinity Fabric)**: Modern multi-GPU nodes use specialized high-speed bridges like NVLink[20] to connect accelerators directly, bypassing the host CPU. Bandwidth ranges from 600 GB/s to 900 GB/s per GPU (NVIDIA Corporation 2020c; Choquette 2023). This link matters whenever tensors must move between accelerators within one server, including model partitioning, activation exchange, and gradient synchronization during training. The architectural principle is the boundary: traffic that stays on the accelerator fabric is far cheaper than traffic that falls back through the host.
2. **Host-device interconnect (PCIe)**: The link between the CPU and the accelerator. Bandwidth ranges from 32 to 64 GB/s (PCIe Gen4/Gen5). Host-staged training data can bottleneck here, although resident data, direct storage or network I/O, and coherent accelerator links can use other paths. Multi-GPU servers may also provide multiple PCIe links rather than a single shared 64 GB/s path.

A third tier, the network link from one server to others, continues the taper beyond the node (section 11.9). Together the levels produce a characteristic bandwidth taper:



$$\begin{aligned}\text{HBM (3350 GB/s)} &\gg \text{NVLink (900 GB/s)} \\ &\gg \text{PCIe (64 GB/s)} > \text{Network (50 GB/s)}\end{aligned}$$

System efficiency depends on keeping tensors on the highest-bandwidth links available. Because PCIe and network links offer orders of magnitude less bandwidth and higher latency than on-package memory, placement and scheduling must minimize crossings across these boundaries.

11.5.4.2 Transfer optimization

The standard remedy for transfer overhead is the asynchronous pipeline of section 7.5.2. Batches staged in pinned (page-locked) host memory are copied by dedicated DMA engines while the accelerator computes on the previous batch. This double buffering conceals transfer latency behind arithmetic runtime whenever computation time exceeds transfer time ($T_{\text{compute}} \geq T_{\text{transfer}}$). When compute duration is too short to amortize the transfer, execution remains bus bound and the compute units stall.

Unified Memory takes the opposite approach, presenting a single virtual address space that spans host DRAM and device HBM while the driver migrates pages on demand whenever either processor touches an address. On-demand migration removes staging code at the cost of predictability, because each page fault stalls execution and scattered accesses can thrash pages across the PCIe bus. High-throughput production workloads therefore rely on explicit, pipelined DMA transfers and reserve Unified Memory for prototyping or for applications where programmer productivity outweighs sustained hardware utilization.

Bandwidth tapers steeply as data moves farther from the accelerator.

20 **NVLink (NVIDIA Link)**: This direct GPU-to-GPU interconnect exists to keep accelerator-to-accelerator traffic off PCIe when tensors must move inside a server. Its 600–900 GB/s aggregate bidirectional bandwidth is roughly 300–450 GB/s per direction under balanced full-duplex traffic, several times the directional bandwidth of a standard PCIe link, so workloads with frequent cross-device tensor movement can remain in the fast part of the bandwidth taper (NVIDIA Corporation 2020c; Choquette 2023). Training algorithms determine how much tensor traffic must cross this link; the hardware fact needed here is the bandwidth gap.

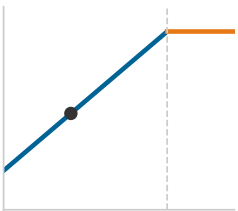
↩ The feeding problem, in which data delivery fails to keep pace with compute throughput, is established in section 4.9.3.

11.5.5 Model memory pressure

An optimization that relieves memory pressure for one model family can leave another untouched: caching weights helps nothing when ResNet-50's early convolutions spill large activation maps to DRAM, and spatial activation tiling helps nothing when GPT-2 decode streams gigabytes of weights for a single token. Model architecture determines which memory term binds. The architectural reasons each family stresses memory as it does were traced in section 6.9.1; the hardware consequence differs by family, and the lighthouse models of table 1.4 cover the cases.

Dense layers, the multilayer perceptron (MLP) blocks that every family contains, are bound by weight traffic at small batch. At batch size $B = 1$, each parameter loaded from off-chip memory serves a single multiply-accumulate operation (often ≤ 1 FLOP/byte), so execution sits on the bandwidth slope; batching reuses each loaded weight across B inputs and moves the layer toward the compute ceiling. Dense weight matrices regularly exceed the tens of megabytes of on-chip SRAM, so parameters reside in HBM and stream through tiles that the accelerator double-buffers into SRAM (Chen et al. 2017). The host link enters the critical path only when inputs stream from the host or when the model exceeds device memory.

Convolutional layers, the core of ResNet-50, place their memory pressure on activations rather than weights. Small filters sliding across feature maps supply three forms of reuse: neighboring windows share input activations, each filter is applied at every spatial position, and each input channel feeds every output filter. Early layers therefore carry compact parameter tensors but large activation maps that exceed on-chip SRAM, and unoptimized layer-by-layer execution spills those maps to device DRAM. Spatial tiling keeps activation tiles, with their overlapping boundary pixels, in on-chip buffers so adjacent convolutions consume them without refetching (Chen et al. 2017).



Transformers such as GPT-2 stress both capacity and bandwidth, differently in each phase. During training and prefill, standard attention materializes an $S \times S$ score matrix for sequence length S and moves $\mathcal{O}(S^2)$ bytes through HBM; IO-aware kernels such as FlashAttention (Dao et al. 2022) keep those tiles in on-chip SRAM instead (section 8.6.4). During autoregressive decode, each generated token reads the weights and the accumulated key-value (KV) cache from HBM for a vector-matrix product, which binds generation speed to memory bandwidth.

↩ How much memory one request's KV cache claims as its sequence grows is established in section 6.7.4.2.

Two other lighthouses stress memory in other ways: DLRM's sparse embedding lookups stress random-access bandwidth rather than dense compute, and MobileNetV2's depthwise convolutions trade arithmetic intensity for a smaller parameter footprint, so both reappear as memory-bound rows in the roofline operations table (table 11.7). Accelerators answer these divergent demands with the tiered hierarchy. On-chip SRAM captures high-reuse activations and tiled matrix blocks at tens of terabytes per second, HBM stages large weight tensors and sequence state, and NVLink-class links carry tensors between accelerators when a model exceeds one device, avoiding the narrower host PCIe bus. Table 11.14 later pairs each family's memory profile with the mapping that answers it. Because a reference off-chip DRAM access costs far more energy per event than arithmetic (figure 11.4), reducing repeated external accesses improves efficiency, but deciding whether a given kernel is limited by compute throughput or by memory bandwidth requires an analytical boundary. The roofline model supplies that boundary by comparing operational intensity against hardware performance limits, so that optimization effort targets the resource that actually binds.

11.6 Performance Bounds

The compute units fix how fast an accelerator can calculate, and the memory system fixes how fast it can be fed. A kernel's performance is bounded by whichever of the two runs out first. Putting numbers on that statement takes three pieces: the roofline's ceilings for each precision path, the ridge point at which they meet, and the hardware balance that moves the ridge from one generation to the next. The ResNet-50 INT8 workload meets its sharpest lesson in these bounds. The INT8 path doubles the H100's arithmetic ceiling without moving its bandwidth ceiling, so a layer that cleared the ridge at FP16 can fall below it at INT8.

Low arithmetic intensity places the modeled throughput ceiling on the bandwidth slope.

11.6.1 The roofline model

Quoting an accelerator's peak FLOP/s cannot explain why one kernel runs near the hardware ceiling while another stalls below 1 percent of peak on the same chip, because peak compute measures only what execution units can retire when operands are already in registers. Sustained throughput is

bounded by whichever limit—arithmetic capacity or memory bandwidth—runs out first. With the compute units and memory systems that set those two ceilings now in place, the **roofline model**[21] (Williams et al. 2009), which sorted training kernels in section 8.3.4, makes this diagnosis quantitative. It plots attainable performance against arithmetic intensity and identifies the lower modeled ceiling, compute or memory bandwidth, for the chosen execution path before profiling establishes which physical resource limits execution.

Performance is bounded by two ceilings, as equation 11.2 formalizes; it writes the bound of the arithmetic intensity law (principle 6) as an idealized equality that ignores launch and synchronization overheads. Here, attainable performance R_{attain} and peak compute R_{peak} are in FLOP/s (often reported as TFLOP/s), peak bandwidth BW is in bytes/s (often TB/s), and arithmetic intensity I is in FLOP/byte:

$$R_{\text{attain}} = \min(R_{\text{peak}}, \text{BW} \times I) \tag{11.2}$$

Arithmetic intensity $I = O/D_{\text{vol}}$ is the ratio of operations to bytes moved across the memory interface being modeled (definition 5.3), and it depends on the implementation as well as the operation. Under the stated traffic models, a large well-tiled 1024×1024 multiply reaches about 341.3 FLOP/byte, while standalone ReLU is about 0.125 FLOP/byte, so the two meet different ceilings on the same hardware.

The roofline visualization shows performance (TFLOP/s) on the vertical axis and arithmetic intensity (FLOP/byte) on the horizontal axis. At low arithmetic intensity, the upper bound increases linearly along the memory bandwidth slope ($\text{BW} \times I$). Above the ridge point, the upper bound is peak compute (R_{peak}). A kernel approaching the slope is bandwidth limited, while one approaching the flat roof is compute limited on the specified path. Merely lying below either line does not establish the cause; profiling explains that remaining gap. Section A.5.3 maps each regime to the optimizations that pay off and the ones that waste effort, so classifying a kernel tells the engineer whether more bandwidth, less traffic, or more arithmetic throughput is the investment to test first.

21 **Roofline model**: Introduced by Williams et al. (2009) at UC Berkeley, building on earlier I/O complexity work from the 1980s. Their specific contribution was making the compute vs. bandwidth trade-off visual and actionable: the characteristic roofline plot immediately reveals whether a kernel is compute bound (hitting the flat ceiling) or memory bound (hitting the sloped bandwidth line) and quantifies the gap to hardware limits. A kernel operating at only 50 percent of its ceiling has 2× theoretical headroom, but instruction mix, latency, and occupancy may prevent it from closing that gap.

11.6.2 Hardware ridge points

A kernel with 200 FLOP/byte that was comfortably compute bound on a V100 or A100 falls below the compute ceiling when migrated unchanged to an H100, because different devices place the compute-bandwidth boundary at different intensities. The **ridge point**, the balance point between a machine's memory and compute limits previewed alongside the iron law, is a property of the device. Computer architects call the same ratio the **hardware balance** (I_{ridge}), peak arithmetic throughput divided by peak memory bandwidth, the intensity at which the roofline's compute and bandwidth ceilings intersect:

$$I_{\text{ridge}} = \frac{R_{\text{peak}}}{\text{BW}}$$

The ratio sets a device-specific boundary. Depending on the chosen precision, the H100 requires about 295.2 FLOP/byte on its dense FP16 path (989 TFLOP/s over 3.35 TB/s) to reach its arithmetic ceiling, and twice that on its INT8 path, whereas a microcontroller may have a much lower ridge point. The same kernel can therefore be bandwidth bound on a compute-dense accelerator and compute bound on an edge processor. Hardware balance does not label either device as universally efficient; it identifies how much reuse a workload needs on that device.

Peak computational capability has expanded faster than memory bus performance across accelerator generations, and the size of that mismatch is what sets how much data reuse a kernel needs to stay fed. Across 2017–2024, NVIDIA's data center generations multiplied dense FP16 compute by 18× and memory bandwidth by only 8.9×, a 2.0× rise in the reuse a kernel needs on B200 relative to V100.

That ratio measures how far the hardware ridge point, the threshold a kernel must clear to become compute bound, has risen since the V100. Figure 11.9 plots it generation by generation, leaving out the H200 exception, so the doubling of the gap appears directly as the ridge point roughly doubling from V100 (139 FLOP/byte) to H100 (295 FLOP/byte) and then holding near that level on B200 (281 FLOP/byte). A kernel that cleared the V100 ridge comfortably can fall below the H100 ridge without any change to its code, so newer hardware demands more operational reuse before execution reaches peak throughput.

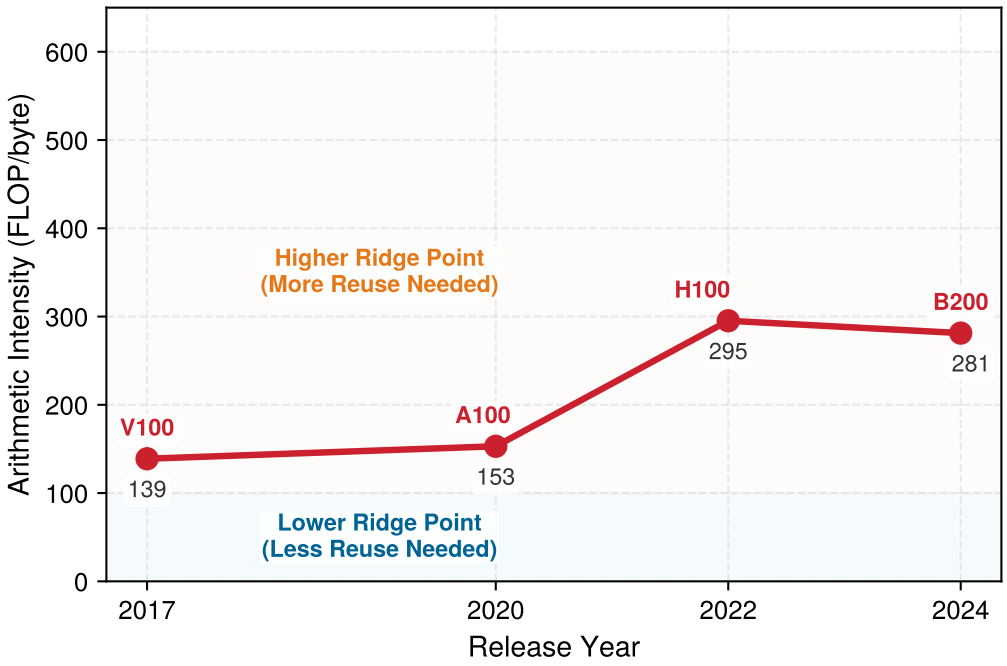


Figure 11.9: The Rising Ridge: Hardware arithmetic intensity (FLOP/byte) over time computed as each chip's dense FP16 tensor peak divided by its memory bandwidth: 125 TFLOP/s over 0.9 TB/s for V100, 312 TFLOP/s over 2.04 TB/s for A100, and 989 TFLOP/s over 3.35 TB/s for H100. This is the arithmetic intensity a kernel must reach before compute rather than bandwidth limits it. As compute capability grows faster than memory bandwidth, the ridge point rises from V100 through H100 and remains high on B200. This trend explains why architectures with high data reuse flourish while low-reuse workloads face a growing performance penalty.

The generations in figure 11.9 come from one vendor, but the divergence is industry-wide. Figure 11.10 tracks the best memory bandwidth and the best dense FP16/BF16 tensor throughput among 52 accelerators from every major vendor released since 2017 (Epoch AI 2026b). Measured from TPU v2, the best compute rate grew about 55× while the best bandwidth grew about 13×, so the ridge point of the leading devices rose several-fold; the ratio is larger than the NVIDIA-only one above because TPU v2's 16-bit baseline was low. Since early 2025 the best bandwidth has held near 8 TB/s, and the best dense FP16 rate has leveled as well, because new devices put their added arithmetic into FP8 and FP4 paths rather than 16-bit ones. For a kernel whose reuse stays fixed, this rising ridge shows up as a ceiling on achievable utilization that falls with each generation.

Napkin Math 11.3: The utilization gap

Problem: Why is it harder to get 100 percent utilization on an H100 than a V100?

Metric: The ridge point $I_{\text{ridge}} = R_{\text{peak}}/\text{BW}$ (FLOP/byte), the number of operations the hardware must perform for every byte loaded to keep its compute units busy.

Result: The intensity needed to reach the tensor peak has increased. Under this simple HBM roofline, a kernel with $I = 200$ FLOP/byte lies above the A100 ridge but below the H100 ridge. If its intensity and implementation remain unchanged, its idealized gain is then closer to the 1.6× bandwidth ratio than the 3.2× peak-compute ratio.

Systems insight: Fusion is valuable for low-intensity chains because it can remove intermediate round-trips; it is not automatically the best optimization for every kernel.

Operations such as depthwise convolution, embedding lookup, LayerNorm, and softmax serve as low-intensity reference points that commonly fall below the HBM ridge on compute-dense ac-

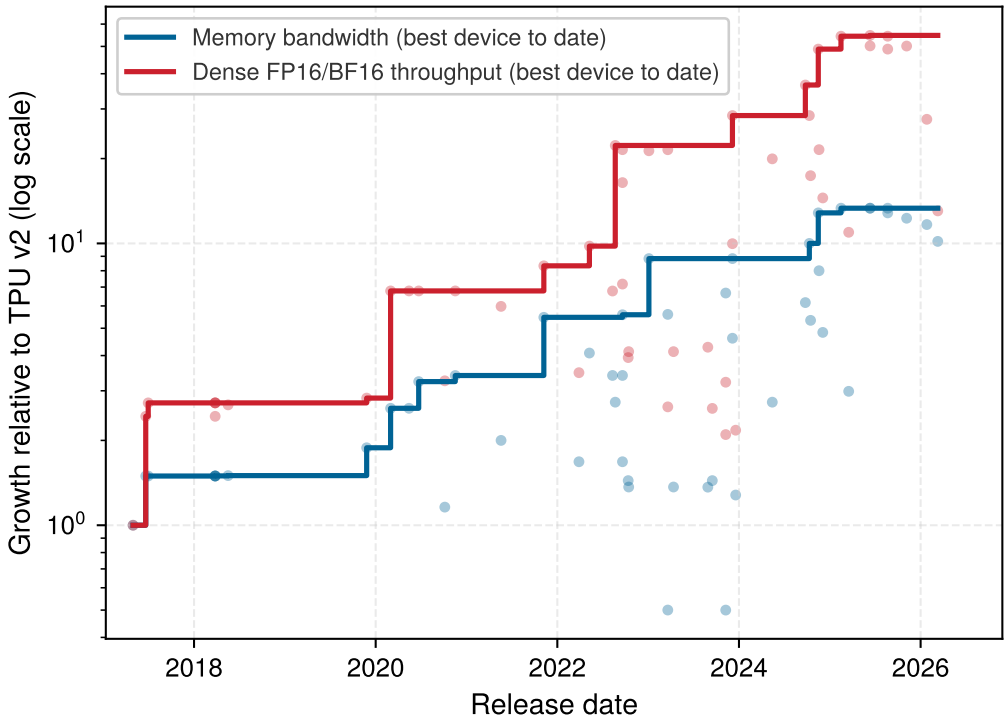

Figure 11.10: Compute and Bandwidth Across Vendors: Dense FP16/BF16 tensor throughput and memory bandwidth of machine learning accelerators from all major vendors with at least 16 GB of off-chip memory, each relative to TPU v2 (2017) on a logarithmic axis. Points are individual devices; step lines track the best device released to date. Compute pulls away from bandwidth, and both best-device envelopes level off in 2025 and 2026 as added arithmetic moves into lower-precision formats. Data from Epoch AI (2026b).

celerators under the stated traffic models. Table 11.7 maps common neural network operations to their representative roofline regimes and to the lighthouse workload that exercises each. Classification depends on the implementation, memory interface, and target path; profiling distinguishes a bandwidth ceiling from latency, limited parallelism, or other execution constraints.

Table 11.7: Operations on the Roofline: Neural network layers span a wide range of arithmetic intensities. Large, well-tiled convolutions and batched GEMMs can be compute-bound, while MobileNet depthwise layers, attention softmax, normalization, and DLRM embeddings are often memory-bound. To see how these intensity values translate into real performance predictions, a transformer layer provides a complete arithmetic-intensity calculation across its major sub-operations.

Operation	Arithmetic Intensity	**Classification**	**Lighthouse example**
Conv2D (Dense)	50–200 FLOP/byte	Straddles ridge; high-reuse cases compute-bound	ResNet-50
Dense MatMul (large batch, well-tiled)	~150–1,000+ FLOP/byte	Compute-bound once above the target's ridge	GPT-2 (batched projections)
Depthwise conv	10–20 FLOP/byte	Below modeled HBM ridge	MobileNet
Attention Softmax	Convention-dependent	Below modeled HBM ridge	GPT-2 (Generation)
LayerNorm	1–2 FLOP/byte	Below modeled HBM ridge	GPT-2/Llama
Embedding lookup	$<$ 1 FLOP/byte	Below modeled HBM ridge	DLRM

Napkin Math 11.4: Transformer layer analysis

For one GPT-2 XL layer during prefill, with hidden dimension $d = 1600$, batch size $B = 8$, sequence length $S = 1024$, and $N_{\text{heads}} = 25$ attention heads:

Attention QKV projection:

- FLOPs: $2 \times 3 \times 8 \times 1024 \times 1600 \times 1600 = 125.8$ GFLOP
- Bytes: (input + weights + output) = $(8 \times 1024 \times 1600 + 3 \times 1600 \times 1600 + 8 \times 1024 \times 1600 \times 3) \times 2 \approx 120.2$ MB
- $I = 125.8$ GFLOP / 120.2 MB = 1046.7 FLOP/byte, which is compute bound on the H100 (above the 295.2 FLOP/byte ridge point)

Softmax:

- FLOPs: $8 \times 25 \times 1024 \times 1024 \times 3 \approx 629.1$ MFLOP (exp, sum, div)
- Bytes: $8 \times 25 \times 1024 \times 1024 \times 2 \times 2 = 838.9$ MB
- $I = 629.1$ MFLOP / 838.9 MB = 0.75 FLOP/byte under this simple operation count, placing it below the reference tensor-path HBM ridge. Counting exponentials and division as multiple operations raises the numerical intensity, but those instructions use different execution units. The relevant vector, reduction, and special-function ceilings, together with profiling, determine whether bandwidth actually binds.

Systems insight: This analysis explains why FlashAttention focuses on reducing memory traffic in attention rather than reducing FLOPs.

The roofline supplies an initial resource bound; profiling determines which physical subsystem limits the kernel. When a kernel approaches its relevant off-chip bandwidth ceiling, optimization should focus on conserving memory traffic: fusing adjacent operators keeps intermediate activations in on-chip registers or shared memory (SRAM), lower-precision numeric formats reduce the physical byte count of memory transfers, and algorithmic refactorings like FlashAttention restructure access patterns to compute within SRAM tiles. When a kernel approaches the compute ceiling of its actual execution path, high data reuse keeps execution units supplied and off-chip bandwidth is no longer the binding resource. Performance here depends on saturating arithmetic execution pipelines: structuring matrix tiles to sustain Tensor Core throughput, hiding instruction latencies through software pipelining, and scaling batch sizes to distribute work across all available streaming multiprocessors.

↪ How a benchmark determines where a workload actually sits against its roofline ceiling is developed in section 12.4.3.

11.6.3 Memory bandwidth bounds

When a kernel's arithmetic intensity falls below the ridge point, adding more Tensor Cores cannot speed it up because off-chip memory bandwidth cannot deliver operands fast enough to sustain the target compute rate R_{ops} (FLOP/s). For a workload with arithmetic intensity I (FLOP/byte), keeping the compute units fed at rate R_{ops} requires the memory subsystem to transfer data at the rate defined by equation 11.3:

$$\text{BW}_{\text{req}} = \frac{R_{\text{ops}}}{I} \text{ bytes/s} \tag{11.3}$$

When this required bandwidth exceeds the hardware's peak memory bandwidth BW, memory transfers cap attainable throughput according to equation 11.4:

$$R_{\text{attain}} = \text{BW} \times I \tag{11.4}$$

Evaluating an operation against its execution path's ridge point identifies the lower modeled ceiling. Extensive data reuse can raise arithmetic intensity above that ridge, making compute the tighter bound; profiling must establish whether execution approaches it. ResNet-50's stage-3 3×3 convolution demonstrates this behavior.

Napkin Math 11.5: Convolutional layer analysis

Consider the 3×3 convolution in a stage-3 bottleneck block of ResNet-50, with input shape (batch = 32, channels = 128, height = 28, width = 28) and 128 output channels, on an H100 at FP16:

Computational requirements:

- Output size: $32 \times 128 \times 28 \times 28$ = 3.2M elements
- FLOPs per output: $128 \times 3 \times 3 \times 2$ = 2,304 (multiply-add)
- Total FLOPs: 3.2M × 2,304 = 7.4 GFLOP

Memory traffic analysis:

- Input: $32 \times 128 \times 28 \times 28 \times 2$ = 6.4 MB (FP16)
- Weights: $128 \times 128 \times 3 \times 3 \times 2 \approx$ 0.3 MB (FP16)
- Output: $32 \times 128 \times 28 \times 28 \times 2$ = 6.4 MB (FP16)
- Total: 13.1 MB

Arithmetic intensity: I = 7.4 GFLOP / 13.1 MB = 563.1 FLOP/byte

Systems insight: This is well above the H100's FP16 ridge point of 295.2 FLOP/byte, so the simple roofline model places the operation in the compute-limited region. The dense FP16 tensor peak of ~989 TFLOP/s is therefore the ceiling, but realized performance still depends on tiling, occupancy, instruction mix, and library efficiency.

The convolutional layer's high arithmetic intensity arises from spatial weight reuse: the same 3×3 kernel is applied across every spatial location in the feature map, amortizing the cost of loading weights from off-chip memory across millions of multiply-accumulate operations. Keeping active tiles in registers and shared memory reduces repeated off-chip transfers, making high arithmetic throughput possible. Whether a particular kernel then saturates the Tensor Cores depends on tiling, occupancy, and instruction mix, which the roofline does not model. Moreover, the FP16 analysis is only half of the chapter's workload, because the profile chapter 10 ended on runs ResNet-50 in INT8; quantization changes both sides of the roofline at once, and the two changes need not cancel.

Napkin Math 11.6: When INT8 moves a layer below the ridge

Problem: The H100's INT8 tensor path offers about 2× the operations per second of its FP16 path from the same 3.35 TB/s of memory bandwidth. Which ResNet-50 layers stay compute bound when the model moves from FP16 to INT8?

The two ridges: The ridge rises from 295.2 FLOP/byte at FP16 to 590.7 FLOP/byte at INT8. A layer keeps its position relative to the ridge only if every byte it moves halves along with the operand width.

Three layers at batch 32 (operations per byte, one read of input and weights and one write of the output):

- **Stage-3** 3×3 **convolution** (the layer of notebook 11.5): 563 at FP16, above the FP16 ridge. With INT8 activations it reaches 1,126, above the INT8 ridge. If its activations stay FP16 between layers, as when the kernel reads and writes 16-bit tensors for FP16 neighbors, its intensity stays near 569, below the INT8 ridge.
- **Stage-2** 3×3 **convolution** (56×56 positions, 64 channels in and out): 287 at FP16 and 574 at INT8, just below the ridge in both precisions.
- **Stage-2** 1×1 **expansion** (56×56 positions, 64 channels in and 256 out): 51 at FP16 and 102 at INT8, far below the ridge in both.

Systems insight: INT8 raises the arithmetic ceiling but leaves the bandwidth ceiling where it was, so the layers that were already bandwidth bound gain only the halved bytes, and a

compute-bound layer whose activations stay wide crosses below the new ridge. The INT8 speedup of chapter 10's profile therefore depends on whether activations travel at INT8 between layers, a decision made by the compiler and runtime (section 11.8), not by the quantized weights alone.

Not all neural network layers reuse data so heavily. Fully connected (dense) layers, such as ResNet-50's classification head, feed-forward networks, and linear projections in transformer attention blocks, lack spatial dimensions. When evaluated at small batch sizes, their arithmetic intensity drops substantially, shifting execution into the bandwidth-bound regime:

Napkin Math 11.7: Dense layer analysis

Consider ResNet-50's final fully connected layer, which maps 2,048 pooled features to 1,000 class scores for a batch of 32 images on the same H100:

Computational requirements:

- Matrix multiply: $(32 \times 2048) \times (2048 \times 1000)$
- Total FLOPs: $2 \times 32 \times 2048 \times 1000$ = 131.1 MFLOP

Memory traffic analysis:

- Input: $32 \times 2048 \times 2$ = 131.1 KB (FP16)
- Weights: $2048 \times 1000 \times 2$ = 4.1 MB (FP16)
- Output: $32 \times 1000 \times 2$ = 64 KB (FP16)
- Total: 4.3 MB

Arithmetic intensity: I = 131.1 MFLOP / 4.3 MB = 30.5 FLOP/byte

This intensity sits below the H100's ridge point of 295.2 FLOP/byte, making this operation memory bound under the stated traffic model. Attainable performance: R_{attain} = 3,350 GB/s $\times$ 30.5 FLOP/byte = 102.3 TFLOP/s

Systems insight: Attainable throughput is only 10.3 percent of peak compute capability, so at batch 32 the memory wall caps this layer long before the Tensor Cores do.

The dense layer's lower arithmetic intensity stems from limited parameter reuse. While a convolutional kernel is reused across every spatial location in an activation map, a dense weight matrix is reused only across the batch dimension. At a batch size of 32, each fetched weight contributes to 32 sample products in this operation. When the weights stream from HBM on each invocation, as modeled, the bandwidth ceiling caps throughput at 10.3 percent of peak compute capacity. The fraction is a bound rather than a measured stall count, and a layer whose weights stay cached between invocations would do better. The same arithmetic explains why transformer inference at low batch sizes is governed by memory bandwidth rather than arithmetic capability, a regime the throughput-ceiling notebook below quantifies for GPT-2.

While small-batch matrix multiplications suffer from restricted parameter reuse, elementwise and reduction operators represent an even more acute memory bottleneck. Operations such as layer normalization, activation functions, and residual additions perform only a few arithmetic operations per element loaded from memory, driving arithmetic intensity to its physical floor:

Napkin Math 11.8: LayerNorm analysis

LayerNorm over one GPT-2 XL layer's activations, with input shape (batch = 8, sequence = 1024, hidden = 1600):

Computational requirements:

- Elements: $8 \times 1024 \times 1600$ = 13.1M

- Approximate operations per element: mean reduction (1 ADD), variance (2 ADD, 1 MUL), normalization and affine transform (2 ADD, 2 MUL) ≈ 8; reciprocal-square-root overhead is amortized across each hidden vector
- Total FLOPs: 13.1M × 8 = 104.9 MFLOP

Memory traffic:

- Input: 13.1M × 2 = 26.2 MB
- Parameters (scale, bias): 1600 × 2 × 2 = 6.4 KB (negligible)
- Output: 13.1M × 2 = 26.2 MB
- Total: 52.4 MB

Arithmetic intensity: I = 104.9 MFLOP / 52.4 MB = 2.0 FLOP/byte

This arithmetic intensity sits severely below the H100 ridge point (148× below). The HBM performance upper bound is: R_{attain} = 3,350 GB/s × 2.0 FLOP/byte = 6.7 TFLOP/s

Systems insight: The simple HBM roofline bounds this standalone LayerNorm at about 0.7 percent of the H100's tensor peak. That tensor peak is a reference, not the throughput available to LayerNorm's vector and reduction instructions. Actual latency also depends on their execution ceilings, fusion, launch overhead, and which memory level supplies the data.

Standalone normalization performs minimal arithmetic relative to the memory traffic it generates, as the LayerNorm analysis demonstrates. Under the modeled unfused HBM read/write boundary, the implementation performs approximately 2 FLOP/byte, giving a low bandwidth ceiling relative to the tensor peak. Reaching that ceiling still requires enough parallel work and an efficient reduction. Cache residency changes the physical HBM byte count and can shift the relevant bound to another memory interface. In the D·A·M framework, when the machine constraint is a memory bandwidth wall, the algorithmic response is kernel fusion, which collapses adjacent projections, bias additions, normalization, and activations into one kernel so that intermediate values stay in registers or SRAM. Fusion pays off when the grouping preserves numerical behavior and fits the local register and SRAM budget, and profiling confirms that the saved traffic outweighs any loss of occupancy.

11.6.4 Optimization by intensity regime

Tuning thread-block occupancy on a bandwidth-bound LayerNorm kernel wastes engineering effort for zero speedup, just as fusing two already compute-bound matrix multiplications cannot raise throughput past the Tensor Core ceiling. The roofline's intensity regimes (table 11.8) match each bottleneck to the lever that can move it.

Table 11.8: Optimization by Arithmetic Intensity Regime: Position relative to the target execution path's ridge guides compute and traffic optimization. Profiling confirms the bottleneck; fusion removes intermediate round-trips when dependencies and local storage permit it.

Intensity regime	Typical operations	Optimization priority	Common techniques	Expected impact
Above the target path's ridge	Large convolutions	Maximize compute utilization.	Tensor Cores, thread-block tuning, and high occupancy.	Raises sustained compute utilization when the kernel already clears the ridge.
Near the target path's ridge	Medium-sized dense layers	Balance compute and memory optimization.	Larger batches, register tiling, and fusion with adjacent operations.	Can move the binding bottleneck between memory and compute.
Below the target path's ridge	Small dense layers and element-wise operations	Reduce memory traffic.	Aggressive kernel fusion, reduced precision (FP16 → INT8), and algorithmic changes.	Reduces external-memory traffic when fusion or layout changes are legal.
Low-intensity operator chains	Normalization layers and activation functions	Eliminate memory round-trips.	Fuse with adjacent operations and use in-place computation where legal.	Removes intermediate round-trips when adjacent operations can be fused.

For low-intensity operations, kernel fusion is often the decisive optimization: LayerNorm combined with the Gaussian Error Linear Unit (GELU), for example, can become a single fused kernel. One of the most accessible levers for moving an operation up and right on the roofline is batching.

Napkin Math 11.9: Batch size and arithmetic intensity

Increasing batch size improves arithmetic intensity for matrix operations by amortizing weight loading. Equation 11.5 formalizes this relationship for an idealized FP16/BF16 dense layer $(B \times d_{\text{in}}) \times (d_{\text{in}} \times d_{\text{out}})$, counting one read each of the input and weights and one write of the output, where B is batch size and d_{in} and d_{out} are the layer's input and output widths:

$$I = \frac{2Bd_{\text{in}}d_{\text{out}}}{2Bd_{\text{in}} + 2d_{\text{in}}d_{\text{out}} + 2Bd_{\text{out}}} \approx \frac{2Bd_{\text{in}}d_{\text{out}}}{2d_{\text{in}}d_{\text{out}}} = B \quad (\text{when } 2d_{\text{in}}d_{\text{out}} \gg 2B(d_{\text{in}} + d_{\text{out}})) \tag{11.5}$$

Example: Dense layer with $d_{\text{in}} = d_{\text{out}} = 2048$ (FP16)

- Batch = 1: $I \approx 1$ FLOP/byte (memory bound)
- Batch = 32: $I \approx 31$ FLOP/byte (memory bound)
- Batch = 512: $I \approx 341.3$ FLOP/byte (compute bound on the H100)

Systems insight: This explains why batching can produce large throughput improvements in production inference systems, as MLPerf Inference, the standardized benchmark suite, demonstrates by separating bulk-throughput runs from latency-constrained serving runs (Reddi et al. 2019).

↪ The MLPerf Inference execution scenarios that separate throughput runs from latency-constrained runs are developed in section 12.4.4.1.

The batch size analysis reveals why inference serving systems are designed around batching: it changes the arithmetic intensity regime of bandwidth-bound workloads. However, batching introduces latency trade-offs, since requests must wait in a queue until a batch forms. This tension between throughput (favoring large batches) and latency (favoring small batches) is a central challenge in ML serving systems, explored in depth in section 13.5.4. When service latency limits batching, batch-1 or small-batch LLM decode often retains low weight reuse and low arithmetic intensity, and the next worked model quantifies that particular regime rather than treating all LLM inference as identical.

Napkin Math 11.10: The throughput ceiling

Problem: A batch-1 GPT-2 calculation makes this bandwidth ceiling concrete: what is the maximum possible utilization of an NVIDIA H100 when running GPT-2 inference (batch size 1)?

The hardware constraints (the denominators)

- **Peak compute**: 989 TFLOP/s (FP16 Tensor Core).
- **Peak bandwidth**: 3.35 TB/s (HBM3).
- **Ridge point** ($R_{\text{peak}}/\text{BW}$): 989 TFLOP/s / 3.35 TB/s = 295.2 FLOP/byte (for FP16 Tensor Core).
  Interpretation: Saturating this chip at FP16 precision requires 295.2 FLOP/byte operations for every byte loaded. The ridge point varies by precision: FP32 operations (67 TFLOP/s peak) have a ridge point of only ~20 FLOP/byte.

The workload characteristics (the numerator)

- **Model**: GPT-2 XL (1.5 billion parameters).
- **Operation**: Autoregressive generation (1 token at a time).
- **Data movement**: Must load all weights (3 GB @ FP16) for every token.
- **Compute**: Vector-Matrix multiplication. Two FLOPs per parameter, $2P \approx 3$ GFLOP.

- **Arithmetic intensity**: 3 GFLOP / 3 GB = 1 FLOP/byte

The prediction (iron law)
Since the modeled intensity I (1) $\ll$ the ridge point I_{ridge} (295.2 FLOP/byte), batch-1 decode is bandwidth bound.

- **Maximum throughput**: 1 FLOP/byte $\times$ 3.35 TB/s = 3.4 TFLOP/s.
- **Utilization ceiling**: 3.4 TFLOP/s (Bound) / 989 TFLOP/s (Peak) $\approx 0.3\%$

Systems insight: Without batching, a ~$25,000 accelerator cannot exceed 0.3 percent of its compute peak in this weight-streaming decode scenario. Batching and weight quantization address that gap; key-value caching instead avoids recomputing prior attention states. The ceiling also assumes that the decode step is launched as a captured graph (section 7.3.6); executed one eager kernel at a time, launch overhead rather than weight streaming would set the floor.

Placed on one roofline, the layers and the decode step analyzed above fall on either side of two ridges, and only the stage-3 3×3 convolution reaches a flat ceiling (figure 11.11). Through this derivation, the roofline model provides a diagnostic framework for identifying whether operations are compute bound or memory bound. Knowing that batch-1 decode is bandwidth bound at a ceiling of 0.3 percent of peak is only the first step; the next challenge is translating this diagnosis into efficient execution plans that exploit accelerator architectures.

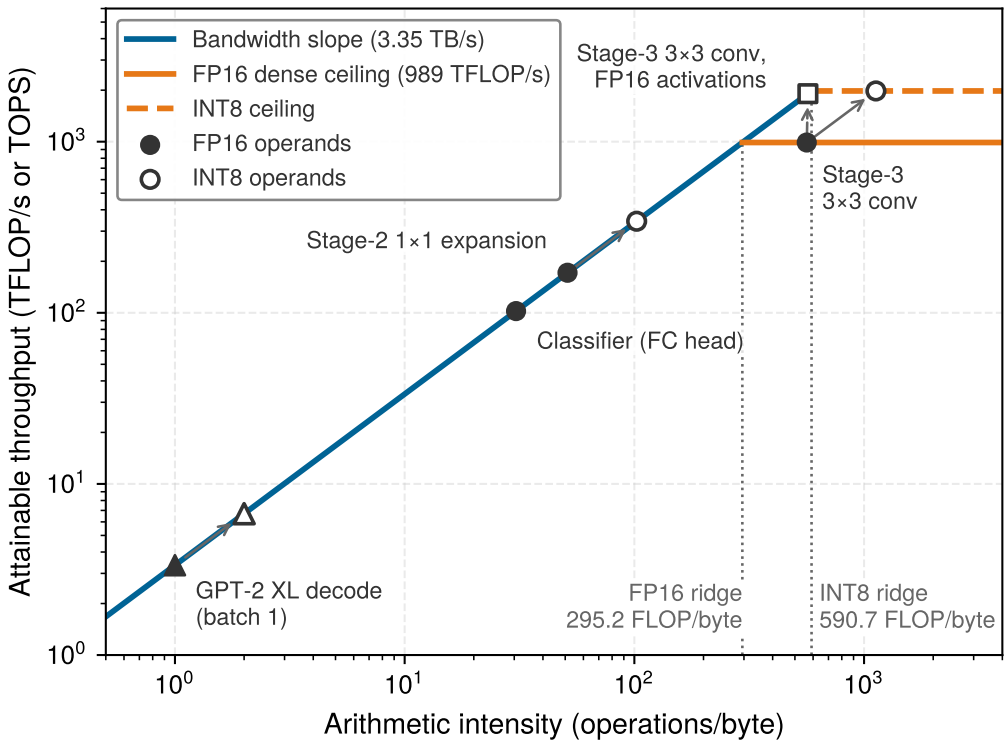

Figure 11.11: ResNet-50 and GPT-2 XL on the H100 Roofline: Attainable throughput against arithmetic intensity on log-log axes, with the dense FP16 ceiling and the INT8 ceiling sharing one bandwidth slope. INT8 raises the ridge from 295.2 FLOP/byte to 590.7 FLOP/byte. Arrows connect each layer's FP16 point to its INT8 point. ResNet-50's stage-3 convolution clears the ridge in both precisions when its activations move at the format's width, but falls below the INT8 ridge when its activations stay FP16; its stage-2 expansion and classifier sit far below either ridge, and GPT-2 XL decode sits more than an order of magnitude further left.

Checkpoint 11.3: The machine and its ceilings

The first half of the chapter has assembled the accelerator and its two ceilings. Before turning to how software reaches them, check that you can work from the anatomy to a bound.

Compute units

- ☐ **The INT8 path**: name the two sources of the INT8 tensor path's advantage over FP16, and explain why a 2:4 sparse kernel speeds up only weights that satisfy the pattern.

Memory systems

- ☐ **Operand supply**: explain why a matrix unit cannot be fed directly from HBM, and which tier a ResNet-50 activation tile occupies while a Tensor Core consumes it.

Performance bounds

- ☐ **Two ridges**: from the H100's FP16 and INT8 peaks and its memory bandwidth, compute both ridge points, then place GPT-2 XL batch-one decode and the ResNet-50 stage-3 convolution against each.
- ☐ **The crossing**: explain why a layer that is compute bound at FP16 can become bandwidth bound at INT8, and what change to its traffic would move it back above the ridge.

11.7 Hardware Mapping

Consider one of ResNet-50's 3×3 convolutions running on an accelerator tile. The mathematical operation is fixed, but the execution plan is not. One schedule can keep a filter in local registers while many output pixels stream past it; another can advance pixel by pixel and reload the same filter values repeatedly from a slower memory tier. Both schedules compute the same tensor. Only one turns the reuse in the convolution into real bandwidth savings.

Definition 11.4: Mapping in AI acceleration

Mapping in AI acceleration is the accelerator-compiler process of binding the logical computation graph to the physical hardware topology by deciding which operations execute on which processing elements, which data resides in which memory tier, and in what temporal order.

1. **Significance**: Within the D·A·M taxonomy, mapping is a machine-axis decision that helps determine how closely an operation approaches the roofline bound $\min(R_{\text{peak}}, \text{BW} \times I)$. A poor tiling choice that forces unnecessary DRAM accesses can reduce effective arithmetic intensity enough to move a nominally compute-bound operation into the bandwidth-bound regime.
2. **Distinction**: Traditional compilation often emphasizes instruction selection, register allocation, and scheduling for general-purpose processors. Accelerator mapping gives equal prominence to spatial placement and explicit data movement across a dataflow architecture. The reason is physical: as quantified by the storage-tier energy ladder in figure 11.4, an off-chip DRAM access costs about 173× the energy of an FP32 multiply, making operand placement as critical to efficiency as the execution unit that evaluates it.
3. **Common pitfall**: A frequent misconception is that mapping is automatically handled by frameworks. For general GPU workloads, compilers such as Accelerated Linear Algebra (XLA) can find strong mappings for common kernels; for specialized accelerators (systolic arrays, custom ASICs), compiler-generated mappings may still lag hand-tuned schedules because the compiler's search space is limited by the time budget at compilation.

The convolution example exposes the three decisions that recur throughout accelerator compilation. Placement assigns the multiply-accumulate work to processing elements so parallelism does not turn into idle time or interconnect congestion. Allocation keeps weights, activations, and partial sums in the memory tier where their next use will occur, rather than letting reuse spill back to

DRAM. Scheduling orders loops and kernels so the chosen placement and allocation remain valid over time. A poor choice in any one dimension can collapse a high-arithmetic-intensity operation back into a bandwidth-bound execution. In practice, these choices are too coupled for developers to manage by hand at model scale, which is why systems such as XLA, TVM, and TensorRT lower high-level models and search or select execution plans within their compile-time and hardware budgets. Section 11.8 examines that compiler support in detail.

11.7.1 Placement and allocation

Translating a model's computational graph into efficient hardware execution requires solving two tightly coupled problems. Computation placement determines which operations run on which processing elements, balancing parallelism against communication costs. Memory allocation determines where data resides within the memory hierarchy, trading capacity against access latency. These two decisions interact: placing operations on distant processing elements increases the memory bandwidth required to shuttle data between them, while allocating data to fast but small on-chip memory limits which operations can execute concurrently. Getting either wrong leaves thousands of processing elements idle or starved for data.

11.7.1.1 Computation placement

Computation placement is the process of assigning operations to an accelerator's processing elements (PEs) to expose parallelism, limit idle time, and reduce unnecessary data movement. Modern accelerators contain many such resources: the NVIDIA H100 has more than 16,000 CUDA cores and more than 500 Tensor Cores (Choquette 2023), TPUs organize thousands of multiply-accumulate units into systolic arrays (Jouppi et al. 2017), and wafer-scale processors such as Cerebras' CS-2 integrate more than 850,000 cores (Systems 2021). At these scales, placement inefficiencies become measurable because idle cores and redundant transfers waste both time and energy.

The difficulty of placement depends on workload regularity. Convolutional networks and dense transformer operations possess regular access patterns that tile predictably, though transformer architectures mix operations with distinct tensor shapes and reuse profiles. Graph neural networks (GNNs) present greater difficulty: sparse, input-dependent neighborhood aggregations introduce load imbalance and non-uniform communication across processing elements. Table 11.9 summarizes these core placement challenges and their operational impact.

Table 11.9: Computation Placement Challenges: Effective neural network deployment requires strategic allocation of computations to processing elements, balancing workload distribution, data movement costs, and hardware constraints to maximize execution efficiency. These challenges guide the design of mapping strategies that optimize resource utilization and minimize communication overhead.

Challenge	Impact on execution	Key Considerations for Placement
Workload imbalance	Some processing elements finish early while others remain overloaded, leading to idle compute resources.	Distribute operations evenly to prevent stalls and ensure full utilization of PEs.
Irregular computation patterns	Sparse graphs, routing, and variable shapes can create nonuniform work that complicates static placement.	Use adaptive placement when workload characteristics vary at run time.
Excessive data movement	Frequent memory transfers introduce latency and increase power consumption.	Keep frequently used data close to the compute units and minimize off-chip memory accesses.
Limited interconnect bandwidth	Poorly placed operations can create congestion, slowing data movement between PEs.	Optimize spatial and temporal placement to reduce communication overhead.
Model-specific execution needs	CNNs, transformers, and GNNs require different execution patterns, making a single placement strategy ineffective.	Tailor placement strategies to match the computational structure of each model type.

Static spatial mappings suffice for regular dense operations whose shapes and loop bounds are known ahead of time. Workloads with dynamic shapes, sparsity, or mixture-of-experts routing instead require runtime scheduling to balance execution across processing elements. Yet even an optimal computation placement stalls if the required operands are not staged in time: compute units can execute only as fast as operands arrive from the memory hierarchy.

11.7.1.2 Memory allocation

While computation placement determines where operations execute, memory allocation defines where data resides and how it flows through the hierarchy. The goal is to keep reused data near the processing elements without exceeding faster-tier capacity. GPUs expose global memory, shared memory, caches, and registers that kernels coordinate through tiling (NVIDIA Corporation 2020a). TPUs use on-chip SRAM buffers to stage the activations that flow horizontally through the 2D systolic-array dataflow (Jouppi et al. 2017) of figure 11.5, with partial sums flowing vertically, while wafer-scale processors partition memory and computation to control interconnect traffic (Systems 2021). General-purpose processors and accelerators both use memory hierarchies, but many accelerators expose more placement decisions to compilers and kernels. When allocation fails to exploit locality, processing elements stall waiting for operands, driving down utilization and dissipating energy across the memory bus.

The severity of these penalties varies by workload. Convolutional networks rely on structured, localized access patterns and benefit from well-defined memory layouts that support predictable reuse (Y.-H. Chen et al. 2016). Transformers require access to large parameter sets and intermediate activations, making them sensitive to capacity and bandwidth. Graph neural networks add irregular sparse structures that complicate allocation and prefetching.

Capacity is only the first allocation test. A tensor can fit in accelerator memory yet still dominate execution if each kernel rereads it from a distant tier; conversely, tiling can keep a larger working set efficient by preserving reuse locally. The allocation diagnostic is therefore traffic, not capacity alone: compilers must track how frequently values cross each memory boundary and keep high-reuse tensors in the fastest feasible tier. Systems combine static memory plans for known shapes with dynamic buffer management when shapes vary, while device capacity limits which models fit without partitioning or offload. Table 11.10 summarizes these allocation challenges across the hierarchy.

Table 11.10: Memory Allocation Challenges: Efficient memory management in AI accelerators balances data access speed with hardware constraints, mitigating performance bottlenecks caused by latency, bandwidth limitations, and irregular data patterns. Complex models such as transformers and graph networks impose variable and demanding memory requirements that amplify these challenges.

Challenge	Impact on Execution	**Key Considerations for Allocation**
High memory latency	Slow data access delays execution and reduces throughput.	Prioritize placing frequently accessed data in faster memory locations.
Limited on-chip storage	Small local memory constrains the amount of data available near compute units.	Allocate storage efficiently to maximize data availability without exceeding hardware limits.
High off-chip bandwidth demand	Frequent access to external memory increases delays and power consumption.	Reduce unnecessary memory transfers by carefully managing when and how data is moved.
Irregular memory access patterns	Some models require accessing data unpredictably, leading to inefficient memory usage.	Organize memory layout to align with access patterns and minimize unnecessary data movement.
Model-specific memory needs	Different models require different allocation strategies to optimize performance.	Tailor allocation decisions based on the structure and execution characteristics of the workload.

11.7.2 Combinatorial complexity

The convolution that opened this section illustrates why hardware mapping becomes a combinatorial search problem. Keeping a filter resident in local storage improves reuse only if the assigned processing elements have sufficient storage and if the loop schedule revisits that filter before eviction. Similarly, parallelizing across more processing elements improves throughput only until synchronization overhead and interconnect contention erode the benefit. Because changing one decision alters the feasible and efficient choices for the others, compilers must evaluate placement, allocation, and scheduling jointly rather than independently. Table 11.11 summarizes these recurring trade-offs across the execution stack.

Table 11.11: Placement-Allocation-Scheduling Trade-Offs: AI accelerator performance depends on mapping computations to hardware, allocating data to memory tiers, and scheduling execution over time. Careful consideration of these interdependent factors is essential for maximizing throughput and minimizing energy consumption.

Dimension	**Placement considerations**	**Allocation and Scheduling Considerations**
Computational granularity	Fine-grained placement enables greater parallelism but increases synchronization overhead.	Coarse-grained scheduling reduces synchronization overhead but may limit flexibility.
Spatial vs. Temporal Mapping	Spatial placement enhances parallel execution but can lead to resource contention and memory congestion.	Temporal scheduling balances resource sharing but may reduce overall throughput.
Memory and Data Locality	Placing data closer to compute units minimizes latency but may reduce overall memory availability.	Allocating data across multiple memory levels increases capacity but introduces higher access costs.
Communication and synchronization	Co-locating compute units reduces communication latency but may introduce contention.	Scheduling synchronization mechanisms mitigates stalls but can introduce additional overhead.
Dataflow and Execution Ordering	Static placement simplifies execution but limits adaptability to workload variations.	Dynamic scheduling improves adaptability but adds scheduling complexity.

11.7.2.1 Counting the search space

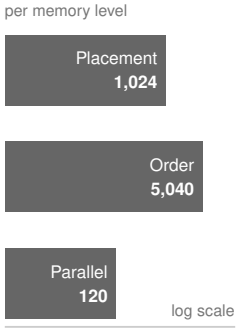
Evaluating these trade-offs requires navigating an unconstrained search space governed by three structural decisions: loop execution order, spatial parallelization across processing elements, and memory placement across the hierarchy. Counting each dimension on its own shows why exhaustive search is impractical.

Machine learning workloads are expressed as nested loops over tensor dimensions, and the loop execution order dictates which tensor elements remain resident in registers or SRAM between iterations. Ignoring dependences and equivalent orderings, the number of ways to arrange n_{loops} loops has the toy upper bound:

$$N_{\text{order}} = n_{\text{loops}}!$$

A convolutional layer with seven loop dimensions already has $7! = 5{,}040$ possible execution orders. If each memory level could choose an ordering independently, the toy upper bound would expand as:

$$(n_{\text{loops}}!)^{N_{\text{mem}}}$$



where N_{mem} is the number of memory hierarchy levels. A suboptimal ordering evicts values prematurely and multiplies DRAM traffic, whereas an optimized ordering maximizes reuse in local SRAM and caches (Sze et al. 2017).

Parallelization multiplies the count again. Parallelizing outer independent loops (such as batch or output feature channels) lets each core execute without interconnect traffic, whereas parallelizing an inner reduction loop requires cross-core synchronization and collective communication. Before legality and capacity constraints are applied, the number of ordered ways to select loops for parallel execution has the upper bound:

$$\mathcal{P}_{\text{parallel}} = \frac{n_{\text{loops}}!}{(n_{\text{loops}} - k_{\text{parallel}})!}$$

where k_{parallel} is the number of loops selected for parallel execution; three of six loops already give $6!/3! = 120$ candidates, each with different demands on synchronization, interconnect bandwidth, and PE utilization. Memory placement is the third dimension, and physical capacity bounds it. Because an off-chip DRAM fetch costs roughly 128× more energy than a read from an 8 KB SRAM array (figure 11.4), where each tensor resides directly dictates the achieved arithmetic intensity, yet an operand tile can remain in on-chip SRAM only if its working set fits the allocated buffer. Larger resident tiles raise reuse but consume scarce capacity and register pressure, potentially reducing thread concurrency or forcing spills to slower tiers.

These structural choices (loop ordering, spatial parallelization across processing elements, tile sizing, and memory placement) are deeply coupled. Choosing an output-stationary schedule, for example, pins accumulators in local registers and dictates which loops can be mapped spatially across

Per memory level, from the section's separate toy examples: $4^5 = 1{,}024$ placements, $7! = 5{,}040$ orders, $6!/3! = 120$ parallelizations. The product is raised to the number of levels, so three levels give 4^{15} placements alone.

processing elements without requiring inter-core reduction networks. Conversely, parallelizing across more execution units reduces the per-core SRAM budget available for operand staging, forcing smaller tile dimensions and increasing off-chip memory traffic.

While the unconstrained Cartesian product of these decisions suggests a massive combinatorial space, hardware capacity limits, data dependencies, and symmetry prune the vast majority of candidates as either physically illegal or strictly dominated. Exhaustive search across arbitrary loop permutations and placement choices is therefore both unnecessary and intractable. Production compilers and kernel developers manage this complexity by structuring their search around a small family of canonical dataflow patterns, spatial and temporal schedules engineered to exploit the specific reuse properties of neural network operators.

11.7.3 Dataflow optimization

As example 11.4 shows for a small convolution, two mathematically identical schedules can differ 36-fold in weight reads, and every avoided read that would have reached DRAM saves the most expensive access on the energy ladder. While spatial and temporal mapping establish where operations execute and where operands reside, **dataflow optimization** governs the exact trajectories and schedules of data moving through processing elements and the memory hierarchy to maximize operand reuse. In a systolic array or tiled vector unit, the temporal schedule and spatial routing of weights, inputs, and partial sums dictate how frequently operands must be fetched from energy-expensive DRAM rather than reused from local registers or scratchpads. By controlling off-chip traffic, the dataflow establishes the effective operational intensity of the kernel, determining whether execution achieves the compute-bound plateau or stalls in the bandwidth-bound regime of the roofline model. Optimizing compilers (section 11.8) and runtime systems (section 11.8.3) therefore tailor dataflow patterns to match the reuse characteristics of each layer to the hardware constraints of the target accelerator.

Three recurring architectural decisions structure this design space, providing a compact vocabulary for navigating dataflow choices without exhaustive search across billions of candidate schedules:

1. **Locality**: Stationary operand selection (weight-stationary, output-stationary, or input-stationary) dictates which tensor remains pinned in local registers or processing-element scratchpads, trading off memory traffic against register pressure.
2. **Organization**: Physical tensor layouts (such as channels-last `NHWC` versus channels-first `NCHW`) govern whether memory accesses match hardware memory controller burst sizes and SIMD vector widths, preventing uncoalesced memory transactions.
3. **Combination**: Kernel fusion and loop tiling partition iteration spaces and merge adjacent operations to eliminate round-trips to off-chip memory for intermediate tensors.

11.7.4 Stationary dataflows

Dataflow design exists to exploit the steep energy divergence isolated in figure 11.4, where fetching an operand from DRAM requires orders of magnitude more energy than executing an arithmetic operation on it (Y.-H. Chen et al. 2016). Whether a workload executes dense matrix operations that exceed on-chip cache capacity or irregular sparse lookups, data movement strategy dictates overall execution latency and total power consumption. If data cannot be staged and supplied to processing elements at the rate required by their arithmetic throughput, the execution units stall on memory latency, stranding theoretical compute capacity and inflating memory subsystem energy.

To prevent arithmetic pipelines from stalling, a data movement strategy must capture the inherent algorithmic reuse of tensor operations within local, low-energy storage. Listing 11.14 illustrates the canonical three-nested-loop implementation of matrix multiplication, exposing the operand reuse across weights, inputs, and partial sums that a hardware mapping must capture in local storage.

Listing 11.14: Naïve Matrix-Multiplication Dataflow: The loop nest revisits weight rows, input columns, and output accumulators, exposing the reuse that a mapping must capture in local memory.

```
# Matrix multiplication where:
# weights: [512x256] - model parameters
# input:   [256x32]  - batch of activations
# Z:       [512x32]  - output activations

# Computing each output element Z[i,j]:
for i in range(512):
    for j in range(32):
        for k in range(256):
            Z[i, j] += weights[i, k] * input[k, j]
```

Every operand in this loop nest is reused, but along a different loop. Each weight `weights[i, k]` is used once for each of the 32 output columns, each input `input[k, j]` is used once for each of the 512 output rows, and each output `Z[i, j]` accumulates 256 products before it is final. A processing element's local storage holds only a small tile at a time, so the mapping cannot capture all three reuses at once. Fetching from DRAM whichever operand is not held locally, on every use, is what turns a compute-bound kernel into a memory-bound one (Han, Liu, et al. 2016).

The central dataflow decision is therefore which operand to keep local. The loop order answers it: whatever the innermost loops touch repeatedly without changing stays resident, and everything else streams. Listing 11.15 reorders the same computation three ways, and the three orders are the three classic stationary dataflows.

Listing 11.15: Three Stationary Dataflows: The same matrix multiplication as the naïve loop, reordered three ways; the operand held fixed across the innermost loop is the one fetched once and reused from local storage, while the other two stream.

```
# Weight stationary: hold one weight, stream inputs and partial sums past it
for i in range(512):
    for k in range(256):
        w = weights[i, k]  # fetched once, reused 32 times
        for j in range(32):
            Z[i, j] += w * input[k, j]

# Output stationary: hold one partial sum, stream weights and inputs past it
for i in range(512):
    for j in range(32):
        acc = 0  # stays in a local accumulator
        for k in range(256):
            acc += weights[i, k] * input[k, j]
        Z[i, j] = acc  # written once

# Input stationary: hold one input, stream weights and partial sums past it
for k in range(256):
    for j in range(32):
        x = input[k, j]  # fetched once, reused 512 times
        for i in range(512):
            Z[i, j] += weights[i, k] * x
```

A weight-stationary dataflow keeps parameters on chip, so each weight crosses the expensive memory boundary once no matter how many inputs it touches. That pays off wherever one filter or weight tile is applied to many inputs, as in convolutions and batched matrix multiplication, and it is the canonical TPU dataflow traced cycle by cycle in section 11.7.5. The saved traffic reappears on the other operands: inputs must arrive fast enough to keep the resident weights busy, and partial sums must move between processing elements as they accumulate. The resident tile is also bounded by on-chip capacity, so a layer whose weights far exceed it must cycle weight tiles through, reloading the inputs for each one.

An output-stationary dataflow keeps each running sum in a local accumulator until all of its contributions have arrived, so every output is written to memory exactly once (Y.-H. Chen et al.

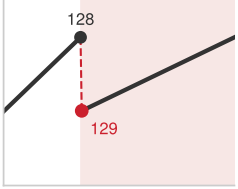
2016). It suits layers with wide fan-in, such as fully connected layers and attention projections, where writing a partial sum out after every step would cost far more than the reads it avoids. The cost is two operand streams at once, since both weights and inputs must now be delivered from memory. The naïve loop in listing 11.14 already has this order, because its innermost loop runs over k while i and j stay fixed.

An input-stationary dataflow keeps an activation tile local while weights stream past it. It pays off when one activation feeds several computations before eviction, as when a transformer token's activation feeds the query, key, and value projections. Its costs mirror weight stationary's, with weights now streaming from memory and partial sums still moving as they accumulate.

Example 11.4: Loop ordering in a small convolution

Consider a convolution applying 16 filters of size 3×3 to an 8×8 single-channel input. The computation can be expressed as five nested loops iterating over output rows (H_{out}), output columns (W_{out}), filter count (d_{out}), filter height (K_h), and filter width (K_w). The $5! = 120$ permutations are an unconstrained upper bound: legal orderings preserve the mathematical result, although floating-point reduction order can change rounding, and they generate different memory traffic.

Ordering A (weight-stationary): Place the filter loops (d_{out}, K_h, K_w) outermost and the spatial loops (H_{out}, W_{out}) innermost. Each 3×3 filter is loaded into registers once and then applied across all 36 output positions before the next filter is loaded. Total weight loads: $16 \times 9 = 144$ values, each loaded exactly once.



Ordering B (output-stationary, filters spilled): Place the spatial loops outermost and the filter loops innermost. For every output position, all 16 filters must be loaded, applied, and their partial sums accumulated before advancing to the next position. If the register file cannot hold all 16 filters simultaneously, filters are repeatedly fetched from cache or DRAM. In the worst case, each of the 36 output positions reloads all 144 filter weights, producing $36 \times 144 = 5{,}184$ weight reads.

Systems insight: Under these two limiting assumptions, Ordering A reduces modeled weight reads by 36× relative to the worst case for Ordering B. Real kernels also account for activation and partial-sum traffic, register capacity, cache behavior, and vectorization. The example nevertheless shows why two mathematically equivalent loop orders can place very different demands on the memory system.

The three strategies form a decision framework rather than a quality ranking. The right choice is the operand with the highest reuse relative to the on-chip storage it would occupy, which depends on layer dimensions and batch size, so compilers select among them per layer. Convolution-specific designs add a fourth label, row-stationary. The Eyeriss accelerator maps one-dimensional rows of filter weights and input activations to processing-element registers and accumulates rows of partial sums locally, a hybrid that captures more of a convolution's multidimensional reuse than fixing any single operand (Y.-H. Chen et al. 2016).

11.7.5 Tiling

↩ Tiling in its software form, the cache-aware blocking a framework applies to matrix multiplication, is established in section 7.5.4.2.

Exceeding the tile width along a single dimension tips utilization along that axis off a cliff.

A stationary dataflow decides which operand stays local; tiling decides how large a block of it local storage can hold. A fundamental mismatch exists between the *computational graph* (which sees a single 4,096 × 4,096 matrix multiplication) and the *physical silicon* (which possesses a fixed 128 × 128 systolic array). Bridging this gap requires **tiling**, which partitions a large tensor operation into tiles that fit exactly into the hardware's fast local memory (SRAM or scratchpad memory), so that each tile is reused many times before it is evicted.

To process the 4,096-wide worked-example layer on a 128-wide systolic array, the compiler decomposes the result into 1,024 output tiles. Each output tile accumulates across 32 reduction-dimension tiles, so the complete matrix multiplication executes 32,768 **A**-tile-by-**B**-tile products. This decomposition is a physical requirement imposed by memory hierarchy limits: operand tiles are fetched from high-capacity, high-latency HBM, staged in fast SRAM, and pulsed through the systolic array.

Tile dimensions balance on-chip capacity against arithmetic intensity. A larger tile reuses each loaded byte across more multiply-accumulate operations, raising operational intensity toward the compute-bound regime of the roofline model; the capacity ceiling is how much of **A**, **B**, and **C** fits simultaneously in fast on-chip memory. Tiling sustains high hardware efficiency (η_{hw}) by ensuring that for every byte loaded from main memory, the data is reused 128× within the systolic grid. When a layer dimension is not an exact multiple of the hardware tile size, the accelerator pays a *fringe penalty* in idle silicon. Consider a layer where only one output dimension expands from 128 to 129 while the other dimensions remain perfectly aligned to the 128-element tile. Processing that single extra column requires scheduling a second 128-wide tile across the systolic array, leaving 127 execution units idle during the fringe pass. Two tiles execute where one nearly sufficed, so the utilization factor along that dimension falls to $129/256$, or approximately 50 percent, creating the efficiency cliff illustrated in the margin figure. When multiple dimensions misalign simultaneously, these padding losses multiply across the tiled axes: a 129×129 output block partitioned into four 128×128 physical tiles yields a useful-area efficiency of $(129/256)^2$, or barely 25 percent. Algorithm 11.1 formalizes the resulting loop nest emitted by the compiler to orchestrate this on-chip staging and accumulation.

Algorithm 11.1 Tiled (blocked) matrix multiply

Require: $\mathbf{A} \in \mathbb{R}^{M \times K}$, $\mathbf{B} \in \mathbb{R}^{K \times N}$; tile sizes $M_{\text{tile}}, N_{\text{tile}}, K_{\text{tile}}$
Ensure: $\mathbf{C} = \mathbf{AB}$

```
for each row tile i_0 (size M_tile) do
    for each column tile j_0 (size N_tile) do
        initialize the C-tile accumulator to zero on chip
        for each k_0 over K in steps of K_tile do
            load A-tile [i_0, k_0] and B-tile [k_0, j_0] on chip
            accumulate the tile product on chip ▷ reuse N_tile/M_tile per byte
        end for
        write the C-tile back to memory
    end for
end for
```

Once operand tiles reside in fast local SRAM, the hardware executes the tile product without further off-chip memory traffic. Systolic arrays achieve computational efficiency by routing operands through a structured 2D grid of processing elements (PEs) that communicate directly with adjacent neighbors across dedicated registers, bypassing shared-memory bus contention. In a weight-stationary design, the canonical TPU arrangement of figure 11.5, weights from the **B**-tile are preloaded into local PE registers and held stationary. Input activations from the **A**-tile stream horizontally across rows from left to right, while partial sums accumulate vertically down columns. On each clock cycle, every active PE multiplies its incoming activation by its stationary weight, adds the result to the incoming partial sum from above, and passes the activation rightward to its adjacent neighbor for the next cycle.

Because operands propagate one hop per cycle, synchronized execution requires an intentional time skew. Consider a minimal 2×2 tile product where output element $C_{ij} = A_{i0}B_{0j} + A_{i1}B_{1j}$ requires two products and one accumulation. The weight matrix **B** is held stationary across four PEs: PE_{00} stores B_{00}, PE_{01} stores B_{01}, PE_{10} stores B_{10}, and PE_{11} stores B_{11}. Activation A_{i0} enters the top row and A_{i1} the second row, because each row holds the weights for one reduction index. If A_{00} enters the top row at PE_{00} in cycle 0, its partial product $A_{00}B_{00}$ moves down to PE_{10} in cycle 1. That PE holds B_{10}, so the activation it needs is A_{01}, which must therefore enter the second row at PE_{10} one cycle later than A_{00} entered the first. In cycle 1, PE_{10} adds $A_{01}B_{10}$ to the arriving partial sum and emits C_{00}. Meanwhile A_{00} has moved right to PE_{01}, and its product $A_{00}B_{01}$ reaches PE_{11} in cycle 2, just as A_{01} arrives there from PE_{10}, so C_{01} emerges one cycle after C_{00}. Inputs along each successive row and column are staggered in the same way, so operands meeting at any physical coordinate represent identical reduction indices. Local reuse amortizes the initial fill and drain overhead: each loaded activation is reused across an entire row of N_{tile} processing elements, while each stationary weight serves an entire sequence of input vectors before eviction. Sustained throughput, however,

remains bounded by off-chip memory bandwidth whenever operand replenishment cannot keep pace with array retirement (section 11.5.1).

11.7.5.1 Tiling across the memory hierarchy

The systolic case is one instance of a general rule. Tiling bounds the operand blocks actively reused at each memory tier, and the partitioning that fits a graph-level matrix onto a fixed array, with its fringe penalty and the loop nest of algorithm 11.1, recurs at every tier of the memory hierarchy. Tiling[22] restructures a computation into blocks that fit within fast local memory (caches, shared memory, or registers), so that each block is reused before eviction rather than refetched from DRAM (Lam et al. 1991).

[22] **Tiling (loop blocking)**: This restructuring partitions a computation into blocks sized for a fast local tier. A naive loop makes repeated references to the same elements; caches may capture some, while blocking deliberately concentrates reuse before eviction (Lam et al. 1991). This reduction in lower-tier traffic is a primary source of the gap between naive matrix multiplication and optimized GEMM routines.

The naïve loop nest of listing 11.14 shows the cost of leaving reuse to chance. Written as $\mathbf{C} = \mathbf{AB}$, with the weights as **A** and the input batch as **B**, it references the same elements of both operands again and again, and without tiling those repeated accesses consume unnecessary bandwidth. Some references can hit in cache, but large matrices and an unfavorable traversal order can still cause excessive lower-tier traffic. Tiling partitions this multiplication across its three principal dimensions (M, K, and N) (figure 11.12). Each highlighted region represents the working set staged in fast memory at one moment: an $M_{\text{tile}} \times K_{\text{tile}}$ block of **A** (within the green row band) multiplies a $K_{\text{tile}} \times N_{\text{tile}}$ block of **B** (within the pink column band) to accumulate one $M_{\text{tile}} \times N_{\text{tile}}$ output tile ($\text{Block}_{m,n}$, shaded blue) of **C**. Processing all inner-product operations for an active tile before evicting it amortizes off-chip DRAM latency across $M_{\text{tile}} \cdot N_{\text{tile}} \cdot K_{\text{tile}}$ arithmetic operations.

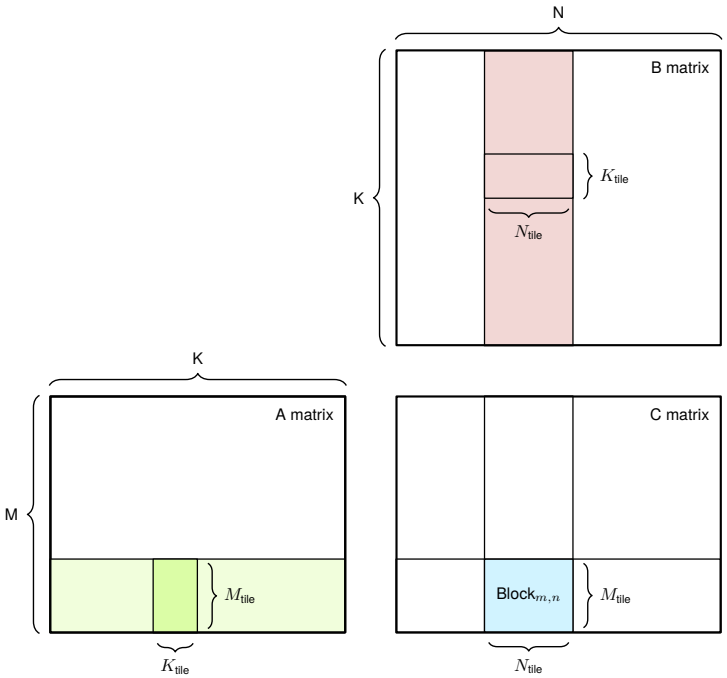


Figure 11.12: Matrix Tiling Mechanics: Partitioning large matrix multiplication ($\mathbf{C} = \mathbf{AB}$) into $M_{\text{tile}} \times K_{\text{tile}}$ and $K_{\text{tile}} \times N_{\text{tile}}$ blocks aligns memory footprints with fast on-chip SRAM/registers. Maximizing register reuse within each tile amortizes slow off-chip DRAM accesses and keeps compute engines operating at peak throughput.

Tiling fundamentals In listing 11.14, every iteration of the innermost loop fetches A_{ik} and B_{kj}, multiplies them, and updates C_{ij}. When the matrices are large, the processor reloads values it used moments earlier, and each reload that misses on chip pays the DRAM penalty in latency and energy (Horowitz 2014; Sze et al. 2017).

Performance benefits of tiling Tiling processes one submatrix at a time, so that once a block is loaded it is reused many times before the loop moves on. Listing 11.16 demonstrates cache-friendly

loop blocking: the loop bounds partition the matrices into tiles, and the hardware cache hierarchy keeps recently used tile data close to the compute units when access order has locality.

Listing 11.16: Cache-Blocked Matrix Multiplication: This high-level loop blocking approach divides matrices into smaller index ranges so hardware caches can reuse data within each tile, improving computational efficiency without explicit scratchpad loads.

```
TILE_SIZE = 32  # Choose a tile size based on hardware constraints

# Cache blocking: partition data via loop bounds.
# Loads are implicit through the hardware cache hierarchy.
for i in range(0, N, TILE_SIZE):
    for j in range(0, N, TILE_SIZE):
        for k in range(0, N, TILE_SIZE):
            # Each tile computed independently
            for ii in range(i, min(i + TILE_SIZE, N)):
                for jj in range(j, min(j + TILE_SIZE, N)):
                    for kk in range(k, min(k + TILE_SIZE, N)):
                        C[ii, jj] += A[ii, kk] * B[kk, jj]
```

The restructuring produces a chain of effects. A small tile is revisited while it is still likely to be cached, so most operand references hit in L1/L2 or shared memory instead of DRAM. DRAM traffic falls as a result, and the processing units spend less time waiting for operands. When an untiled access pattern repeatedly fetches operands from lower memory tiers, that traffic can impose a bandwidth ceiling below the arithmetic ceiling.

Tiling methods Tiling implementations differ along one axis, which is whether the hardware or the program decides what stays in fast memory. The two ends are implicit (cache) blocking and explicit (scratchpad) staging, and practical kernels often combine them.

Implicit (cache) blocking restructures only the loop bounds. The tiled matrix multiplication in listing 11.16 issues no explicit loads; its tile-shaped access pattern lets hardware caches reuse nearby values before they are evicted. It suits CPUs and GPUs with capable caches and large tensors that exceed fast-memory capacity.

Explicit (scratchpad) staging copies each tile into shared memory, a scratchpad, or registers and reorganizes the computation around the staged copy. It is the only option on accelerators whose fast memory is software managed, and it guarantees reuse that a cache might lose to eviction. Convolution is the classic case, because staging a filter once lets it serve many input regions without being refetched. Listing 11.17 loads blocks of **A** and **B** into temporary fast storage and reuses them across the inner loops, including shortened boundary tiles when N is not divisible by `TILE_SIZE` (the software counterpart of the fringe penalty that a fixed-size array pays in idle processing elements).

Listing 11.17: Explicit Tile Staging Pseudocode: A backend maps the temporary tile objects to fast storage and reuses them across inner-loop operations.

```
# Explicit tile staging: load data into fast
# temporary storage before the inner loops.
for i in range(0, N, TILE_SIZE):
    for j in range(0, N, TILE_SIZE):
        for k in range(0, N, TILE_SIZE):
            # Pseudocode: map these tile objects to fast memory
            A_tile = A[i : i + TILE_SIZE, k : k + TILE_SIZE]
            B_tile = B[k : k + TILE_SIZE, j : j + TILE_SIZE]

            # Reuse loaded tiles for all inner iterations
            for ii in range(A_tile.shape[0]):
                for jj in range(B_tile.shape[1]):
                    for kk in range(A_tile.shape[1]):
                        C[i + ii, j + jj] += (
                            A_tile[ii, kk] * B_tile[kk, jj]
                        )
```

Tiling challenges and trade-offs Tiling improves performance only when the tile matches the locality budget of the hardware. If the tile is too small, memory fetches still dominate execution time because reuse is too limited. If the tile is too large, it exceeds fast memory and causes cache thrashing or scratchpad spills. Selecting the right tile size therefore directly determines computational efficiency and memory bandwidth usage.

The capacity test counts every buffer that is live at the same time. For the tile dimensions in algorithm 11.1, the operand blocks contain $M_{\text{tile}}K_{\text{tile}}$ and $K_{\text{tile}}N_{\text{tile}}$ elements, while the output accumulator contains $M_{\text{tile}}N_{\text{tile}}$ elements. Suppose a hypothetical accelerator retains all three in one software-managed local store, uses FP16 operands and an FP32 accumulator, and loads only the current operand pair. Element storage size s_{elem} is then 2 bytes for each operand and 4 bytes for each accumulator entry. After reserving space for other live state, the tile must satisfy

$$(2\text{ bytes})M_{\text{tile}}K_{\text{tile}} + (2\text{ bytes})K_{\text{tile}}N_{\text{tile}} + (4\text{ bytes})M_{\text{tile}}N_{\text{tile}} \leq \text{available local bytes}. \tag{11.6}$$

Keeping the output dimensions fixed while doubling the reduction tile doubles both operand buffers without changing the accumulator. Reject that larger candidate if the revised left-hand side of equation 11.6 exceeds the available capacity, even if its longer reduction amortizes accumulator handling over more products. Double buffering has the same operand-capacity effect at fixed tile dimensions: retaining the next **A** and **B** tiles while computing the current pair requires a second copy of each operand buffer, while the running accumulator remains single buffered.

Actual storage tiers must be budgeted separately. A GPU kernel may stage operand tiles in shared memory while keeping output accumulators in thread registers; unused register capacity cannot make an oversized shared-memory allocation fit. Its shared-memory test counts the staged operand copies and any other shared state, while its register test counts accumulators, operand fragments, and temporary values across the participating threads. Passing both tests establishes capacity feasibility. It does not establish speed: alignment, bank conflicts, occupancy, synchronization, and measured traffic still determine whether the tile improves execution.

The tile choice also controls load balance. In architectures such as GPUs and TPUs, computations execute in parallel across thousands of processing units. If tiles are not evenly distributed, some units remain idle while others are overloaded, leading to suboptimal utilization of computational resources. Effective tile scheduling keeps parallel execution balanced and efficient.

Data movement remains a cost after tiling, even when another resource becomes the throughput limit. Although tiling reduces the number of slow memory accesses, transferring tiles between hierarchy levels still incurs latency and energy cost, especially when data falls from cache or scratchpad back to DRAM. Efficient memory prefetching and scheduling strategies minimize this residual movement and ensure that data is available when needed.

Hybrid tiling combines implicit blocking and explicit staging when neither alone captures the workload's reuse, for example relying on caches for an outer tier while staging convolution weights explicitly in a scratchpad. Register blocking, double buffering, and hierarchical tiling extend the same locality principle at smaller and larger memory tiers. AI compilers and runtime systems such as TensorFlow XLA, TVM, and MLIR automatically select these tiling strategies based on hardware constraints, enabling fine-tuned performance optimization without manual intervention. Table 11.12 compares implicit, explicit, and hybrid tiling.

Table 11.12: Tiling Strategies: Implicit, explicit, and hybrid tiling optimize memory access patterns for improved performance. Implicit (cache) blocking shapes loop bounds and lets caches decide residency, explicit (scratchpad) staging copies tiles into software-managed memory to guarantee reuse, and hybrid tiling combines both across memory tiers. AI compilers and runtime systems use these techniques to automatically optimize model execution on diverse hardware.

Aspect	**Implicit (Cache) Blocking**	**Explicit (Scratchpad) Staging**	**Hybrid tiling**
Who Decides Residency	Hardware cache replacement policy	The program, through explicit copies into software-managed memory	Caches for some tiers, explicit copies for others
Optimization Focus	Loop bounds shaped so accesses stay within cache-sized blocks	Staging tiles and reordering computation around the staged copy	Matching each memory tier to the mechanism it supports

Aspect	Implicit (Cache) Blocking	Explicit (Scratchpad) Staging	Hybrid tiling
Memory usage	Improves cache locality and reduces DRAM access	Keeps frequently used data in fast memory for multiple iterations	Minimizes data movement while ensuring high reuse
Common use cases	Matrix multiplications, CNNs, self-attention in transformers	Convolutions, recurrent neural networks (RNNs), iterative computations	AI accelerators with hierarchical memory, mixed workloads
Performance gains	Reduced memory bandwidth requirements, better cache utilization	Lower memory fetch latency, improved data locality	Maximized efficiency across multiple hardware types
Challenges	Reuse is not guaranteed; eviction can discard a tile before it is reused	Can increase register pressure, requires loop restructuring	Complexity in tuning tile size and execution order dynamically
Best when	Hardware caches are capable and the working set exceeds fast memory	Fast memory is software managed or reuse must be guaranteed	Different memory tiers favor different mechanisms

11.7.6 Memory-efficient tensor layouts

Stationary dataflows (section 11.7.4) and tiling determine which operands stay close to compute units and in what blocks; tensor layouts determine whether those operands can be accessed efficiently once they arrive. A well-chosen weight-stationary schedule still stalls if weights are laid out in a format that produces strided, non-coalesced memory fetches. Tensor layout is a kernel requirement. The physical ordering of multidimensional data in linear memory must match the memory access stride expected by the accelerator's execution units, or the processor pays in memory stalls, cache underutilization, and redundant bus transactions.

Hardware accelerators fetch data from device memory in fixed-size transactions, typically 32 to 128 bytes per transaction. When compute units request non-contiguous addresses, each transaction delivers only a fraction of useful payload, degrading effective memory bandwidth. Aligning tensor layout with the execution model lets concurrent threads or SIMD lanes access nearby aligned locations in fewer transactions; the count depends on access width and device granularity (NVIDIA Corporation 2021b).

Machine learning frameworks and compilers often manage this layout selection automatically. Optimization tools such as cuDNN for NVIDIA GPUs, XLA for TensorFlow and JAX, and MLIR-based compiler stacks transform tensor layouts as they lower operations to backend-specific kernels (NVIDIA Corporation 2021b; Google 2025; Lattner et al. 2020). In high-level frameworks, layout transformations are typically applied transparently, but developers authoring custom kernels or targeting low-level APIs such as CUDA, Metal, or OpenCL must manage tensor formats directly.

In PyTorch, for example, view operations such as `tensor.permute()` adjust tensor strides without moving data in memory, requiring an explicit `tensor.contiguous()` call to materialize a packed buffer when a downstream kernel requires contiguous storage (PyTorch Contributors 2026b). Conversely, TensorFlow defaults to channels-last (NHWC) for convolutional models on NVIDIA GPUs, warning that NCHW inputs introduce automatic transpose overhead when lowered to GPU kernels (TensorFlow Developers 2024b). Hardware-optimized libraries such as cuDNN on GPUs and oneDNN on CPUs implement tailored memory formats to maximize cache line utilization and SIMD throughput. The governing principle is to treat memory layout as an intrinsic property of the backend execution path: the fastest tensor format is the one that minimizes layout conversion overhead and makes memory accesses contiguous across hardware execution units.

11.7.6.1 Channels-last layout

In an NHWC channels-last layout, the channel index varies fastest in a contiguous tensor, placing the channel values for each spatial coordinate adjacent in memory. The label names the order in which dimensions are laid out in memory, from slowest-varying to fastest-varying, so NCHW and NHWC hold the same values in different linear orders.

Consider an RGB image tensor of shape $(\text{Height}, \text{Width}, \text{Channels}) = (3,3,3)$. The elements $X(h,w,c)$ are laid out in linear memory as follows:

$$X(0,0,0), X(0,0,1), X(0,0,2), X(0,1,0), X(0,1,1),$$
$$X(0,1,2), X(0,2,0), X(0,2,1), X(0,2,2), ...$$

All channel values for a given pixel are adjacent, and memory addresses advance across width before advancing down height. This layout supports vectorized execution when a compute kernel processes multiple channels simultaneously: CPU SIMD registers and GPU Tensor Cores can load contiguous channel vectors directly without intra-register shuffling.

The advantage of channels-last storage depends on the target operator and hardware unit. TensorFlow uses NHWC by default, whereas PyTorch provides a dedicated channels-last memory format that decouples logical dimension ordering from physical storage. Modern Tensor Core kernels in cuDNN favor NHWC because matrix-multiply units pack channel dimensions directly into accumulator tiles. When kernels require channel-contiguous inputs, passing an incompatible format forces the framework runtime to insert an explicit memory transpose, incurring a memory bandwidth penalty before computation begins.

11.7.6.2 Channels-first layout

In a contiguous NCHW channels-first layout, the spatial width index varies fastest, and all spatial values across an entire channel are stored contiguously before the next channel begins. Accelerators process data in parallel across thread warps or SIMD lanes; when consecutive threads in a warp access consecutive memory addresses, the memory controller coalesces those requests into fewer memory transactions (**memory coalescing**).[23]

[23] **Memory coalescing**: The GPU hardware mechanism that combines memory requests from threads in a warp into transactions according to address locality, alignment, access width, and device granularity. Tensor layout therefore decides how many transactions a warp's loads become, and whether a given layout helps depends on how the kernel assigns threads to tensor dimensions.

Consider the same RGB image tensor with dimensions reordered in channels-first order as $(\text{Channels}, \text{Height}, \text{Width}) = (3,3,3)$. Retaining $X(h,w,c)$ as semantic coordinate notation, the data are stored in channels-first order as follows:

$$X(0,0,0), X(0,1,0), X(0,2,0), X(1,0,0), X(1,1,0), X(1,2,0), ...,$$
$$X(0,0,1), X(0,1,1), X(0,2,1), ..., X(0,0,2), X(0,1,2), X(0,2,2), ...$$

In this format, all red channel values for the entire image are stored first, followed by all green values, and then all blue values. This arrangement allows kernels that parallelize across spatial coordinates (H,W) to issue coalesced reads along image rows, which suited earlier GPU convolution algorithms and SIMD execution pipelines (Chetlur et al. 2014).

The relative advantage of NCHW versus NHWC depends on how the underlying kernel maps computation to hardware threads. Convolutional layers evaluate filters across spatial and channel dimensions simultaneously. In classic direct or FFT-based convolutions, channels-first ordering enabled efficient spatial sliding without stride jumps. However, modern GEMM-lowered convolutions and Tensor Core pipelines map channel reduction directly to matrix multiply accumulators, favoring channels-last structures. When a model operates in NCHW but invokes a Tensor Core-optimized backend, the runtime must either run an unoptimized fallback kernel or dynamically transpose the tensor into NHWC, burning memory bandwidth in both cases.[24]

[24] **NHWC vs. NCHW**: NHWC lists dimensions as batch, height, width, channel; NCHW lists batch, channel, height, width. Physical memory format determines whether adjacent threads read adjacent addresses, so the performance effect is backend-specific. Layout-to-hardware mismatch is not a micro-optimization; it can create multi-fold performance gaps, especially when a conversion prevents Tensor Core convolution or fusion paths from being used.

11.7.6.3 Comparing channels-last and channels-first layouts

Both channels-last (NHWC) and channels-first (NCHW) layouts address specific hardware access patterns, with their efficiency determined by whether a kernel parallelizes over spatial coordinates or vectorizes across channel dimensions. Layout choice directly governs cache line utilization, memory bus transaction count, and compute unit occupancy. Table 11.13 contrasts the performance trade-offs and hardware compatibility between these two approaches.

Table 11.13: Data Layout Strategies: Channels-last (NHWC) and channels-first (NCHW) layouts optimize memory access patterns for different backend kernels. NHWC often suits CPU vectorization and modern Tensor Core convolution and fusion paths, while NCHW remains the default PyTorch tensor shape and suits older FP32 GPU kernel paths. Choosing the appropriate layout directly impacts performance by maximizing cache utilization and memory bandwidth efficiency.

Feature	**Channels-Last (NHWC)**	**Channels-First (NCHW)**
Memory storage order	Pixels are stored row-by-row, channel interleaved	All values for a given channel are stored together first
Best for	CPU loops, element-wise operations, many channels-last kernels	Many legacy GPU convolution paths and channel-first model code
Cache efficiency	High cache locality for sequential row/channel-last access	Can improve coalescing for channel-first kernels
Convolution performance	Often preferred by modern Tensor Core convolution/fusion paths	Efficient for older FP32 cuDNN paths and direct convolutions
Memory fetching	Good when kernels vectorize over adjacent channel data	Good when kernels process channel-major tiles
Default in frameworks	Common TensorFlow convention; PyTorch channels-last option	Common PyTorch tensor shape convention

While compilers such as XLA, TensorRT, and PyTorch Inductor automate layout propagation and insert layout conversions when beneficial, format conversions are not free: transposing a tensor requires reading every element from memory and writing it back in a different order, consuming memory bandwidth without executing useful arithmetic. In production deployments, matching the model's memory layout to the accelerator's native kernel format eliminates these layout transformations entirely. Even when tensor layout is perfectly aligned with the hardware, however, executing operations as isolated kernels introduces a separate bottleneck: intermediate values must be exposed through global-memory buffers between operations, even when caches absorb some physical traffic. Resolving that bottleneck requires changing how operations are scheduled rather than how tensors are laid out.

11.7.7 Kernel fusion on the accelerator

Kernel fusion[25] entered the book as a framework optimization that combines successive operations into a single kernel to avoid intermediate memory round trips. The LayerNorm analysis (notebook 11.8) shows why it matters on an accelerator. At 2.0 FLOP/byte, a standalone normalization kernel can reach at most 6.7 TFLOP/s, about 0.7 percent of the H100's tensor peak, however its arithmetic is scheduled. The hardware questions are which intermediates fusion removes from the memory bus and what the fused kernel costs in registers and occupancy.

The case for fusion rests on a traffic count. Run as separate kernels, a chain of three elementwise operations writes each intermediate result to device memory and reads it back for the next operation, whereas a fused kernel reads the input once, keeps the intermediates in registers or on-chip SRAM, and writes only the final output, which cuts idealized external traffic by roughly $3\times$. On an accelerator the saving matters most for elementwise operators, whose arithmetic intensity sits far below one FLOP per byte, so moving each intermediate across the memory bus takes longer than computing it (Jia et al. 2019). Fused execution also shortens the lifetime of intermediate buffers, although an optimizing runtime can often reuse those buffers anyway; what fusion guarantees is the removed write and read for each eliminated intermediate, and how much of that removed traffic would have reached DRAM depends on cache behavior.

11.7.7.1 Performance benefits and constraints

Because high-bandwidth memory is the scarce resource on GPUs and TPUs, eliminating redundant memory transactions translates directly into higher compute utilization (NVIDIA Corporation 2020a). Not all operations can be fused arbitrarily, however. Element-wise operations and frozen inference normalization are strong candidates because their computations do not require batch-wide reductions, whereas training-mode batch normalization computes batch statistics and is not purely element-wise. Matrix multiplications and convolutions constrain fusion further because they involve reductions and large data movement; compilers routinely fuse them with element-wise epilogues such as bias or activation, yet cannot freely merge them with unrelated global operations.

[25] **Kernel fusion**: Separate GPU kernels expose intermediate results through device memory, although caches can absorb some traffic. A fused kernel can keep intermediates in registers or local storage and avoid corresponding external write/read cycles. The resulting speedup depends on cache behavior, occupancy, launch overhead, and whether memory traffic was the bottleneck; it is not necessarily proportional to the byte reduction.

↩ Kernel fusion (also called operator fusion), with its LayerNorm, dropout, and ReLU example and the traffic count for unfused versus fused chains, is established in section 7.3.2.

Even when two operators are algebraically compatible, register pressure bounds how aggressively they should be fused. Keeping intermediate values in registers eliminates redundant memory writes, but if a fused kernel exceeds the available registers per thread, the compiler spills excess values to per-thread local memory backed by device DRAM, adding latency that can negate the benefits of fusion. On GPUs, where thread occupancy (the number of threads active in parallel) is bounded by the register file, excessive fusion can also starve parallelism. Different accelerators and compilers therefore strike different balances: NVIDIA GPUs favor warp-level parallelism where element-wise epilogue fusion is straightforward (NVIDIA Corporation 2020a), while TPUs prioritize systolic-array execution coupled to vector post-processing (Jouppi et al. 2017), and compiler stacks such as TVM, XLA, TensorRT, and MLIR use graph rewrites and engine-building heuristics to weigh memory savings against register and occupancy limits (Chen et al. 2018; Google 2025; NVIDIA 2024c; Lattner et al. 2020). When debugging performance regressions or modifying models frequently, frameworks also allow developers to disable fusion selectively so that memory savings, register usage, and hardware execution constraints can be evaluated independently.

Checkpoint 11.4: Data movement and kernel fusion

The dataflow building blocks are now in place: data locality, tensor layout, and kernel fusion. These fusion decisions are ultimately about data locality, which ties together the chapter's core data movement strategies:

- ☐ **Locality choice**: given weight-stationary, output-stationary, and input-stationary dataflows, which tensor does each hold near the compute units, and how does that choice shift where the memory traffic lands?
- ☐ **Layout match**: a kernel runs on a backend expecting NHWC but receives an NCHW tensor. Predict what happens to its memory access pattern and to delivered throughput.
- ☐ **Fusion eligibility**: for a Conv2D, a BatchNorm, and a ReLU executed in sequence, decide which pairs are worth fusing and what determines whether fusing them pays off.
- ☐ **Remaining gap**: an operation still repeatedly fetches operands because its active blocks exceed fast-memory capacity. How could tiling from section 11.7.5 change this access pattern, and what capacity and reuse evidence would justify that choice?

11.7.8 Applying mapping strategies to neural networks

While section 11.5.5 diagnosed how convolutional networks, transformers, and multilayer perceptrons stress memory subsystems, the mapping strategies above provide the systems remedies. Mapping is a systematic search over loop permutations, tiling factors, and stationarity policies that maximizes data reuse under hard SRAM and register constraints. Because each model family presents a distinct ratio of weights to activations and differing opportunities for temporal locality, optimal mapping policies diverge across workloads. Convolutional networks exploit 2D spatial weight reuse across receptive fields; transformers split between compute-bound matrix multiplications during prefill and bandwidth-bound KV-cache streaming during autoregressive decoding; and dense MLPs demand blocked GEMM execution across batch dimensions. Table 11.14 consolidates how dataflow, memory layout, kernel fusion, and tiling align with these three architectural archetypes.

11.7.8.1 Convolutional neural networks (ResNet-50)

For ResNet-50 and similar CNNs, a key mapping opportunity is spatial weight reuse. A small filter is applied across many spatial locations, so its weights participate in many multiply-accumulate operations. Weight-stationary mappings can capture that reuse by retaining filter tiles locally, while row-stationary or output-stationary mappings may better balance activation and partial-sum traffic on other architectures. Favorable convolution shapes can achieve high arithmetic intensity, which makes them well suited to matrix and systolic execution paths. The model family does not determine one universal dataflow: layer shape, batch size, local-storage capacity, and the target's supported kernels decide which reuse pattern is worth retaining.

Table 11.14: Memory Pressure and Mapping by Model Family: The first four rows profile each family's memory demands, and the remaining rows give the mapping that answers them. Standard dense transformers demand bandwidth and capacity because large weights, KV caches, and attention traffic dominate their traffic, while CNNs benefit from spatial locality and high activation reuse.

Property or technique	CNNs	Transformers	MLPs	Rationale
Weight size	Small, reused	Large, usually dense; sparse in MoE or pruned variants	Large, dense	Sets whether weights can stay on chip or must stream from HBM on every use.
Activation reuse	High	Low to medium	Low	Sets how much each loaded activation is worth keeping in local storage.
Memory access pattern	Spatial locality	Mostly regular GEMM plus KV-cache and attention traffic	Regular, sequential (streamed)	Regular patterns tile and prefetch well; KV-cache reads grow with context length.
Potential memory pressure	Feature-map movement	Memory capacity and bandwidth	Bandwidth at low batch	Starting hypotheses that execution phase, batch size, and data movement can change, not fixed bottleneck classifications.
Dataflow strategy	Weight, row, or output stationary	Phase- and kernel-dependent	Weight or output stationary	CNNs expose filter and spatial reuse; transformer attention and MLP blocks impose different traffic; dense MLPs reuse weights across a batch and accumulate outputs.
Memory-aware tensor layouts	Backend-dependent (channels-last on Tensor Core paths, NCHW on older FP32 paths)	Backend-dependent (row-major activations typical)	Row-major typical	Layout choice depends on backend kernel path and precision mode (section 11.7.6 compares the layouts); the entries name common defaults, not universal prescriptions.
Kernel Fusion	Convolution + Activation	Fused Attention	GEMM Fusion	CNNs optimize convolution+activation fusion; Transformers fuse attention mechanisms; MLPs benefit from fused matrix multiplications.
Tiling for Memory Efficiency	Explicit staging of feature-map tiles	Explicit staging of attention blocks	Blocked GEMM	CNNs stage feature-map subregions in on-chip SRAM; transformers stage query and key/value blocks in fused attention; MLPs block large matrix multiplications, implicitly or explicitly.

This spatial regularity also enables aggressive fusion and tiling. For inference with frozen BatchNorm statistics, compilers can fold or fuse convolution, normalization, and activation to avoid unnecessary intermediate writes. Training-mode BatchNorm requires reductions over batch statistics and does not have the same element-wise structure that permits fusion. Spatial tiling partitions the feature map into subregions sized to fit within on-chip SRAM, so the fused kernel processes each tile from fast memory before moving to the next.

11.7.8.2 Transformer architectures (GPT-2/Llama)

Transformer mapping depends on execution phase. During training and prefill, attention creates large intermediate matrices unless a tiled implementation avoids materializing them; during autoregressive decoding, attention reads the growing key-value (KV) cache. Each new query vector must access the stored key and value pairs across the preceding sequence. As sequences grow, the full KV cache usually lives in HBM or device DRAM, while attention kernels tile active blocks through SRAM, registers, or shared memory. This access pattern motivates staging active K/V tiles in SRAM so attention consumes them from fast local storage. During training and prefill, the memory traffic created by standard attention implementations similarly explains why fused attention kernels, such as FlashAttention (Dao et al. 2022), can deliver large performance gains: they tile the query-key product, softmax, and value summation through on-chip SRAM so the full attention matrix never reaches HBM, while the $\mathcal{O}(S^2)$ computation is preserved (section 8.6.4 develops the algorithm).

11.7.8.3 Multilayer perceptrons and DLRM

MLPs present the most straightforward mapping problem because their computation reduces largely to dense GEMM.[26] Each fully connected layer multiplies an activation matrix by a weight matrix. The

[26] **GEMM**: The operation $\mathbf{C} = \alpha\mathbf{AB} + \beta\mathbf{C}$, with scalars α and β, is the dense linear-algebra primitive that many deep-learning layers lower to. Optimized GEMM libraries such as cuBLAS and oneDNN use register blocking, vectorization, and hierarchical tiling to approach hardware limits on favorable shapes (NVIDIA 2024a; Intel Corporation 2021b). Modern AI accelerators are heavily specialized for GEMM-like tiles: Tensor Cores, systolic arrays, and matrix extensions all exist to accelerate this primitive, which is why GEMM performance is an important predictor of end-to-end throughput across architectures.

weight matrix is fixed across samples, so batching reuses each loaded weight across more activations and raises arithmetic intensity. A batch size of one provides little cross-sample weight reuse and often leaves wide matrix engines underused, while larger batches can move execution toward the compute-bound regime.

↪ How GEMM arithmetic intensity scales with matrix dimension is collected for reference in section C.1.3.

Because MLP layers are typically followed by activation functions and bias additions, GEMM fusion combines these steps into a single kernel, avoiding intermediate memory writes. Blocked tiling partitions the large matrix multiplications into sub-blocks sized for the accelerator's shared memory, ensuring high cache utilization throughout computation. The simplicity of the MLP mapping, dominated by a single primitive with predictable access patterns, is precisely why hardware vendors optimize GEMM libraries so aggressively: gains in GEMM performance translate directly to MLP throughput. DLRM is not purely an MLP workload, however. Its large sparse embedding tables and feature-interaction stage can dominate capacity and memory traffic, so the dense mapping described here applies to its bottom and top MLP towers rather than to the entire model (Naumov et al. 2019).

11.7.9 Hybrid mapping strategies

The preceding architectural subsections treat each architecture in isolation, but real models rarely consist of a single layer type. A vision transformer, for example, combines a patch embedding stage, self-attention layers, and MLP blocks (Dosovitskiy et al. 2021). Those layers create different reuse patterns: the embedding stage can benefit from weight-stationary mapping, attention emphasizes activation movement and tiling, and MLP blocks demand blocked GEMM tiling and fusion. No single dataflow strategy is optimal across all these layers, so hardware mapping becomes hybrid and layer-specific.

Hybrid mapping addresses this heterogeneity by allowing the accelerator to switch strategies at layer boundaries. Each layer presents a different balance of compute intensity, data reuse, and memory access pattern, and the optimal mapping must shift accordingly (Sze et al. 2017). Rather than committing to one dataflow for the entire model, hybrid approaches consider weight stationary execution when weights can be reused locally, input-stationary execution when activation reuse justifies its storage, and output stationary execution when partial-sum traffic is costly. Layer dimensions and available local memory determine which candidate pays off.

TPU-style systolic arrays, NVIDIA GPUs, and tile-based accelerator designs expose different combinations of local memory, tensor layouts, fusion, and scheduling controls, allowing compilers and runtimes to choose layer-specific strategies rather than one global dataflow for the whole model (Jouppi et al. 2023; NVIDIA Corporation 2020a; Chen et al. 2018). These implementations depend on programmable memory hierarchies, efficient interconnects, and specialized execution pipelines. However, hybrid mapping remains a design-time optimization: in production workloads, execution conditions change dynamically due to varying input sizes, memory contention, and hardware resource availability. Machine learning compilers and runtime systems extend these static mapping choices by introducing dynamic scheduling, memory optimizations, and automatic tuning, ensuring that deep learning workloads operate efficiently across diverse accelerators and deployment environments.

11.8 Compilers and Runtimes

The roofline gives each ResNet-50 layer a ceiling, and hardware mapping showed which schedules can approach it, but neither reaches the silicon by itself. Every layer needs a tiling, a stationary operand, a tensor layout, a precision for the activations it reads and writes, and a fusion boundary, and the resulting plan must then run on a device whose input shapes, free memory, and clock rate change while it serves. Across a whole model these choices number in the thousands, which is why compilers and runtimes, not engineers, make them. Graph capture and dispatch overhead, which decide how a model reaches a compiler, belong to chapter 7, and the choice of a deployment runtime for a service belongs to section 13.6. What remains here is lowering, the path from a captured graph to the accelerator's units, and the runtime that executes the result. The decode floors this chapter quotes for GPT-2 XL assume that the step is launched as a captured graph (section 7.3.6); executed one eager kernel at a time, launch overhead rather than memory bandwidth would set the floor.

A single convolution can be implemented with dozens of valid tiling strategies, kernel variants, and memory layouts, most of which perform poorly on a given target. **Machine learning com-**

pilers navigate this space by translating high-level dataflow representations into target-specific executable code, making the mapping and dataflow decisions of the preceding sections automatically. Compiling ResNet-50 for GPU inference illustrates the core compiler stages:

1. **Graph optimization** fuses repeated Conv2D-BatchNorm-ReLU patterns into single compound kernels, eliminating intermediate round-trips to HBM.
2. **Kernel selection** chooses specialized Tensor Core implementations for compatible matrix multiplications, exploiting the high arithmetic intensity of dense convolutions.
3. **Memory planning** determines activation lifetimes to safely overlap and reuse intermediate buffer allocations.
4. **Computation scheduling** pipelines memory copies with execution across independent hardware queues to hide data transfer latencies.

↩ Graph compilation, kernel fusion, and framework dispatch overhead are established in section 7.3.

On the reference H100, the modeled batch-one forward pass falls from 3.53 ms in an eager framework to 0.33 ms as a compiled FP16 engine, a 10.6× improvement without altering the model's mathematical output. The arithmetic per image is unchanged. The gain comes from fusing the network's 174 framework kernels into 56 and launching them as one graph instead of one Python dispatch at a time, which removes the fixed cost that dominates a single image. That answers the question the chapter opened with. The INT8 arithmetic for one image takes about 4 µs on the H100 (8 µs at FP16), so even the compiled pass spends almost all of its time on launch and overhead; batch-one latency sits on the overhead floor rather than on either roofline ceiling, which is why halving the arithmetic barely moves it. The latencies are modeled rather than measured, and section 13.6 separates the same gap into the contribution of each runtime, but the mechanism is general. Graph rewrites, kernel selection, memory planning, and scheduling systematically apply kernel fusion (section 11.7.7) and memory-efficient tiling (section 11.7.5.1) to convert theoretical hardware FLOP/s into delivered throughput (Chen et al. 2018; NVIDIA 2024c).

11.8.1 ML compiler design

Machine learning compilers specialize conventional compilation techniques for programs expressed as tensor graphs and operator libraries. General-purpose compilers optimize scalar control flow, vector instructions, register allocation, and cache locality; ML compiler stacks operate at a higher semantic level, optimizing graph topology, tensor memory layouts, shape specialization, accelerator kernel dispatch, and inter-device execution planning (Li et al. 2021). Table 11.15 contrasts the emphasis of these two compiler layers. The boundary is complementary rather than disjoint: an ML compiler stack lowers high-level tensor operations into intermediate representations that feed into an LLVM, GPU, or vendor-specific backend.

Table 11.15: Compiler Optimization Priorities: ML compiler stacks add tensor- and graph-level decisions to conventional instruction- and loop-level compilation. In a production toolchain, the two layers commonly cooperate rather than replace one another.

Aspect	**Traditional compiler**	**Machine learning compiler**
Input representation	Source or intermediate-representation program	Tensor graph or tensor-level intermediate representation
Execution Model	Control flow, loops, threads, vectors, and tasks	Tensor operators, kernels, graphs, and accelerator streams
Optimization priorities	Instruction selection, loop transforms, vectorization, registers	Graph rewrites, fusion, layouts, shapes, and kernel selection
Memory management	Objects, stack/heap, caches, locality, and prefetching	Tensor lifetimes, buffer reuse, layouts, tiling, and device transfers
Target Hardware	CPUs, GPUs, and other programmable targets	CPUs, GPUs, TPUs, and custom accelerators
Compilation output	Machine code or lower-level intermediate representation	Kernels plus a hardware-specific graph or execution plan

The distinction in table 11.15 explains why compiler configuration dictates delivered performance even when the underlying neural network code remains unmodified. ML compilers manage the translation layer between high-level tensor operations and hardware execution units; when this

mapping fails to expose reuse or efficient access, execution can be limited by memory traffic, latency, or insufficient parallel work.

11.8.2 ML compilation pipeline

Machine learning models defined in modern frameworks are represented as high-level dataflow graphs describing operations on multidimensional tensors. Lowering these representations into executable code for CPUs, GPUs, TPUs, or custom ASICs requires an ML compilation pipeline (Chen et al. 2018; Google 2025; Lattner et al. 2020). A standard compilation pipeline adds a fifth stage, code generation, to the four that the ResNet-50 example illustrated, emitting target-specific machine instructions, assembly, or interpreted bytecode. Across these stages, the compiler applies the dataflow strategies developed in section 11.7.3: kernel fusion, memory tiling, and compute placement. Hardware acceleration delivers its theoretical throughput only when these compiler-driven transformations expose sufficient arithmetic intensity and align memory access with the hardware hierarchy.

11.8.2.1 Graph optimization

Machine learning frameworks represent models as high-level computation graphs, where nodes represent mathematical operators (such as convolutions, matrix multiplications, and activations) and directed edges represent tensor data dependencies. Executing each operator as a separate kernel can incur intermediate-buffer traffic and repeated launches. An edge denotes a dependency, not necessarily a new allocation or an off-chip transfer, and asynchronous dependencies need not synchronize the host. When intermediate materialization and dispatch dominate execution, graph transformations can remove substantial overhead.

Graph optimization transforms this computation graph into an efficient execution plan before hardware code generation (Chen et al. 2018; Jia et al. 2019). Working primarily at a target-independent intermediate representation (IR) level before lowering (section 11.8.2.5), graph passes apply four core transformations. Kernel fusion merges adjacent operations into a single compound kernel to eliminate off-chip memory round-trips and launch overheads: in convolutional networks, fusing Conv2D, batch normalization with frozen inference statistics, and ReLU keeps activations in local registers or shared SRAM throughout the sequence (section 11.7.7), while in transformers, pattern matchers replace multi-operator self-attention subgraphs (score matrix multiplication, scaling, masking, softmax, and multiplication by the value matrix) with IO-aware attention kernels that keep active tiles and running reduction statistics in fast on-chip memory (Dao et al. 2022). Redundant computation elimination and constant folding remove work that need not happen at runtime at all, folding frozen normalization parameters into the weights and biases of the preceding linear or convolutional layer (section 10.4.1) while pruning dead subgraphs and merging identical parallel paths through common subexpression elimination.

The remaining two passes reduce data movement and live memory footprint without changing the operator set. Algebraic simplification and layout adjustments reorder mathematically equivalent operations—pushing transpositions through elementwise ops or canceling them against inverse permutations—to avoid runtime reshape traffic, while memory-aware node reordering evaluates topological sorts of the dependency graph and schedules independent operations so intermediate activations are consumed and deallocated promptly before memory pressure forces spills to host DRAM. Production compilers execute these rewrites through pattern-matching rules, producing a coarse-grained execution graph aligned with the accelerator's bandwidth constraints before binding each node to a concrete hardware routine.

11.8.2.2 Kernel selection

Kernel selection binds each node in the optimized graph to a concrete hardware implementation. Accelerators provide dozens of valid kernel implementations for a single tensor operation, each parameterized by tile dimensions, thread block configurations, memory staging patterns, and target precision. Choosing the optimal kernel determines whether the execution engine achieves high compute utilization or stalls on uncoalesced memory accesses and pipeline bubbles (Chen et al. 2018; Zheng et al. 2020).

In most production pipelines, compilers draw from vendor-optimized kernel libraries (NVIDIA's cuDNN and cuBLAS for GPUs, Intel's oneDNN for x86) rather than synthesizing kernels from

scratch. These libraries encode microarchitectural details such as register file capacity, cache latency, and vector lane width, so the compiler can invoke pre-tuned implementations.

AI compilers trade compilation time against execution speed across three strategies when choosing among candidate kernels, with numerical precision constraining all three. Rule-based selection is the fastest at compile time, relying on static heuristics over tensor shapes, alignment, data types, and target support to pick implementations such as a Tensor Core GEMM without benchmarking a large candidate set, at the risk of missing faster configurations on irregular shapes. Cost-model selection refines that choice without running hardware benchmarks by estimating kernel latency, register pressure, cache hit rates, and arithmetic intensity with analytical models that prune unpromising candidates (Lattner et al. 2020). When compilation budgets allow hardware measurement, profile-guided selection benchmarks candidates directly on the target device: autotuners such as TVM's AutoTVM and Ansor search over tile sizes, unrolling factors, and thread configurations to converge on the fastest implementation (Chen et al. 2018; Zheng et al. 2020), and TensorRT similarly times candidate tactics against the target batch sizes. Across all three strategies, precision-aware constraints govern which candidates are legal: inference can use lower-precision paths after quality validation, but selecting INT8 without appropriate range handling degrades accuracy, whereas selecting a wider path unnecessarily forgoes available throughput.

11.8.2.3 Memory planning

Memory planning assigns physical storage locations, buffer offsets, and tensor lifetimes across the accelerator's memory hierarchy (Roesch et al. 2018; Chen et al. 2018). High-performance execution plans fail if memory management introduces uncoalesced memory transactions, bank conflicts, or unnecessary memory allocations that exhaust accelerator memory, so the compiler coordinates three core memory management mechanisms.

Tensor layout optimization chooses the physical arrangement of tensor dimensions that each kernel needs for coalesced access and vectorization, such as channels-last `NHWC` for Tensor Core convolutions (section 11.7.6) (NVIDIA Corporation 2021b; Google 2025). Compilers perform layout assignment globally across the graph to prevent back-to-back layout transformation kernels that consume memory bandwidth.

Liveness analysis and buffer reuse prevent out-of-memory errors by sharing physical memory across non-overlapping tensors. Deep neural networks generate dozens of intermediate activation tensors during forward propagation. Allocating a unique memory buffer for every tensor would quickly exceed the capacity of device memory (such as 16 to 80 GB on typical accelerator GPUs). The compiler analyzes the graph to compute the liveness interval of each tensor, from its generation to the completion of its last consumer. By modeling memory allocation as an interval graph coloring or 2D bin-packing problem, the compiler assigns multiple non-overlapping intermediate tensors to the same physical memory offsets (Roesch et al. 2018). This static reuse reduces peak device memory requirements to the working set size of concurrently active tensors, avoiding runtime allocation overhead and fragmentation.

Memory hierarchy placement optimizes the staging of data between external memory (HBM or GDDR) and on-chip scratchpad memories (SRAM or shared memory). External memory bandwidth is a scarce resource; moving intermediate tiles back and forth across the memory bus creates memory-bound stalls. Compilers synthesize tiling parameters that guarantee intermediate blocks remain resident in on-chip SRAM until all local compute operations complete, minimizing round-trip traffic across the memory bus. With memory layouts fixed and buffer addresses assigned, the compiler schedules operation execution across hardware compute resources.

11.8.2.4 Computation scheduling

Computation scheduling determines the execution timeline and hardware resource binding for operations in the compiled graph (Zheng et al. 2020). Modern accelerators feature deep hardware pipelines, multiple independent compute engines, and dedicated DMA copy engines. Effective scheduling coordinates these resources across three distinct architectural dimensions to maximize hardware occupancy, preserve data dependencies, and prevent pipeline stalls (Chen et al. 2018).

Task partitioning maps computational subgraphs onto the target's physical execution units. On GPUs, computations are partitioned into grids of thread blocks dispatched across Streaming Multiprocessors (SMs). On TPUs, matrix multiplications are partitioned into tile sequences matched to

the physical dimensions of systolic arrays (e.g., 128×128 or 256×256 processing elements) (Norrie et al. 2021). On CPUs, tasks are split into thread pools matching physical cores and vectorized to fill SIMD registers.

Execution ordering resolves dependencies while minimizing live memory pressure. Operations that depend on prior results must wait for producer kernels to complete, but independent branches (such as multi-head attention projections or parallel residual paths) can execute concurrently or interleave to maintain uniform compute utilization. Compilers analyze the dependency graph to schedule operations in an order that keeps compute pipelines full while keeping activation lifetimes short, preventing buffer bloat.

Asynchronous overlap hides memory latency by executing data transfers concurrently with compute kernels. Accelerators feature dedicated DMA engines that operate independently of arithmetic pipelines. Compilers exploit this architectural separation by scheduling memory transfers (such as host-to-device weights or inter-accelerator halo exchanges) in separate hardware queues or CUDA streams, overlapping transfer latency behind long-running compute operations (Chen et al. 2018; NVIDIA 2024c). When compute and transfer overlap completely, data movement costs are hidden behind arithmetic execution. Poor scheduling instead introduces execution bubbles where arithmetic units sit idle waiting for kernel dispatches or serialized data copies, so synchronizing kernels via explicit compiler-generated events and stream schedules ensures the hardware sustains continuous execution without CPU driver intervention (NVIDIA 2024c; Zheng et al. 2020).

11.8.2.5 Code generation

With scheduling complete, the final compilation stage translates the scheduled execution plan into target-specific machine instructions. Code generation applies traditional backend compiler passes (instruction selection, register allocation, instruction scheduling, and peephole optimization) tailored to accelerator architectures.

Instruction selection for ML targets must emit instructions that directly engage specialized matrix ISA extensions. On NVIDIA GPUs, code generators emit PTX instructions such as `mma.sync.aligned` to invoke Tensor Cores directly, as shown in listing 11.13. On Intel CPUs with Advanced Matrix Extensions (AMX), the backend targets tile-multiply instructions operating on 2D register tiles. On Arm architectures with the Scalable Matrix Extension (SME), the target is outer-product accumulation across scalable vector tiles. A backend that emits generic floating-point vector instructions instead of these matrix extensions leaves the primary compute engines idle, reducing effective throughput by an order of magnitude. For CPUs and GPUs, compilers emit machine code or optimized assembly; for TPUs, field-programmable gate arrays (FPGAs),[27] and proprietary NPUs, the output is often an optimized bytecode or binary execution package executed by a specialized hardware runtime.

[27] **Field-programmable gate array**: "Field-programmable" means the logic fabric is configurable after manufacturing, contrasting with fixed-function ASICs. FPGAs can improve performance for latency-sensitive data center services by implementing custom pipelines matched to a particular workload (Putnam et al. 2014). This reconfigurability makes FPGAs attractive for rapidly evolving ML architectures where committing to an ASIC risks obsolescence, but the requirement for hardware description languages (Verilog/VHDL) and compilation times measured in hours creates a productivity barrier that limits adoption to deployments where the efficiency benefit justifies the engineering cost.

11.8.3 Runtime support

A compiler transforms a high-level model into an execution plan tailored to target hardware, but that plan embeds static assumptions about runtime conditions: tensor shapes, workspace allocation limits, device capabilities, and execution concurrency. Ahead-of-time (AOT) compilation optimizes graph structures, fusion boundaries, and memory layouts for fixed shapes and known hardware configurations. While just-in-time (JIT) compilation can compile specialized variants dynamically as new shapes arrive, each compiled kernel still executes a fixed execution plan. Production serving breaks those assumptions: request arrival rates fluctuate, batch sizes vary, several inference workloads compete for shared accelerator memory, and thermal throttling can pull clock frequencies below their rated values. Request batching and admission control belong to the serving layer (chapter 13); the concern here is how the accelerator runtime dispatches compiled execution plans once a batch reaches the hardware.

An AI runtime bridges static graph compilation and the dynamic realities of accelerator execution. Compilers optimize and lower computational graphs under fixed structural assumptions, but production systems encounter variable batch sizes, fluctuating sequence lengths, and constrained memory budgets. The runtime executes compiled engines while managing input-dependent tensor shapes, device-memory buffers and workspace, asynchronous hardware streams, and precompiled execution profiles. In production inference stacks such as NVIDIA TensorRT, the offline builder optimizes the network and benchmarks candidate tactics to construct an execution engine, while the

runtime engine binds input buffers, selects valid optimization profiles, and dispatches kernels to the accelerator (NVIDIA Corporation 2026b, 2026c).

This execution lifecycle spans three core responsibilities. First, the runtime selects and dispatches precompiled kernel variants matched to runtime tensor dimensions and hardware capabilities. Second, it manages device memory through arena allocators and static buffer reuse, reducing repeated allocation and associated host-device synchronization overhead. Third, in distributed environments, framework runtimes coordinate cross-device execution boundaries, as demonstrated in pipeline-parallel frameworks such as GPipe (Huang et al. 2019) and automated device-placement systems (Mirhoseini et al. 2017). While serving schedulers oversee request batching and admission control across clusters, the accelerator runtime governs local execution on the device.

11.8.3.1 ML runtime architecture

General-purpose runtimes manage threads, preemptive tasks, heap allocations, and asynchronous I/O across arbitrary control-flow paths. In contrast, an AI runtime operates over dataflow graphs composed of multidimensional tensors, pre-scheduled kernel grids, device memory arenas, and hardware command queues, as contrasted in table 11.16.

Table 11.16: Runtime Execution Models: AI runtimes add tensor-, graph-, and accelerator-aware resource management to conventional runtime services. The exact boundary among framework, compiler runtime, device library, and serving scheduler varies by stack.

Aspect	**Traditional runtime**	**AI runtime**
Execution Model	Functions, threads, tasks, events, and asynchronous I/O	Tensor graphs, kernels, streams, and device events
Task scheduling	Threads and tasks across processor resources	Dependency-aware kernel and transfer dispatch
Memory Management	Objects, stacks, heaps, pools, and virtual memory	Tensor buffers, workspaces, device memory, and buffer reuse
Optimization Priorities	Responsiveness, throughput, locality, and resource sharing	Shape compatibility, transfer overlap, reuse, and utilization
Adaptability	Dynamic scheduling and allocation within program semantics	Runtime choices within compiled graphs and available kernels
Target Hardware	CPUs and heterogeneous devices	CPUs, GPUs, TPUs, and custom accelerators

Tensor memory management represents a primary architectural divergence. In traditional systems, general-purpose allocators manage variable-sized heap objects using runtime metadata. Traditional device allocation calls such as `cudaMalloc` can introduce costly driver work and synchronization. AI runtimes reduce repeated allocation overhead by combining lifetime analysis with pooled or arena allocation. For fixed-shape graphs, the compiler computes static memory offsets, mapping non-overlapping intermediate tensors to shared physical buffers. For variable-shape tensors, the runtime can carve device-memory buffers from preallocated pools, avoiding repeated driver allocation calls within the reserved capacity.

Production environments introduce physical constraints that differ from offline benchmarks. For example, an NVIDIA A100 SXM accelerator operates with a maximum TDP of 400 W, whereas the A100 PCIe variant is constrained to a 300 W TDP envelope. Because sustained clock frequencies scale with available power and thermal dissipation, a compiled kernel tuned for an SXM module may experience thermal throttling or fail to meet latency bounds on a PCIe card. The runtime cannot re-synthesize loop structures or change thread-block dimensions dynamically in response to thermal constraints; it must execute within precompiled profiles while the serving system handles request batching and admission control.

11.8.3.2 Dynamic kernel execution

While static compilation generates high-performance machine code for fixed shapes, production inference requires executing requests with dynamic dimensions. In language models, input sequence length S and batch size B vary across requests. Recompiling an execution plan for each unexpected shape can violate a request deadline: exploring loop unrolling, shared-memory tiling, and register allocation requires seconds or minutes, while serving deadlines operate on millisecond timescales.

↪ How serving runtimes form batches of varying size under latency deadlines is developed in section 13.5.3.

Profile-based inference stacks address this mismatch with precompiled shape ranges. The engine is built for a declared range of each dynamic dimension (the minimum, typical, and maximum shapes), with device-memory workspace reserved for that range. A request inside the range binds its tensors to preallocated buffers and launches precompiled kernels without compilation overhead; a request outside it must be padded, split, or routed to a slower general-purpose kernel, because the runtime cannot synthesize new tiling strategies on the fly. TensorRT's optimization profiles are the common example, and choosing and configuring such a runtime for a service is developed in section 13.6.

Variable requests also keep the host link busy, and the runtime hides those transfers with the asynchronous streams and double buffering of section 11.5.4.2, copying batch $k+1$ while batch k executes. The overlap holds only while compute duration exceeds transfer duration.

11.8.3.3 Runtime kernel selection

An operation may have multiple kernel implementations, termed tactics in TensorRT. The builder selects tactics while constructing an engine; other stacks may retain variants for runtime dispatch. The available choice depends on tensor dimensions, the compiled plan, and permitted device-memory workspace.

Operational batch size changes the available reuse and parallelism. At $B = 1$ in weight-streaming autoregressive decoding, GEMV kernels often target memory throughput. Larger prompt-processing batches can favor GEMM kernels using Tensor Core paths, register tiles, and shared memory. The transition depends on dimensions, precision, traffic, and hardware balance; no fixed batch threshold establishes compute-bound execution.

Device-memory workspace availability further constrains tactic selection. A GEMM with a small output and a long reduction dimension K launches too few thread blocks to occupy every streaming multiprocessor. A split-K variant partitions the reduction across multiprocessors at the cost of a device-memory buffer for partial sums, so a plan built under a tight workspace limit may forgo it and accept lower occupancy.

Runtime selection remains strictly bounded by the numerical formats established during compilation. In mixed-precision training and inference systems such as Megatron-LM, executing matrix multiplications in FP16 or BF16 on Tensor Cores with FP32 accumulation is a numerical requirement of the chosen recipe, validated prior to deployment (Shoeybi et al. 2019). The runtime does not monitor loss values or dynamically alter precision; it only chooses among the validated tactics that implement the specified numerical precision.

11.8.3.4 Kernel scheduling and utilization

Kernel dispatch represents the final stage of runtime execution, coordinating host-side task queues with device-side execution. The software runtime manages host-side command queues (such as CUDA streams or TPU command rings) and records hardware events or semaphores to enforce dataflow dependencies asynchronously. When independent operations (such as parallel multi-head attention projections) have no mutual data dependencies, the runtime dispatches them onto separate streams to enable concurrent execution on the accelerator. Once submitted to the device queue, however, execution control transfers entirely to hardware schedulers. On a GPU, the hardware warp scheduler and work distribution engine assign thread blocks to SMs based on register file availability, shared memory capacity, and maximum warp occupancy; the software runtime cannot schedule individual threads or dictate L1/L2 cache replacement policies. Similarly, TPU runtimes submit macro-instructions to on-chip command queues, while hardware sequencers feed systolic matrix units and vector units (Jouppi et al. 2017).

A low achieved rate alone cannot distinguish runtime gaps from a memory bottleneck. Consider three supplied illustrative profiles of low-intensity kernels, not measurements from a particular device. In the first, the timeline shows continuous kernel execution and HBM traffic close to the sustainable bandwidth ceiling. Reducing transferred bytes or increasing reuse addresses that observed limit. In the second, kernels remain active but dependent loads produce long stalls while HBM traffic stays well below its ceiling. More bandwidth alone need not help: independent requests or a different access schedule must expose enough concurrency to hide the latency. In the third, short kernels alternate with device-idle gaps while the host submits work. Reducing dispatch and synchronization overhead addresses those gaps; changing the arithmetic instruction rate does not.

The discriminating evidence is the timeline together with traffic and stall observations. If added independent requests raise bandwidth and shorten load stalls, they support the latency hypothesis; if bandwidth is already sustained near its ceiling, traffic reduction is the more direct lever. The roofline bounds the resource opportunity, while the profile identifies which mechanism leaves the kernel below it. Even with aggressive kernel fusion, optimal tactic selection, and zero-allocation memory reuse, the execution capacity of a single accelerator is physically bounded by its silicon area, thermal dissipation limit, and high-bandwidth memory capacity, so scaling beyond these physical boundaries requires distributing computation across multiple accelerators.

11.9 Beyond One Accelerator

Everything so far has assumed one accelerator, which is enough for the chapter's ResNet-50 workload and for GPT-2 XL decoding. Some workloads are not served by one device, either because their arithmetic would take too long on it or because their weights and runtime state do not fit in its memory. The techniques covered earlier remain the foundation past that point, since each device still needs an efficient dataflow, but communication adds further boundaries to the hierarchy. Moving data through on-chip storage, HBM, an intra-node link, and a network fabric generally increases latency and energy at each step, so scaling is not merely a question of adding chips.

Each step outward moves the communication boundary and changes the dominant trade-off. Inside the package, chiplet-based architectures partition a large design into smaller dies joined at relatively low latency, bypassing the manufacturing limits of a monolithic chip, while wafer-scale integration takes the opposite approach and keeps more computation on one device. At the node, a multi-accelerator server joins several chips, each with its own memory, through board- or server-level interconnects such as NVLink. A workload then splits through data parallelism (each accelerator processes different batches) or model parallelism (different accelerators hold different layers, or individual matrix multiplications are sliced across devices). When a model's weights and runtime state exceed one device's HBM, that split becomes a placement requirement rather than a speed choice. How training uses the accelerators of one machine, including how they synchronize gradients, is developed in section 8.7.1. Within a server, the engineering test compares the computation or device-memory capacity that partitioning saves with the communication it exposes, accounting for overlap and the actual directional link bandwidth.

Beyond the node, the network interface card links each machine to the others over Ethernet or InfiniBand. It is the narrowest, highest-latency step of the bandwidth taper measured in section 11.5.4.1, and traffic that must cross it leaves single-node reasoning behind. Work that spans several machines lies beyond this book's one-machine scope.

11.10 Heterogeneous SoC Design

Edge, mobile, and automotive deployments operate under strict physical constraints: sealed enclosures without active fans limit thermal dissipation to a few watts, while battery capacity caps total energy consumption. To deliver machine learning capabilities within these boundaries, heterogeneous system-on-chip (SoC) architectures integrate general-purpose CPU cores, GPU shader arrays, digital signal processors (DSPs), and specialized neural processing units (NPUs) onto a single silicon die sharing a unified memory subsystem. The workload mapping problem introduced for discrete accelerators persists, but it expands to include hardware operator coverage, cross-engine transfer overheads, real-time deadlines, and dynamic thermal throttling. Two of the book's lighthouses take over from ResNet-50 here. MobileNetV2, compute-bound in its efficient regime and built for phone cameras, runs its convolutions on a phone's NPU within a few watts. KWS, the power-bound lighthouse, listens continuously on a DSP or microcontroller within milliwatts. Both run on silicon that shares one memory system among every engine on the chip.

11.10.1 Mobile SoC architecture evolution

Mobile system-on-chip architectures implement heterogeneous computing by coupling distinct execution engines, namely multicore CPUs, wide SIMD GPU shader cores, fixed-point DSPs, and dedicated neural processing units (NPUs) over an on-chip network connected to shared low-power DRAM (LPDDR). Workload partitioning routes sensory and perceptual tasks to the compute engine best aligned with their arithmetic structure: continuous audio feature extraction and keyword

spotting run on low-power DSPs, dense convolution and matrix-multiplication layers execute on systolic or tensor-array NPUs, parallel graphics and image postprocessing map to GPUs, and sequential control flow runs on the CPU. Meeting real-time frame deadlines without triggering aggressive thermal throttling requires scheduling execution across these engines while respecting their differing power profiles.

Example 11.5: Heterogeneous microcontrollers

Scenario: An embedded smart doorbell must run periodic person detection within a tight memory, energy, and latency budget.

Diagnosis: On a supported deployment, a general-purpose Cortex-M path misses the measured energy or latency target. A micro-NPU such as Arm Ethos-U can offload compatible convolution operators, while the CPU retains control flow and unsupported operations.

Systems lesson: Micro-NPU specialization can improve the energy and latency of supported operators, but feasibility must be measured for the whole pipeline, including fallbacks and sensor processing.

Modern mobile SoCs use unified memory architectures where all processing units share a common physical address space in LPDDR. Unlike discrete accelerator architectures that incur explicit PCIe transfer latencies, unified memory allows zero-copy buffer passing between the image signal processor (ISP), CPU, GPU, and NPU. Sharing physical DRAM does not guarantee zero software overhead, however. Non-coherent engines need explicit cache maintenance (section 11.10.4), and specialized NPUs often require hardware-specific tensor layouts (such as channels-last (NHWC) with 16- or 32-byte channel alignment to feed vector register lanes), forcing memory-bound transpositions when interfacing with CPU layers structured in channels-first (NCHW) formats.

SoC architects customize these compute blocks according to domain-specific physical constraints. High-end smartphone SoCs emphasize peak burst performance and low idle leakage for interactive tasks such as real-time computational photography and on-device text generation. In contrast, embedded and automotive SoCs prioritize deterministic memory access, hardware fault detection, and bounded worst-case latency to satisfy real-time control constraints.

11.10.2 Strategies for dynamic workload distribution

Partitioning neural network workloads across heterogeneous SoC cores requires matching the arithmetic intensity and memory regularity of each computational graph operator to the microarchitecture best equipped to execute it. Consider a real-time object detection pipeline executing on a mobile SoC with an integrated CPU, GPU, and NPU. The pipeline comprises three consecutive stages: a MobileNetV2 backbone for feature extraction, nonmaximum suppression (NMS) for postprocessing candidate bounding boxes, and a display overlay to render final detections onto a camera feed. The convolutional backbone has regular, deterministic memory access and dense arithmetic suited to the NPU's fixed-function tensor engine, even though depthwise separable layers have lower arithmetic intensity than standard convolutions. NMS, by contrast, relies on score-based sorting and conditional intersection-over-union loops evaluated across variable-length candidate lists. This irregular, branch-heavy control flow maps poorly to an NPU's spatial array but executes efficiently on out-of-order CPU cores with branch prediction and hardware caching. Finally, the display overlay requires per-pixel rasterization and alpha blending across a high-resolution frame (an embarrassingly parallel, memory-bandwidth-bound task that maps directly to the GPU's rasterizers and texture units). Splitting the pipeline across the three engines, with the NPU for feature extraction, the CPU for NMS, and the GPU for display compositing, is a candidate mapping. Its compute savings must exceed transfer, layout, and synchronization costs before it improves end-to-end latency or energy over a single-engine implementation.

This pipeline partitioning reflects the broader relationship between algorithmic structures and machine architectures. Regular matrix contractions and convolutions map cleanly to systolic or vectorized NPU datapaths, whereas data-dependent control flow maps to CPU execution resources. Transformer attention layers span both paradigms: the projection GEMMs ($\mathbf{Q}, \mathbf{K}, \mathbf{V}, \mathbf{O}$) and attention score contractions ($\mathbf{Q}\mathbf{K}^T$, and the product of the attention weights with $\mathbf{V}$) execute efficiently on

NPU matrix units, but intermediate softmax reductions, causal masking, and layer normalizations involve elementwise operations. If the NPU runtime cannot fuse these elementwise operations into on-chip SRAM scratchpads, intermediate tensors must spill to LPDDR, eroding the accelerator's throughput advantage.

Optimal processor assignment is dynamic rather than static. As device thermal conditions deteriorate or battery reserves drop, the runtime must adapt its scheduling policy. However, migrating an executing model across processor backends carries non-trivial overhead: weights must be re-bound in memory, intermediate buffers may require layout reformatting, and device drivers incur kernel dispatch latency. If the overhead of synchronizing state across processors exceeds the compute savings of offloading, retaining execution on a single suboptimal engine can yield lower total latency and energy than continuous cross-engine migration.

Shared memory subsystems introduce cross-engine interference during simultaneous execution. Because the CPU, GPU, NPU, camera ISP, and display engine share a single LPDDR memory bus, the SoC memory controller enforces Quality of Service (QoS) priorities to satisfy real-time hardware deadlines. The display engine and camera ISP must receive guaranteed memory bandwidth and bounded latency to prevent display flicker and sensor FIFO overflow; the memory controller consequently prioritizes display and camera transactions over NPU and GPU traffic. During memory-intensive phases (such as autoregressive language model decoding where model weights must be read from DRAM for every generated token) high-priority ISP or display traffic reduces effective NPU memory bandwidth, increasing token generation latency.

Automotive computing platforms expose a stricter form of the same interference. A perception pipeline with a hard deadline may share the SoC and memory system with a cabin assistant or infotainment model. If the convenience workload streams weights from DRAM without a bandwidth limit, it can delay the perception pipeline even when the two use different compute engines. Such deployments require resource isolation and validation under concurrent load; average inference throughput alone cannot establish deadline compliance. The hardware lesson is the interference boundary: assigning work to separate engines does not isolate workloads that still share memory bandwidth.

11.10.3 Power and thermal management

Fanless mobile devices operate within strict continuous power budgets and thermal envelopes, typically dissipating no more than 3 to 5 watts sustained across the entire chassis before touch temperatures exceed safety thresholds. Although transient bursts can draw 10 to 15 watts, continuous inference rapidly saturates the thermal capacitance of the device, heating the silicon junction and requiring active power management across the SoC.

Heterogeneous SoCs manage power across distinct silicon partitions using **dynamic voltage and frequency scaling (DVFS)**, which exploits the cubic dependence of dynamic power on frequency behind the power wall (equation 2.2). Total power in complementary metal-oxide-semiconductor (CMOS) digital circuits is the sum of dynamic switching power and static leakage power:

$$P_{\text{total}} = P_{\text{dynamic}} + P_{\text{leakage}} = \alpha C V^2 f + I_{\text{leak}} V$$

where α is the gate switching activity factor, C is physical load capacitance, V is supply voltage, f is clock frequency, and I_{leak} is temperature-dependent leakage current. Over an operating range where increasing clock frequency f requires supply voltage V to rise approximately proportionally, fixed activity and capacitance give the cubic approximation for dynamic power dissipation:

$$P_{\text{dynamic}} \propto f^3$$

Under that approximation, doubling clock frequency can incur an eightfold penalty in dynamic power (Le Sueur and Heiser 2010), and the same relation run in reverse is what DVFS exploits: dropping the clock lets the core voltage fall, and dynamic power falls faster than throughput. The cubic penalty also explains why ML accelerators favor massive parallel arrays of simple execution units clocked at moderate frequencies over narrow pipelines clocked at extreme frequencies.

On a heterogeneous SoC, CPU clusters, GPU shader cores, and NPU engines occupy separate power and voltage domains. Increasing the voltage and frequency of the NPU to meet a tight latency deadline consumes electrical current and thermal headroom that would otherwise be available to

the CPU or GPU. System power governors continuously adjust these operating points based on workload queues, temperature sensor readings, and frame deadline targets.

When sustained computation exceeds the chassis dissipation rate, the platform initiates thermal throttling. Because specialized NPUs achieve higher energy efficiency (TOPS/W) for tensor math than general-purpose cores, offloading matrix workloads to a CPU or GPU during a thermal event often increases total energy dissipation, exacerbating thermal accumulation. Instead, runtimes manage thermal limits by capping clock frequencies, reducing inference duty cycles (such as throttling a perception model from 30 frames per second to 15 frames per second), or dynamically switching to a smaller, pruned model checkpoint. Task migration is applied selectively to move non-tensor preprocessing away from localized silicon hot spots on the die. Battery state further shapes runtime scheduling: when battery charge drops below critical thresholds or the device enters a low-power mode, the system scheduler trades inferencing fidelity for battery life by selecting prevalidated lower-precision or sparse model variants, or by batching asynchronous inference requests to maximize the time cores spend in deep low-power sleep states.

11.10.4 Software stack challenges

Heterogeneity shifts the primary systems challenge from silicon design to software coordination. Standard programming models like OpenCL and Vulkan provide portable low-level execution abstractions across compute devices, but they do not eliminate the need for microarchitecture-specific kernel tuning. Machine learning inference runtimes partition computation graphs through hardware-specific delegates or backends targeting CPUs, GPUs, DSPs, and NPUs. When a model contains an operator unsupported by an NPU delegate (such as a custom activation, dynamic tensor shape, or non-standard reduction) the runtime splits the graph into subgraphs, inserting fallback paths to the CPU or GPU. Each boundary crossing requires synchronizing execution and translating data representations, transforming an algorithmic graph into a fragmented sequence of hardware dispatches.

Shared memory subsystems require explicit cache and memory management across non-coherent execution domains. While CPUs maintain cache coherence across their own cores via hardware snooping protocols, mobile NPUs and DSPs frequently interface with system memory as non-coherent DMA bus masters. When the CPU writes input tensors to cached DRAM and hands control to an NPU, software must explicitly flush the CPU's dirty cache lines to DRAM before NPU execution begins. Similarly, upon NPU completion, the CPU must invalidate its own cache lines over the destination memory range to prevent reading stale cached data. If unsupported operators cause an inference graph to ping-pong repeatedly between CPU and NPU, the latency of cache maintenance and intermediate DRAM round-trips can exceed the execution time of the operators themselves.

Runtimes navigate this scheduling complexity using ahead-of-time compilation, empirical profile databases, and dynamic dispatch heuristics. Device telemetry (monitoring frame completion times, core temperatures, and battery drain) informs runtime decisions to throttle clock frequencies or swap execution delegates. However, dynamic adaptation cannot replace deterministic graph lowering for latency-sensitive applications; deployment requires validating the compiled, lowered partition on physical target silicon under worst-case thermal and memory contention.

On an SoC, speed comes from keeping work and data on the right engine, not from how many engines the chip has. In the D·A·M taxonomy, an SoC represents a composite Machine layer whose components have different memory hierarchies, arithmetic strengths, and thermal envelopes. The iron law's data term and the energy-movement principle (7) together make data movement the governor of both runtime and energy: when software coordination fails to maintain tensor locality or induces frequent cross-engine fallbacks, energy dissipation is dominated by interconnect and DRAM traffic rather than arithmetic. Maximizing performance on heterogeneous SoCs requires minimizing data movement across domain boundaries while matching each algorithmic operation to the specialized datapath architected to accelerate it. From the microcontroller that runs keyword spotting to the data-center accelerator that serves GPT-2 XL, that matching ends in a choice of machine, which the next section makes explicit.

11.11 Choosing an Accelerator

Every section of this chapter ends in the same question asked at a different level: which machine should run a given workload. The question cannot be answered from a datasheet, because the resource that binds belongs to the workload on a particular machine rather than to the machine alone. The book's five lighthouses make the point on a single reference machine. Their bytes and operations differ by orders of magnitude, and each one exhausts a different resource of an H100 first (table 11.17).

Table 11.17: Lighthouse Memory and Compute: Model bytes and operations for the book's five lighthouses from the model registry, with the resource each exhausts first on one H100. The operation counts are per inference, and per generated token for GPT-2 XL decode; DLRM's bytes are dominated by its embedding tables, whose lookups perform little arithmetic.

Lighthouse	Home regime	Model bytes (FP16)	Model bytes (INT8)	Operations per inference	Binding resource on one H100
ResNet-50	Compute bound	51.2 MB	25.6 MB	8.2 GFLOP	Arithmetic, once batching amortizes the weights
MobileNetV2	Compute bound	7.0 MB	3.5 MB	0.6 GFLOP	Launch overhead and depthwise-layer bandwidth; built for a phone NPU
GPT-2 XL (decode)	Bandwidth bound	3 GB	1.5 GB	3 GFLOP per token	HBM bandwidth: every token rereads every weight
DLRM	Capacity bound	100 GB of tables	Tables dominate either way	Few per lookup	Memory capacity: tables exceed one device's 80 GB
Keyword spotting (KWS)	Power bound	400 KB	200 KB	20 MFLOP	None on an H100; built for a microcontroller's milliwatt budget

The table turns the chapter's diagnosis into a selection rule. ResNet-50 rewards arithmetic throughput on a supported INT8 path, GPT-2 XL decode rewards memory bandwidth, DLRM rewards memory capacity, and MobileNetV2 and KWS reward energy per inference on chips that never see a data center. The rest of the section applies that rule at three levels: the configurations accelerator families adopt for their target deployments, the cost of delivered throughput, and the energy each request consumes.

11.11.1 Processor configurations across deployment targets

SIMD lanes, Tensor Cores, and systolic arrays are building blocks, but their full-chip organization varies significantly across AI processors; the choice of execution units, their numerical precision support, and their connectivity shape how effectively hardware serves a given deployment. Modern AI processors make distinct design trade-offs based on their intended applications, and comparing their configurations reveals how deployment constraints drive architectural divergence. Training-optimized accelerators such as the NVIDIA A100 pack many Streaming Multiprocessors with wide SIMD units and FP16 Tensor Cores because training throughput scales with aggregate multiply-accumulate capacity across general kernels (NVIDIA Corporation 2020a), whereas Google's TPUv4 concentrates each chip into just two cores built around massive BF16 systolic arrays, trading per-thread flexibility for area and energy efficiency on dense matrix multiplications (Jouppi et al. 2023). Inference and edge targets shift the balance again: Intel's Sapphire Rapids dedicates Advanced Matrix Extensions (AMX) tile engines to INT8 and BF16 because server inference models tolerate reduced precision (Intel Corporation 2021a), and mobile neural engines shrink those matrix datapaths into low-power SoC blocks that prioritize energy per operation over peak throughput. Table 11.18 compares these architectural configurations.

Table 11.18: AI Processor Configurations: Modern AI processors prioritize different execution unit characteristics for specific workloads: NVIDIA A100 uses wide SIMD and Tensor Cores for training, Google TPUv4 emphasizes high-throughput BF16 matrix multiplication, Intel Sapphire Rapids focuses on INT8-optimized inference, and mobile NPUs prioritize low-power execution. These variations in SIMD width, Tensor Core size, and processing element count reflect the growing diversity in AI hardware architectures.

Processor	**Vector execution**	**Matrix engine**	Processing Elements	**Primary workloads**
NVIDIA A100	CUDA FP/INT lanes	Tensor Core instruction tiles	108 SMs	Training, HPC
Google TPUv4	Vector unit	128×128 BF16 systolic arrays	2 cores/chip	Training
Intel Sapphire	512-bit AVX-512	AMX tiles (up to 16 rows by 64 bytes each)	Up to 60 cores	Inference
Mobile NPU	CPU/GPU/DSP vectors	Small matrix engines	Integrated NPU blocks	Mobile inference

The pattern across these configurations reveals a consistent engineering principle: each design sacrifices generality to optimize for its target workload's dominant operation and precision. Training chips invest silicon in wide floating-point datapaths; inference chips trade precision for throughput; mobile chips trade throughput for energy efficiency. No single design dominates across all workloads, which is precisely why hardware selection depends on workload analysis rather than headline specifications.

11.11.2 Cost-performance analysis

Architectural specifications define computational potential, but deployment decisions require cost-performance analysis. Raw compute is only one input: delivered performance may be limited by arithmetic throughput, memory bandwidth, interconnect latency, software overhead, or low operational utilization. The energy gap established in section 11.2.3 drives this specialization. Because memory access costs dominate computation, accelerators achieve only a fraction of their peak throughput on memory-bound kernels. Conversely, architectures that maximize data reuse, such as systolic arrays executing dense matrix multiplications, sustain substantially higher utilization by amortizing each memory fetch across multiple arithmetic operations.

Consider an engineering team choosing between deploying a larger cluster of older accelerators or a smaller cluster of newer units. Peak FLOP/s figures mislead whenever dominant kernels are memory-bandwidth or communication bound. In a large model pipeline, dense feed-forward and attention projection layers may remain compute bound, whereas embedding lookups, layer normalization, residual additions, and small-batch autoregressive decoding often have low arithmetic intensity. Their measured bottlenecks can include memory bandwidth, dependent access latency, reductions, and launch overhead; the operator name alone does not identify the limiting resource. The decisive metric is delivered workload throughput per dollar under realistic cluster utilization, memory capacity constraints, available memory bandwidth, and scale-out interconnect efficiency.

These architectural and economic constraints explain the rapid industry adoption of newer accelerators despite substantial increases in nominal unit price. For bandwidth-bound workloads, generational improvements in memory bandwidth and compiler code generation dominate end-to-end execution time. Cloud deployments introduce additional trade-offs: hourly rental rates, dynamic instance utilization, and infrastructure overhead continuously shift the economic break-even point between purchasing on-premises hardware and leasing cloud capacity.

Price-per-peak worksheets for named products age quickly. List prices vary with vendor, region, contract terms, and procurement volume, and each product's headline peak uses a different precision, so the ratio of price to peak is meaningful for one device but not as a comparison across devices. A dated worksheet for several accelerator generations is kept with the other specifications in Appendix E. The durable rule is the one the lighthouse table states: divide cost by the throughput the workload delivers on its binding resource, not by the advertised peak.

No worksheet reduces accelerator selection to a single headline specification. A bandwidth-bound kernel benefits more from the H100's 3,350 GB/s memory subsystem than from an incremental gain in peak arithmetic, whereas a compute-bound GEMM shows the opposite sensitivity. Device memory capacity dictates whether working sets fit on-chip without spilling or partitioning, while

compiler and driver maturity determines whether the application can actually reach the advertised datapath.

11.11.3 Energy per request

At fleet scale, energy per useful inference becomes an important hardware-selection criterion. Operational emissions depend on workload throughput, measured system power, utilization, cooling overhead, and the electricity mix; embodied emissions add another lifecycle cost. Peak performance per watt is therefore a screening metric, not a substitute for end-to-end energy per request. The following scenario shows how useful throughput and a common power boundary determine the fleet needed for the same inference service.

Napkin Math 11.11: An illustrative operational-energy comparison

Problem: An inference service must complete 1 billion requests per day. Which of two hypothetical server platforms uses less operational energy for that service?

Supplied observations: For the same model, input distribution, accuracy, and latency target, a CPU server sustains 100 requests/s, and an NPU-equipped server sustains 1,000 requests/s. Their whole-server wall powers are 100 W and 200 W, respectively, including hosts and attached accelerators. These are hypothetical observations for this exercise, not product benchmarks. Assume requests arrive steadily through the day. Both fleets operate at no more than 80 percent of the supplied throughput to reserve capacity for arrival-rate variation. Assume the listed wall power throughout the 24 h day, including spare capacity. Facility cooling and embodied emissions are outside this operational boundary.

Calculation:

1. **Size the fleets from useful work.** Multiplying useful throughput by the operating fraction and the day length gives 6,912,000 requests per CPU server per day and 69,120,000 per NPU-equipped server. Divide the daily target by each capacity and round up to whole servers. The service requires 145 CPU servers or 15 NPU-equipped servers.
2. **Account for the provisioned fleet.** Server count multiplied by wall power and day length yields 348 kWh per day for CPUs and 72 kWh for NPUs. Dividing each fleet's energy by the same completed-request target gives 1.2528 J per request and 0.2592 J per request. These values include capacity headroom and integer fleet rounding.
3. **Translate the energy difference.** At a common grid factor of 0.429 kg/kWh, the NPU-equipped fleet avoids approximately 43.2 t of operational CO_2 emissions per year at the stated system boundary.

Decision: Choose the NPU-equipped fleet if the objective is to minimize operational energy under these supplied conditions. Each server draws more power, but its greater useful throughput reduces the required fleet enough to lower joules per completed request. This conclusion depends on meeting the same quality and latency targets; a faster peak arithmetic rate alone would not establish the advantage. A procurement decision must additionally compare acquisition costs, software support, and embodied emissions.

Energy per request completes the selection rule that the lighthouse table began. Hardware selection is not determined by peak speed alone: energy per useful result, carbon intensity, embodied impact, and total cost of ownership belong beside latency, throughput, and memory capacity, and each is measured against the resource the workload actually exhausts. The misconceptions that follow are the ways teams skip that measurement and choose the wrong hardware path.

11.12 Fallacies and Pitfalls

Hardware acceleration often defies intuition because headline specifications mask workload-specific bottlenecks. The fallacies and pitfalls here capture selection, scaling, and optimization errors that leave expensive compute resources underused. Sound system evaluation follows one diagnostic habit instead: characterize the workload arithmetic intensity, identify the physical bottleneck metric,

match execution to the appropriate datapath, and account for interconnect, scaling, and portability costs.

Fallacy: *More specialized hardware always provides better performance than general-purpose alternatives.*

Specialized accelerators achieve high efficiency only when workload access patterns match underlying execution datapaths: the core tenet of algorithm-machine co-design. On the roofline (section 11.6), the A100 reference tensor path has a ridge point of 153 FLOP/byte; below that ridge, increasing its 312 TFLOP/s arithmetic peak does not raise the modeled bandwidth ceiling. A transformer attention softmax with I = 2 FLOP/byte–5 FLOP/byte is capped at 4.1 TFLOP/s–10.2 TFLOP/s (3.3 percent of tensor peak) on an A100. On a CPU, whose ridge point sits around 10 FLOP/byte–20 FLOP/byte, the same traffic model places the kernel below the reference ridge, and its bandwidth ceiling represents 10 percent–50 percent of the CPU's compute capacity. These fractions are modeled bandwidth bounds, not measured utilization. When workloads have irregular memory access, tiny batch sizes, or dynamic control flow, massively parallel execution pipelines stall on memory latency and thread divergence. General-purpose CPUs with large cache hierarchies, out-of-order execution, and branch predictors often deliver superior latency and resource efficiency under these conditions. Hardware selection requires matching workload arithmetic intensity and dataflow regularity to architectural ridge points rather than assuming specialization guarantees speed.

Pitfall: *Ignoring memory bandwidth limitations when selecting acceleration strategies.*

Procurement decisions frequently target peak arithmetic throughput while overlooking memory interface constraints. Off-chip data movement imposes severe performance and energy penalties: fetching an operand from DRAM consumes roughly 640 pJ compared to 0.5 pJ for a small, register-adjacent L1 SRAM access, the cheapest tier noted in the caption of figure 11.4. Consider an accelerator providing 300 TFLOP/s of compute alongside 2 TB/s of memory bandwidth, setting a ridge point of 150 FLOP/byte. A normalization kernel such as LayerNorm with an arithmetic intensity of 1.5 FLOP/byte has a bandwidth ceiling of 3 TFLOP/s (1 percent of compute peak). Under the stated HBM streaming assumption, memory bandwidth supplies this upper bound, and adding compute units alone does not raise it.

Fallacy: *Hardware acceleration benefits scale linearly with additional accelerators.*

Distributed training need not deliver $8\times$ throughput on eight accelerators because exposed inter-chip communication can reduce parallel efficiency. Synchronizing gradients across ranks via ring AllReduce makes each rank send and receive about twice the gradient payload (equation 8.12), or 1.75× payloads across eight devices. With an interconnect such as NVLink providing 600 GB/s bidirectional bandwidth (half that per direction), transmitting a 1 GB gradient payload consumes 5.83 ms. For a model with a 50 ms compute step, this data exchange adds 11.7 percent communication overhead before counting software collective latency. Without compute-communication pipelining, an eight-accelerator node reaches only 7.2× speedup (89.6 percent parallel efficiency). Stragglers, barrier synchronizations, and collective protocol overhead widen the gap between linear expectations and physical cluster scaling.

Pitfall: *Planning accelerator capacity from peak FLOP/s specifications.*

Peak FLOP/s measures arithmetic unit capacity under ideal instruction mixes and continuous operand availability, not delivered application throughput. Realized performance depends on kernel arithmetic intensity, matrix dimensions, memory coalescing, and runtime launch overhead. The roofline model (section 11.6) bounds the gap between peak compute and bandwidth-limited execution. On an A100 GPU with a 312 TFLOP/s peak, an illustrative dense-transformer scenario supplies a sustained range of 120 TFLOP/s–180 TFLOP/s (40 percent–60 percent model FLOPs utilization). This supplied range is illustrative, not a measurement or a prediction for every model. Sizing cluster capacity from peak FLOP/s creates severe under-provisioning; capacity planning must rely on measured sustained throughput or roofline-bounded kernel projections.

Fallacy: *One peak FLOP/s rating describes a workload at every precision.*

Accelerators have separate datapaths for different precisions, and the peak throughput varies dramatically across them. An H100 delivers roughly 989 TFLOP/s in FP16 tensor operations but only about 67 TFLOP/s in FP32 CUDA-core operations: a roughly 15× gap within the same chip

(Choquette 2023). Dividing achieved BF16 model FLOP/s by the smaller FP32 peak inflates the reported utilization, while using that FP32 peak to estimate ideal training time overestimates the time. Matching against the wrong roofline misclassifies kernels as compute-bound when they are memory-bound (or vice versa). Useful model FLOP utilization divides the model's useful operations per elapsed second by the matching supported precision and execution-path peak. Hardware busy time is a different metric: an active device can spend time on transfers, redundant work, or fallback execution. Quote the denominator and precision explicitly.

Pitfall: *Deploying small-batch inference workloads on high-compute accelerators.*

Small-batch dense inference can use only a small fraction of arithmetic peak because single-sample execution lacks cross-sample parameter reuse. For a dense linear projection with widths $d_{\text{in}} = d_{\text{out}} = 2048$, a single request ($B = 1$) is modeled as streaming the entire weight tensor from device memory to execute a matrix-vector product, yielding an arithmetic intensity of only 1 FLOP/byte. At batch size $B = 256$, weight reuse amortizes memory transfers across tokens, elevating arithmetic intensity to 204.8 FLOP/byte. At $B = 1$, memory bandwidth bounds performance at 2.04 TFLOP/s on an A100 and 0.32 TFLOP/s on a T4. Although the T4 provides a lower peak of 65 TFLOP/s with a ridge point of 203.1 FLOP/byte, the two batch-1 ceilings differ by 6.4×, which is exactly their memory-bandwidth ratio; the A100's 4.8× advantage in peak compute contributes nothing. The A100 costs 6× as much as the T4, so their modeled batch-1 throughput ceilings per dollar are nearly the same. Actual procurement requires measured latency, throughput, memory fit, and the intended request mix.

Fallacy: *Vendor-specific optimizations have no long-term portability cost.*

Optimizing exclusively for a single vendor runtime captures immediate kernel efficiency but introduces severe architectural lock-in (section 11.8). Codebases saturated with proprietary device intrinsics, vendor-specific assembly, and non-standard memory layouts require months of engineering labor to port when newer, more cost-effective accelerators emerge. This technical debt delays hardware transitions and prevents multi-vendor procurement. To preserve flexibility, systems must isolate vendor-tuned micro-kernels behind hardware abstraction layers or target intermediate compiler representations (such as Triton or MLIR).

Checkpoint 11.5: Feasibility assessment: Can you run it?

Before procuring hardware, validate each physical constraint. These failure modes translate into a concrete feasibility test:

- ☐ **Memory capacity**: use $M_{\text{total}} = M_{\text{weights}} + M_{\text{KV}} + M_{\text{activations}}$ (weights, KV cache, and activation buffers) to list the inputs needed to test $M_{\text{total}} < M_{\text{device}}$ for a 7-billion-parameter Llama model with 14 GB FP16 weights on a 16 GB GPU. What sequence length, concurrency, model dimensions, and runtime workspace information is missing before a complete fit decision?
- ☐ **Bandwidth**: compute the weight-streaming lower bound $T_{\text{token}} = D_{\text{vol}}/\text{BW}$ for a 70-billion-parameter model (140 GB) on 1 TB/s memory bandwidth, then compare the result with a 50 ms latency target. Assume one dense FP16 weight read per generated token; what additional traffic and overhead would a measured latency include?
- ☐ **Compute**: identify the operation count, numerical path, and measured efficiency needed to use $T_{\text{compute}} = O/(R_{\text{peak}} \cdot \eta_{\text{hw}})$. With serialized frame processing, 30 FPS leaves 33.3 ms per frame for the whole pipeline. How does overlapped processing change the distinction between frame latency and sustained throughput?
- ☐ **Roofline placement**: for an accelerator at roughly 2 TFLOP/s peak and 200 GB/s bandwidth, estimate the ridge-point arithmetic intensity, then place a 10 FLOP/byte kernel against it: how do the two ceilings compare, and would increasing only the compute clock raise the overall bound? What measurements would test the actual bottleneck?

11.13 Summary

Hardware acceleration co-designs compute engines, memory hierarchies, numerical formats, and dataflows. For a chosen memory interface, the iron law compares compute time $O/(R_{\text{peak}}\eta_{\text{hw}})$ with movement time D_{vol}/BW; the roofline restates that competition as $\min(R_{\text{peak}}, \text{BW} \times I)$. End-to-end latency also includes launch, synchronization, communication, and fixed overheads. Accelerators improve efficiency only when supported paths capture reuse locally. Hardware selection therefore begins with the workload's measured or modeled bottleneck, not a vendor peak. For ResNet-50, INT8 multiplies large-batch throughput because large batches sit near the arithmetic ceiling, while batch-one latency sits on the overhead floor and moves only when compilation removes launch cost.

The chapter map (table 11.1) can now be read row by row for the INT8 ResNet-50 workload that opened the chapter. Its convolutions lower onto matrix units, its INT8 path doubles the H100's arithmetic ceiling without moving the bandwidth ceiling, its activation tiles stay on chip only when the mapping and the tile sizes allow it, and whether a given layer gains from INT8 depends on whether its activations travel at INT8, a choice the compiler and runtime make. GPT-2 XL decode, the single contrast, gains from none of the arithmetic and from every byte saved.

The bounds developed across the chapter fit in one table (table 11.19). Together they let an engineer estimate, before profiling, whether a kernel on a given accelerator is limited by arithmetic, by memory bandwidth, by on-chip capacity, or by work the accelerator never touches.

Table 11.19: Key Equations: The chapter's bounds in the notation of the sections that derive them. Each ceiling is specific to one precision path and one memory interface; the tile-capacity form assumes FP16 operands and an FP32 accumulator held in one software-managed local store.

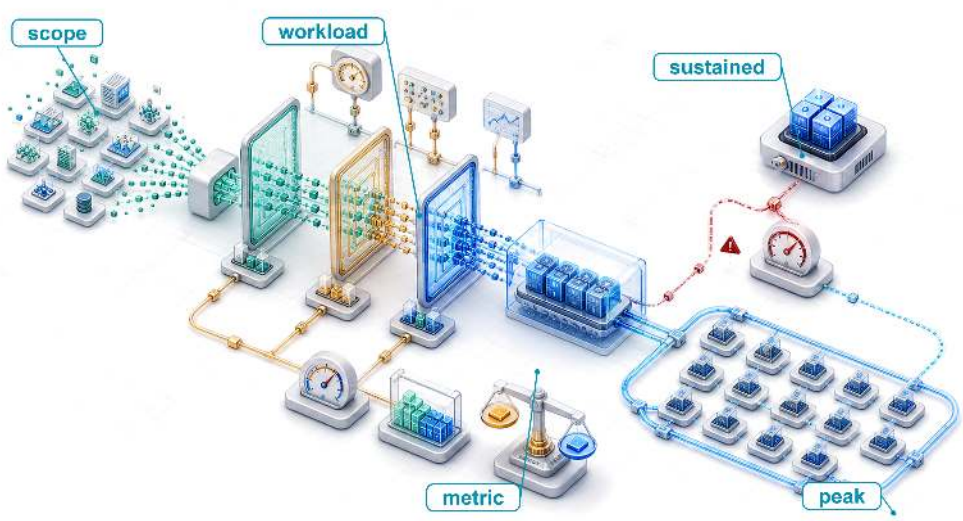
Quantity	Formula	Where derived
Amdahl bound	$\text{Speedup} = \frac{1}{(1-f_{\text{parallel}})+f_{\text{parallel}}/G_{\text{accel}}}$	equation 11.1
Memory and compute time	$T_{\text{memory}} = D_{\text{vol}}/\text{BW}$; $T_{\text{compute}} = O/(R_{\text{peak}} \cdot \eta_{\text{hw}})$	section 11.5.2
Arithmetic intensity	$I = O/D_{\text{vol}}$	definition 5.3
Ridge point (hardware balance)	$I_{\text{ridge}} = R_{\text{peak}}/\text{BW}$, per precision path	section 11.6.2
Roofline bound	$R_{\text{attain}} = \min(R_{\text{peak}}, \text{BW} \times I)$	equation 11.2
Required bandwidth	$\text{BW}_{\text{req}} = R_{\text{ops}}/I$	equation 11.3
Dense-layer intensity	$I \approx B$ when weight traffic dominates	equation 11.5
Decode floor	$T_{\text{token}} = D_{\text{vol}}/\text{BW}$, with D_{vol} the weight bytes read per token	Notebook 11.10
Tile capacity	$(2\text{ bytes})M_{\text{tile}}K_{\text{tile}} + (2\text{ bytes})K_{\text{tile}}N_{\text{tile}} + (4\text{ bytes})M_{\text{tile}}N_{\text{tile}} \leq$ local bytes	equation 11.6
Transfer overlap	Hidden when $T_{\text{compute}} \geq T_{\text{transfer}}$	section 11.5.4.2

Key Takeaways: Moving data costs more than computing it

- **The roofline model bounds attainable performance**: Compare a kernel's arithmetic intensity with the ridge for its memory interface and supported execution path (295.2 FLOP/byte for the H100's dense FP16 tensor path and 590.7 FLOP/byte for its INT8 path). Below it, bandwidth supplies the tighter modeled ceiling; above it, compute does. Profiling establishes whether the kernel approaches that ceiling or is limited by dependencies, dispatch, or another execution resource.
- **Memory bandwidth constrains performance**: GPU compute capacity has grown faster than memory bandwidth. Many inference phases are memory bound, especially low-batch decoding and embedding lookup, while large-batch GEMMs can remain compute bound.
- **Hardware-software co-design compounds performance**: Matching algorithm patterns to architectural capabilities, such as dense GEMM on systolic or tensor units and supported sparsity on sparse paths, can produce large improvements.

- **Tensor Cores require a compatible path**: Precision, dimensions, layouts, and library support must match the architecture. Batch and shape affect reuse and utilization, but no single batch threshold guarantees peak performance.
- **End-to-end speedup stops at the next bottleneck**: Accelerating one kernel leaves launch, transfer, synchronization, communication, and unsupported work unchanged. Use Amdahl's law (principle 8) and profiling to decide whether further silicon, better mapping, or less movement will improve the complete workload.

An accelerator is not a uniformly faster computer. It provides efficient paths for particular operations and dataflows, and each of those paths is a way of moving fewer bytes per useful operation. Tiling, fusion, stationary dataflows, and systolic execution pay off only when the workload, numerical format, and software path can use them. The diagnostic habit the chapter leaves is therefore an ordering. Place the kernel on the relevant roofline to bound its performance, bound the end-to-end gain with Amdahl's law, and only then choose among more silicon, a better mapping, or less movement. Each step is a prediction that measurement must confirm, and the same habit is what keeps the bitter lesson affordable: scale keeps winning only while each additional operation gets cheaper in time and energy, and on modern accelerators the operation is rarely the expensive part; the bytes that feed it are.



What's Next: From optimization to validation

Data selection, model compression, and hardware acceleration each end with a favorable local number. Data selection reaches target accuracy on fewer examples, compression produces a smaller artifact, and the roofline places a kernel below a ceiling that the vendor's peak overstates. Each number is a prediction made for one stage in isolation, and the stages interact once they run together on a real device under real load. Chapter 12 takes up that test, beginning with this chapter's ResNet-50 workload, whose predicted roofline position becomes the first claim a measurement must confirm. It asks which local gains survive deployment-representative conditions, and it supplies the measurement scope, standardized suites, and statistical protocols that let different systems be compared on the same terms.

12.11 Summary

Purpose

How can ML systems be compared fairly when hardware, models, data, and deployment all interact?

Every optimization claim must eventually face deployment-representative conditions, and many do not survive the encounter. Each decision targets one dimension (latency, accuracy, throughput, or energy), but an ML system is the product of all these dimensions simultaneously: a pruned model may run faster on one accelerator yet slower on another, while a larger batch size improves accelerator utilization at the cost of violating a latency service-level agreement. Similarly, an edge device may advertise peak throughput that thermal throttling sharply reduces within minutes of sustained load, and a speedup measured on a warm, idle machine with synthetic inputs can vanish or reverse once real requests, cold caches, and competing jobs share the hardware. The challenge is not whether a local metric improves but whether the combined system improves under conditions that actually matter. Benchmarking makes such comparisons systematic rather than anecdotal. It requires defining what to measure, at what granularity (a single kernel, a full model, an end-to-end pipeline), and under which conditions (batch size, input distribution, thermal state, concurrent load). Without this structure, teams compare numbers that were never measured on the same terms, and decisions that looked sound in a spreadsheet collapse under production workloads. Choosing hardware, a model, or a deployment configuration on such numbers can commit an organization to millions of dollars of infrastructure that delivers a fraction of the capacity it was bought to provide. Benchmarking validates each optimization, bringing claims into contact with evidence and quantifying the gap between promise and delivery. In D·A·M terms, benchmarking holds co-design to account by revealing whether Data, Algorithm, and Machine were matched or merely assembled.

Learning Objectives

- Explain the benchmark–production gap and benchmarking as D·A·M validation that tests whether optimization claims hold under representative conditions
- Design a benchmark that turns an optimization claim into a test by fixing its task, data, model, metrics, harness, and run rules
- Select micro, macro, or end-to-end granularity based on the engineering decision being tested, and compare a roofline prediction with a measurement
- Compare training and inference benchmarks using standardized run rules, time to quality, throughput, and latency percentiles
- Measure energy per inference and average power with matched measurement boundaries, windows, and duty cycles
- Determine whether a measured difference exceeds noise using repeated runs, paired tests, and confidence intervals
- Evaluate model and data quality with confidence calibration, robustness, representativeness, and slice-level metrics, and diagnose benchmark–production gaps caused by drift, thermal throttling, and dynamic load

12.1 The Benchmark–Production Gap

A model quantized to INT8 may benchmark 2× faster on a synthetic workload and show no improvement under real traffic with variable input sizes and concurrent requests; a pruned model may hold its accuracy on the test set and fail on the edge cases the benchmark never covered. Every engineering claim about speed, size, or energy is a number measured somewhere: on a warm accelerator or a cold one, at a batch of 256 or a batch of one, on curated test images or on whatever a camera returns at night. The **benchmark–production gap** is the difference between how a machine learning system performs under the conditions a measurement fixed and how it performs under the conditions it meets in deployment. Benchmarking is the engineering discipline that measures this gap before a deployment pays for it, and that narrows it by making the measured conditions match the deployed ones.

Chapter 11 ended on predictions. Its roofline placed ResNet-50's layers against an accelerator's compute and bandwidth ceilings, and at INT8 the doubled ridge point moved some of those layers off the compute roof. Before it, chapter 10 produced an INT8 artifact a quarter of the FP32 size, and chapter 9 reached target accuracy on fewer examples. Each is a favorable local number, computed for one stage in isolation, and the stages interact once they run together on a real machine under real load. Benchmarking measures which of those numbers survive. It comes before serving and operations because every later decision, from how many accelerators to provision to when to roll a model back, rests on measurements made the way this chapter prescribes.

Definition 12.1: Machine learning benchmarking

Machine learning benchmarking is the empirical measurement of ML workloads under specified conditions, used to test claims about components, models, or end-to-end systems against representative evidence rather than peak specifications alone.

1. **Significance**: The gap between peak and sustained performance can be large. An H100 delivers 989 TFLOP/s of dense FP16 arithmetic at peak, yet ResNet-50 training at the MLPerf per-accelerator throughput of about 5,000 images/s sustains about 123 TFLOP/s of model arithmetic, a model FLOPs utilization (MFU, achieved model FLOP/s divided by the hardware's peak FLOP/s) of about 12.4 percent. Memory-bound layers, the input pipeline, and launch and synchronization overhead account for the difference. Benchmarking quantifies the actual η_{hw} gap for a workload; vendor spec sheets do not.

2. **Distinction**: ML benchmarking spans multiple scopes. Micro-benchmarks isolate operations such as matrix multiplication, model-level benchmarks evaluate complete training or inference workloads, and end-to-end benchmarks include surrounding work such as data loading, preprocessing, optimization, checkpoint I/O, or serving infrastructure. The scope must match the engineering claim.
3. **Common pitfall**: A frequent misconception is that benchmark numbers are stable references. Both the workload (new model architectures) and the hardware (new GPU generations) evolve, so a result that leads a benchmark under one version often becomes the baseline under a later version, making year-over-year comparisons meaningful only when the benchmark version is held constant.

The iron law predicts how long a workload should take, and a benchmark measures how long it does; the difference between the two is the benchmark–production gap made quantitative. For bandwidth-bound workloads, the gap between peak and sustained performance follows from the memory wall. Compute-bound workloads can approach peak, yet ResNet-50's training step shows how much of a nominally compute-bound workload still falls outside the arithmetic. Every later section that quotes a peak number is measured against this gap.

↩ The iron law, whose utilization term η_{hw} benchmarks measure against peak, is established in section 1.7.

Systems Perspective 12.1: The fallacy of peak performance

A long-standing computer architecture quip calls peak performance "the performance the manufacturer guarantees you will not exceed." For ML systems, the gap can be wide because of the memory wall. A bandwidth-bound model leaves much of the advertised FLOP/s unreachable no matter how fast the arithmetic units run. Standardized benchmarks like MLPerf require systems to run specified models and data, revealing sustained performance at a documented operating point rather than a universal rate for every workload.

ML benchmarking operates across three interdependent dimensions that map directly to the components of any deployed system. **System benchmarking** measures whether the hardware delivers promised performance under realistic workloads or whether memory bandwidth saturation and software dispatch overhead erode the gains. **Model benchmarking** measures whether optimization techniques preserve model quality across the full input distribution, not just on curated test sets. **Data benchmarking** measures whether the model generalizes to real-world data with all its noise, bias, and distributional shift. Each dimension can independently reveal problems invisible to the others, and a system that passes all three provides far stronger deployment confidence than one evaluated along any single axis. The three dimensions do not receive equal space. System benchmarking carries most of the chapter, because its measurement problems (how a benchmark is built, at what granularity it measures, which standardized suite it follows, and how it measures training, inference, and power) also shape how models and data are evaluated. Model and data evaluation follow once that machinery is in place, and the summary asks whether all three survive live traffic.

Systems Perspective 12.2: Benchmarks as moving targets

In traditional systems (for example, SPEC CPU), the benchmark is a *rigid specification*. A sorting algorithm is correct if it sorts the list. Correctness is absolute and unchanging. In ML systems, the benchmark is a *soft specification*: correctness is defined by a finite set of examples (ImageNet), and the world moves. A model that scores highly on ImageNet can still underperform on user photos taken years after the benchmark was created.

In computer architecture, engineers design for the benchmark because the benchmark represents the workload. In ML engineering, designing solely for the benchmark is overfitting. Robustness comes from acknowledging that the benchmark is only a proxy for a shifting reality.

Two lighthouse workloads carry the chapter, one per half, each chosen because it sits in a home regime and arrives with claims from the preceding chapters. ResNet-50, the book's compute-bound lighthouse, carries the measurement and training half. It is the MLPerf Training reference workload, with a published quality target (75.9 percent top-1 on ImageNet) and a published per-accelerator throughput, and its INT8 profile is the one chapter 10 modeled and chapter 11 placed on the roofline. MobileNetV2, compute-bound in its efficient regime, carries the deployment half. It runs on one edge board in a labeled composite scenario, a wildlife camera trap whose low-power host CPU and attached INT8 accelerator must classify each frame within its deadline on battery power, and the measurements made on that board recur from the harness through the energy budget. Keyword spotting (KWS), the power-bound lighthouse, carries the power section, where the question is the energy a wake-word detector spends listening rather than how fast it answers. Table 12.1 lists each workload's operations and bytes, the quantities every later benchmark either confirms or refutes.

Table 12.1: Lighthouse Operations and Bytes: Forward-pass operations per input and the bytes each workload occupies as FP32 weights, INT8 weights, and full mixed-precision training state, so that every later measurement can be checked against what the workload must compute and move. Activations and runtime buffers are excluded.

Workload	Parameters	Forward FLOPs	Weights (FP32)	Weights (INT8)	Training state (16 B/param)
ResNet-50	25.6M	8.2 GFLOP	102.4 MB	25.6 MB	409.6 MB
MobileNetV2	3.5M	600 MFLOP	14 MB	3.5 MB	56.1 MB
KWS (DS-CNN)	200K	20 MFLOP	800 KB	200 KB	3.2 MB

The table already separates the halves of the chapter. ResNet-50 does 13.7× MobileNetV2's arithmetic per image, so its training benchmarks are about whether an accelerator sustains its rate; MobileNetV2's INT8 weights fit in a few megabytes, so its deployment benchmarks are about latency, sustained thermal state, and energy on a small board.

↩ MobileNetV2, the lighthouse model for edge latency, is established in section 6.3.5.

Lighthouse 12.1: MobileNetV2 deployment validation

MobileNetV2 serves as the lighthouse example for validating the complete optimization pipeline. MobileNetV2 refines v1's depthwise separable design with inverted residuals and linear bottlenecks while maintaining a similar parameter scale (Sandler et al. 2018). It exemplifies the deployment challenges where benchmarking determines success or failure: compression can reduce model size, hardware acceleration can reduce inference latency, and only benchmarking can determine whether those gains survive the full deployment pipeline.

1. **Model compression** (chapter 10): INT8 quantization reduces this MobileNetV2 worked example from 14 MB to 3.5 MB (4× compression)
2. **Hardware acceleration** (chapter 11): in this illustrative scenario the board's attached INT8 accelerator runs inference in 2 ms against 15 ms on its host CPU
3. **Benchmarking validation**: Verify the pipeline delivers in practice

A systematic evaluation isolates the accelerator's latency from preprocessing and data transfer overhead, confirms INT8 quantization preserves accuracy on edge cases such as unusual lighting, and verifies that throughput holds on the camera trap's own frames rather than on curated ImageNet test images alone.

Each stage of that pipeline arrives with a favorable number from its own chapter, such as a smaller model file or a faster kernel. The benchmarking question is which of those local numbers still hold once the stages run together on the target device, and three principles guide how the chapter answers it.

First, *benchmarks are proxies, not truth.* Every benchmark measures specific conditions that may not match the target deployment. A system can achieve high sample throughput in Offline mode (bulk throughput with all inputs available) and much lower queries per second (QPS) in Server

mode (latency-constrained requests arriving over time). The critical question is always what the benchmark does not measure.

Second, Goodhart's Law governs benchmark rankings.[1] "When a measure becomes a target, it ceases to be a good measure." Teams that optimize for benchmark rankings often produce systems that excel in evaluation but fail in production. Benchmark-specific optimizations frequently degrade characteristics that matter for deployment: robustness, calibration, and efficiency.

Third, end-to-end beats component metrics. A component speedup is diluted by every stage of the request it does not touch, and the dilution follows Amdahl's law; section 12.3 quantifies it on a vision pipeline. These principles reappear throughout the methodology and return as misconceptions in section 12.10.

Two terms recur from here on. A service-level objective (SLO) is the target a deployed service commits to meet for a measured quantity, such as answering 99 percent of requests within a stated time; section 12.6.2.1 defines it formally. The 99th-percentile latency (p99) is the response time that 99 percent of requests meet or beat, so it describes the slowest 1 percent of requests rather than the typical one.

The chapter builds the measurement before it applies it (table 12.2). Benchmark carpentry turns a claim into a test that fixes the task, data, model, metrics, harness, and run rules. Granularity decides how much of the system a test spans, from one kernel to the whole request path, and it is where the roofline's prediction for ResNet-50 meets a measurement. Benchmark suites standardize those choices across organizations. The training and inference sections apply them to ResNet-50 and to MobileNetV2 on its edge board, and power measurement adds the joules, with keyword spotting as the case. Best practices supply the statistics that decide whether a measured difference is real, and model and data evaluation test the two dimensions that a hardware result cannot certify. The fallacies and the summary close by asking whether the evidence survives production traffic.

[1] **Goodhart's law**: Goodhart (1984) articulated the original 1975 Bank of England observation on monetary policy; Strathern (1997) generalized it into the form quoted above. The original context was macroeconomics: once a monetary aggregate became an official policy target, banks changed behavior to game the metric, destroying its predictive value. In ML, the same failure mode recurs structurally: BLEU rewards n-gram overlap (Papineni et al. 2002), ImageNet rewards performance on a fixed visual distribution (Deng et al. 2009; Recht et al. 2019), and benchmark leaderboards can incentivize test-set-specific tuning.

Table 12.2: Chapter Map: Each section turns one optimization claim into a measurement, names the granularity and unit the measurement uses, and names the trap that a careless version of the measurement falls into.

Section	Claim it tests	What is measured	Granularity	Unit	Trap it guards against
Benchmark Carpentry	ResNet-50 at INT8 is faster than at FP32	The claim restated as task, data, model, metric, harness, and run rules	Set by the claim	Stated per metric	A number reported without its conditions
Benchmarking Granularity	A kernel speedup speeds up the request	Kernel, model, and request-path time; predicted against measured roofline	Micro, macro, end to end	s, FLOP/s, B/s	A component speedup diluted by untouched stages
Benchmark Suites	Two vendors' numbers are comparable	A reference workload under shared divisions, scenarios, and run rules	Model and system	Time to quality, QPS	Favorable conditions chosen separately by each vendor
Training Benchmarks	More accelerators train a model proportionally faster	Time to target accuracy, throughput, scaling efficiency, MFU	Model on one to eight accelerators	s, images/s, percent	Throughput that never reaches the quality target
Inference Benchmarks	MobileNetV2 meets its frame deadline on the board	Latency percentiles, throughput, memory, cold start	End to end on one board	ms (p50, p99), FPS, B	A mean that hides the tail; a burst that hides throttling
Power and Energy Measurement	The device lasts on its battery	Energy over a matched window; average power across the duty cycle	Device or system boundary	J per inference, W	Efficiency quoted at an operating point the device never holds
Benchmarking Best Practices	A measured difference is real	Repeated runs, paired tests, confidence intervals	Any	Interval	A one-point gap inside sampling noise
Model and Data Evaluation	The compressed model is still right on deployed data	Confidence calibration, slices, coverage, label quality, shift	Model and dataset	ECE, percent per slice	Aggregate accuracy that hides calibration and subgroup loss

Knowing *what* to measure is only half of the problem. Measuring incorrectly, with the wrong workload, a biased baseline, or an uncontrolled variable, produces numbers that look precise and mislead the decision they inform. The history of computing benchmarks[2] is full of technically sound metrics applied with flawed methodology, from compiler-gamed Whetstone scores to throughput claims that predict nothing about sustained workloads (section 12.4.1). The defense is construction. A benchmark must be built so that it measures what its claim says, and that construction is where the chapter begins.

[2] **Benchmark**: From surveying, where a "bench mark" was a horizontal cut in stone serving as a fixed elevation reference. The term entered computing in the 1970s to describe standardized comparison points, and the surveying metaphor carries a systems lesson. Just as an elevation measurement is meaningless without a calibrated reference, an ML throughput number is meaningless without controlled workloads, thermal state, and precision settings.

12.2 Benchmark Carpentry

A claim that ResNet-50 runs faster at INT8 than at FP32 can reverse depending on whether timing starts at a JPEG on storage or at a preprocessed tensor in accelerator memory, or whether the quantized weights drop accuracy below the target floor. **Benchmark carpentry** is the craft of building a benchmark that measures what its claim says. It fixes the task, data, model, metrics, harness, system specification, and run rules so that the number the benchmark produces answers the engineering question and no other. A synthetic matrix-multiplication loop, a ResNet-50 training run over ImageNet, and a full serving pipeline all need these specifications, and changing one component changes what the next can measure. The components follow the D·A·M taxonomy. The problem definition fixes the input representation (Data), the dataset and task objective bound the feasible models (Algorithm), and the target hardware's memory, energy envelope, and deadlines bound how the model may execute (Machine).

Evaluating an ML system requires coupling statistical task metrics with physical efficiency metrics. Quantization and pruning reduce parameter footprint and memory bus traffic, but they alter numerical representations and risk degrading task accuracy. A benchmark that records execution latency without statistical accuracy (such as area under the ROC curve (AUC) or classification error) rewards aggressive approximations that produce invalid outputs; conversely, reporting accuracy without latency or memory consumption conceals whether the model satisfies the target system's physical constraints.

The measurement harness and run rules provide the experimental controls that make these evaluations reproducible. The protocol follows the question being tested. A controlled steady-state experiment can use warm-up iterations, fixed processor clocks, and pinned host memory to isolate execution differences. A deployment benchmark instead retains the relevant dynamic voltage and frequency scaling (DVFS) policy, cold starts, and competing workloads, documenting their effects. Recording tail latency distributions (p95, p99) alongside the mean exposes delays hidden by averages. Each component is built here on the claim the chapter inherited, that ResNet-50 runs faster at INT8 than at FP32, and MLPerf Tiny's anomaly-detection benchmark at the end shows every component fixed at once on a small embedded model.

12.2.1 Turning a claim into a test

Every benchmark begins as a claim. The claim from the preceding chapters, that ResNet-50 at INT8 runs faster than at FP32 without unacceptable accuracy loss, is not yet testable, because it names neither the inputs, the output, nor the conditions under which faster must hold. Fixing those boundaries is the first act of carpentry. Without an explicit task specification, hardware and software optimizations cannot be evaluated on equivalent terms: altering an input resolution, a numerical datatype, or a latency deadline changes how much work the machine does. For ResNet-50 the input is a decoded 224×224 RGB image and the output is one of a thousand ImageNet class labels. Whether the task is natural language processing (Hirschberg and Manning 2015) or computer vision (Everingham et al. 2009; Lin et al. 2014), a complete problem definition establishes three specifications: an input specification, an output specification, and a performance specification.

The input and output specifications fix the data each run must move and define the exact scope of timed execution. The input specification fixes tensor dimensions, batching behavior, numerical representations (such as FP16 or INT8), and ingestion rates. For the ResNet-50 claim, it decides whether timing starts at a JPEG on storage or at a preprocessed tensor already in accelerator memory, a choice that can change the measured time more than the precision change being tested. Conversely, the output specification defines the termination boundary of the computation. Benchmarks frequently introduce measurement bias by timing only accelerator forward passes while ignoring

the CPU post-processing required to turn raw tensor outputs into usable decisions. A robust output specification defines whether the system emits raw logits, intermediate embeddings, or final class labels, accounting for any downstream thresholding or reduction kernels that consume host memory bandwidth.

The performance specification defines the operational envelope that governs whether an optimization is viable. Unconstrained throughput numbers are meaningless if statistical accuracy degrades below acceptable thresholds, and high average throughput cannot rescue a system that violates a latency service-level agreement (SLA). For the ResNet-50 claim, the performance specification couples a quality floor (MLPerf Training requires 75.9 percent top-1, and an INT8 deployment might permit at most one percentage point of loss against FP32) with hardware execution limits: a tail-latency ceiling, sustained throughput matching the arrival rate of images, and a resident memory footprint that leaves room for activations at the chosen batch size. By defining these three boundaries up front, the benchmark ensures that the later stages, from dataset construction to measurement harness configuration, evaluate system optimizations against the true operational constraints of deployment.

12.2.2 Task and dataset

A task definition is only as rigorous as the data used to evaluate it. Standardized datasets enforce identical evaluation conditions across competing approaches, preventing teams from cherry-picking private slices that obscure comparative weaknesses. In computer vision, ImageNet (Deng et al. 2024, 2009), COCO (Lin et al. 2014), and CIFAR-10 (Krizhevsky 2009) establish reference tasks across classification and detection; in natural language processing, SQuAD[3] (Rajpurkar et al. 2016), GLUE[4] (A. Wang et al. 2018), and WikiText (Merity 2016; Merity et al. 2016) fulfill equivalent roles by standardizing comprehension, classification, and language modeling across diverse textual domains.

Dataset selection is the first place a benchmark can lose contact with deployment reality. ImageNet's validation set fixes ResNet-50's quality target, but its curated, centered photographs are not the frames a camera trap returns at dusk, a gap that section 12.9.2 returns to. A benchmark dataset must be representative enough to expose deployment failures and hard enough to separate models.

12.2.3 Model and metrics

With the task and dataset fixed, the benchmark must specify the model architecture and its baseline implementations. In systems benchmarking, the model defines the execution workload. Its computational graph determines arithmetic intensity, memory footprint, and communication topology. Selecting the benchmark model determines whether measured performance variations reflect architectural efficiency, software runtime optimizations, or raw accelerator capacity. Evaluating an architectural modification requires holding the runtime and hardware target constant. Conversely, evaluating hardware platforms or software execution engines requires standardizing on a fixed, representative model graph so that throughput differences isolate execution efficiency rather than mathematical changes to the workload.

Baseline models establish the empirical reference point for a target domain. Rather than toy algorithms, systems benchmarks rely on canonical workloads whose computational profiles and memory access patterns are well-characterized. In vision, ResNet-50 plays this role, which is why the chapter's claim is stated on it. In language processing, BERT[5] serves as a standard baseline because its multi-head self-attention and dense feed-forward blocks exercise both compute-bound matrix multiplications and memory-bandwidth-bound reduction operations. However, a baseline specification cannot stop at the mathematical graph. Two implementations of the identical architecture across different frameworks or runtimes often behave differently at runtime. Differences in kernel fusion (such as fusing normalization and activation functions directly into general matrix multiply (GEMM) output epilogues to avoid round-trips to high-bandwidth memory (HBM)), kernel launch overhead, and memory allocator behavior can exceed the performance impact of minor architectural variations. A comparison that isolates hardware must control the runtime implementation alongside the mathematical model; a runtime comparison instead names that implementation as the intervention and documents both stacks.

A benchmark must select the operational regime relevant to its engineering question. In training, memory capacity and interconnect bandwidth can be binding constraints, because storing forward activations, backward gradients, and optimizer states across multiple accelerators limits batch

[3] **SQuAD (Stanford question answering dataset)**: Introduced in 2016 with more than 100,000 question-answer pairs from Wikipedia (Rajpurkar et al. 2016). AI systems exceeded the SQuAD 1.1 human baseline of 91.2 percent F1 by 2018 (Devlin et al. 2019), but the "superhuman" result reflects a benchmarking failure mode. The task's extractive format (answers are text spans within the passage) makes it easier than open-ended question answering, inflating perceived capability relative to production NLP systems.

[4] **GLUE (general language understanding evaluation)**: Introduced in 2018 as a broad language-understanding benchmark (A. Wang et al. 2018), GLUE was quickly saturated by systems such as BERT (Devlin et al. 2019). Once GLUE became a target, leaderboard optimization reduced its discriminating power, as Goodhart's Law predicts. The pattern motivated harder follow-on evaluations such as SuperGLUE and BIG-bench.

[5] **BERT (bidirectional encoder representations from transformers)**: BERT-Large (340M parameters) is a language-processing workload in MLPerf Inference. The benchmark fixes the task, data, quality target, and applicable execution scenarios so systems can be compared on the same workload. BERT latency still depends on sequence length, batching, and implementation.

size and demands high-bandwidth collective communication. Training benchmarks therefore measure time-to-accuracy under fixed convergence criteria rather than raw iteration speed alone. In inference, backward passes and optimizer states disappear. Evaluation instead emphasizes the serving objective, such as tail latency under SLAs, while low-batch autoregressive decode often faces bandwidth pressure. Transitioning a model to production frequently requires precision reduction, quantizing FP32 or BF16 weights and activations to INT8 or FP8. Moving eligible tensors from a 16-bit to an 8-bit format halves their raw storage and can reduce traffic or raise supported arithmetic throughput. Whole-model gains depend on the execution path, and validation must establish whether numerical error stays within the quality target. A development-to-deployment comparison may need both regimes because efficient training does not establish serving feasibility; a deployment decision for a fixed pretrained model can focus on inference.

Evaluation metrics[6] translate raw model behavior into numbers that can be compared, ranked, and used to make engineering decisions. The difficulty lies in choosing the right numbers. A metric that captures accuracy but ignores latency may declare the winner to be a model too slow for production; one that rewards throughput but ignores energy may optimize for a deployment budget that does not exist. Table 12.3 categorizes evaluation measures by the failure mode each exposes and the deployment context it serves.

[6] **Metric**: In mathematics, a metric is a distance function satisfying strict axioms including the triangle inequality. ML borrows the term loosely for quantitative measures such as BLEU and perplexity, which are scoring rules rather than mathematical metrics. Leaderboard rankings can change when the evaluation protocol, dataset slice, or metric weighting changes, making the choice of metric an engineering decision that shapes which system wins, not just how performance is measured.

Table 12.3: ML Benchmarking Metric Taxonomy: Metrics organized by evaluation category, unit, and primary use case. Accuracy metrics quantify model quality, throughput and latency metrics capture system speed, and efficiency metrics combine multiple dimensions. Selecting the right metric for the deployment context is often more important than optimizing any single metric to its maximum.

Category	Metric	Unit	Primary Use Case
Accuracy	Top-1/Top-5 Accuracy	Percentage	Classification
	mAP (mean Average Precision)	0–1 score	Object detection
	BLEU/ROUGE	0–100 score	NLP generation
	Perplexity	Score (lower = better)	Language modeling
Throughput	Samples/second	Samples/s	Batch inference
	Token throughput	tokens/s	LLM inference
	Time-to-train	Hours/days	Training benchmarks
Latency	p50 latency	Milliseconds	Median response time
	p99 latency	Milliseconds	Tail latency (SLA)
	First-token latency	Milliseconds	LLM responsiveness
Efficiency	Samples/second/watt	Samples/s/W	Energy efficiency
	Accuracy/FLOP	percent/PFLOP	Algorithmic efficiency
	TCO per inference	$/inference	Economic efficiency

The metrics in table 12.3 expose physical trade-offs governed by the accelerator architecture. Throughput measures aggregate processing capacity, whereas latency measures individual request completion time. These two objectives conflict directly at the hardware boundary. Maximizing throughput requires aggregating requests into larger batches to amortize weight-loading memory bandwidth across multiple inputs, raising arithmetic intensity on tensor units. That batching mechanism inflates per-sample latency, because individual requests wait in arrival queues while a batch forms, and larger matrix operations take longer to complete. Furthermore, arithmetic mean latency masks tail behavior. Queuing jitter, memory allocation stalls, and accelerator thermal throttling cause execution times to diverge; a system with a 10 ms mean latency can still suffer a 500 ms p99 latency that violates service-level agreements. Benchmarks must therefore report distribution percentiles (p50, p95, p99) rather than averages. Compound metrics such as samples/second/watt compress multiple dimensions into a single scalar, simplifying high-level comparisons but obscuring where bottlenecks reside. Reporting atomic metrics (latency distributions, throughput, and power draw) alongside compound figures isolates which physical constraint limits the system.

↪ The batch size at which waiting for a batch to form pushes latency past its budget is measured with a batch-size sweep in section 13.5.2.

Task-specific metrics evaluate the algorithmic dimension, quantifying whether the model solves the statistical problem. Classification workloads evaluate accuracy (the fraction of correct predictions), precision, recall, and the F1 score (Sokolova and Lapalme 2009). Precision and recall isolate true positive rates from false alarms, which is essential when class distributions are imbalanced.

Continuous estimation tasks rely on Mean Squared Error (MSE) or Mean Absolute Error (MAE), while sequence generation uses specialized scoring rules such as BLEU[7] to measure modified n-gram precision against human reference translations (Papineni et al. 2002).

Task metrics evaluate algorithmic quality in isolation, but deployment viability depends on physical machine constraints. Model capacity, measured in parameter count and memory footprint, determines whether weights fit into on-chip SRAM or accelerator memory, or whether they spill across high-latency interconnects. Per-inference execution latency dictates whether a system meets real-time deadlines, while energy consumption per inference (measured in joules or millijoules) bounds thermal dissipation and battery life.

Benchmarks must also account for measurement sensitivity across software runtimes. As established in chapter 8, different frameworks handle loss computation, kernel fusion, and gradient accumulation differently, altering reported benchmark numbers. Subtle implementation differences, such as whether batch normalization is configured to use stored running statistics or current mini-batch statistics during evaluation, or how non-associative floating-point additions are reordered in reduction kernels, shift measured accuracy and latency enough to invert benchmark rankings when candidate models differ by narrow margins.

7 | **BLEU (bilingual evaluation understudy)**: Introduced by IBM in 2002, BLEU measures translation quality through modified n-gram precision with a brevity penalty against reference translations (Papineni et al. 2002). BLEU is a canonical example of Goodhart's Law in ML, because optimizing for n-gram matches can reward surface-level word overlap even when meaning, fluency, or deployment usefulness diverges from the target.

12.2.4 Benchmark harness

Metrics define *what* to measure; the benchmark harness determines *how* to measure it. The harness is the software and instrumentation scaffold that feeds inputs to the system under test, coordinates execution, collects timing and power traces, and enforces reproducibility. In an ML system, measuring execution down to the metal requires accounting for the asynchronous execution boundary between the host CPU and the accelerator. When host software initiates an inference or training step, the framework runtime merely enqueues commands onto an accelerator work queue (such as a CUDA stream or hardware command buffer) and returns control immediately. A naive timer wrapping the host-level call measures only this sub-microsecond queue dispatch latency rather than actual device execution. A rigorous harness inserts explicit device synchronization barriers (such as `torch.cuda.synchronize()`) or queries on-device timestamp events (such as `torch.cuda.Event`), ensuring that recorded timings reflect complete kernel execution and memory transfers across the bus rather than mere host enqueue overhead.

Harness architecture must align with the operational regime of the deployment target. In server environments, the harness generates concurrent request traffic using an open-loop load generator, often parameterizing inter-arrival times with a Poisson distribution.[8] An open-loop harness issues requests according to an independent arrival schedule regardless of server responsiveness. This decoupling exposes queuing delays and tail latency (such as p99 response times) when arrival bursts saturate available compute.

In contrast, a naive benchmarking client often employs a closed-loop pattern: sending a request, blocking until the response arrives, and only then issuing the next request. This design introduces the severe measurement distortion known as **coordinated omission**. Consider a server that experiences a transient 500 ms garbage collection pause or memory reallocation stall. In an open-loop production environment, independent users continue submitting queries, causing dozens of requests to accumulate in the server's ingress queue; once the pause ends, every queued query suffers inflated tail latency. In a closed-loop benchmark, however, the client blocks idly during the entire 500 ms pause, sending zero traffic while the server is struggling. The benchmark records a single slow query and zero queue backlog. By coordinating request generation with server responsiveness, the closed-loop harness artificially paces traffic, systematically erasing the very queue collapse and p99 latency spikes it was constructed to measure. Conversely, offline batch processing eliminates arrival scheduling entirely; the harness pre-stages large input batches in memory to saturate accelerator execution units, maximize memory bandwidth utilization, and measure peak sustained throughput.

In embedded and edge deployments, workloads are neither stochastic network streams nor unconstrained batch queues. Instead, inputs arrive sequentially from physical sensors (such as an audio analog-to-digital converter or an image sensor) governed by fixed hardware sampling clocks. The harness must inject these sensor streams through direct memory access into limited on-chip SRAM buffers, verifying that each inference completes within the inter-sample arrival deadline to prevent buffer overflow. Furthermore, edge harnesses must integrate physical instrumentation, such

8 | **Poisson distribution**: Named after Siméon Denis Poisson, who formalized it in 1837 while modeling wrongful conviction rates in French courts. The distribution models independent events at a constant average rate (λ_{arr}) and is a common baseline for server request arrivals. Real ML serving traffic often violates its assumptions through burstiness, correlation, and time-varying rates. A Poisson harness can therefore misestimate tail latency unless traces or stress cases cover those production patterns.

as shunt resistors or external power analyzers, to sample voltage and current across active execution cycles and low-power sleep states, capturing the true energy consumed per inference.

Reproducibility requires specifying which runtime and environmental conditions are controlled and which are part of the workload. Warm-up matters at every scale, from a single kernel to a whole run, because modern accelerators and runtime frameworks have substantial cold-start transients. Initial inference passes trigger on-demand memory allocations, dynamic just-in-time (JIT) compilation, driver initialization, and weight transfers from secondary storage into accelerator memory. For steady-state measurements, the harness executes unmeasured warm-up iterations until caches populate, memory allocators stabilize, and the intended thermal operating state is reached. Controlled experiments may fix clocks and remove competing processes; deployment tests retain and report the relevant DVFS policy and contention. Cold-start measurements time initialization separately instead of discarding it. Finally, telemetry logging must minimize the probe effect by recording execution timestamps and performance counters into non-blocking, pre-allocated memory buffers. The remaining instrumentation overhead should be checked against a minimally instrumented run.

12.2.5 Specifications and run rules

Complementing the harness that controls execution conditions, system specifications record the computational environment, the physical hardware and software stack that establishes the Machine (M) boundaries of the system, and run rules govern how the benchmark runs on it. Without both, a reported throughput or latency measurement cannot be interpreted. An execution metric reflects the interaction between an algorithm's arithmetic intensity and a machine's physical limits: peak arithmetic throughput, memory hierarchy bandwidth, and interconnect latency. A throughput figure reported without accelerator model, memory bandwidth, or operating clocks conceals whether an observed speedup stems from algorithmic efficiency or upgraded silicon, and a result reported without its seed policy conceals whether it is reproducible at all, because the stochastic processes catalogued in section 12.4.2 mean that two runs on identical hardware can produce different numbers. A protocol may fix seeds and data order when isolating system effects, or require repeated runs and quality thresholds when stochastic variation is part of the workload. Table 12.4 lists what a reproducible report records.

Table 12.4: Benchmark Specification and Run Rules: What a reproducible benchmark report records about the machine, the software, and the run, and why each item changes the measured result.

Item	What the report records	Why the result depends on it
Accelerator	Microarchitecture, active core count, base and boost clocks, power limit (TDP)	Sets the peak arithmetic rate and how long boost clocks persist
Device memory	Capacity, bus width, peak bandwidth	Sets the bandwidth ceiling and the largest batch that fits
Multi-accelerator topology	Host interface (PCIe lanes) and accelerator links (NVLink or shared PCIe switches)	All-reduce time is bounded by link bandwidth and topology
Software stack	Operating system, driver, compute runtime (CUDA or ROCm), math libraries (cuBLAS, CUTLASS)	Kernel selection, tiling, and reduction order change with library version
Framework layer	Framework version, eager or compiled execution (`torch.compile`), fusion settings	Separates framework overhead from model cost
Power and thermal	Sustained board power, throttling events, energy per sample or token	A speedup from transient clock boosting does not persist
Randomness	Seed policy, data order, known nondeterministic kernels	Two runs on identical hardware can produce different numbers
Configuration	Every hyperparameter, including the learning-rate schedule	A learning-rate change shifts convergence and final accuracy
Data	Dataset version, splits, preprocessing; any privacy or licensing limit on sharing	Different splits or preprocessing define a different workload
Code	Version of model, preprocessing, training, and evaluation code; container image	Lets another team inspect and, where access permits, reproduce the run

Reference suites may distribute containerized environments that encapsulate dependencies and configurations, while experimental logs retain training metrics, checkpoints, and any mid-run adjustments. Together, these records turn a one-time measurement into evidence another team can inspect and, when access permits, reproduce.

12.2.6 Interpreting results

Producing raw benchmark numbers requires only execution; interpreting them requires understanding the conditions that produced them, the statistical confidence behind them, and the operational boundaries that determine whether the numbers translate to production behavior. A single reported metric, such as latency or accuracy, rarely reveals whether an optimization succeeds in deployment.

Translating benchmark numbers into engineering decisions requires two methodological checks: a defined intervention and statistical rigor. First, state what changes and what remains comparable. ResNet-50 versus MobileNet can be a valid architecture comparison at matched task and quality requirements; FP32 versus INT8 can be a valid precision comparison on a supported execution path. Hold the other relevant conditions fixed or report their changes, including batch size, hardware, runtime, input distribution, and service targets. Second, distinguish steady-state execution from initialization, using the harness's warm-up protocol (section 12.2.4). A single run conflates cold-start overhead (kernel compilation, page faults, and cache warming) with sustained throughput, while a prolonged stress test may instead capture the thermal throttling examined for edge devices in section 12.6.4. Report cold-start and steady-state results according to the deployment question, and record variation across repeated trials. Whether a measured difference exceeds that variation is a statistical question, answered with the interval and paired-test rules of section 12.8.1.

> Systems Perspective 12.3: Interpreting a benchmark claim
>
> A vendor claims "Our system achieves 10,000 inferences/second on ResNet-50." Taken alone, the number cannot support deployment planning because the conditions that determine its meaning are unstated.
>
> Four unstated conditions determine what the claim means:
>
> 1. **Batch size**: Large batches amortize weight transfers and maximize compute utilization but inflate queuing delay; batch 1 minimizes latency but leaves execution units underutilized.
> 2. **Precision**: INT8 execution exploits higher-throughput integer pipelines and cuts memory traffic, but requires quantization-range calibration that can compromise numerical fidelity.
> 3. **Measurement boundary**: The measurement window must state whether it isolates pure accelerator kernel execution or includes host-to-device transfers, JPEG decoding, and tensor format conversions.
> 4. **Accuracy**: The claim must state whether the optimized model retains baseline validation accuracy (such as 76.1 percent Top-1 on ImageNet) or trades task quality for raw execution speed.
>
> **Example**: "10,000 inferences/second on ResNet-50 at batch size 32, INT8 precision, 76 percent Top-1 accuracy, including JPEG decoding, on NVIDIA H100 at 700 W thermal design power (TDP)."
>
> **Systems insight**: A throughput figure lacking batch size, precision, measurement scope, and accuracy targets is a marketing metric rather than an engineering specification.

A claim whose workload boundary, precision, and excluded costs cannot be reconstructed should be rejected. Marketing phrases compress such omissions into a few words, usually reporting the most favorable operating point without saying so; table 12.5 translates common ones into the technical caveats behind each.

Table 12.5: Decoding Vendor Benchmark Claims: Four common marketing phrases and the technical caveats that determine whether a claim describes end-to-end performance, a narrow accelerator measurement, or an unsupported efficiency comparison.

Vendor Claim	What It Often Means
"Up to 10,000 images/sec"	Peak throughput at maximum batch size, INT8, without preprocessing
"Sub-millisecond latency"	Accelerator compute only, excluding data transfer
"5× more efficient"	Per-operation efficiency, not total system efficiency
"Optimized for AI"	May only accelerate specific operations or precisions

Which metric governs viability depends on the deployment. In safety-critical applications such as medical imaging or autonomous driving, a 1 percent accuracy gain justifies substantial computational cost; in interactive search or speech transcription, tail latency within a tight service-level agreement dominates, so a minor accuracy gain is irrelevant if it breaches the latency budget. Systems evaluation must also guard against *benchmark overfitting*, in which an optimization targets the idiosyncratic computational patterns of a standardized suite at the expense of production workloads. For example, aggressive kernel fusion or operator tiling tuned exclusively for fixed sequence lengths in a benchmark harness can degrade throughput when deployed against dynamic, variable-length user requests. Robust interpretation requires validating performance across diverse input distributions, perturbed batch sizes, and representative operational duty cycles.

Checkpoint 12.1: Decoding vendor benchmark claims

When evaluating hardware or software based on vendor-reported benchmarks, check whether the claim identifies the workload, measurement boundary, and operating conditions.

- ☐ Measured quantity: Does the latency number include preprocessing and postprocessing, not just model execution?
- ☐ Precision boundary: Can the precision behind a throughput claim, such as INT4 versus INT8 or FP16, be identified?
- ☐ Workload boundary: Are the model, batch size, and input distribution used to produce the comparison explicitly named?
- ☐ Excluded costs: Are memory transfers, model loading, initialization, sustained thermal behavior, and power accounted for at the claimed performance level?
- ☐ Claimed vs. achieved: Given a 1,000 TFLOP/s peak claim and a benchmark that sustains 350 TFLOP/s, estimate the MFU and state whether that utilization ratio alone identifies the bottleneck.

12.2.7 A complete reference benchmark

MLPerf Tiny's anomaly-detection benchmark shows every component fixed at once on one small embedded model. The multi-stage pipeline in figure 12.1 traces this industrial audio benchmark across nine sequential phases, carrying the task from problem definition in the top chevrons through spectrogram extraction, autoencoder training, and INT8 quantization down to embedded deployment on an ARM mbed OS microcontroller. Each stage fixes boundary conditions for the next: the problem definition dictates the acoustic sampling rate and input representation (Data); the dataset properties and task objective determine feasible model architectures (Algorithm); and the microcontroller's hardware limits (SRAM capacity, energy envelope, and real-time latency deadlines) dictate INT8 quantization and memory-efficient kernel compilation (Machine). Here every choice constrains the next, so a benchmark that measures only classification accuracy or only raw inference latency misses cross-stage interactions, where an engineering decision at any stage narrows the feasible design space downstream.

Its problem definition fixes the same three specifications that the ResNet-50 claim needed. The input is single-channel audio streamed at 16 kHz in fixed one-second windows, which sets a rigid ingestion rate and memory buffer requirement before feature extraction begins. The output is a

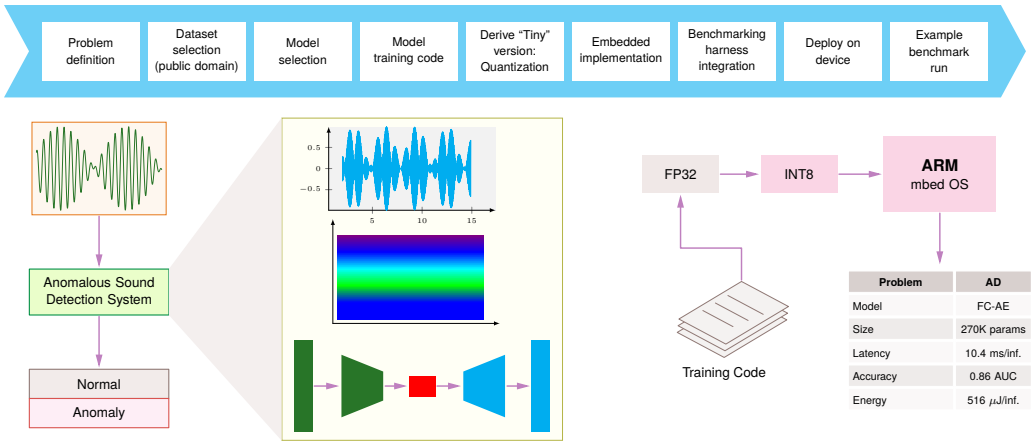

Figure 12.1: Benchmark Workflow Components: Read left to right: each stage fixes assumptions for the next, carrying an audio anomaly-detection task from problem definition to a reproducible embedded-device benchmark run. Values from C. Banbury, Reddi, Torelli, Holleman, Jeffries, Kiraly, et al. (2021).

binary "Normal" or "Anomaly" flag, including any thresholding that turns a reconstruction error into that decision. The performance specification couples a quality metric, area under the ROC curve (AUC), with execution limits: a per-inference latency that keeps pace with the one-second input windows, sustained throughput matching the arrival rate, and a resident footprint that avoids out-of-memory faults on the microcontroller.

At the dataset selection stage (the second chevron), the benchmark pipeline ingests representative audio waveform samples of normal machine operation alongside anomalous conditions before spectrogram feature extraction. Domain-specific collections cover different audio tasks: ToyADMOS[9] (Koizumi et al. 2019) supports controlled anomaly-detection research, while Google Speech Commands (Warden 2018) supports keyword recognition. Simplified datasets like ToyADMOS are valuable for methodological development but may not capture the full complexity of production environments.

This interdependence between statistical quality and hardware constraints is evident in anomaly detection. In industrial monitoring, extreme class imbalance renders raw accuracy deceptive. If anomalies constitute only 0.1 percent of operating samples, a trivial model that constantly predicts normal operation achieves 99.9 percent accuracy while failing to detect any faults. The benchmark must instead report AUC, which scores how well the model ranks anomalous samples above normal ones across every decision threshold, alongside physical resource metrics.

This multi-metric evaluation approach governs the anomaly detection pipeline, which balances four simultaneous constraints: a model size of 270K parameters whose stored representation and runtime buffers must fit the embedded SRAM budget, a processing latency of 10.4 ms per inference to maintain real-time sampling, a detection accuracy of 0.86 AUC, and an energy consumption of 516 µJ per inference within the target battery budget. Evaluating across all four axes prevents declaring a model superior when its accuracy gain stems from an architecture too large to fit in memory or too power-hungry to survive sustained deployment.

The deployed anomaly detection workflow in figure 12.1 records the four measurements from section 12.2.3 in its terminal reporting table (lower right). For the fully connected autoencoder (FC-AE) on the ARM mbed OS target, each certifies something different. Parameter count and per-inference latency certify computational resources, the AUC certifies task effectiveness, and energy per inference certifies operational efficiency.

On a microcontroller, each metric governs a different failure: energy per inference sets battery life on untethered devices, model size decides whether weights fit in fast on-chip SRAM or spill into off-chip DRAM, and latency determines whether streaming audio is processed without dropped frames. The metrics trade against one another: reducing model size below 270K parameters can reduce memory traffic and execution time on a supported path, but risks degrading the 0.86 AUC detection accuracy. Whether these measurements constitute a passing benchmark depends on

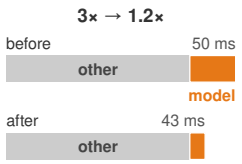
[9] **ToyADMOS**: Developed by NTT Communications in 2019 for acoustic anomaly detection, containing audio recordings from toy car, toy conveyor, and related miniature-machine operating sounds (Koizumi et al. 2019). The "toy" prefix is intentional: the controlled environment enables reproducible benchmarking but can create a domain gap when models are moved to noisier industrial environments with different machines, sensors, vibration, and background sound.

the operational envelope; the benchmark specification standardizes the evaluation protocol, but application requirements dictate the acceptance thresholds.

The reference flow fixes the task, data, model, and measurement boundary, but it measures one model on one device at one scope. Before choosing that scope, a benchmark should pass three methodological checks.

Checkpoint 12.2: Benchmarking methodology

Three practices distinguish rigorous benchmarks from misleading ones:



- ☐ Representative data: Compare the benchmark input distribution against the production distribution.
- ☐ Warm-up: State whether the goal is steady-state or cold-start performance, and which initialization work is timed or discarded.
- ☐ Isolation: Document the machine, runtime, and competing workloads; explain which controls isolate the intervention and which conditions represent deployment.

A benchmark that passes those checks has still made a second choice, often implicitly. It decides how much of the system it measures. A single kernel, the whole model, and the request path around the model each answer a different question, and each fails in a different way.

12.3 Benchmarking Granularity

A kernel that runs 3× faster in isolation may deliver no end-to-end speedup if the data pipeline cannot keep the accelerator fed. In an illustrative request, a 3× inference speedup applied to a 10 ms model stage inside a 50 ms request yields only about a 1.2× end-to-end improvement, or less if the optimization increases memory pressure. The dilution makes the measurement boundary a design choice. Carpentry specifies *how* a measurement is built, while **benchmarking granularity** specifies *what* physical boundary it measures. System validation spans multiple architectural scales, from individual tensor operations to complete production pipelines, with each granularity diagnosing distinct bottlenecks:

- Micro benchmarks isolate individual components: kernel execution time, memory bandwidth utilization, and single-layer numerical behavior. These diagnose *where* low-level hardware inefficiencies occur.
- Macro benchmarks evaluate composed model subsystems: full model training convergence, inference pipeline throughput, and dataset accuracy metrics. These reveal *what* architectural trade-offs exist across layer compositions.
- End-to-end benchmarks measure complete operational pipelines: client request-to-response latency including preprocessing, training time-to-accuracy including storage I/O, and model robustness on production data distributions. These show whether the combined system satisfies real-world service-level objectives.

Component speedup rarely survives as end-to-end benchmark speedup.

Optimization techniques operate across distinct granularities: kernel fusion targets micro-level execution, structured pruning alters macro-level parameter structures, and data curation determines end-to-end generalization. System validation must align with these respective boundaries. An isolated micro-benchmark may show substantial kernel speedup, yet a macro-benchmark can reveal that increased activation memory footprints force smaller batch sizes that degrade overall throughput. Similarly, an end-to-end benchmark exposes storage or host deserialization stalls that remain completely invisible at the accelerator kernel level.

Measurement perimeters widen from left to right in figure 12.2, and the figure inserts one tier between macro and end-to-end. Micro-benchmarks isolate kernel layers (ML Layers) and macro-benchmarks evaluate composed models (ML Model). An application benchmark then adds the supporting host compute around the model (AI Task), and the end-to-end benchmark adds the non-AI compute nodes the request also traverses. The three granularities in this section fold the application tier into end-to-end, but the four-tier view shows where bottlenecks migrate as the boundary widens: out of the accelerator and into the host systems around it.

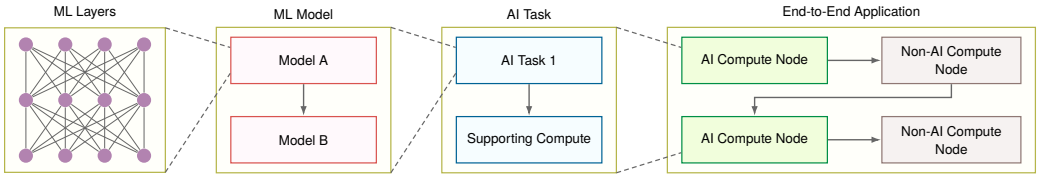


Figure 12.2: Benchmarking Granularity: Four-panel block diagram showing micro, macro, application, and end-to-end evaluation layers. Each panel maps a distinct scope of assessment, from isolated kernel operations through full-system deployment, enabling targeted optimization at every level of the ML stack.

12.3.1 Micro benchmarks

While end-to-end metrics govern service-level agreements, optimizing an accelerator pipeline requires isolating the specific mathematical operations that consume execution time and energy. Micro-benchmarks serve this diagnostic role by evaluating individual tensor operations in isolation, measuring the accelerator's hardware primitives directly. When profiling a slow inference service, macro-benchmarks report aggregate latency violations, but only micro-benchmarks reveal whether execution time is dominated by matrix multiplications, self-attention projections, memory copies across the host-accelerator interconnect, or elementwise activation kernels.

Tensor operations constitute the primary target of micro-benchmarking because matrix multiplications and convolutions dominate the arithmetic budget of deep neural networks. Highly optimized runtime libraries such as cuDNN[10] (Chetlur et al. 2014) provide hand-tuned kernel implementations tailored to specific microarchitectures. Micro-benchmarks also evaluate standalone activation functions (such as ReLU, Sigmoid, and GELU) and structural submodules (such as multi-head attention projections or transformer feed-forward blocks) across standardized input shapes. Benchmark suites such as Baidu's DeepBench (Baidu Research 2016) formalized this methodology by evaluating raw GEMM, convolution, and collective communication primitives across diverse hardware platforms, isolating silicon-level execution efficiency from higher-level framework dispatch overhead.

Measuring isolated kernels requires rigorous experimental control. Without disciplined measurement protocols, dynamic hardware frequency scaling, asynchronous execution queues, and cache state introduce transient artifacts that distort kernel runtime.

↩ The compute primitives that micro-benchmarks isolate, vector and matrix operations and special function units, are established in section 11.3.

10 **cuDNN (CUDA deep neural network library)**: Released by NVIDIA in 2014, cuDNN provides hand-tuned kernel implementations for convolutions, pooling, and normalization. The benchmarking implication: reported inference latencies depend heavily on which cuDNN version and algorithm autotuner settings were used, making cuDNN version a mandatory element of any reproducible benchmark specification.

> Systems Perspective 12.4: Micro-benchmarking rules
>
> Five rules keep a micro-benchmark measuring the kernel rather than a hardware artifact:
>
> 1. **The warm-up rule**: Do not measure cold-start iterations as steady-state performance. Modern hardware uses DVFS (dynamic voltage and frequency scaling) and dynamic frequency boosting; caches, kernels, and clocks need warm-up before the measured loop represents sustained behavior.
> 2. **The variance rule**: Report the coefficient of variation (CV) ($\text{CV} = \sigma_{\text{run}}/\mu_{\text{run}}$), where σ_{run} and μ_{run} are the standard deviation and mean across repeated runs. Investigate values above the protocol's workload-specific tolerance; common causes include background OS jitter, thermal throttling, and memory contention, and 5 percent is not a universal cutoff.
> 3. **The "speed of light" (SOL) check**: Compare the achieved throughput against the roofline. If a kernel achieves 10 TFLOP/s on an H100 (peak ~989 TFLOP/s FP16, or ~1,979 TFLOP/s FP8 dense), the diagnostic step is to identify the cause of low utilization (often kernel launch latency from too many small kernels) before optimizing the code itself.
> 4. **The cache-state rule**: Set cache state to match the claim. Flush or exceed the L2 cache when measuring cold dynamic random-access memory (DRAM) bandwidth; preserve a warmed cache when measuring steady-state reuse. Otherwise a nominal DRAM result may instead reflect cache bandwidth (~5 TB/s–10 TB/s) rather than DRAM bandwidth (~1 TB/s–2 TB/s).

5. **The synchronization barrier rule**: Accelerator kernel launches are asynchronous on the host CPU. Timing GPU operations using CPU clocks without an explicit device barrier (such as `torch.cuda.synchronize()`) measures host enqueue latency rather than kernel execution; always place synchronization barriers immediately before and after the timed region, or use GPU-side timestamp events (`cudaEventRecord`).

The roofline model[11] of section 11.6, which plots the bound of the arithmetic intensity law (principle 6), is a prediction, and a benchmark is the measurement that tests it. The roofline bounds where a kernel can sit; a benchmark determines where it does sit, and the gap between the two is the diagnostic. A kernel far below its predicted ceiling is losing time to something the model omits (launch overhead, poor coalescing, synchronization), which is exactly what profiling looks for. Making the prediction requires the workload's arithmetic intensity at a named memory interface and the target's matching compute and bandwidth limits. For an NVIDIA H100 with 989 TFLOP/s of dense FP16 Tensor Core performance (FP32 is 67 TFLOP/s)[12] and 3.35 TB/s of memory bandwidth, the ridge point (peak compute divided by peak bandwidth, the intensity at which the two ceilings meet) falls at 295 FLOP/byte. Below it, bandwidth sets the lower ceiling; above it, compute does (section 11.6.2 derives the threshold).

A profiler translates these measurement rules into physical diagnostics by decomposing kernel execution time into the three governing terms of the iron law: data movement, compute throughput, and latency overhead. Comparing the measured utilization of each resource against hardware limits reveals which term dominates the trace.

11 **Roofline model**: Williams et al. (2009) introduced the Berkeley model, named for the visual shape of its performance ceiling. Its ridge point (peak FLOP/s divided by peak bandwidth) separates bandwidth-limited from compute-limited ceilings, suggesting which interventions to test against measured execution.

12 **FLOP/s (floating-point operations per second)**: The gap between advertised peak FLOP/s and achieved FLOP/s is the central tension in hardware benchmarking. The H100 advertises 989 TFLOP/s of dense FP16 Tensor Core arithmetic, but real workloads achieve different fractions of peak depending on arithmetic intensity, memory access patterns, precision, and runtime overhead. Reporting peak FLOP/s without utilization context is the most common benchmarking distortion.

↪ The H100 ridge point, with a compute-bound matrix multiplication and a memory-bound element-wise kernel placed on either side of it, is collected for reference in section D.2.1.1.

Systems Perspective 12.5: Measuring the iron law terms

Moving from theory to trace means mapping the iron law equation onto a profiler timeline (like Nsight Systems or PyTorch Profiler).

Measuring the data term $\left(\frac{D_{\text{vol}}}{\text{BW}}\right)$

- **Signal**: Look for the "Memory Throughput" or "DRAM Bandwidth" line.
- **Formula**: $\text{BW}_{\text{effective}} = \frac{D_{\text{vol}}}{T_{\text{kernel}}}$.
- **Diagnosis**: If $\text{BW}_{\text{effective}} \approx \text{BW}_{\text{peak}}$ (for example, close to the H100's 3.35 TB/s peak), bandwidth pressure is a strong candidate bottleneck. Test whether reducing traffic or increasing bandwidth improves time; a high bandwidth reading alone does not establish that changing compute (O) has no effect.

Measuring achieved compute throughput $(R_{\textbf{peak}} \cdot \eta_{\textbf{hw}})$

- **Signal**: Distinguish "SM Active," the fraction of time the GPU's Streaming Multiprocessors (SMs), its parallel execution cores, have work resident, from executed-operation throughput. A busy multiprocessor does not imply high useful-model FLOP/s.
- **Formula**: $R_{\text{peak}} \cdot \eta_{\text{hw}} = \frac{O}{T_{\text{kernel}}}$, reported in TFLOP/s.
- **Diagnosis**: If $\eta_{\text{hw}} \ll 1$ AND $\text{BW}_{\text{effective}} \ll \text{BW}_{\text{peak}}$, neither quoted peak is being approached. Kernels too small to amortize launch latency or too few threads to occupy the SMs are candidate explanations, but low aggregate rates alone do not exclude dependency stalls or an inefficient memory-access path. Separate inter-kernel gaps from in-kernel stalls, then inspect the corresponding dispatch, dependency, occupancy, or memory-access evidence before selecting an optimization.

Measuring the latency term $(L_{\textbf{lat}})$

- **Signal**: Look for gaps (empty space) between colored kernel bars on the timeline.
- **Formula**: Kernel gap fraction $= \frac{T_{\text{gap}}}{T_{\text{kernel}} + T_{\text{gap}}}$.
- **Diagnosis**: A "Sawtooth" pattern (Compute, Gap, Compute, Gap) suggests exposed waiting; correlate CPU dispatch, dependencies, and transfers before attributing it to

software overhead. If dispatch dominates, candidates include kernel fusion, covered in section 11.7.7, or the CUDA Graphs of section 7.3.6, which capture a repeated sequence of GPU launches so the runtime can replay it with less CPU dispatch overhead.

Profilers supply the measurements this mapping needs. A framework profiler such as the PyTorch Profiler isolates the dominant layer on the step timeline, and a kernel profiler such as NVIDIA Nsight Compute explains it from on-chip performance counters, the top-down method developed on a training step in section 8.5. Counter collection and kernel replay perturb timing, so diagnostic traces are compared against a minimally instrumented run. The benchmarking use is narrower, confirming or refuting a prediction.

↩ The feeding problem, the wall-clock time an accelerator loses waiting on input I/O, is established in section 4.9.3.

These granular measurements enable precise kernel optimization, but they cannot reveal how components interact when assembled into complete models. Macro-benchmarks address this gap.

12.3.2 Macro benchmarks

Micro-benchmarks verify that isolated operators achieve high compute or memory efficiency. Macro-benchmarks determine whether those gains persist when layers are composed into a complete model. Composing layers introduces physical interactions that isolated benchmarks cannot observe: intermediate activation tensors expand peak memory footprint, sequential kernel launches expose CPU driver dispatch overhead, and memory access streams from preceding operations evict shared cache lines before downstream kernels can reuse them.

Macro-benchmarks serve a central engineering objective: evaluating model architectures and runtime configurations under standardized workloads. Model-level evaluation captures the trade-offs that emerge from layer composition: generalization accuracy on unseen validation data, dynamic memory allocation across batch sizes and context lengths, and aggregate throughput across varied request arrival patterns. These dimensions interact directly. An architecture that achieves higher accuracy may require an activation footprint that forces a smaller batch size under device memory constraints, collapsing the computational throughput that justified its adoption. ResNet-50's training step tests the roofline's prediction at exactly this granularity, because the prediction is made layer by layer and the measurement is made on the composed model.

Napkin Math 12.1: ResNet-50 on the roofline: Predicted versus measured

Problem: The roofline predicts the fastest an H100 can train ResNet-50, and MLPerf measures how fast it does. How large is the gap, and what does it say about where the time goes?

Prediction: One training image costs about 24.6 GFLOP, three times the 8.2 GFLOP forward pass, because the backward pass computes gradients with respect to both activations and weights. At training batch sizes, the convolution layers reuse each weight across hundreds of images and sit above the 295 FLOP/byte ridge, so the roofline places the step on the compute roof. Dividing the 989 TFLOP/s peak by the work per image gives a ceiling of about 40,200 images/s.

Measurement: The MLPerf Training per-accelerator result for H100-class systems is about 5,000 images/s, which delivers about 123 TFLOP/s of model arithmetic, 12.4 percent of peak.

Diagnosis: The measurement sits 8.0× below the prediction. The roofline did not err; it bounded the convolutions and omitted the rest of the step. Normalization and elementwise layers have intensities far below the ridge and run on the bandwidth slope, the host must decode and augment thousands of JPEG images every second, and every step pays launch and synchronization overhead. The prediction cannot say which of these dominates. A profiler attributes the gap among them (perspective 12.5), and section 8.5 works that attribution for a training step.

Systems insight: A prediction and a measurement together locate a bottleneck; either alone does not. The roofline says ResNet-50 could train 8.0× faster on this accelerator, and the measurement says something other than arithmetic is setting its pace.

The claim the chapter inherited, that ResNet-50 runs faster at INT8 than at FP32, needs a different measurement from this training one. An inference run under MLPerf Inference rules settles it directly. The ResNet-50 Offline scenario, run at INT8 and at the higher-precision baseline on the same accelerator with each required to hold the reference top-1 accuracy within the benchmark's quality gate, reports both throughputs under one set of rules. The chapter's own deployment measurement moves to MobileNetV2 on the camera-trap board, where the full path from claim to delivered speedup can be traced on one device.

Evaluating complete models requires standardized datasets, fixed reference tasks, and reproducible metric definitions. In computer vision, standard benchmarks evaluate models on ImageNet (Deng et al. 2024), measuring top-1 classification accuracy alongside inference latency across fixed batch sizes. In natural language processing, standardized tasks evaluate sequence-to-sequence translation and autoregressive generation, quantifying output quality against token generation rate across defined context lengths.

Several industry-standard suites establish reproducible model-level comparisons across platforms. The MLPerf suite standardizes evaluation across data centers, edge appliances, mobile devices, and microcontrollers, as detailed in section 12.6.3. For resource-constrained embedded targets, EEMBC's MLMark quantifies inference throughput and energy consumption under strict memory budgets, while the AI-Benchmark (Ignatov and Timofte 2024) suite evaluates mobile systems-on-chip across heterogeneous compute units.

12.3.3 End-to-end benchmarks

End-to-end benchmarks encompass the entire production pipeline, capturing every stage required to ingest raw data, generate model predictions, and deliver results to downstream clients. While micro- and macro-benchmarks focus on accelerator execution, real-world serving pipelines frequently find their primary bottlenecks outside the model itself.

Data preprocessing forms the initial phase of the pipeline, converting raw external inputs into model-ready tensor representations. In computer vision pipelines, image ingestion requires decoding compressed file formats (such as JPEG decompression), resizing, cropping, and color normalization. When executed on host CPUs without hardware acceleration, these preprocessing steps can take several times longer than model inference on a modern accelerator, leaving high-throughput tensor cores idle while waiting for host memory transfers. Similarly, in natural language pipelines, subword tokenization and dynamic sequence padding on the host CPU often bound serving throughput. Postprocessing introduces analogous latency bottlenecks: object detection pipelines require non-maximum suppression (NMS) and bounding-box coordinate transformations, which create sequential execution stalls if not integrated efficiently into the execution graph.

Distributed infrastructure components introduce further performance constraints beyond the compute fabric. Remote storage systems bound training throughput when reading large multimodal datasets, and network interface card (NIC) saturation in distributed clusters throttles collective communication. End-to-end benchmarks must measure pipeline throughput under realistic network latencies, concurrent query arrival patterns, and actual storage I/O constraints to ensure reproducible evaluation of the deployment as an integrated system.

Public benchmark suites rarely measure storage, networking, and compute within a single unified protocol. While MLPerf Training and Inference evaluate end-to-end scenarios more closely than isolated operator tests, their closed divisions deliberately standardize input data loading to isolate accelerator performance from storage and network variability. Consequently, production end-to-end benchmarking remains primarily an internal engineering practice, evaluated through distributed tracing and production telemetry on live query distributions.

12.3.4 End-to-end vs. component latency

Measured at the request, the critical distinction is between component latency (time spent in model computation) and end-to-end latency (total time from request arrival to response delivery). Many benchmarks report only model inference time, obscuring the remaining overhead that determines actual user experience. The overhead is not marginal: serialization, network hops, and queue wait time can dominate total request time, making model-only optimizations yield diminishing returns.

Clipper's designers measured exactly this effect. For lightweight models, CPU-side JSON deserialization and interprocess data copying took more wall-clock time than the accelerator's model execution (Crankshaw et al. 2017). Reporting model latency alone would have hidden the largest component, a serialization cost that section 13.2.2.1 develops for serving systems.

Table 12.6 gives an illustrative latency breakdown for an inference request. The model inference stage that vendors report as their "benchmark" number spans 5 to 100 ms, yet the queue wait time it sits behind ranges from 0 to over 1,000 ms. Under load, the single component a benchmark measures is dwarfed by one it never sees, so the reported number can be a small slice of what the user actually experiences.

Table 12.6: Inference Latency Breakdown: Different pipeline components contribute to end-to-end latency, and model inference (the number vendors typically report) can be only one part of total request time. Queue wait time can dominate under load, making end-to-end measurement essential for realistic performance assessment. Ranges are illustrative rather than universal.

Component	Example Range	Notes
Network round-trip	10–100 ms	Varies by region
Request parsing	0.1–1 ms	JSON/protobuf
Input preprocessing	1–50 ms	Tokenization, image resize
Queue wait time	0–1000+ ms	Load-dependent
Model inference	5–100 ms	The "benchmark"
Output postprocessing	0.5–10 ms	Decoding, format
Response serialization	0.1–1 ms	JSON/protobuf

These component-level contributions explain why optimizing any single stage yields diminishing returns on end-to-end performance, an *optimization ceiling* formalized by Amdahl's Law (principle 8). The bound itself appears as equation 11.1, where hardware acceleration states it for an accelerated path; the notebook below applies it to a measured pipeline.

Napkin Math 12.2: Amdahl's Law: Optimization ceiling

Problem: A vision pipeline spends 8 ms on preprocessing (JPEG decode, resize, normalize) and 10 ms on inference. If inference alone is optimized by 5×, how much does end-to-end latency actually improve?

Math: Assume fixed work, sequential stages, and unchanged preprocessing, with no queueing feedback. Optimizing inference from 10 ms to 2 ms reduces total latency from 18 ms to only 10 ms, a 1.8× improvement rather than 5×. Amdahl's Law formalizes this ceiling: if inference, the part being accelerated, is fraction f_{parallel} of total latency, then even infinitely fast inference yields at most $1/(1-f_{\text{parallel}})$ speedup, because the preprocessing fraction $1-f_{\text{parallel}}$ remains. With preprocessing at 44.4 percent of total latency, the remaining fraction $1-f_{\text{parallel}}$ is 0.444, which yields a maximum achievable speedup $1/(1-f_{\text{parallel}})$ of 2.25×, regardless of model optimization.

Systems insight: Aggressive model optimization yields disappointing end-to-end results whenever the nonmodel fraction dominates. Any component speedup quoted in isolation shrinks once the untouched stages are measured alongside it, and the shortfall grows as those stages take a larger share of the pipeline. Comprehensive benchmarks must either include preprocessing in measurements or state explicitly that reported speedups apply only to the inference component.

A latency report that supports a deployment decision therefore states which components it includes, the load it was measured under, and whether each figure is a component or an end-to-end number. Choosing that boundary is the trade-off between isolating a component bottleneck and measuring what the user experiences.

12.3.5 Granularity trade-offs and selection criteria

Table 12.7 contrasts the diagnostic focus, scope, and engineering trade-offs across the three benchmarking granularities. Micro-benchmarks isolate low-level operations to guide kernel optimization and hardware selection, macro-benchmarks evaluate complete models to guide architectural choices, and end-to-end benchmarks measure full pipelines to ensure production deployments satisfy real-world service requirements.

Table 12.7: Benchmarking Granularity Levels: Different benchmark scopes target distinct stages of ML system development. Micro-benchmarks isolate individual operations for low-level optimization, macro-benchmarks evaluate complete models to guide architectural choices, and end-to-end benchmarks assess full system performance in production environments.

Component	Micro Benchmarks	Macro Benchmarks	End-to-End Benchmarks
Focus	Individual operations	Complete models	Full system pipeline
Scope	Tensor ops, layers, activations	Model architecture, training, inference	Extract, transform, load; model; infrastructure
Example	Conv layer performance on cuDNN	ResNet-50 on ImageNet	Production recommendation system
Advantages	Precise bottleneck identification, Component optimization	Model architecture comparison, Standardized evaluation	Realistic performance assessment, System-wide insights
Challenges	May miss interaction effects	Limited infrastructure insights	Complex to standardize, Often proprietary
Typical Use	Hardware selection, Operation optimization	Model selection, Research comparison	Production system evaluation

Selecting a single granularity level is rarely sufficient because benchmarking presents an inherent trade-off between diagnostic isolation and production fidelity. Along the descending diagonal in figure 12.3, evaluation regimes trade diagnostic power for operational realism: micro-benchmarks (the red point at the top left) isolate kernel-level memory bandwidth and warp occupancy at the expense of end-to-end context, macro-benchmarks (the blue center point) capture composed model topologies, and end-to-end benchmarks (the green point at the bottom right) encompass live production traffic but obscure the root causes of latency spikes. Effective evaluation requires strategically combining all three tiers to verify that kernel speedups survive full-system deployment.

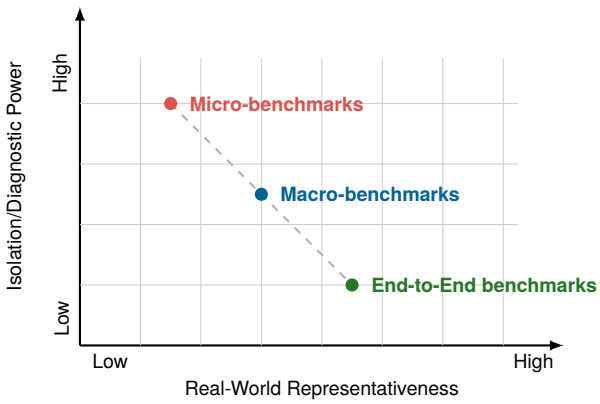

Figure 12.3: Isolation vs. Representativeness: The core trade-off in benchmarking granularity. Micro-benchmarks provide high diagnostic precision but limited real-world relevance, while end-to-end benchmarks capture realistic system behavior but offer less precise component-level insights. Effective ML system evaluation requires strategic combination of all three levels.

This trade-off maps directly onto the D·A·M taxonomy. Micro-benchmarks assess the physical capability of the Machine (M) executing a primitive Algorithm (A). Macro-benchmarks evaluate how the Algorithm (A) orchestrates tensor data flow across composed layers on the Machine (M). End-to-end benchmarks evaluate how raw Data (D) ingestion from external storage and network infrastructure interacts with both Algorithm and Machine under production load. Systematic performance engineering requires evaluating all three tiers to ensure local kernel optimizations translate into global system speedups.

Carpentry and granularity let one team build a trustworthy measurement. Comparing that measurement with another team's, or with a vendor's, requires that both were built the same way, and that agreement is what standardized benchmark suites provide.

12.4 Benchmark Suites

A team evaluating edge deployment hardware must compare five candidate system-on-chip (SoC) designs for the camera trap's next board. Vendor A reports 8 TOPS at INT8; Vendor B reports 15 TOPS at INT4; Vendor C reports inference latency on a proprietary model; Vendor D cites MLPerf scores from two generations ago; Vendor E provides only peak throughput at maximum batch size. None of these figures can be directly compared. The team cannot make an informed procurement decision because each vendor isolates a favorable metric under idiosyncratic conditions, obscuring true operating trade-offs. Benchmarking suites resolve this fragmentation by enforcing uniform measurement harnesses and standardized evaluation rules.

Each generation of benchmark suites arose to close a gap of exactly this kind, when the metrics of the day stopped predicting what users experienced. Their history explains the rules modern suites enforce.

12.4.1 From Whetstone to MLPerf

Three shifts mark that history: from isolated kernels to representative application suites, from single-metric throughput to multi-objective energy profiles, and from generic compute metrics to domain-specific execution constraints. The earliest computing benchmarks were open to benchmark gaming. Whetstone (Curnow and Wichmann 1976) used a synthetic mix of scientific operations, while LINPACK (Dongarra et al. 1979) measured dense linear-system solving. Because both relied on predictable computational loops, compiler and hardware vendors could optimize for the benchmark kernels (unrolling synthetic loops, or tailoring cache tiling to exact matrix dimensions) without improving general application performance. SPEC CPU (1989) addressed this by evaluating complete, portable software suites that stressed integer branching, irregular memory hierarchies, and floating-point pipelines (Dixit 1993). The same vulnerability applies to ML, since model-specific kernel tuning can overfit a single workload. Model compression claims therefore require validation on representative tasks such as ResNet-50 and BERT across the full software runtime.

Distributed computing added a further lesson, that component-level microbenchmarks fail to predict cluster-level throughput when interconnect latency, serialization, and collective communication dominate wall-clock time, as they do in distributed ML training. To capture these interactions, DAWNBench (Coleman et al. 2019) pioneered time-to-accuracy evaluation, tying hardware throughput to algorithmic convergence. Maximizing samples per second has no engineering value if numerical instability or poor batch sizing prevents the model from reaching its target validation accuracy. MLPerf[13] (2018) combined these lessons and institutionalized full-system measurement, multi-objective constraints, and representative workloads spanning vision, language, and recommendation (Mattson et al. 2020; Reddi et al. 2019).

Energy followed the same path. SPEC Power (2007) (Lange 2009) and Green500 (2007) (Feng and Cameron 2007) made performance per watt a ranking metric for servers and supercomputers, and MLPerf Power (MLCommons 2024b) carried it to ML workloads, whose rapid power swings and shared host components demand calibrated instruments and explicit measurement boundaries (section 12.7.4).

Energy benchmarking also exposes algorithmic efficiency. Compression and efficient architectures such as MobileNet (Howard et al. 2017; Sandler et al. 2018) save energy by reducing operations and off-chip traffic. Traffic reduction is a primary lever, because a DRAM read costs orders of magnitude more energy than an arithmetic operation (section 10.3.2.1).

As specialized accelerators emerged, generic benchmarks failed to capture domain-specific execution constraints. Data center training clusters optimize aggregate throughput within rack-level power envelopes, mobile AI operates within thermal limits (typically under 5 watts), and embedded microcontrollers function within milliwatt budgets, which decides whether a benchmark prioritizes samples per second or joules per inference. Application requirements add functional constraints such as calibration for clinical models, hard tail-latency cutoffs for trading systems, and bounded worst-case latency for autonomous vehicles.

[13] **MLPerf**: Launched in 2018 by a consortium of industry and academic institutions, MLPerf takes its name from "ML" combined with "Perf" (performance), echoing SPEC's benchmarking tradition. MLPerf's design principles (representative workloads, full-system measurement, and open submission) directly address the gaming that plagued Whetstone and LINPACK. Vendors who could previously report peak kernel throughput on cherry-picked problem sizes must now report end-to-end system performance on standardized tasks (Mattson et al. 2020; Reddi et al. 2019).

Because ML workloads couple tensor execution units, memory bandwidth, and communication fabrics, no single metric or workload can characterize a system. MLPerf therefore splits into distinct deployment suites: MLPerf Training evaluates multi-node scaling and high-bandwidth interconnects under time-to-quality targets (Mattson et al. 2020); MLPerf Inference measures throughput and latency percentiles under SLAs across server and client systems (Reddi et al. 2019); MLPerf Tiny tests ultra-low-power microcontrollers operating with tight memory constraints (C. Banbury, Reddi, Torelli, Holleman, Jeffries, Kiraly, et al. 2021); and the cross-cutting MLPerf Power track measures useful work per watt across each environment. Reading the constraint column of table 12.8 from top to bottom, cluster-scale interconnect bandwidth gives way to latency percentiles at the edge, and finally to strict memory footprints on microcontrollers.

Table 12.8: MLPerf Benchmark Suite Variants: Each variant addresses a different deployment context, from data-center-scale training to ultra-constrained microcontroller inference, targeting specific operational constraints and measuring metrics relevant to its deployment scenario.

MLPerf Variant	Target Domain	Key Constraints	Primary Metrics
MLPerf Training	Data center	Multi-node scaling, high bandwidth interconnects	Time-to-quality, throughput (samples/sec)
MLPerf Inference	Server/Edge	Latency SLAs, throughput requirements	QPS, latency percentiles, accuracy preservation
MLPerf Tiny	MCU/IoT	Ultra-low-power inference, limited memory	Latency, accuracy, energy per inference
MLPerf Power	Cross-cutting	Energy budgets, thermal constraints	Performance/W, energy per query

Table 12.9 summarizes the progression from early synthetic loops to multi-dimensional ML systems evaluation; each row's lesson survives as a rule that modern suites enforce. Those rules become even more demanding in machine learning, where training and inference add variability that deterministic software benchmarks never faced.

Table 12.9: Benchmark Evolution: Evolution of computing benchmarks from synthetic operations to ML-specific evaluation. Each generation addressed limitations of its predecessors, culminating in MLPerf's synthesis of representative workloads, multi-objective metrics, and integrated system measurement.

Benchmark	Year	Primary Focus	Key Metric(s)	Lesson for ML Benchmarking
Whetstone	1976	Synthetic floating-point operations	MWIPS	Gaming synthetic tests undermines evaluation validity
LINPACK	1979	Linear algebra (matrix operations)	FLOP/s	Isolated operations miss system-level complexity and bottlenecks
SPEC CPU	1989	Real application workloads	SPECrate, SPECspeed	Representative workloads reveal true deployment performance
SPEC Power	2007	Server energy efficiency	ssj_ops/W across load levels	Energy efficiency requires multi-load evaluation, not just peak performance
Green500	2007	HPC energy efficiency	GFLOP/s per watt	Efficiency rankings complement raw performance rankings
MLPerf	2018	ML systems (training + inference)	Time-to-quality, QPS, latency, accuracy	Synthesizes all lessons: representative workloads + multi-objective + system

12.4.2 ML measurement challenges

Three lessons from benchmark history (representative workloads, multi-objective evaluation, and integrated system measurement) converge on a requirement unique to machine learning: managing statistical approximation. Traditional computing benchmarks specify correctness checks, which may require exact outputs or permit stated numerical tolerances. In ML systems, low-level engineering choices routinely alter numerical output: aggressive weight quantization, kernel pruning, or reduced-precision accumulators trade accuracy for execution speed and lower memory bandwidth pressure. Consequently, an ML benchmark cannot evaluate execution time in isolation; output accuracy serves as an inviolable operational constraint.

Evaluating an ML system therefore means testing the coupled Data, Algorithm, and Machine (D·A·M) choices together rather than measuring raw compute throughput. A suite earns trust by

solving three problems. It must produce valid measurements despite run-to-run noise, finite test sets, unrepresentative workloads, and misaligned metrics. It must then isolate what the hardware-software stack contributes, which is the job of a system benchmark and its roofline diagnostic. Finally, it must make results comparable across organizations, which is the job of community standardization.

ML systems combine several sources of measurement variability that classical software benchmarks were not designed to evaluate together. These fluctuations originate at both the machine and algorithmic layers. On the machine side, sustained execution pushes accelerators against thermal and power envelopes, triggering dynamic voltage and frequency scaling (DVFS) that throttles processor clocks mid-run. Host operating-system activity (thread scheduling jitter, memory paging, and PCIe bus contention during batch staging) further introduces latency variance across runs. On the algorithmic side, floating-point addition is non-associative, so reduction orders that change across parallel execution threads shift results slightly, while mini-batch shuffling, pseudo-random augmentations, stochastic dropout masks, and weight initialization perturb the trajectory that stochastic gradient descent takes across a non-convex loss surface.

Distinguishing a genuine systems optimization from background measurement noise requires isolating these overlapping sources of variance with repeated runs, paired comparisons, and confidence intervals. Those statistical controls apply to every benchmark in the chapter, so section 12.8.1 collects them in one place, including how large a test set must be before it can resolve a one-point accuracy difference.

Beyond run-to-run variance, benchmark validity depends on workload representativeness. Synthetic microbenchmarks generate uniform, statically sized tensors directly in accelerator HBM. By executing continuous, compute-bound GEMM operations in an isolated loop, microbenchmarks measure theoretical peak arithmetic throughput. However, they conceal the memory hierarchies and scheduling bottlenecks that dominate production deployments. Synthetic workloads bypass host-to-device PCIe data transfers, input decoding pipelines, dynamic memory allocation churn, and GPU cache evictions. In contrast, **trace-based benchmarking** replays timestamped request logs recorded from live serving clusters. Production traces capture Poisson and bursty request arrival distributions, variable sequence lengths, and concurrent query streams. Replaying live traces forces the serving infrastructure to manage dynamic batching (grouping requests that arrive within a short time window into one batch), key-value (KV) cache allocation under memory pressure, and queuing delays, stress-testing the system under operational conditions that synthetic steady-state loops obscure.

↩ The key-value (KV) cache, the per-request attention state that grows with every generated token, is established in section 6.7.4.

A representative workload can still mislead if the evaluation metric fails to reflect deployment constraints. When an engineering team optimizes a single algorithmic figure of merit (such as an offline BLEU score, top-1 classification accuracy, or token perplexity) in isolation from system SLOs, the metric ceases to measure genuine operational fitness. This divergence is the chapter's second principle, Goodhart's Law, operating inside a single team's choice of metric, and once the proxy becomes the sole optimization target it stops reporting overall system health. In neural machine translation, an offline accuracy optimization can break the serving deadline outright.

Example 12.1: Goodhart's Law in action

Scenario: An engineering team optimizes a neural machine translation model for offline BLEU score, increasing the beam search size (the number of candidate partial translations kept at each decoding step) from 1 to 10.

Diagnosis: The larger beam search achieves a 0.5-point BLEU gain on paper but increases candidate evaluations by 10×, increasing inference latency from 50 ms to 200 ms (4× slowdown), exceeding the serving deadline.

Systems lesson: Optimizing offline accuracy without latency constraints invites Goodhart's Law failures. Production benchmarks must enforce strict SLOs for serving latency (e.g., latency < 100 ms).

The translation example shows an algorithmic change (a tenfold wider beam) multiplying computational load and memory traffic for a marginal quality gain while violating a hardware latency

deadline. Fixed benchmarks also assess execution under an unvarying input distribution, which conceals how systems degrade under production distribution shifts. Model and data evaluation must test those distribution limits. System comparisons address a separate question by isolating infrastructure execution efficiency from model architecture and dataset variation. Standardized suites like MLPerf establish reference workloads, datasets, quality targets, and permitted implementation changes, enabling reproducible comparisons of hardware-software execution efficiency within a specified benchmark version and division.

12.4.3 System benchmarks

Hardware specifications advertise peak arithmetic rates that application workloads do not sustain—the gap between an H100's dense FP16 peak and the model arithmetic ResNet-50 training actually achieves (section 12.1). System benchmarks expose that gap by running standardized ML workloads across hardware architectures, memory systems, and interconnects rather than relying on spec-sheet peaks alone.

The underlying hardware, whether CPUs, GPUs, Tensor Processing Units (TPUs),[14] and application-specific integrated circuits (ASICs),[15] determines ML-system speed, efficiency, and scale. System benchmarks provide standardized methods for comparing hardware across AI workloads by computational throughput, memory bandwidth, power efficiency, operator coverage, and scaling (Reddi et al. 2019; Mattson et al. 2020).

System benchmarks serve two functions. For practitioners, they enable informed hardware selection by providing comparative data across configurations. For manufacturers, they quantify generational improvements and guide accelerator development. Both functions require separating what the hardware contributed from what the model and data contributed.

> **Definition 12.2: Machine learning system benchmarks**
>
> ***Machine learning system benchmarks*** are standardized evaluation protocols that hold the workload and quality target constant while varying the hardware-software stack, measuring $\eta_{\text{hw}} = R_{\text{sustained}}/R_{\text{peak}}$ (the measured sustained rate $R_{\text{sustained}}$ over the peak rate) and L_{lat} to isolate infrastructure efficiency from algorithmic improvements.
>
> 1. **Significance**: The same ResNet-50 model can report the same ImageNet Top-1 accuracy while delivering very different throughput across hardware stacks, precision formats, batch sizes, and compiler configurations. Only a system benchmark exposes that gap.
> 2. **Distinction**: Unlike algorithmic benchmarks (which vary the Data and Algorithm factors, Samples/Task and FLOPs/Sample, to improve convergence or accuracy), system benchmarks hold the algorithm and quality target fixed and vary the implementation (kernel libraries, quantization formats, batch sizes, and hardware generations) to measure how efficiently the hardware-software stack executes the workload, lowering the iron law's realized Machine factor (Seconds/FLOP) across compute ($O/(R_{\text{peak}} \cdot \eta_{\text{hw}})$), data movement ($D_{\text{vol}}/\text{BW}$), and fixed latency ($L_{\text{lat}}$).
> 3. **Common pitfall**: A frequent misconception is that a system benchmark result generalizes across workloads. An accelerator that achieves high utilization on ResNet-50 (a compute-friendly vision workload) may achieve much lower utilization on a recommendation system, whose embedding lookups are bound by memory capacity and bandwidth rather than arithmetic. System benchmarks are workload-specific; no single metric characterizes a hardware platform.

System benchmarks evaluate performance across scales, ranging from single-chip configurations to large distributed systems and covering both training and inference. The ImageNet challenge shows why separating the hardware's contribution from the model's is hard to do after the fact. Between 2010 and 2014, top-5 error (the blue line in figure 12.4) fell from 28.2 percent to 7.3 percent while GPU-accelerated entries (the green bars) rose from zero to over 100, with the steepest single drop at AlexNet's arrival in 2012 (Krizhevsky et al. 2012; Russakovsky et al. 2015; Gray 2015). These paired series plot contemporaneous empirical trends, not a causal attribution of how much accuracy

[14] **TPU (tensor processing unit)**: Google's custom ASIC for neural network workloads. A TPU v4 pod (4,096 chips) delivers 1.1 exaFLOP/s peak BF16 (Jouppi et al. 2023), but benchmarking TPUs requires caution: their systolic-array architecture favors regular tensor operations, so peak FLOP/s overstate performance on irregular workloads like sparse attention or dynamic control flow.

[15] **ASIC (application-specific integrated circuit)**: An ASIC's peak TOPS number applies only to the specific operators it was designed for. An unsupported layer may require a host fallback or a different implementation, adding transfer and coordination costs. This makes operator coverage an early question in any ASIC benchmark: workload compatibility can explain part of the gap between peak and achieved throughput.

gain stemmed from hardware throughput versus algorithmic design, training schedules, or dataset expansion. A system benchmark avoids that ambiguity by construction: it fixes the model and quality target so that any change in the result belongs to the hardware-software stack.

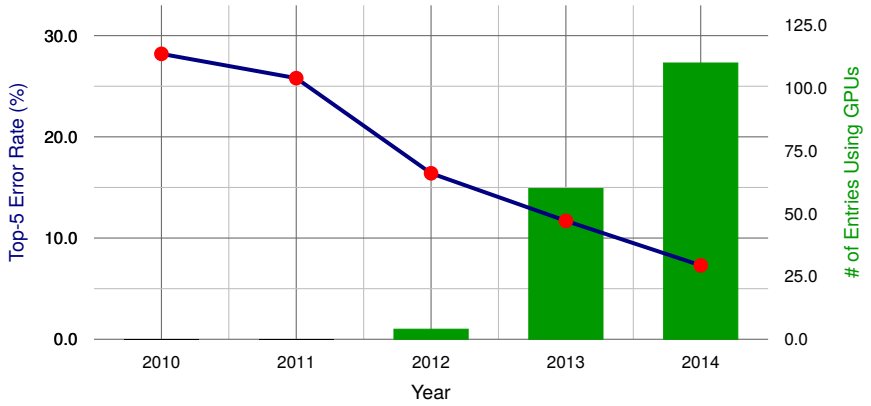

Figure 12.4: ImageNet Error and GPU Adoption: Sourced top-5 error rates are shown beside GPU use among challenge entries. The temporal association does not isolate hardware's causal contribution. Error-rate sources: (Russakovsky et al. 2015; Krizhevsky et al. 2012). Gray (2015) charts the per-year GPU entry counts.

While section 12.9.1 evaluates model compression against task accuracy baselines, system benchmarking isolates the execution efficiency of the hardware-software stack under a fixed model. Modern accelerators rarely sustain theoretical peak throughput because physical execution depends on the coupling between tensor shapes and memory hierarchies; ResNet-50 training, which the roofline places on the compute roof, sustains about 12.4 percent of an H100's peak (notebook 12.1). Parameter-heavy transformer decodes and activation-heavy convolutional passes stress entirely different levels of the memory subsystem, causing achievable throughput to diverge across precision formats.

Measuring sustained utilization rather than peak capability establishes two critical scope boundaries. First, energy consumption scales with execution efficiency, because performance per watt varies widely across hardware platforms, and an underutilized accelerator draws substantial static power for minimal computational output. Second, multi-accelerator execution introduces communication boundaries. While multi-node cluster scaling involves network-topology effects beyond this book's single-node scope, intra-node benchmarking must account for interconnect bandwidth, memory sharing across accelerators, and gradient synchronization over NVLink or PCIe.

12.4.4 Community-driven standardization

Without shared measurement boundaries, utilization numbers cannot be compared. If one benchmark includes host-side preprocessing and PCIe transfers while another measures only device kernel execution, or if one power meter reads only the accelerator voltage rail while another includes host processors and chassis fans, the resulting figures reflect incompatible boundaries rather than architectural efficiency. No single vendor can resolve this discrepancy, because each has a commercial incentive to draw the boundary around its own hardware strengths. Formal standards bodies move too slowly for hardware and model structures that change every year, so consortia such as MLCommons maintain living benchmark suites. These pair open-source reference implementations with compliance rules so that numbers from different laboratories describe comparable workloads under the same version, division, quality target, and scenario.

Standardizing system benchmarks requires formalizing the D·A·M taxonomy so that evaluations isolate the Machine without confounding changes to the Algorithm or Data. The MLPerf Training benchmark enforces this separation by measuring time-to-train to a specified quality target rather than raw floating-point throughput or epoch duration (Mattson et al. 2020). High TFLOP/s from aggressive low-precision scaling helps only if faster steps outweigh any extra work needed to reach the target, and a run that misses the target is invalid. MLPerf splits submissions into two divisions.

In the closed division, every submitter must run the reference model and reach the same quality target, so differences in time-to-train belong to the system; the open division permits model and algorithm changes, so its results compare whole solutions rather than machines. Within the closed division, the rules constrain the workload while permitting specified tunable hyperparameters and approved numerical formats. Quality and compliance checks establish which hardware, compiler, and training-configuration improvements constitute valid submissions.

The MLPerf Inference benchmark applies this discipline to production deployment constraints (Reddi et al. 2019). An accelerator cannot simply report peak throughput under infinite batching if interactive serving requires guaranteed responsiveness. The benchmark therefore fixes how queries arrive, through execution scenarios matched to physical operating regimes: one query at a time for a single interactive user, randomly arriving queries under a tail-latency bound for a shared service, and all inputs supplied upfront for bulk throughput. By standardizing these execution boundaries, community benchmarks account for queueing delays and host-to-device PCIe transfers, making the tested load and timing boundary explicit when interpreting a throughput claim.

12.4.4.1 MLPerf execution scenarios

The same hardware can report dramatically different benchmark numbers depending on *how* requests arrive, which explains why vendor claims often fail to predict production performance. Classic MLPerf Inference defines four execution scenarios that characterize distinct traffic patterns, each requiring different optimization strategies (Reddi et al. 2019). Current client and generative-AI benchmark variants also include interactive measurements for latency-sensitive large language model (LLM) workloads, where time to first token and time per output token, the two measured quantities defined in section 12.6.2.2, become central (MLCommons 2026b).

SingleStream SingleStream processes one request at a time, measuring latency for sequential inference. This scenario models mobile and embedded applications where a single user interacts with the device: a smartphone camera app classifying images, a voice assistant processing speech, or a wearable detecting gestures. The key metric is a tail percentile of per-query latency (the 90th percentile in MLPerf's rules), and inter-request batching is unavailable because the next query arrives after the previous one completes. Optimization focuses on preprocessing efficiency and power consumption rather than throughput.

MultiStream MultiStream processes multiple synchronized input streams simultaneously, modeling scenarios like autonomous vehicles with multiple cameras that must be processed together for spatial fusion. The application motivation is synchronized processing, but the benchmark rule is version-specific: current MultiStream rules issue a group of samples per query, wait for its completion before the next query, and report a specified latency percentile. Earlier versions used fixed arrival intervals. Grouped-query latency helps assess multi-input execution; it does not establish a hard-deadline guarantee for a vehicle planning loop.

Server Server generates requests following a Poisson distribution, simulating cloud API traffic where requests arrive independently and unpredictably. This scenario models web services handling millions of queries from different users. Unlike SingleStream's guaranteed sequential arrival, Server traffic creates queuing dynamics where multiple requests compete for resources. The key metrics are throughput (queries per second) and the workload's tail-latency bound, typically set at the 99th percentile, and dynamic batching can improve efficiency by grouping requests that arrive within a time window. Optimization balances throughput against latency SLOs.

Offline Offline provides all inputs upfront, measuring maximum throughput when latency constraints are removed. This scenario models batch processing pipelines: overnight data processing, scientific computing, or precomputing recommendations. With no per-query latency requirement, systems can tune batch size for sustained throughput within memory and execution limits. The key metric is pure throughput (samples per second), and optimization focuses entirely on hardware efficiency. Table 12.10 maps the classic execution scenarios, plus the newer Interactive LLM-oriented case, to their deployment contexts and optimization strategies.

Table 12.10: MLPerf Execution Scenarios: Classic MLPerf Inference scenarios map to distinct deployment contexts, each requiring different optimization strategies, and newer Interactive scenarios extend the framework to latency-sensitive LLM workloads. SingleStream and MultiStream prioritize latency, Server balances throughput and latency, Offline maximizes throughput, and Interactive emphasizes token-level responsiveness. Matching the scenario to deployment context determines which benchmark results are relevant.

Scenario	Context	Strategy	Focus
SingleStream	Mobile apps, embedded devices	No batching (batch = 1)	Preprocessing, power efficiency
MultiStream	Autonomous driving, video analytics	Synchronized sensor fusion	Grouped-query latency percentile
Server	Cloud APIs, web services	Dynamic batching with timeout	Throughput-latency trade-off tuning
Offline	Batch processing, data pipelines	Maximum batch size	Throughput, hardware utilization
Interactive	Chat, agents, local generative AI	Token streaming, KV-cache management	Time-to-first-token, time-per-output-token

Community standards fix the workload, the divisions, and the arrival pattern. The training and inference sections apply those rules to the chapter's two lighthouse workloads, beginning with the one that consumes the most arithmetic per result: training ResNet-50 to its quality target.

12.5 Training Benchmarks

Training and inference fail in opposite ways on the same accelerator. A training run stalls when synchronizing gradients across accelerators saturates the interconnect; a serving deployment violates its SLO when request bursts build a queue. The two regimes also measure different resources. Training iteratively refines parameters over billions of samples and must hold parameters, gradients, optimizer state, and the activations retained for the backward pass, a footprint that can far exceed the weights alone (table 12.1 gives ResNet-50's); its figure of merit is wall-clock time to a target accuracy. Inference evaluates fixed parameters against arriving queries, discards the backward graph and optimizer state, and is judged by latency percentiles and throughput under bursty load. A training result and an inference result on the same accelerator therefore measure different resources and cannot stand in for each other, which is why MLPerf maintains separate Training and Inference suites (Mattson et al. 2020; Reddi et al. 2019). This chapter measures training on ResNet-50 and serving on MobileNetV2 (section 12.6).

↩ The training memory budget of weights, gradients, optimizer state, and retained activations is established in section 8.3.2.5.

In an illustrative procurement failure, a team purchases a larger GPU cluster expecting proportional training-speed gains, only to discover that communication overhead and memory bottlenecks limit the actual speedup. Training benchmarks exist to catch this kind of gap before procurement. Training benchmarks span six dimensions (table 12.12), anchored by three: convergence metrics that measure learning progress, throughput metrics that measure computational efficiency, and scalability metrics that measure distributed performance.

Definition 12.3: ML training benchmarks

ML training benchmarks are machine learning system benchmarks that measure the time to reach a target quality metric (for example, a specified validation accuracy or loss threshold) on a fixed dataset and model, quantifying the rate of convergence per unit of resource.

1. **Significance**: Training benchmarks reveal large gaps invisible to hardware specs. Holding the model and quality target fixed, the time to convergence can vary widely across hardware-software stacks because training performance depends on the full pipeline: data loading $(D_{\text{vol}}/\text{BW})$, compute utilization (η_{hw}), gradient synchronization $(\text{BW}, L_{\text{lat}})$, and fault recovery overhead. A peak FLOP/s spec sheet captures none of these interactions.
2. **Distinction**: Unlike inference benchmarks, which measure per-query latency and throughput under load, training benchmarks measure time-to-accuracy across the full optimization loop: data loading, forward pass, backward pass, gradient synchronization, and optimizer step. As scale increases, communication (BW) can displace compute (R_{peak}) as the binding constraint; profiling establishes the transition for a particular workload.

3. **Common pitfall**: A frequent misconception is that training benchmarks measure "how fast the GPU runs." At large scale, interconnect bandwidth (BW) for gradient synchronization and fault tolerance overhead (checkpoint I/O, straggler mitigation) often dominate the benchmark result more than peak FLOP/s.

Training benchmarks validate whether hardware acceleration delivers promised training throughput. Accelerators and multi-chip systems all claim dramatic speedups, and training benchmarks reveal which claims hold under realistic workloads. They evaluate how hardware configurations, data loading mechanisms, and distributed training strategies perform when training production-scale models. These benchmarks are vital because training represents the largest capital expenditure in ML systems, and only rigorous time-to-accuracy measurement reveals whether that capital delivers proportional value rather than dissipating into scaling inefficiencies, memory bottlenecks, or communication overhead. The metrics themselves (time-to-accuracy, scaling efficiency, utilization, checkpoint overhead) are defined and worked at the scale of one machine with one to eight accelerators, the scale of the scaling-efficiency notebook below.

12.5.1 Training benchmark motivation

MLPerf Training (Mattson et al. 2020; MLCommons 2024c) provides the standardized framework for this time-to-quality measurement. The longitudinal scaling curves in figure 12.5 track cumulative relative performance gains across nine model workloads between 2018 and 2024 against the orange Moore's Law baseline. Every workload curve outpaces cumulative transistor scaling (which reaches 6.6× by mid-2024), led by Mask R-CNN climbing to 48.8× and ResNet reaching 34× as distributed scaling and compiler optimizations compound hardware improvements (Tschand et al. 2024). This trajectory documents improvements in the full hardware-software system beyond transistor scaling alone; the plotted results do not isolate the contribution of competitive pressure from other causes.

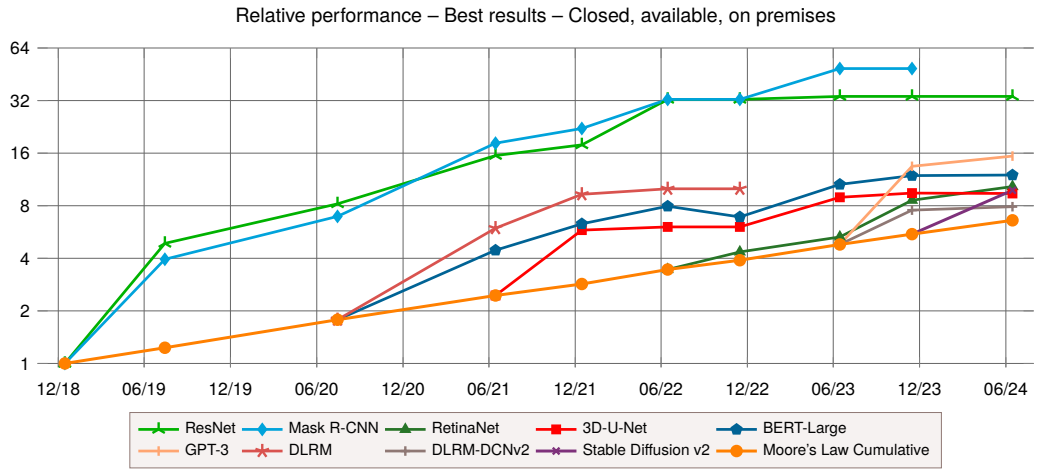

Figure 12.5: MLPerf Training Progress: Workload lines report cumulative relative performance across benchmark versions against the plotted cumulative Moore's Law baseline. Every workload's latest point exceeds the baseline at the same date, and Mask R-CNN reaches the largest plotted gain at 48.8×; the comparison captures combined hardware and software progress, not hardware scaling alone. Source: (Tschand et al. 2024).

Training benchmarks also expose inefficiencies such as slow data loading, underutilized accelerators, excessive memory overhead, and communication bottlenecks that erode scaling efficiency. Advertised hardware capability (for example, accelerator TFLOP/s) becomes a training speedup only to the extent that a benchmark verifies it under realistic conditions.

Training benchmarks serve four interconnected functions. First, they enable hardware and software optimization by providing vendor-neutral comparisons across accelerator architectures and frameworks (TensorFlow, PyTorch) on standardized tasks, guiding hardware selection for data

[16] **Mixed-precision training**: Uses lower precision for most arithmetic while preserving higher-precision accumulation where needed (Micikevicius et al. 2018). The benchmarking consequence: mixed-precision and full-precision runs are not directly comparable because reduced memory traffic and larger feasible batch sizes can change convergence dynamics. MLPerf addresses this by fixing the accuracy target, making time-to-accuracy the comparable quantity regardless of precision strategy.

centers and cloud environments. Software optimizations including mixed-precision training[16] and memory-efficient data loading are similarly quantified. Second, they evaluate scalability: adding GPUs should reduce training time proportionally, but communication overhead, synchronization latency, and memory bottlenecks limit scaling efficiency in practice. Training benchmarks quantify these losses, revealing whether infrastructure investments deliver proportional returns. Third, they provide cost and energy accountability: with a single large-scale training run consuming energy on the scale of the GPT-3 estimate in section 12.5.2.4, benchmarks that track cost per training run and power consumption per unit of progress help organizations balance computational power with sustainability goals. Finally, standardized evaluation criteria, controlled randomness, submission rules, and audits make comparisons more reproducible and constrain implementation-specific shortcuts.

12.5.2 Training metrics

From a systems perspective, training benchmarks assess the rate of convergence toward a verified quality threshold rather than the raw processing speed of an execution loop. Metrics such as sample throughput and scaling efficiency become meaningful only when the workload reaches target convergence; without that operational constraint, raw throughput rewards numerical instability and divergence. MLPerf Training formalizes this requirement by coupling wall-clock time directly to task-specific validation targets across each standardized workload.

12.5.2.1 Time and throughput

A training cluster that processes twice as many images per second by doubling the minibatch or dropping precision has not sped up training if the run requires twice as many epochs to converge—or never reaches the quality floor at all. That is why the primary metric for evaluating training efficiency is the time required to reach a predefined accuracy threshold. Training time (T_{train}) measures how long a model takes to converge to an acceptable performance level, reflecting the overall computational efficiency of the system. Let $\text{Accuracy}_{\text{val}}(t)$ be the model's validation accuracy at training time t, and let the target accuracy be the benchmark-specific threshold (for example, 75.9 percent top-1 accuracy for ResNet-50 on ImageNet in MLPerf). Equation 12.1 formally defines this metric, keeping the benchmark focused on how quickly a system achieves meaningful results:

$$T_{\text{train}} = \inf\{t \geq 0 : \text{Accuracy}_{\text{val}}(t) \geq \text{target accuracy}\} \tag{12.1}$$

A run that never reaches the target has no finite time-to-accuracy, preventing raw training speed from rewarding a system that fails the benchmark's quality criterion.

Throughput,[17] often expressed as the number of training samples processed per second, provides an additional measure of system performance. Let N_{samples} be the total number of training samples processed and T_{train} the training time from equation 12.1. Equation 12.2 makes the rate explicit by dividing processed samples by training time:

$$\text{Throughput} = \frac{N_{\text{samples}}}{T_{\text{train}}} \tag{12.2}$$

Throughput alone cannot certify system capability. A platform may sustain high sample rates using aggressive low-precision formats or enormous minibatches, yet fail to reach target accuracy because of gradient divergence or poor generalization. In MLPerf Training, for instance, a ResNet-50 benchmark on ImageNet is valid only if the model achieves the required 75.9 percent top-1 validation accuracy (Mattson et al. 2020; MLCommons 2024c). Evaluating throughput strictly as the rate of progress toward convergence ensures that reported gains reflect genuine learning productivity rather than wasted arithmetic cycles.

12.5.2.2 Scalability and parallelism

Scalability measures how effectively training performance improves as resources are added. Ideally, doubling GPU count should halve training time. In practice, communication overhead, memory bandwidth limits, and parallelization inefficiencies constrain scaling well below linear.

[17] **Throughput**: Originating in manufacturing to measure units produced per unit time, the term entered computing in the 1960s batch-processing era. The manufacturing origin carries a systems lesson: throughput and latency are inherently opposed, because batching increases throughput (more units per hour) at the cost of individual item wait time. In ML serving, this manifests as the batch-size trade-off: larger batches improve GPU utilization but increase per-request latency.

Napkin Math 12.3: Scaling efficiency calculation

Problem: A team trains an image classifier on a fixed dataset. Single-GPU training takes 24 hours. With 8 GPUs, training takes 4 hours. Is this good scaling? Where did the efficiency go?

Step 1: Define scaling efficiency. For strong scaling (fixed problem size, more processors), let $T(1)$ be the training time on a single GPU, and $T(N_{\text{GPU}})$ the training time on N_{GPU} GPUs. Equation 12.3 defines efficiency:

$$\text{Eff}_{\text{scaling}}(N_{\text{GPU}}) = \frac{T(1)}{N_{\text{GPU}} \times T(N_{\text{GPU}})} \times 100\% \tag{12.3}$$

Step 2: Calculate efficiency. $\text{Eff}_{\text{scaling}}(8) = \frac{24\,\text{hours}}{8 \times 4\,\text{hours}} \times 100\% = 24/32 = 75$ percent

With perfect scaling, 8 GPUs would complete in 3 hours (24 hours/8 GPUs). The actual 4 hours represents 75 percent efficiency.

Step 3: Investigate the efficiency loss. The two elapsed times establish the "missing" 25 percent, but do not attribute it. Table 12.11 lists illustrative contributions and profiling signals for gradient synchronization, memory copy, load imbalance, and batch-size effects. Strong-scaling comparisons hold total work fixed; time-to-quality comparisons must also account for any change in steps to convergence.

In multi-accelerator data-parallel training (such as 2, 4, or 8 GPUs connected over PCIe or NVLink within a host), each accelerator computes gradients on its own local slice of the minibatch, and the AllReduce collective of section 8.7.1.1 must sum them so every worker receives the identical global gradient average before the next step. Gradient tensors have one entry per trained parameter, but their byte payload equals weight storage only when their representations match. Moving them across interconnects adds communication whose cost depends on topology, the collective algorithm, and overlap. With fixed total work and ideal partitioning, compute time per step shrinks ($T_{\text{compute}} \propto 1/N_{\text{GPU}}$), while communication may shrink more slowly or grow. Exposed synchronization then occupies a larger fraction of the step; traces determine how much of the observed scaling loss it explains.

Table 12.11: Scaling Efficiency Loss Sources: Illustrative decomposition of the missing efficiency budget into measurable overhead categories and the corresponding measurement signal used to attribute each loss. Actual percentages depend on model, interconnect, storage, batch schedule, and framework implementation.

Source	Example Contribution	Measurement
Gradient synchronization	10–15%	AllReduce time per step
Memory copy (CPU↔GPU)	3–5%	Data transfer profiling
Load imbalance	2–5%	Per-GPU step time variance
Batch size effects	2–5%	Larger batches converge differently

Step 4: The systems insight. Scaling efficiency can decrease as N_{GPU} grows when exposed communication and other overheads fail to shrink with per-GPU compute. In this worked example, eight GPUs reach 75 percent efficiency; at larger scales, the same arithmetic makes clear why sophisticated communication and input-pipeline optimization become necessary.

MLPerf reports raw performance, while scaling efficiency can be calculated across matched submissions: a system achieving 2× throughput at 50 percent efficiency may be worse than 1.5× throughput at 90 percent efficiency, depending on cost constraints.

Parallelism strategies (data, model, and pipeline parallelism) and the synchronization each requires are developed in section 8.7.1.1; within one machine of two to eight accelerators, data parallelism is the common case. A benchmark's job is narrower: to report how much of the added capacity a configuration converts into speedup without degrading convergence. That conversion is **scaling efficiency**. While strong scaling evaluates whether adding processors reduces training time on a fixed total workload, **weak scaling** scales the problem size proportionally with processor count to

↩ The AllReduce collective that averages gradients across data-parallel workers is established in section 8.7.1.1.

keep the per-device workload constant, measuring whether the system can train larger models or ingest larger datasets within a fixed time budget without communication bottlenecks dominating.

12.5.2.3 Resource utilization

Training efficiency depends on learning speed, cluster scalability, and how effectively the hardware resources are used. Compute utilization requires an explicit numerator. Model FLOPs utilization (MFU), the metric of definition 8.3, compares the useful model operation rate with the matching hardware peak; activity counters instead report whether units are busy. MFU contrasts with hardware FLOPs utilization (HFU), which counts all executed operations including activation recomputation; recomputation adds executed FLOPs without adding useful model FLOPs for the same step. Comparing them separates useful model work from work expended to relieve memory capacity limits. Low utilization may indicate bottlenecks in data movement, memory access, or inefficient workload scheduling.

For instance, when training ResNet-50, decoding and augmenting thousands of JPEG images per second on the host can limit throughput even when the accelerators have compute to spare, the crossing from compute-bound to input-bound that section 8.4.2 traces. If storage retrieval or preprocessing cannot keep up, the accelerators wait. Profiling resource utilization identifies the bottleneck, and optimizations such as prefetching, caching, and more parallel input processing can improve sustained performance.

Memory bandwidth is another limiting factor, as deep learning models require frequent access to large volumes of data during training. If memory bandwidth saturates, increasing compute power alone will not improve training speed. Benchmarks assess how well models use available memory, ensuring that data transfer rates between storage, main memory, and processing units do not become performance bottlenecks.

I/O performance also plays a direct role in training efficiency, particularly when working with large datasets that cannot fit entirely in memory. Benchmarks evaluate the efficiency of data loading pipelines, including preprocessing operations, caching mechanisms, and storage retrieval speeds. Systems that fail to optimize data loading can experience large slowdowns, regardless of computational power.

12.5.2.4 Energy efficiency and cost

Training GPT-3 was estimated to consume 1,287 MWh of electricity (Patterson et al. 2021). At that scale, energy efficiency metrics quantify the power usage of training workloads so teams can identify systems that reach target accuracy without wasted energy. Fewer iterations reduce energy only when their total energy cost is lower; a more expensive step can offset the reduced count, so suites such as MLPerf Training measure total energy over the complete run to the same quality target. The same power accounting governs inference, where precision is one potential energy lever; section 12.7 works through why INT8 quantization cuts per-inference energy by attacking both memory traffic and arithmetic cost.

Cost considerations extend beyond electricity usage to include hardware expenses, cloud computing costs, and infrastructure maintenance. Training benchmarks provide insights into the cost-effectiveness of different hardware and software configurations by measuring training time in relation to resource expenditure. Organizations can use these benchmarks to balance performance and budget constraints when selecting training infrastructure.

12.5.2.5 Fault tolerance and robustness

Training workloads often run for extended periods, sometimes spanning days or weeks, making fault tolerance an essential consideration. A resilient system must handle unexpected failures (hardware malfunctions, network disruptions, and memory errors) without compromising accuracy convergence.

Production systems checkpoint for fault tolerance, periodically saving progress so a failure does not restart the run. On a single host, a benchmark records the save interval, the state written, and the pause each save exposes to training. Model weights and optimizer states consume storage bandwidth, and any pause extends wall-clock time to the quality target. Asynchronous saving can overlap I/O with computation, but its staging buffers and competing storage traffic remain part

of the measured workload. Cluster recovery and parallel file systems extend this problem beyond the local machine; the local benchmarking lesson is to include the intended saving behavior in sustained performance measurements. MLPerf Training primarily measures time-to-quality under standardized workloads and does not benchmark failure recovery directly.

Training runs are also where reproducibility is hardest, because stochastic processes interact with hardware-specific behavior over many hours. What a training report must preserve to make its result reproducible, the full run envelope rather than the random seed alone, is collected with the other statistical controls in section 12.8.2.

12.5.3 Training performance evaluation

A comprehensive training benchmark considers multiple dimensions of system behavior because each dimension identifies a different way hardware investment can fail to become convergence. Table 12.12 summarizes the core categories and associated metrics commonly used to benchmark system-level training performance, providing a framework for understanding how training systems behave under different workloads and configurations.

Table 12.12: Training Benchmark Dimensions: Key categories and metrics for evaluating machine learning training systems beyond simple speed, covering resource efficiency, reproducibility, and overall performance trade-offs across different training approaches and infrastructure configurations.

Category	Key Metrics	Example Benchmark Use
Training Time and Throughput	Time-to-accuracy (seconds, minutes, hours); Throughput (samples/sec)	Comparing training speed across different GPU architectures
Scalability and Parallelism	Scaling efficiency (percent of ideal speedup); Communication overhead (latency, bandwidth)	Analyzing distributed training performance for large models
Resource Utilization	Compute utilization (percent GPU/TPU usage); Memory bandwidth (GB/s); I/O efficiency (data loading speed)	Optimizing data pipelines to improve GPU utilization
Energy Efficiency and Cost	Energy consumption per run (MWh, kWh); Training throughput per watt (FLOP/s/W)	Evaluating energy-efficient training strategies
Fault Tolerance and Robustness	Checkpoint overhead (time per save); Recovery success rate (percent)	Assessing failure recovery in cloud-based training systems
Reproducibility and Standardization	Variance across runs (percent difference in accuracy, training time); Framework consistency (TensorFlow vs. PyTorch vs. JAX)	Ensuring consistency in benchmark results across hardware

The scaling notebook supplies a concrete interpretation of table 12.12. The measured completion times establish a speedup and a resource-efficiency cost, but they do not identify which overhead caused the difference. A procurement decision therefore uses the time-to-quality result first, then the utilization and communication measurements to decide whether additional hardware or a different execution configuration would address the limiting resource.

Across matched runs, GPU boost-clock[18] behavior and thermal state must follow the same protocol; otherwise a short fast run can be mistaken for a durable improvement. The repeated-run controls in section 12.8.1 determine whether the difference exceeds experimental uncertainty.

In the worked case, 8 GPUs reach 75 percent scaling efficiency. If the required quality target and completion deadline are met, the configuration clears the time constraint, but the remaining scaling overhead still matters for cost. If the deadline is missed, the efficiency ratio alone does not justify buying more accelerators. The next experiment must measure exposed synchronization, input stalls, and per-device work under the intended batch and checkpoint schedule before choosing an intervention. If convergence changes between configurations, compare complete time-to-quality runs rather than interpreting the difference as pure strong-scaling loss.

A training report can therefore support a configuration choice without claiming that every measured overhead has already been explained. Its acceptance gates concern learning; an efficiently trained model still needs separate evidence that it can serve requests under deployment constraints.

[18] **GPU boost clock**: Dynamic frequency scaling raises clocks above base when thermal and power headroom permit. Short benchmark runs can capture this burst performance, while sustained training may settle to a different operating point. The benchmark must document the measured thermal state and clock policy.

Checkpoint 12.3: Measuring a training claim

The first half of the chapter built the measurement and applied it to training. Before moving to deployment, you should be able to:

- ☐ Restate "ResNet-50 at INT8 is faster" as a benchmark by naming its input boundary, output, quality floor, and timing statistic.
- ☐ Explain why a 3× model-stage speedup inside a 50 ms request yields only about 1.2× end to end, and name the granularity that exposes it.
- ☐ Use the roofline ceiling and the measured MLPerf throughput for ResNet-50 on one accelerator to compute its utilization, and name two candidate causes of the gap.
- ☐ Explain what MLPerf's closed division holds fixed and what its open division compares instead.
- ☐ Compute strong-scaling efficiency for a run that takes 24 hours on one accelerator and 4 hours on eight, and explain why the two elapsed times alone do not attribute the loss.

12.6 Inference Benchmarks

A camera trap running MobileNetV2 on an edge board must classify each frame within a 33-millisecond deadline to keep up with a 30-frame-per-second video stream. If an unbenchmarked garbage collection pause, dynamic batching timeout, or kernel launch hiccup stretches the p99 latency well past that deadline, frames are dropped, and an animal that crosses the field of view in under a second may go unrecorded, no matter how high the board's average throughput. An autonomous vehicle's perception loop runs against the same deadline arithmetic with far higher stakes. Training benchmarks measure how quickly a system learns; inference benchmarks measure how reliably it serves under real-world operational constraints. The two regimes differ in what they tolerate: training tolerates variable iteration times as long as gradient descent converges, but inference enforces service-level objectives where every delayed prediction compromises the application.

Inference is also where the optimization chapters converge, because the accelerated hardware runs the compressed models to deliver real-time predictions. Inference benchmarks reveal whether those theoretical speedups become actual latency reductions under realistic deployment conditions. Their central quantity is end-to-end request latency $L_{\text{lat,total}}$, the full time from a request's arrival to its response, including queueing, preprocessing, model execution, and postprocessing. It is distinct from the iron law's latency term L_{lat}, which counts only the fixed overhead (orchestration, serialization, dispatch) that one execution pays regardless of how much data it moves or arithmetic it performs; queueing delay, which grows with load, belongs to $L_{\text{lat,total}}$ but not to L_{lat}.

Definition 12.4: ML inference benchmarks

ML inference benchmarks are machine learning system benchmarks that quantify a system's ability to meet latency constraints ($L_{\text{lat,total}}$) at specified throughput levels, measuring scenario-defined latency statistics, throughput (queries per second), and power efficiency across representative serving scenarios.

1. **Significance**: Inference benchmarks expose the workload- and system-specific gap between unconstrained throughput and throughput while meeting a service-level objective (SLO), such as a p99 latency target. Queuing delays push tail latency above the target at high load, and only a benchmark that enforces the target at each throughput level shows it.
2. **Distinction**: Unlike training benchmarks, which measure time-to-accuracy over a fixed dataset, inference benchmarks measure per-query response time under realistic load patterns, capturing queuing effects, batching trade-offs, and cold-start overhead that determine real-world serving economics.

3. **Common pitfall**: A frequent misconception is that average latency is a sufficient benchmark. A low mean can coexist with a long p99 tail, and at high request rates the slowest 1 percent becomes a large number of affected users. The benchmark must report the statistic the service objective names.

12.6.1 Inference benchmark motivation

Large-scale benchmark training commonly runs on dedicated data center hardware, whereas inference spans dramatically different deployment scenarios, from real-time applications like autonomous driving and conversational AI to mobile devices, IoT systems, and embedded processors. This diversity extends to hardware: while GPUs and TPUs dominate large-scale training, inference workloads often use specialized accelerators like NPUs, field-programmable gate arrays, and dedicated inference chips such as Google's Edge TPU.[19] Inference benchmarks evaluate how well hardware selection, model optimization, and data pipeline design work together across these deployment environments.

Deployment differences of this breadth motivate inference benchmarks, which evaluate the bottlenecks that emerge when models transition from development to production serving. The motivating factors parallel those for training (hardware optimization, scalability, cost, fair comparison) but differ in specifics. Software optimization frameworks apply inference-specific techniques such as kernel fusion, precision calibration, and kernel tuning, whose impact on latency, throughput, and power efficiency must be measured under realistic conditions to confirm they deliver real improvements without degrading accuracy. Auto-tuning compilers add a hidden variable: the compiler itself can require hours of optimization per model-hardware pair, meaning benchmark results reflect the tuning budget as much as the hardware capability, and comparing results across submissions requires normalizing for compiler optimization time.

Scalability concerns also shift character. Training scales by adding GPUs to reduce time-to-accuracy on a fixed workload, whereas inference must scale dynamically in response to fluctuating user demand, handling traffic spikes without violating latency guarantees. Applications that load models on demand, such as serverless deployments, also expose the model's loading time, its cold start, directly to users.

The cost and energy profile of inference differs sharply from training. Training concentrates cost in discrete runs that may recur as data, objectives, or models change; inference cost accumulates continuously with production traffic. Running an inefficient model at scale can multiply cloud compute expenses, and on battery-powered devices, excessive computation directly affects usability. Benchmarks that measure cost per inference request and efficiency per watt help organizations optimize for both performance and sustainability across deployment platforms.

MLPerf Inference extends the standardized comparison principles established for training benchmarks to deployment scenarios, defining evaluation criteria for tasks such as image classification, object detection, and speech recognition across different hardware platforms, so that inference comparisons remain reproducible under deployment constraints such as latency requirements and energy efficiency (Reddi et al. 2019).

12.6.2 Inference metrics

A camera trap must classify each frame before the next one arrives, a voice assistant must respond quickly enough that users do not perceive lag, and a recommendation engine must score enough candidates to keep pace with user scrolling. These constraints (latency and throughput) define the performance envelope within which all serving optimizations must operate. Inference metrics formalize these real-world demands into measurable quantities, and they differ from training metrics in kind, not just degree, because the optimization target shifts from convergence rate during training to latency predictability during serving. Training optimizes for throughput and time-to-accuracy; inference optimizes for latency consistency, resource efficiency, and service-level predictability, spanning cloud data centers handling millions of requests to edge devices operating under strict power constraints.

[19] **Edge TPU (tensor processing unit)**: Google's fixed-function edge AI accelerator. It illustrates a benchmarking constraint specific to fixed-function accelerators: its headline throughput applies only to quantized TensorFlow Lite models with supported operator types, so models requiring unsupported operators fall back to the host CPU or need graph rewrites before the accelerator result is meaningful.

12.6.2.1 Latency and tail latency

An inference service that averages 10 ms per request can still time out for thousands of users every hour if queueing bursts or garbage-collection pauses push the slowest 1 percent of requests past its deadline. Latency measures the time for an inference system to process an input and produce a prediction, and because averages conceal those high-percentile delays, benchmarks also report tail latency[20]—commonly the 95th percentile (p95) or 99th percentile (p99), the time within which 95 percent or 99 percent of inferences complete. Applications with hard deadlines require explicit deadline-miss or worst-case analysis beyond these percentiles. These measurements form the basis for SLOs and SLAs, which formalize performance expectations.

[20] **Tail latency**: A high-percentile response time, such as p95 or p99, determines production SLO or SLA compliance only when that objective or agreement specifies the percentile. Dean and Barroso (2013) showed that in fan-out architectures (common in recommendation systems), even 1 percent slow responses compound: a request touching 100 backend shards has about a 63 percent chance that at least one shard hits its 1 percent tail. Benchmarks reporting only mean latency hide this failure mode.

> **Definition 12.5: SLOs and SLAs**
>
> ***SLOs and SLAs*** are performance commitment specifications for production ML serving systems: a service-level objective (SLO) is a target value or range for a service-level indicator, while an SLA is a contract that specifies service objectives and the consequences of failing to meet them.
>
> 1. **Significance**: A latency SLO bounds end-to-end request latency $L_{\text{lat,total}}$ by setting a target for a specified latency indicator, and the iron law's L_{lat} is only the fixed-overhead part of that budget. Request queueing and transient spikes consume part of that budget.
> 2. **Distinction**: An SLO has no contractual consequence by itself, while missing an SLA objective triggers the consequences specified in the agreement, which may include credits or penalties. Teams commonly set the internal SLO tighter than the external agreement to leave operational headroom, though the definition does not require it.
> 3. **Common pitfall**: A frequent misconception is that meeting average latency satisfies a tail-latency SLO. SLOs can use averages, percentiles, rates, or other indicators; when the objective is defined at p99 or p99.9, an excellent mean does not establish compliance.

Engineering teams optimize toward SLOs while the business commits to SLAs. A usable latency objective also fixes the request population, the offered load, and the measurement window. Otherwise, two teams can report the same percentile threshold over different traffic mixes and reach incompatible conclusions about compliance.

> **Checkpoint 12.4: Metric selection**
>
> The metric shapes the optimization.
>
> Apply three rules before finalizing metric selection:
>
> - ☐ Throughput vs. latency: Name the objective to optimize and the quality, latency, and cost limits the benchmark must preserve.
> - ☐ Tail latency: State what p99 exposes that mean latency hides.
> - ☐ End-to-end: List the preprocessing, model execution, and postprocessing stages included in the reported latency.

At production scale, small p99 degradations affect many users. If 1 percent of requests take 10× longer (for example, 1000 ms instead of 100 ms), 10,000 requests per million are slow enough to risk timeouts and customer churn. Search engines and recommendation systems demonstrate this sensitivity: Google's search-latency experiments found measurable reductions in daily searches per user after 100–400 ms server-side delays (Brutlag 2009), which is why interactive services often treat sub-100 ms response times as a practical design target. Because occasional slow responses weigh heavily on user satisfaction, such services define percentile-based objectives, and large-scale systems may track deeper tails such as p99.9.

The challenge of meeting these tail latency targets is that the source of the tail is often architectural, not algorithmic. A garbage-collected runtime, a shared kernel driver, or a priority-inversion bug in the serving stack can inject latency spikes that no model optimization will remove.

↪ Provisioning serving capacity so that p99 latency meets its SLO under peak load is developed in section 13.4.3.

Discord's Read States service shows the effect outside machine learning. Periodic garbage-collection pauses in its Go implementation spiked p99 latency every two minutes until a rewrite in Rust removed the pauses (Howarth 2020). A managed runtime in a feature store or retrieval path can impose the same floor on an ML service's tail, and no model optimization removes it, which is why the complete serving stack belongs inside a production latency benchmark. Section 13.4.3 develops the mechanisms that shape the tail under load.

12.6.2.2 Token latency: TTFT and TPOT

Generative models are served one token at a time, so their latency splits into two measured quantities. **Time to first token (TTFT)** is the interval from a request's arrival to its first output token, dominated by prefill, the pass that processes the whole prompt in parallel. **Time per output token (TPOT)** is the mean interval between subsequent tokens, set by autoregressive decode. The gap between any two successive tokens is the **inter-token latency (ITL)**, so TPOT is the average of a request's ITLs, and the ITL distribution exposes the individual stalls that the average hides. A benchmark that reports a single aggregate throughput hides both: a model can achieve high throughput in tokens per second while still feeling sluggish if the first token arrives late, or it can minimize TTFT while generating subsequent text too slowly for interactive reading.

Token throughput translates these generation rates into user-perceived wall-clock time: for a response of 750 tokens, a generation rate of 25 tokens/s requires 30 seconds, whereas 100 tokens/s finishes in 7.5 seconds. Time-to-first-token and inter-token latency must therefore be reported together: one captures initial responsiveness, and the other captures sustained delivery speed. This latency split reflects contrasting computational regimes: time-to-first-token is governed by prompt prefill, which processes tokens in parallel and is typically compute-bound, whereas inter-token latency is governed by autoregressive decoding, where low-batch execution often streams weights and accesses a growing KV cache with limited reuse. The resulting bandwidth pressure depends on model residency, context length, batch size, and the execution path. Section 13.9.1 builds serving policies on these two measurements; the benchmarking requirement is that both are reported, under the same offered load, for every generative workload.

12.6.2.3 Throughput and resource metrics

Latency is only half of the serving envelope. Throughput counts how many inference requests a system completes per second, typically expressed as queries per second (QPS) or frames per second (FPS), and it is meaningful only together with the latency at which it was measured. Batching raises throughput by processing several inputs at once while adding wait time to each, so a throughput figure reported without its latency percentile and offered load says nothing about whether a serving deadline is met. A benchmark therefore reports **batch throughput** and per-request latency as a pair at the same offered load. Choosing the batch size that balances them is a serving policy (section 13.5.2); the benchmark's job is to measure both sides of that trade.

Speed alone is insufficient because inference optimizations can change model behavior. Reducing numerical precision can accelerate computation while cutting memory and energy, as the simplified MobileNetV2 energy estimate worked out in the power section shows (section 12.7.1), but lower-precision calculations can introduce accuracy degradation. Inference benchmarks therefore evaluate how well models perform under different numerical settings, such as FP32, FP16, and INT8.[21] Model compression techniques[22] further improve efficiency, but their impact on model accuracy varies depending on the task and dataset. Benchmarks help determine whether these optimizations are viable for deployment, ensuring that improvements in efficiency do not come at the cost of unacceptable accuracy loss.

Beyond speed and accuracy, table 12.15 lists the resource terms an inference benchmark must also report, and each exists because a system can pass the latency test and still fail to deploy. Memory footprint decides whether the model fits the device's budget at all, since inference rarely spans accelerators the way training can. Cold-start performance, the load time plus first-request latency,[23] exposes initialization cost to the requesting user. It dominates in serverless AI environments[24] and on devices that evict models to free memory. When provisioning, model transfer, runtime initialization, and the first response lie on the user request path, the benchmark must include them; a warm-instance result answers a different question. Scalability records whether added accelerators

[21] **INT8 (8-bit integer)**: INT8 sits at the aggressive end of the precision hierarchy (FP32 baseline, FP16 halves raw weight storage, INT8 quarters it), and each step demands increasing care to preserve accuracy. Post-training INT8 quantization normally fits its value ranges on a representative calibration dataset (quantization-range calibration, distinct from the confidence calibration of section 12.9.1.2); accuracy depends on the model, operator coverage, quantization method, and how well the calibration data represent deployment inputs. INT8 benchmarks must specify whether they use post-training quantization or quantization-aware training and document any range-calibration procedure.

[22] **Model compression benchmarking**: Compression impact must be measured across four dimensions simultaneously: accuracy degradation, inference speedup, memory reduction, and energy savings. A technique achieving 10× size reduction with 1 percent accuracy loss may still be unsuitable if latency misses the deployment target; unstructured pruning, for example, leaves dense execution unchanged unless a compatible sparse representation and kernel exploit the zeros.

[23] **Cold-start latency**: The initialization time from idle state includes storage reads, host-to-accelerator transfer, and framework setup. For a 7B-parameter model in FP16 (~14 GB) already resident in host memory, PCIe 4.0 transfer at 25 GB/s effective bandwidth alone takes ~560 ms; storage and initialization add to it. This lower bound makes cold-start mitigation (model caching, speculative loading) a systems design requirement.

or concurrent models raise throughput or collide on memory bandwidth, and energy per inference (joules per inference, or QPS/W in the cloud) sets battery life on mobile devices and operating cost in data centers.

12.6.3 MLPerf inference benchmarks

MLPerf Inference turns that balance among latency, throughput, memory, energy, and accuracy into scored scenarios, and it matters because deployment context changes what a result means. The benchmark, developed by MLCommons,[25] provides a standardized framework for evaluating machine learning inference performance across a range of deployment environments. MLPerf began with training benchmarks in 2018; MLPerf Inference was added later to standardize deployment-time evaluation across scenarios. The family of MLPerf inference benchmarks maps each benchmark to a deployment setting, so a score can be interpreted against the latency, throughput, memory, and power constraints the system will face.

12.6.3.1 MLPerf Inference

MLPerf Inference (Reddi et al. 2019) is the baseline inference benchmark, defining standardized scenarios for deployment-time evaluation across data-center and edge settings. Submissions follow the closed and open divisions defined in section 12.4.4. Its workloads span image classification, object detection, natural language processing, and recommendation, and its results are a common reference point for comparing accelerators and CPUs when the submission rules and scenario match the intended deployment. On recommendation workloads, scores on DLRM[26] can inform choices between accelerator generations, although the size of the gain depends on workload, software stack, and system configuration. At the same time, the cost of comprehensive benchmarking limits who can participate and how thoroughly systems are evaluated.

> **Systems Perspective 12.6: The cost of comprehensive benchmarking**
>
> Submitting to MLPerf can require dedicated engineering effort, hardware access, tuning, validation, and careful documentation across the relevant configurations. The cost depends heavily on workload and scope, but it is high enough that submissions are dominated by major technology companies and hardware vendors, while smaller organizations rely on published results rather than conducting their own comprehensive evaluations. That barrier motivates the need for more lightweight, internal benchmarking practices that organizations can use to make informed decisions without the expense of full-scale standardized benchmarking.

The rest of the MLPerf inference family narrows that baseline by deployment context. MLPerf Mobile (MLCommons 2024a) evaluates whether a model stays responsive within smartphone power and memory limits (Janapa Reddi et al. 2022). MLPerf Client (MLCommons 2026b) asks whether consumer devices can run local generative-AI workloads, which makes CPUs, discrete GPUs, and integrated NPUs part of the benchmarked system. MLPerf Tiny (C. Banbury, Reddi, Torelli, Holleman, Jeffries, Kiraly, et al. 2021) covers embedded and ultra-low-power systems, such as IoT devices, wearables, and microcontrollers. Each variant keeps the same benchmark discipline while changing the binding resource.

12.6.4 Mobile and edge benchmarks

Unlike data centers with kilowatt-scale power delivery and active cooling infrastructure, mobile and edge deployments operate within strict milliwatt- to watt-scale power envelopes and passive thermal dissipation limits. Benchmarking these systems means reporting power consumption, inference latency, and model accuracy together, because gains in one usually come at the expense of another. Table 12.13 contrasts these operational constraints against cloud environments.

[24] **Serverless AI**: Deployment paradigm where models scale from zero instances on demand. Cold-start time varies with the model, runtime, storage path, hardware allocation, and provider. Benchmarks for intermittent workloads must report whether initialization and model loading are included, because warm-instance latency alone can understate user-perceived latency.

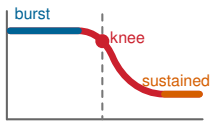
[25] **MLCommons**: Launched in 2020 as a nonprofit consortium evolving from the 2018 MLPerf effort, MLCommons includes members across industry and academia (MLCommons 2026a). Requiring published system specifications improves result comparability, but it does not prevent submitters from selecting which systems or workloads to enter. Published results reveal large performance differences between vendors on identical workloads, making MLCommons the closest the field has to SPEC-style like-for-like hardware comparison.

[26] **DLRM (deep learning recommendation model)**: Facebook's 2019 recommendation architecture combines embedding tables for categorical features with multilayer perceptrons for continuous features (Naumov et al. 2019). DLRM stresses benchmarks differently than vision or language models: its embedding tables can be large enough that memory capacity and bandwidth dominate compute throughput. That makes DLRM the book's capacity-bound workload in MLPerf-style inference evaluation, revealing hardware limitations invisible to compute-bound benchmarks (Reddi et al. 2019).

Table 12.13: Edge vs. Cloud Deployment Constraints: Typical cloud deployments treat power as an operating cost and latency as a service target, while edge deployments often face tighter energy and response-time limits that constrain achievable accuracy.

Constraint	Cloud Impact	Edge Impact
Power	Operational cost	Device energy budget
Latency	Service-level target	Local response deadline
Accuracy	Task-quality target	Balanced with power/latency

Consider a smartphone camera executing real-time object detection at 30 frames per second within a 3 W to 5 W thermal envelope. In this setting, an efficient architecture such as MobileNet serves as a realistic benchmark target where a larger ResNet model would violate thermal limits, despite the larger model's superior accuracy in cloud evaluations. An edge benchmark must therefore evaluate accuracy jointly with sustained power and thermal dissipation. The peak-versus-sustained gap (section 12.1) is especially acute at the edge, because a passively cooled device sheds heat poorly. As junction temperatures rise, the dynamic thermal management (DTM) controller scales down operating voltage and clock frequency, causing sustained throughput to drop sharply below burst-mode peaks. That thermal mechanism makes the cooling configuration part of the benchmark specification.



Example 12.2: Benchmarking the edge

Scenario: An edge engineering team benchmarks a candidate chip for the camera trap's board with a vendor-advertised "1 W AI" power specification.

Diagnosis: Early burst-mode testing matches vendor claims, but continuous inference loop execution builds up junction heat, triggering thermal throttling and dropping steady-state throughput.

Systems lesson: Short burst benchmarks obscure long-term thermal throttling. Benchmarking edge ML workloads requires continuous, sustained execution testing to reflect true operational hardware limits.

Throttling is the most visible way a short measurement flatters edge hardware. Idle power, duty cycle, and the data movement around the accelerator can distort a headline number too, so each needs checking before a vendor claim informs a design decision.

Burst benchmark FPS collapses once thermal throttling sets in.

Systems Perspective 12.7: Edge benchmark reality check

When evaluating edge hardware claims, four factors determine whether vendor numbers translate to real-world performance:

1. **Peak vs. sustained**: A vendor may advertise 45 TOPS peak throughput while a sustained thermal run delivers closer to 20 TOPS. In this scenario, use a sustained run longer than 30 s and verify thermal stabilization; also test the deployment duty cycle.
2. **Power at idle vs. active**: In this scenario, a device consuming 50 mW idle and 2 W active could report active draw for marketing, but if the application runs inference 1 percent of the time, effective power draw is ~69.5 mW, not 2 W.
3. **Thermal envelope**: Edge devices often operate inside a narrow TDP envelope. Exceeding it triggers throttling, so benchmark reports omitting thermal conditions are incomplete.
4. **End-to-end vs. accelerator-only**: NPU benchmarks often exclude data transfer overhead. Moving image data from camera to NPU and back can exceed inference time for small models.

A modern mobile SoC packages CPUs, GPUs, digital signal processors (DSPs), and neural processing units (NPUs) on one die that shares system memory and a common thermal budget, so an edge benchmark must measure the pipeline across those engines rather than one engine's kernel

throughput. Single-engine benchmarks miss three costs that fall between the engines: waking an accelerator from a deep sleep state, contention when several engines access shared DRAM, and converting tensor layouts between the formats different engines require. Section 11.10 develops how these SoCs partition work.

12.6.5 Building the edge-board benchmark

The camera trap's board is the case for the inference measurements above. It pairs a low-power host CPU with an attached INT8 accelerator, and the claim inherited from the compression and acceleration chapters is that INT8 MobileNetV2 on the accelerator meets the camera's frame deadline at a fraction of the host's energy. The benchmark is built in the order a careful engineer would follow: precision on the host first, then the accelerator, then the gates that decide whether the result can ship. The labeled composite values below are illustrative, not measurements of a named product.

Example 12.3: Benchmarking a vision model for edge deployment

Scenario: An edge AI team evaluates MobileNetV2 on the camera trap's host CPU, first at FP32 and then at INT8, under strict latency and model size limits (Sandler et al. 2018).

Diagnosis: FP32 execution yields 50 ms latency (20 FPS) and 14 MB size. INT8 quantization speeds up inference by 3.3× to 15 ms (66.7 FPS) and reduces model size by 4×, at a cost of 0.9 percentage points Top-1 accuracy.

Systems lesson: Edge model benchmarking requires evaluating multi-dimensional trade-offs across latency, accuracy, and memory payload. Quantization enables high-throughput edge execution when modest accuracy drops meet product requirements.

Lighthouse 12.2: MobileNetV2 on the edge accelerator

Extending lighthouse 12.1, the hardware-acceleration claim is evaluated using an illustrative SingleStream-style edge-inference scenario (Reddi et al. 2019; C. Banbury, Reddi, Torelli, Holleman, Jeffries, Kiraly, et al. 2021).

Hardware acceleration claim: In this illustrative edge-accelerator scenario, assume INT8 MobileNetV2 inference takes ~2 ms on the accelerator, approximately 7.5× faster than the same board's low-power host CPU (~15 ms). The host CPU column is the INT8 host result of example 12.3, so both measurements describe the same board. Actual results depend on operator coverage, clock frequency, thermal state, and implementation.

Table 12.14 reports the illustrative SingleStream-style scenario assumptions across distinct measurement scopes.

Table 12.14: Edge Accelerator vs. Host CPU MobileNetV2 Scenario: Illustrative SingleStream-style latency, power, and energy values show how measurement boundaries alter comparative ratios. While end-to-end latency captures host preprocessing and link transfer overhead, the power and energy rows reflect active component execution alone rather than whole-system draw; these are illustrative values rather than controlled laboratory measurements.

Metric	Measurement Scope	Host CPU	Accelerator	Comparative Ratio
Inference latency	Isolated model compute	~15 ms	~2 ms	7.5× faster (isolated headline)
End-to-end latency	Full request path (prep + link + exec)	~18 ms	~6 ms	~3× faster (system-level)
Active power	Component during inference execution	~120 mW	~500 mW	~4.2× higher (component active)
Active energy per inference	Component active energy ($P \times t_{\text{inference}}$)	~1.8 mJ	~1 mJ	~1.8× more efficient (component active)

What this reveals: Under these assumptions, the 7.5× inference speedup narrows to ~3× end to end because preprocessing runs on the host CPU in both cases (figure 12.6). The accelerator path incurs additional latency copying each input across the host-accelerator link and retrieving the result, a transfer overhead the CPU-only path never pays.

Furthermore, the 1.8× energy advantage applies specifically to the active inference interval ($P \times t_{\text{inference}}$), measuring component-level efficiency rather than total system consumption. This metric excludes host CPU preprocessing energy, interconnect transmission power, and baseline idle draw during non-inference phases. Because end-to-end latency improves by only 3×, host baseline power consumed during these non-accelerated phases narrows the whole-system battery efficiency gain.

Workload arrival patterns determine whether component-level energy efficiency translates to extended battery life. For intermittent duty cycles, the lower active inference energy favors the accelerator, but total battery drain depends on sleep power, wake-up latency and energy overhead, host transfer costs, and any standby leakage the accelerator draws while awaiting work. For continuous streaming workloads such as video analytics, the accelerator's lower active energy per inference dominates cumulative energy consumption.

The SingleStream result illustrates why benchmarking requires matching the MLPerf scenario to the deployment context: SingleStream emphasizes latency, while Offline benchmarks would optimize for bulk throughput rather than latency bounds.

The board's INT8 results support further evaluation, but they do not establish that the camera trap's service objective has been met. The decision requires the request population, latency statistic, quality floor, and memory and energy budgets to be specified together.

Table 12.15 identifies the remaining evidence. A camera pipeline needs sustained completion times under its input cadence; an intermittent application also needs initialization and sleep-state costs. For either application, the candidate must retain the required model quality on representative inputs. The same model-level speedup can therefore support one deployment and fail another.

Table 12.15: Inference Performance Metrics: Latency, throughput, and resource usage metrics provide a quantitative basis for optimizing deployed machine learning systems and selecting appropriate hardware configurations, balancing speed, cost, and accuracy in production applications.

Category	Key Metrics	Example Benchmark Use
Latency and Tail Latency	Mean latency (ms/request); Tail latency (p95, p99, p99.9)	Evaluating interactive and soft real-time performance
Throughput and Efficiency	Queries per second (QPS); Frames per second (FPS); Batch throughput	Comparing large-scale cloud inference systems
Numerical Precision Impact	Accuracy degradation (FP32 vs. INT8); Speedup from reduced precision	Balancing accuracy vs. efficiency in optimized inference
Memory Footprint	Model size (MB/GB); RAM usage (MB); Memory bandwidth utilization	Assessing feasibility for edge and mobile deployments

Category	Key Metrics	Example Benchmark Use
Cold-Start and Load Time	Model load time (s); First inference latency (s)	Evaluating responsiveness in serverless AI
Scalability	Efficiency under load; Multi-model serving performance	Measuring robustness for dynamic, high-demand systems
Power and Energy Efficiency	Power consumption (W); Performance per W (QPS/W)	Optimizing energy use for mobile and sustainable AI

The acceptance decision can reject a candidate on any binding constraint. A lower model-only latency does not establish an end-to-end gain if preprocessing dominates, and a smaller weight file does not establish that runtime buffers fit the device. The latency decomposition and Amdahl calculation in section 12.3.4 specify which additional measurements the MobileNetV2 comparison needs.

Because physical constraints differ across environments, no single metric ordering governs all systems. Benchmarking requires establishing a priority hierarchy derived directly from the deployment specification. Table 12.16 illustrates how metric priorities shift across five operational contexts, mapping hardware and operational constraints to optimization targets.

Table 12.16: Illustrative Performance Metric Priorities by Deployment Context: A sample priority ordering shows how operational constraints can change benchmark selection and result interpretation; actual thresholds must come from the deployment specification.

Deployment Context	Primary Priority	Secondary Priority	Tertiary Priority	Key Design Constraint
Real-Time Applications	Latency	Reliability	Memory Footprint	User experience demands immediate response
Cloud-Scale Services	Throughput (QPS)	Cost Efficiency	Average Latency	Business viability requires massive scale
Edge/Mobile Devices	Power Consumption	Memory Footprint	Latency	Battery life and resource limits dominate
Training Workloads	Training Time	GPU Utilization	Memory Efficiency	Research velocity enables faster experimentation
Scientific/Medical	Accuracy	Reliability	Explainability	Correctness cannot be compromised for performance

A metric that dictates architectural success in one deployment context may be irrelevant in another. Latency ranks first for autonomous robotics, where sensor-processing pipelines must complete within strict execution deadlines to maintain vehicle stability, whereas cloud batch services accept higher queuing latency in exchange for lower operational cost per query. A 2× throughput gain represents substantial economic value in a hyperscale cloud cluster, but it provides little benefit on a battery-powered device such as the camera trap, where a 20 percent power reduction extends operational lifetime.

For the camera example, use the required deadline or percentile as the timing gate, the runtime peak allocation as the capacity gate, and the permitted quality loss as the model gate. If any gate lacks a measurement, the decision remains unresolved even when the reported inference speedup is large. A protocol should identify the missing evidence rather than treating the favorable metric as approval. An on-demand deployment adds a fourth gate, cold-start latency, measured on the user request path as section 12.6.2.3 specifies.

Beyond initialization delays, inference benchmarks become misleading when operational metrics are reported without functional validation. Numerical precision optimization introduces a significant comparability trap across accelerator platforms. Accelerators provide substantially higher INT8 operation throughput[27] than baseline FP32 floating-point rates, but these peak figures are meaningful only when the benchmark verifies accuracy retention under quantization noise, confirms hardware support across all model operators, and enforces equivalent operation definitions across architectures.

Once a candidate clears quality and capacity gates, varying offered load tests how far its timing result transfers. A runtime can sustain a favorable latency with one request in flight yet miss the

[27] **TOPS (tera operations per second)**: A measure of raw computational throughput (trillions of operations/second). The H100 delivers 1979 TOPS INT8 vs. the Apple M2 Neural Engine at 15.8 TOPS and Edge TPU at 4 TOPS, but these numbers conflate different operation types (multiply-accumulate, accumulate, or activation). TOPS comparisons across vendors are meaningful only when the operation definition, precision, and sparsity assumptions are identical, conditions rarely met in vendor specifications.

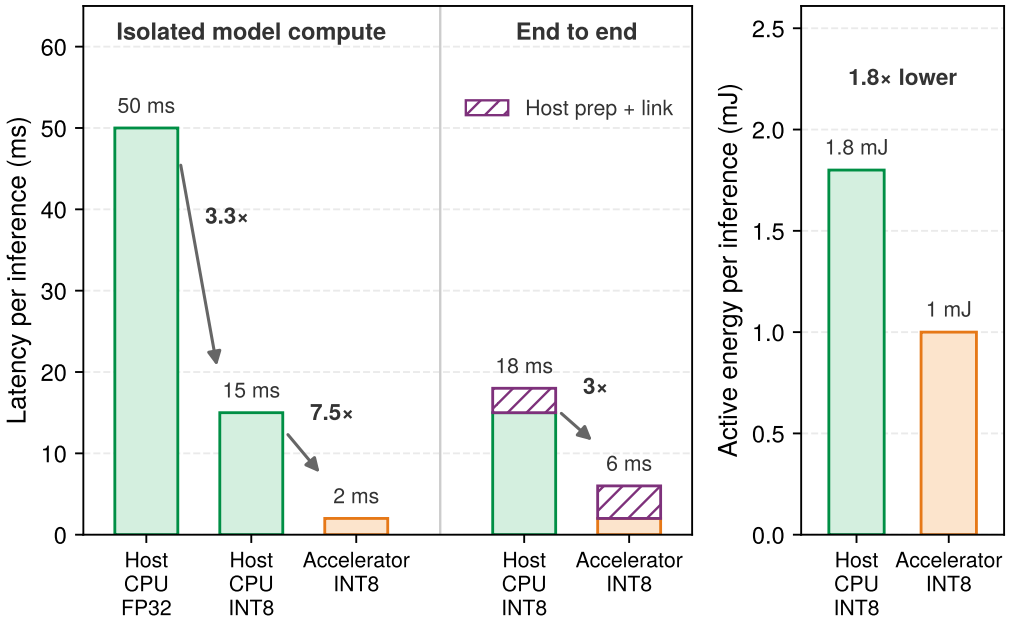


Figure 12.6: From Claimed to Delivered Speedup on the Edge Board: MobileNetV2 latency per inference (left) and active energy per inference (right) on the camera trap's board. INT8 cuts the host CPU's isolated latency by 3.3×, and the accelerator cuts it a further 7.5× when only model compute is timed. Widening the boundary to include host preprocessing and the host-accelerator link (hatched) leaves a 3× end-to-end advantage, and the active-energy advantage is 1.8× before idle and host power are counted. All values are the chapter's illustrative scenario, not measurements of a named product.

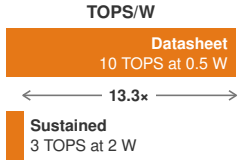

target when queues and shared memory fill. The relevant outcome is the supported load under the declared latency bound, measured with the same input mix and power policy, rather than an isolated peak throughput.

The board now has a latency, a throughput, and a memory footprint. What it lacks is the number that decides whether a battery-powered camera trap lasts a season in the field: the energy each frame costs.

12.7 Power and Energy Measurement

A chip vendor advertises "10 TOPS at 0.5 W," but under sustained inference load, thermal throttling drops actual throughput to 3 TOPS at 2 W—a 13.3× efficiency gap between the datasheet and reality that goes undetected until deployment unless power is measured under load. Energy is the one benchmark quantity that cannot be read off a clock: it must be integrated over a stated measurement boundary and window, and for a duty-cycled device it depends on how the device spends the time between inferences. KWS, the book's power-bound lighthouse, carries the measurement of energy, because a wake-word detector is judged by how long it listens on a battery rather than by how fast it answers; the edge board's frames and the data center's racks appear as contrasts.

This efficiency dimension matters directly because section 11.1 defines acceleration by its compute-density and performance-per-watt gains, making TOPS/W a primary design objective alongside raw TOPS. Power benchmarks validate whether efficiency-optimized accelerators deliver their promised energy savings. TOPS/W is particularly susceptible to gaming precisely because it is a ratio of two separately quotable peaks: a vendor can read the numerator (operations) at the batch size and precision that maximize throughput and the denominator (watts) at a near-idle operating point, so the advertised efficiency describes a state the chip never occupies under real load. Power benchmarks close that loophole by fixing the workload and the measurement window, forcing the numerator and denominator to be read at the same operating point.

Datasheet TOPS/W overstates sustained efficiency by 13.3×.

Measuring power differs from measuring execution time because power is not a single time-stamped interval: instantaneous power (supply voltage times current) fluctuates continuously across

microsecond execution phases and drifts over minutes as silicon heats up, increasing temperature-dependent leakage current. ML deployments also span a wide physical range. The dumbbell plot in figure 12.7 isolates this disparity on a logarithmic power scale, plotting minimum (blue) and maximum (red) envelopes across four deployment tiers: TinyML systems (5.6 mW to 167 mW), edge hardware (3.9 W to 1.1 kW), data center inference nodes (267 W to 6.3 kW), and large-scale training clusters (5.5 kW to 498 kW). Spanning about eight orders of magnitude from the TinyML floor to the training-cluster ceiling, this spectrum explains why no single efficiency metric serves all deployment contexts. A figure of merit optimized for multi-rack data center throughput becomes meaningless for a battery-powered keyword spotter governed by milliwatt budgets.

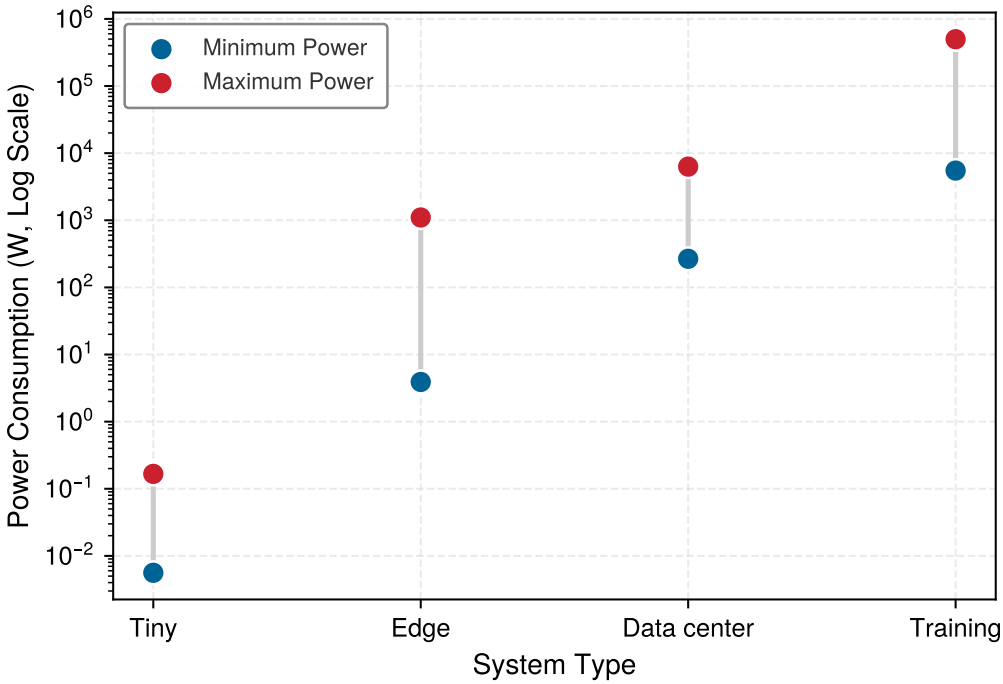

Figure 12.7: Power Consumption Differentials: Measured power spans about eight orders of magnitude across MLPerf divisions, from milliwatts for TinyML submissions through watts at the edge to kilowatts in data center inference and hundreds of kilowatts for training systems. Each pair marks the lowest and highest power among official MLPerf Power submissions in that division, after Tschand et al. (2024).

Because measured power spans from milliwatts to hundreds of kilowatts, no single instrument or measurement protocol applies everywhere. Benchmarking an always-on keyword spotter requires measuring microampere currents at millivolt rails, whereas benchmarking a server rack requires measuring high-voltage three-phase alternating current at the power distribution unit. This divergence forces benchmarking standards to establish precise physical boundaries for what hardware is included in the measured energy.

Energy accounting follows contrasting regimes across training and inference. Training energy is a capital investment amortized across the operational lifetime of the model; a large training run can consume on the order of a thousand megawatt-hours (section 12.5.2.4) (Patterson et al. 2021). Inference energy accumulates continuously with request volume, dominating total lifecycle cost as query counts scale into millions. For an isolated inference window containing one completed request, energy obeys the identity $E_{\text{inf}} = P_{\text{active}} \times L_{\text{lat,infer}}$, with P_{active} the average accelerator power during that window and $L_{\text{lat,infer}}$ its duration; the duty-cycle form used for battery accounting appears in section 12.7.2. With batching or concurrent requests, integrate energy over a common measurement window and divide by completed requests; multiplying total device power by each request's overlapping serving latency would double-count energy. For example, if measured average

accelerator power during the inference window is 300 W, a 10 ms inference uses 300 W $\times$ 0.01 s $=$ 3 J, or about 0.0008 Wh; at 100 ms, that becomes about 0.0083 Wh. An accelerator's TDP rating represents a cooling ceiling rather than dynamic power consumption, making empirical runtime power measurement essential for accurate benchmarking.

12.7.1 Power measurement boundaries

Where an engineer draws the system boundary dictates what counts as efficient. If a benchmark measures only the accelerator core, it ignores the host CPU driving the PCIe bus, the off-chip DRAM holding weights, and the cooling fans dissipating heat. Figure 12.8 partitions these measurement perimeters across three deployment tiers (Tiny, Inference, and Training), where solid olive enclosures demarcate measured components and red dashed boxes isolate excluded infrastructure such as remote storage and data-center chillers (Tschand et al. 2024).

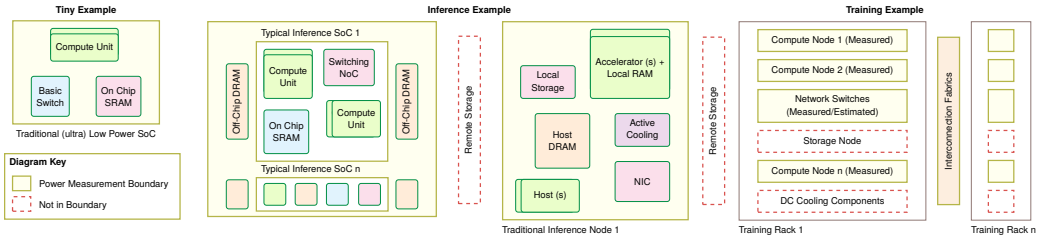

Figure 12.8: Power Measurement Boundaries: MLPerf defines system boundaries for power measurement, ranging from single-chip devices to full data center nodes, to enable fair comparisons of energy efficiency across diverse hardware platforms. These boundaries delineate which components' power consumption is included in reported metrics, impacting the interpretation of performance results. Source: (Tschand et al. 2024).

The three architectural tiers in figure 12.8 (Tiny Example, Inference Example, and Training Example) reflect distinct physical instrumentation points. In TinyML deployments, the entire low-power SoC, including compute cores, internal SRAM, and power management units, falls inside the boundary, measured directly at the DC power rail. Dedicated inference nodes expand this perimeter to include host CPUs, accelerator cards, PCIe buses, local storage, and on-chassis active cooling fans, while excluding remote storage networks. Multi-rack training deployments measure compute nodes and top-of-rack interconnect switches, but exclude centralized data center chillers, facility-level power distribution units (PDUs), and disaggregated storage clusters.

The excluded components can more than double the reported energy. Google measured the energy of the median text prompt served by its Gemini assistant under two boundaries (Elsworth et al. 2025). Counting only the active accelerators, on prompts served by its most efficient data centers, gave 0.10 Wh. Counting everything the service draws to answer that prompt gave 0.24 Wh, about 2.4× more. Of that total, the active accelerators drew 58 percent and the host CPUs and DRAM that feed them 25 percent; the remaining 17 percent went to machines held idle in reserve for traffic spikes and to facility overhead such as cooling and power conversion. An accelerator-only figure therefore understates what a deployed service consumes, and two figures measured under different boundaries are not comparable. Utilization also moves the figure, because the narrow measurement came from the most efficiently used machines. Open benchmark suites such as ML.ENERGY measure energy under realistic serving conditions so that their results reflect deployed utilization rather than an idealized run (Chung et al. 2025).

The measurement boundary determines which components are counted; workload composition determines where their energy is spent. On mobile devices running TensorFlow Mobile, data movement accounts for 57.3 percent of total inference energy (Boroumand et al. 2018), exposing why operation counts alone fail to predict power consumption; under the energy-movement principle (7), total energy depends on how many events of each kind occur and what each one costs, not on arithmetic alone. The worked example in notebook 12.4 decomposes MobileNetV2 inference energy to demonstrate how moving from FP32 to INT8 attacks both the memory-movement bottleneck and arithmetic switching costs.

Napkin Math 12.4: Why INT8 saves energy

Problem: Under the stated 45 nm component-energy model, how much does replacing FP32 with INT8 reduce MobileNetV2 weight-read and arithmetic energy?

Moving data costs far more energy than computing on it (principle 7, grounded in Horowitz's energy estimates (Horowitz 2014)). Understanding *why* quantization reduces energy consumption requires decomposing energy into its physical sources. Two dominant factors determine inference energy: compute operations and memory access.

Narrower datatypes require less switching and storage energy per operation, and off-chip memory costs far more than either. In the 45 nm component model that section 10.3.2 tabulates (table 10.8), an 8-bit multiplier uses about 18.5× less energy than a 32-bit floating-point multiplier, and reading one byte from DRAM, about 160 pJ/byte, costs over 1,600× more than a register access (Horowitz 2014). Absolute values and ratios vary with circuit design and process technology.

Math: Component energy follows the energy corollary, with a load term $D_{\text{vol}} \times E_{\text{move}}$ (model bytes times DRAM energy per byte) and a compute term $O \times E_{\text{compute}}$ (operations times energy per operation). The FP32 terms sum as 2243 µJ + 2,220 µJ = 4,463 µJ; the INT8 terms sum as 561 µJ + 120 µJ = 681 µJ. Dividing the totals gives a 6.6× reduction under this simplified model.

Table 12.17 combines the two effects in a deliberately simplified MobileNetV2 model. It counts one DRAM read per weight and charges every cataloged FLOP at the listed multiplier energy, while excluding activation traffic, cache behavior, additions as a distinct cost, control overhead, and static power:

Table 12.17: MobileNetV2 INT8 Simplified Energy Estimate: One weight read plus a multiplier-energy charge for every cataloged FLOP under a 45 nm component-energy model. This is not a whole-device inference measurement.

Component	FP32 (14 MB)	INT8 (3.5 MB)	Savings
One weight read from DRAM	2243 µJ	561 µJ	4×
Compute (600 MFLOP)	2,220 µJ	120 µJ	18.5×
Total	**4,463 µJ**	**681 µJ**	**6.6×**

Systems insight: Within this simplified model, the weight read and the arithmetic contribute comparable FP32 energy (2243 µJ and 2,220 µJ), and INT8 reduces both, taking the total from 4,463 µJ to 681 µJ. The decomposition explains the physical mechanism behind potential savings, but battery-life or per-inference claims require controlled whole-device power measurements.

Beyond individual server nodes, large-scale deployments introduce shared infrastructure that complicates boundary definition. In data centers, cooling systems and power delivery account for 20 to 30 percent of total facility electricity consumption (Barroso et al. 2019). This facility-level overhead is captured by power usage effectiveness (PUE):

$$\text{PUE} = \frac{\text{Total Facility Energy}}{\text{IT Equipment Energy}}$$

PUE values range from approximately 1.1 in hyperscale facilities using direct-to-chip liquid cooling to over 2.0 in legacy facilities relying on computer room air conditioning (Barroso et al. 2019). When an evaluation reports only server-plug energy, it excludes this facility multiplier. Furthermore, dynamic voltage and frequency scaling (DVFS) continuously modulates processor power and heat dissipation during execution (Kim et al. 2008), creating thermal feedback loops that alter the cooling overhead itself.

12.7.2 Battery and thermal benchmarking

Battery drain depends on total energy consumed over time rather than peak instantaneous power. Computational photography bursts consume multiple watts for hundreds of milliseconds during image capture, whereas background sensor processing must remain within a milliwatt-scale budget

to deliver multi-day battery life. Characterizing battery impact requires measuring the total energy consumption $E_{\text{total}} = \int P_{\text{device}}(t)\,dt$ across representative operational profiles, where $P_{\text{device}}(t)$ is the instantaneous power the device draws at time t.

The dominant operational variable is the workload duty cycle α_{duty}, defined as the fraction of time the accelerator actively runs inference. For an active power draw P_{active} and standby power draw P_{idle}, the average power is:

$$P_{\text{avg}} = \alpha_{\text{duty}} P_{\text{active}} + (1 - \alpha_{\text{duty}}) P_{\text{idle}}$$

For intermittent workloads such as the camera trap waiting for motion ($\alpha_{\text{duty}} \ll 0.01$), standby power P_{idle} and memory retention power dictate battery lifetime, making active inference efficiency secondary. For continuous pipelines like video analytics ($\alpha_{\text{duty}} \approx 1.0$), active inference energy $E_{\text{inf}} = P_{\text{active}} \cdot L_{\text{lat,infer}}$ dominates. Furthermore, elevated operating temperatures increase semiconductor leakage current, causing static power dissipation to climb as the device heats up. Benchmarking battery impact therefore requires measuring both active and standby power across the operational duty cycle while monitoring junction temperature over extended multi-minute runs.

Keyword spotting makes the point concrete. Run DS-CNN (Y. Zhang et al. 2017), the MLPerf Tiny keyword-spotting reference at 20 MFLOP per inference, on an ESP32-S3-class microcontroller board with one inference per one-second audio window. At the board's peak INT8 rate an inference takes about 8.3 ms, a duty cycle of about 0.8 percent, and costs about 3.3 mJ at the board's 0.4 W active power. Between inferences the board idles at 50 mW. Average power is therefore about 52.9 mW, and 94 percent of it is spent waiting. A benchmark that reports only energy per inference describes the remaining 6 percent of the battery drain. Active energy would overtake the idle floor only if inference occupied more than about 11 percent of the time, and real kernels running below peak raise the active share without changing the conclusion. This is why always-on audio moves to dedicated low-power silicon whose idle draw is microwatts, and why a power benchmark for a duty-cycled device must specify the duty cycle along with the inference.

12.7.3 Computational efficiency vs. power consumption

Power in CMOS logic is dynamic switching power plus static leakage power, and over the range where supply voltage tracks clock frequency, dynamic power grows roughly with the cube of frequency (section 11.10.3 derives both). Two measurement consequences follow. A measured efficiency belongs to the operating point at which it was measured, because a few percent of clock frequency moves power far more than throughput, so a boost-clock burst and a sustained run report different efficiencies for the same chip. Leakage rises with temperature, so a warm device is less efficient than a cold one at the same clock, which is why the power protocol below requires a warm-up to the intended thermal state. Across hardware generations, computations per kilowatt-hour historically doubled approximately every 1.5 years, a long-run trend known as Koomey's law (Koomey et al. 2011), so an efficiency comparison across devices must also state which generation each one represents.

Because frequency scaling quickly hits TDP ceilings, system designers optimize efficiency across the Data, Algorithm, and Machine axes. On the algorithm and data side, reduced-precision arithmetic (INT8 or FP8) directly reduces the capacitance switched in the ALUs and compresses memory traffic across interconnect buses, potentially cutting dynamic energy when the chosen format preserves the required model quality (Jacob et al. 2018; Wu et al. 2020; Gholami et al. 2021). On the machine side, the energy-delay product (EDP) measures one trade-off between energy and completion time. Its minimum need not coincide with minimum energy or maximum throughput per watt. Battery-constrained devices and power-limited data centers must choose operating points against their own latency, throughput, and energy requirements, measuring leakage and whole-system power alongside switching power.

12.7.4 Standardized power measurement

General-purpose power benchmarks such as SPECpower_ssj2008 measure server power across stepped load levels (0 to 100 percent in 10 percent increments) using steady-state transactional workloads (Lange 2009). In contrast, ML workloads swing rapidly in power: instantaneous draw alternates between compute-bound matrix multiplications (where systolic arrays or Tensor Cores

draw peak current) and memory-bound stalls or token transfers (where execution units stall waiting for DRAM or interconnect fetches).

Characterizing these fluctuations requires calibrated physical instrumentation. Software interfaces such as Intel RAPL and NVIDIA NVML expose counters or telemetry with device-specific accuracy, update rates, and polling overhead. The instrument must match the measurement boundary and required uncertainty. MLPerf power protocols use external calibrated analyzers for inference systems, while training and HPC measurements can use validated node or power-distribution telemetry; Tiny measurements use instrumentation suited to low-power devices (Tschand et al. 2024).

Resolving an individual transient requires instrument bandwidth and internal sampling appropriate to its duration; a kilohertz log cannot resolve arbitrary microsecond kernel events. Total run energy instead depends on accurate integration over the matched measurement window, which an analyzer may perform internally at a different rate from its exported readings:

$$E_{\text{total}} = \int_{t_{\text{start}}}^{t_{\text{end}}} P_{\text{device}}(t)\, dt$$

For a steady-state energy comparison, the harness separates initialization from the timed workload through three protocol stages:

1. A warm-up phase runs unmeasured inferences until caches, buffers, and temperature reach the intended operating state.
2. A sustained measurement window executes repeated inferences across minutes to average over microarchitectural phase shifts and thermal drift.
3. Hardware-to-software synchronization aligns power and workload timestamps so integrated energy and completed requests cover the same window. Cold-start or intermittent deployments require additional measurements that include initialization, sleep, and wake-up costs.

Workload structure further alters the power profile. In low-batch Transformer execution, decode often has less weight reuse than prefill and can face a lower bandwidth ceiling; their measured power profiles depend on shapes, kernels, and operating policy. DLRM embedding lookups can make memory traffic a substantial energy contributor, which must be measured alongside dense computation and static power. Batch sizing creates another trade-off: larger batches amortize parameter reads over more inputs and can lower energy per inference, while also changing activation traffic, execution time, and instantaneous power. At the edge, the duty cycle governs the outcome through the duty-cycle average power of section 12.7.2, where the keyword-spotting case shows the idle floor setting battery life.

12.7.5 MLPerf power case study

MLPerf Power (Tschand et al. 2024) translates raw electrical measurements into standardized efficiency metrics: completed inferences per second per watt under a rigorously defined system boundary. This protocol applies uniform measurement principles across data center, edge, and tiny inference scenarios, where the binding constraint shifts from rack cooling and operating cost to battery runtime and microwatt energy harvesting.

Standardizing the boundary prevents misleading comparisons across architectural families. By specifying instrumentation, measurement boundaries, matched logging windows, and the applicable workload constraints, MLPerf Power makes efficiency results interpretable within the tested scenario.

Over successive benchmark submission rounds from 2021 to 2024, standardized measurements capture how architectural improvements, compiler optimizations, and lower-precision arithmetic translate into production efficiency gains. Tracking normalized energy efficiency (samples per joule) across eight submission cycles from v1.0 to v4.1, figure 12.9 charts diverging efficiency trajectories across seven distinct MLPerf Inference workloads.

RetinaNet and ResNet show the largest plotted gains, each reaching 3× its initial normalized efficiency. BERT and GPT-J reach about 1.9×, while DLRM-v2 reaches about 1.7×, Llama 2 about 1.5×, and RNN-T about 1.3×. These trajectories combine changes in hardware, software, numerical formats, and submitted configurations. Static convolutional shapes can benefit from supported low-precision kernels and fusion; low-batch decoding and sparse embedding lookups often give

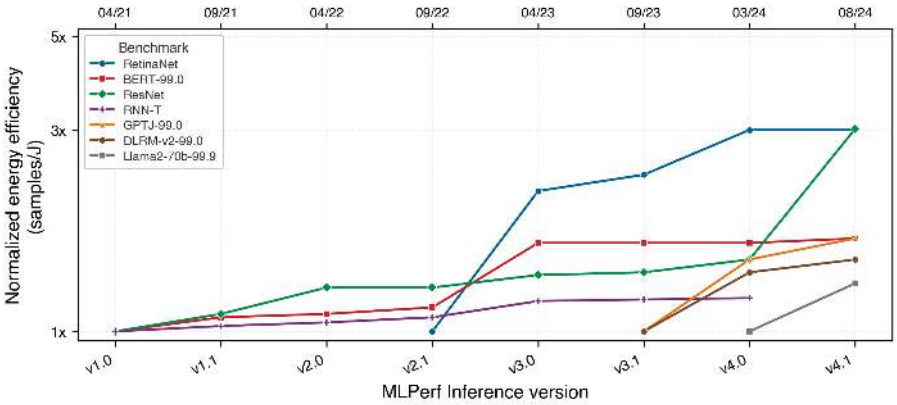

Figure 12.9: Data-Center Energy Efficiency Gains: Each series is normalized to its own first plotted version, so compare improvement within a workload rather than absolute efficiency across workloads. Source: (Tschand et al. 2024).

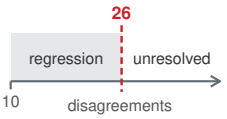
memory improvements greater importance. The plotted ratios alone do not isolate how much each mechanism contributed.

Timing protocols and power instrumentation provide the raw data for benchmarking. Raw data alone, however, does not guarantee sound conclusions. Converting measurements into meaningful comparisons requires understanding the systematic sources of error, bias, and misalignment that can make even carefully collected benchmark numbers misleading.

12.8 Benchmarking Best Practices

An inference stack that passes a steady-state lab run can still miss latency targets when production traffic arrives in bursts, or when the input mix shifts toward expensive examples. Training throughput, inference latency, and power efficiency each have established measurement protocols validated through MLPerf, but knowing what to measure is insufficient without understanding what benchmarks cannot capture and why this gap causes production deployments to violate their service-level objectives.

Benchmarks make simplifying assumptions that enable standardized comparison but diverge from production reality. Training suites freeze datasets and tightly specify randomness even though production data and retraining conditions evolve continuously, while inference suites emphasize a defined steady-state scenario even though production traffic arrives in bursts with variable sequence lengths, and power benchmarks control thermal environments where deployed accelerators instead face variable ambient temperatures and sustained thermal loads. Four categories of limitations (statistical, deployment-related, system design, and organizational) determine whether benchmark results translate to deployment success.



12.8.1 Statistical and methodological issues

A one-point accuracy drop on 1,000 test images or a 2 percent latency improvement between single benchmark runs can sit entirely inside sampling and system noise. Telling a genuine change from a fluke requires the same statistical apparatus for every benchmark in the chapter, from a kernel timing to an accuracy comparison.

To isolate run-to-run variability, benchmark protocols require repeated experimental trials across controlled pseudo-random seeds. The number of runs must satisfy explicit statistical-power targets, specifying the probability of detecting a stated real effect, rather than opportunistic sampling. Reporting must extend beyond single best-of-k scores or isolated arithmetic means: reporting sample variance, standard deviations, or confidence intervals quantifies stability and establishes whether an observed speedup exceeds background system jitter. Without these controls, benchmarking yields misleading conclusions. In reinforcement learning, reported performance advantages frequently evaporate into the statistical noise of random weight initializations and environment dynamics (Henderson et al. 2018). Similarly, unstandardized evaluations of generative adversarial

networks produce rank reversals across random seeds, demonstrating that uncharacterized variance undermines comparative claims (Lucic et al. 2018).

Even when run-to-run execution variance is fully controlled, benchmarking encounters a structural constraint in the evaluation dataset itself: test-set measurement capacity. A test set operates as a measurement instrument with a finite resolution limit. Because accuracy on a finite sample is a binomial proportion, empirical scores carry intrinsic sampling variance that scales inversely with sample size. When an optimization alters accuracy by one or two percentage points, the sample size and paired pattern of disagreements determine whether the test can distinguish a genuine algorithmic effect from sampling fluctuation. As analyzed in the accompanying notebook, marginal accuracy scores on a thousand-sample test set are insufficient to establish the significance of a fine-grained difference without examining the paired outcomes.

At most 26 disagreements reveal a regression; the disagreement count decides.

Napkin Math 12.5: The statistical confidence trap

Problem: A baseline classifier scores 95 percent, while a compressed version scores 94 percent on the same 1,000 images. Does this one-point drop establish a regression?

Math:

1. **Expected errors**: The scores correspond to 50 errors and 60 errors. Under the baseline binomial model, the error count has a standard deviation of about 7 errors.
2. **Difference interval** (95 percent): The same-image comparison requires paired outcomes, which the two marginal scores do not supply. For comparison, suppose the models instead achieved these scores on independent test sets sampled from the same population. Let $\hat{p}_1$ and $\hat{p}_2$ denote their accuracy estimates, and let N be the number of images evaluated for each model. Under that independent-set assumption, the standard error of their difference is

$$\mathrm{SE}(\hat{p}_1 - \hat{p}_2) = \sqrt{\frac{\hat{p}_1(1-\hat{p}_1)}{N} + \frac{\hat{p}_2(1-\hat{p}_2)}{N}}.$$

   The observed 1 percentage point difference has an approximate interval from -1 percentage point to 3 percentage points, which includes zero. Treated as independent samples, the one-point drop is indistinguishable from sampling noise. Pairing can change that verdict, because images that both models classify the same way cancel out of the comparison.
3. **Paired test on the same images**: The stated problem uses one test set, so the decisive evidence is where the two models disagree. Let n_{base} count images only the baseline classifies correctly and n_{comp} count images only the compressed model classifies correctly. Images both models get right or both get wrong carry no information about which is better, and McNemar's test (McNemar 1947) discards them. The scores fix the difference $n_{\text{base}} - n_{\text{comp}}$ at 10 (the compressed model's extra errors) but not the sum. The test statistic, without continuity correction, is

$$\chi^2 = \frac{(n_{\text{base}} - n_{\text{comp}})^2}{n_{\text{base}} + n_{\text{comp}}},$$

   and the drop is significant at 95 percent when χ^2 exceeds 3.84. That happens only when the models disagree on at most 26 images.

   Implication: The marginal scores cannot answer the question; the disagreement count decides it. If the compressed model's 10 extra errors are nearly its only disagreements with the baseline, the paired test supplies evidence of a regression at the stated significance threshold. If the models disagree on many more images, the test leaves the same one-point gap unresolved. Nonsignificance does not establish equivalence or compliance with a permitted quality-loss tolerance. A benchmark report must therefore keep per-image

outcomes, not only the two accuracies; the interval-based decision rule below separates an unresolved difference from a supported improvement.

Systems insight: A small test set limits what a benchmark can resolve. The test set, viewed as a measurement instrument, must be sized to match the precision of the change it is meant to detect. A single accuracy estimate alone needs about 1,825 images for ±1 percentage point precision, and that sample size does not by itself power a comparison between two models.

The same paired logic governs timing comparisons. Suppose an engineer measures baseline and candidate mean latency under the same request mix, offered load, and timing boundary. Each experimental trial pairs a complete baseline run with a complete candidate run, following the same warm-up and thermal-state protocol and randomizing their execution order to limit drift bias. The comparison assumes that separately repeated run pairs are independent, with persistent background load or thermal drift controlled or accounted for. Requests within one run can share queues, caches, and thermal conditions and therefore cannot automatically count as independent trials. The report states the interval method and confidence level and uses the run pairs as the repeated observations. A request-latency p99 describes the slow end of the observed request population. It is neither a confidence interval for mean latency nor a measure of uncertainty in the estimated p99.

Suppose the report supplies an uncertainty interval for the mean latency reduction, defined as baseline latency minus candidate latency. If the interval extends from a negative reduction to a positive reduction, it includes no change, and the experiment cannot resolve whether the candidate is faster. That conclusion does not establish that the implementations perform identically. If a subsequent adequately controlled comparison yields an interval entirely above zero, it supports a latency reduction under the tested conditions. Deployment still requires a prespecified minimum useful reduction, reflecting the cost of adopting the candidate. An interval entirely above zero but extending below that threshold supports a gain without establishing that the gain justifies adoption; an interval entirely above the threshold supports both claims, provided the quality and resource gates also pass.

Two further issues undermine reliability even when runs are repeated and compared correctly. Incomplete problem coverage occurs when a benchmark exercises only a narrow operating point of a system. Controlled datasets such as CIFAR-10 (Krizhevsky 2009) constrain inputs to uniform, low-resolution images (32×32 pixels) with small per-image input footprints. This constrained input shape may exercise memory differently from production images, but the complete working set still depends on the model and batch size, and allocation or kernel-launch overheads remain. A model that achieves high accuracy and throughput on a uniform, downscaled benchmark can stall in deployment when exposed to variable image resolutions, arbitrary aspect ratios, and sensor noise that force frequent kernel recompilations or fallback execution paths.

Statistical insignificance arises when evaluations rely on too few trials to distinguish algorithmic improvements from measurement noise, particularly when the evaluation medium introduces variance. Large language model evaluation exemplifies this vulnerability: whether scoring candidate generations against a reference via human preference ratings or an LLM-as-judge protocol, scores vary substantially based on prompt phrasing, judge model alignment, and response ordering. A reported two-point win can vanish under an alternative prompt template or judge configuration. Rigorous evaluation demands paired hypothesis tests and bootstrap confidence intervals over hundreds of independent prompt pairings. Omitting these confidence bounds obscures whether a reported margin reflects a genuine architectural advance or stochastic evaluation noise.

12.8.2 Reproducibility

Reproducibility studies have repeatedly shown that modest benchmark gains can disappear when random seeds, hardware, framework versions, or implementation details change (Henderson et al. 2018). The stochastic processes that section 12.4.2 identified as measurement noise interact, over a long training run, with hardware-specific behaviors (floating-point rounding, memory layout, compiler optimizations) to produce results that can vary meaningfully across environments.

A deeper layer of non-determinism comes from the parallel hardware itself. Operations such as parallel atomic additions, used during gradient accumulation for sparse embeddings in models like Graph Neural Networks, execute in non-deterministic order across threads when concurrent

updates target the same memory location. The resulting floating-point summation order changes across runs, and because floating-point addition is not associative (section 3.7.4), a different order produces bit-for-bit different gradients even with identical inputs and seeds. Enforcing bit-exact reproducibility in these cases requires a deterministic reduction path, which can reduce training throughput, a direct trade-off between reproducibility and performance that benchmark protocols must explicitly address. Without explicit controls for all these sources of variability, benchmark numbers reflect a specific confluence of conditions rather than a system's genuine capability.

MLPerf Training addresses this through standardized data preprocessing, target-quality rules, and repeated accepted runs that characterize stochastic variation (Mattson et al. 2020). The point is not merely to produce a fast run, but to show that the reported performance reflects system capability rather than a favorable combination of stochastic factors.

For a training benchmark, reproducibility is therefore the full run envelope, not the random seed alone. A credible report must preserve the model commit, dataset checksum, preprocessing pipeline, seed plan, framework and compiler versions, precision policy, batch schedule, hardware topology, thermal and power limits, and checkpoint behavior. It must also report the distribution of accepted runs rather than a single best run. Only then can the benchmark separate a real system improvement from a favorable interaction among software version, hardware state, and stochastic training path.

Reproducibility also limits comparisons across software environments. A compiler or library revision can change kernel tiling, memory access, and reduction order, so an unexplained version change is a second intervention in the experiment. The run envelope above must accompany the result; matching a model name and seed alone does not make two stacks equivalent.

12.8.3 System design challenges

Statistical rigor ensures that benchmark measurements are precise, but precise measurements of the wrong operational regime still lead to production failures. Benchmark suites must align with the physical constraints of deployment, and the mismatch is sharpest where a standardized scenario meets live serving traffic. Misalignment with real-world goals persists even when a standardized benchmark is measured correctly. Offline throughput and Server throughput answer different questions, and the Server scenario still specifies only one arrival distribution. A production trace with correlated bursts or a different input mix can produce a different queue and memory footprint. The experiment must state which operating conditions its conclusion covers, and production qualification tests those boundaries before release. The summary returns to these gaps as a release problem once model and data evaluation are in place.

Beyond deployment alignment, a further category of limitations stems directly from the physical hardware executing the workload. Accelerator behavior fluctuates with thermal conditions, operating system resource contention, and underlying microarchitectural topology.

Environmental controls must match the claim being tested. Fixed clocks, CPU affinity, and isolated memory allocations can reduce noise in a comparison of implementations, while a deployment test must retain the relevant contention and thermal policy. The sustained-state mechanisms in section 12.6.4 apply to servers as well as edge devices. A result obtained under tighter isolation supports an implementation comparison, but does not by itself establish production capacity.

The hardware lottery[28] (Hooker 2021) compounds this physical variation by coupling algorithmic viability to specialized hardware support. Modern accelerators allocate most of their silicon area to dense matrix multiplication units (such as Tensor Cores or systolic arrays) backed by wide vector units and high-bandwidth memory hierarchies. Algorithmic architectures such as dense Transformers achieve high arithmetic intensity by reusing weights across batched tokens, sustaining a large fraction of peak theoretical FLOP/s. Conversely, architectures that rely on dynamic control flow, fine-grained sparsity, or graph message passing suffer from uncoalesced memory transactions and thread divergence, underutilizing available compute silicon. Algorithmic performance on a benchmark often reflects how naturally a model's computation graph maps onto dominant accelerator execution units rather than intrinsic mathematical superiority. The lottery is how the bitter lesson shows up on a leaderboard. General methods win by riding growth in computation, but the computation that grows is the dense form the dominant accelerators supply, so the winning methods are also the ones shaped to fit it.

[28] **Hardware lottery**: Coined by Hooker (2021) to describe how algorithmic success depends on alignment with available hardware and software. Transformer workloads benefit from dense matrix operations that map efficiently to modern accelerators, while graph neural networks and sparse mixture-of-experts models can be harder to evaluate when available silicon and software stacks favor dense kernels. Hardware-specific leaderboards therefore favor architectures aligned with the measured platform and may obscure alternatives that would fare differently under other hardware assumptions.

↩ The bitter lesson, that general methods which scale with computation outrun hand-built structure, is established in section 1.4.

Hardware compatibility dependence introduces systematic biases when evaluating models across heterogeneous execution targets. An architecture optimized for GPU execution may underperform on an embedded CPU, DSP, or custom edge accelerator with differing vector widths, cache hierarchies, and quantization support. Across five hardware targets on a Google Pixel 4, figure 12.10 charts how the latency–accuracy Pareto frontier reshuffles between CPU float, CPU uint8, GPU, EdgeTPU, and DSP execution. The diagonal purple arrow links MobileNetV3 Large at roughly 75 percent top-1 accuracy, from approximately 20 ms on CPU float to 4.5 ms on the DSP. Multi-MAX reaches roughly 75 percent accuracy at 2.2 ms on EdgeTPU and 3.4 ms on DSP; its points at higher accuracy carry higher latency. Comparisons must therefore match both the model variant and the accuracy operating point. The shifted frontiers show why model selection requires measurements on the target execution path rather than a latency ranking inherited from another processor.

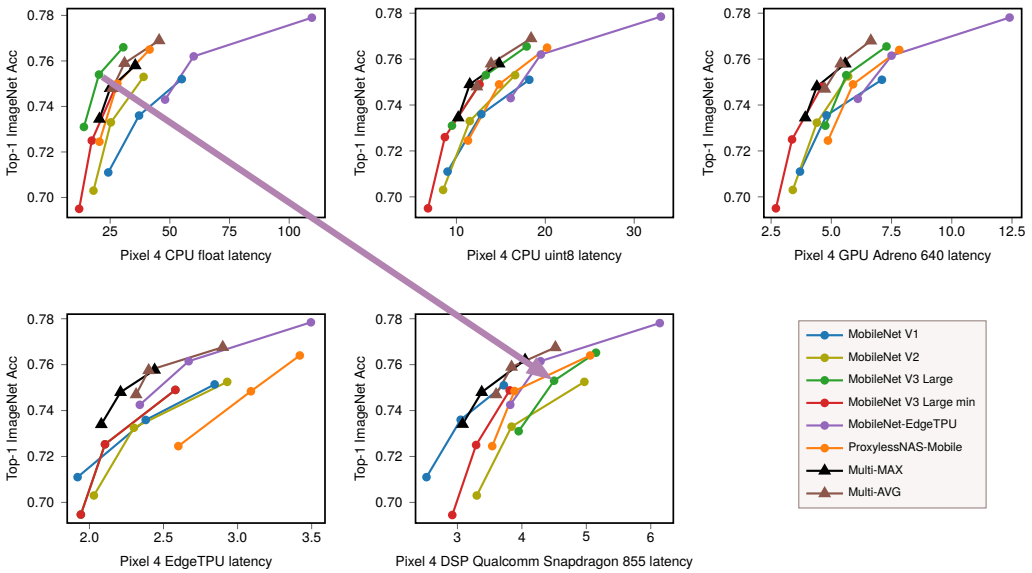


Figure 12.10: Hardware-Dependent Latency–Accuracy Trade-offs: Each panel holds top-1 ImageNet accuracy on the vertical axis while using a target-specific latency scale horizontally. The arrow links MobileNetV3 Large at roughly equal accuracy on CPU float and DSP, exposing the hardware-dependent latency shift. Source: (Chu et al. 2021).

Without benchmarking across heterogeneous hardware configurations, system designers risk selecting architectures solely because they conform to existing accelerator memory hierarchies and instruction sets. Evaluating models across diverse execution engines ensures that architectural decisions reflect computational efficiency rather than platform-specific co-design artifacts.

12.8.4 Organizational and strategic issues

The statistical, deployment, and hardware limitations concern measurement mechanics. A distinct category of failure comes from human incentives, because commercial procurement and academic leaderboards reward a high score more directly than a representative one, and those incentives bias how benchmarks are executed and reported.

12.8.4.1 Benchmark engineering

While the hardware lottery is an unintended consequence of hardware specialization, benchmark engineering is the deliberate practice of tailoring models or systems to exploit the idiosyncrasies of specific benchmark harnesses. This practice yields inflated performance metrics that collapse under production conditions.

Benchmark engineering occurs when developers tune hyperparameters, preprocessing pipelines, or execution paths specifically to maximize benchmark scores rather than generalizable performance. Legitimate optimization respects the run rules and declared workload; misleading benchmark engineering exploits restricted test conditions while making broader claims that the evidence

cannot support. For example, an inference pipeline might hardcode input tensor dimensions and pad batches specifically to match the memory stride of an accelerator's GEMM tile configuration, achieving peak throughput on fixed benchmark shapes while triggering costly kernel fallbacks and memory reallocations on arbitrary production inputs. Similarly, fine-tuning an evaluation pipeline to match the formatting biases of an automated evaluation model produces high leaderboard rankings that fail when interacting with unstructured human dialogue.

Procurement contracts and marketing claims reward exactly this tuning. It is Goodhart's Law (section 12.1) acting on an organization rather than on a single team's choice of metric.

To keep this benchmark gaming from corrupting procurement and engineering evaluations, standardized suites enforce strict run rules backed by reference implementations, submission audits, and division boundaries. Their rules forbid three classes of non-generalizable shortcuts:

1. **Precision truncation without disclosure**: A compiler silently lowers numerical precision (for instance, executing intermediate activations in FP8 or INT8 instead of BF16) to inflate arithmetic throughput, without disclosing the reduced dynamic range or verifying whether the lower precision degrades numerical stability on production workloads.
2. **Work pruning and operator elimination**: An execution engine exploits fixed benchmark test sets to skip operations required by general production inputs, such as bypassing dynamic padding removal, masking out-of-bounds tokens, or skipping input boundary validation.
3. **Benchmark fingerprinting**: A runtime inspects input tensor dimensions, dataset hash fingerprints, or memory layout patterns to identify the benchmark suite, executing hardcoded, pre-tuned execution graphs and bespoke kernel configurations that are inaccessible to arbitrary user workloads.

MLPerf detects and deters these shortcuts through its submission divisions (defined in section 12.4.4), reference-equivalence checks, and peer-reviewed code audits. The closed division permits reproducible runtime optimizations, memory layout transformations (such as converting NCHW to NHWC), hardware-generalizable kernel fusion, and approved low-precision formats with documented, verifiable output quality, while non-generalizable shortcuts remain prohibited. Broader architectural alterations belong in the open division.

12.8.4.2 Bias and over-optimization

System engineers evaluating benchmark results must distinguish legitimate architectural gains from benchmark engineering, and several practices expose the difference. Submissions that publish complete compiler flags, kernel configurations, and execution traces let independent evaluators separate general efficiency gains from harness-specific tuning. Paired results from controlled benchmarks and uncurated production traces expose discrepancies in latency distributions and memory use, and evaluating across several independently maintained suites raises the barrier against overfitting, because an optimization tailored to the quirks of one harness rarely transfers to others.

Third-party verification adds accountability. Independent audits check whether reported speedups reproduce on identical hardware, as in MLPerf's reference-versus-submission validation (section 12.8.4.1), and application-specific stress tests probe failure modes that static benchmarks omit, such as vision models under adverse imaging conditions or inference engines under skewed request traffic.

12.8.4.3 Benchmark evolution

Benchmarks are not static standards; they must evolve alongside model architectures and hardware capabilities. A benchmark that effectively separates system capabilities in one architectural generation becomes obsolete when models saturate its accuracy ceiling or when hardware innovations shift the primary system bottleneck. Stale benchmarks incentivize over-optimizing legacy computational kernels rather than advancing system efficiency.

Early deep learning benchmarks evaluated image classification and object detection on convolutional networks. As workloads expanded to large language models, recommendation systems, and generative AI, those vision benchmarks failed to capture long-context attention, autoregressive decoding, and sparse expert routing, and community benchmarks moved to language understanding (A. Wang et al. 2018, 2019) and foundation model capabilities (Liang et al. 2022). How saturation erodes a static benchmark's discriminating power is a data question, taken up in section 12.9.2.

Benchmark evolution also expands the dimensions of measurement. While early benchmarks focused on throughput and accuracy, contemporary systems require multi-objective evaluation across energy efficiency, memory footprint, and tail latency under resource constraints. Scientific instruments provide a further constraint regime in figure 12.11. Its shaded "Fast ML for Science" envelope places high-throughput trigger pipelines outside typical mobile and IoT operating points (Duarte et al. 2022). The distance between these operating points is why a benchmark must match its application.

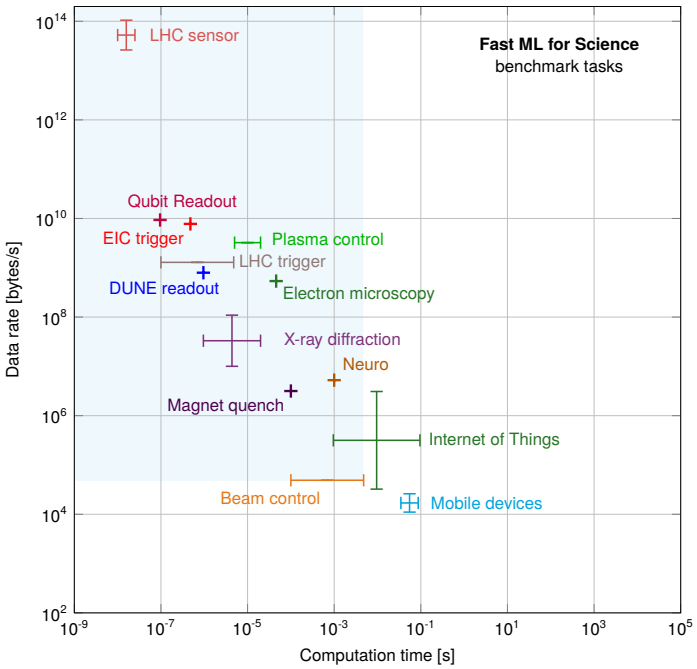

Figure 12.11: Performance Spectrum: Scientific and edge applications occupy widely separated operating points in data rate and available computation time, motivating benchmarks tied to each application's timing and data-movement constraints. Source: (Duarte et al. 2022).

Managing benchmark evolution introduces a direct trade-off between longitudinal stability and architectural relevance. Benchmarks must remain fixed long enough to allow rigorous cross-generation hardware and software comparisons. If benchmarks change too frequently, tracking historical progress becomes impossible. Conversely, freezing a benchmark indefinitely leads to metric stagnation and over-specialization. Modern benchmarking consortia balance this trade-off by operating on fixed release cycles that introduce new representative workloads while deprecating obsolete suites.

Even the most rigorous system benchmarks validate only one dimension of deployment readiness. Achieving record throughput and energy efficiency on an MLPerf workload confirms that the hardware and runtime stack can deliver high computational efficiency, but it cannot determine whether the deployed model generalizes to real-world distributions or whether the underlying dataset represents the operational population. In the D·A·M taxonomy, hardware throughput (Machine) is a necessary foundation, but algorithmic fidelity (Algorithm) and dataset integrity (Data) must hold simultaneously. Validation therefore continues with the model and the data.

12.9 Model and Data Evaluation

A compressed model running on accelerated hardware, such as the camera trap's INT8 MobileNetV2, can still fail if it was trained on unrepresentative data. System benchmarks can confirm that hardware delivers promised training throughput, inference latency, and power efficiency, but hardware validation alone cannot ensure deployment success. The optimization pipeline from Part III also included model compression and data selection, each requiring its own validation. The framework's

other two dimensions address this gap: model benchmarks verify that compression preserved accuracy and essential model properties, while data benchmarks verify that training data enables robust generalization.

12.9.1 Model benchmarking

A pruned model can maintain ImageNet top-1 accuracy while losing robustness to adversarial inputs; a quantized model can preserve average-case performance while degrading on rare edge cases; a distilled model can match its teacher's accuracy while losing confidence calibration. Model benchmarks validate whether compression preserved the properties that matter for deployment beyond top-line accuracy. Historically, benchmarks focused almost exclusively on accuracy, but compression makes multi-dimensional evaluation essential.

↩ Pruning, quantization, and distillation, the compression techniques these benchmarks validate, are established in chapter 10.

Evaluating a compressed model requires comparing its behavior against an uncompressed reference baseline. In computer vision, standard network architectures establish the accuracy and resource baselines against which compression techniques are judged: a pruned or quantized model must demonstrate how much task accuracy it sacrifices for a given reduction in latency, memory footprint, or energy consumption. Canonical reference models such as ResNet-50[29] serve as standard MLPerf workloads precisely because their moderate scale (25.6M parameters) and well-understood compute profile (8.2 GFLOP per image) make them sensitive to both hardware and software optimizations without requiring distributed multi-node setups (He et al. 2016a; Mattson et al. 2020).

29 | **ResNet (residual network)**: Introduced by He et al. (2016a), skip connections enabled deep residual networks and achieved 3.57 percent top-5 ImageNet error (ensemble), surpassing the estimated human error rate in the ImageNet challenge context (Russakovsky et al. 2015).

12.9.1.1 Accuracy metrics and their blind spots

The most common model metrics (accuracy, precision, recall, F1) each reveal different aspects of model behavior while hiding others, and understanding their blind spots is essential for compression validation. Top-k accuracy measures whether the correct label appears in the model's top-k predictions. Top-1 accuracy is strict; top-5 is lenient. The gap between them reveals ranking behavior: a model with 75 percent top-1 but 95 percent top-5 accuracy often ranks the correct class among its leading candidates without placing it first. These rank statistics do not establish whether its confidence scores are calibrated. For deployment, the acceptable gap depends on whether downstream systems can use ranked predictions or require single answers.

Precision and recall matter when classes are imbalanced or errors have asymmetric costs (Sokolova and Lapalme 2009). A camera-trap classifier with 99 percent accuracy might have 10 percent recall on a rare species (catching only one in 10 frames that contain it), an unacceptable outcome despite high accuracy. Precision (the fraction of predicted positives that are correct) and recall (the fraction of actual positives identified) expose failures that aggregate accuracy conceals.

↪ Disaggregated evaluation as a release gate, with the slices, metrics, and thresholds that decide whether a model ships, is developed in section 15.3.2.

Aggregate metrics also conceal subgroup failures. A model achieving 95 percent overall accuracy might achieve 60 percent on a critical demographic subgroup. The Gender Shades project (Buolamwini and Gebru 2018) revealed commercial gender-classification systems for facial analysis performing substantially worse on darker-skinned women than on lighter-skinned men, a disparity invisible to aggregate benchmarks. Disaggregated evaluation across deployment-relevant subgroups is essential.

12.9.1.2 Confidence calibration

For many deployment scenarios, *how confident* the model is matters as much as *what* it predicts. A well-calibrated[30] model's confidence scores correspond to actual correctness probability: among 100 predictions made with 80 percent confidence, about 80 should be correct in expectation.

Calibration failures create severe operational hazards in automated pipelines. An overconfident model automates catastrophic errors that it should defer to human review (for example, reporting 95 percent confidence but failing 30 percent of the time). Conversely, an underconfident model floods manual review queues with decisions it could safely automate (reporting 60 percent confidence while being correct 98 percent of the time).

To quantify calibration across a dataset, predictions are partitioned into N_{bins} confidence bins $\text{bin}_1, \text{bin}_2, \ldots, \text{bin}_{N_{\text{bins}}}$ (such as ten intervals of width 0.1 from 0 to 1). For each bin_m, the evaluator computes the empirical accuracy $\text{acc}(\text{bin}_m)$ (the fraction of correct predictions in that bin) and the

30 | **Calibration**: From Arabic *qalib* (a mold for casting metal) via Latin *calibrare*, originally describing the adjustment of measuring instruments against known standards. In ML, calibration ensures predicted probabilities match empirical frequencies; Guo et al. (2017) formalize this concern for modern neural networks and show that temperature scaling is a simple effective post-hoc correction. The etymology is apt: just as an uncalibrated instrument produces precise but inaccurate measurements, an uncalibrated model produces confident but unreliable predictions, causing downstream systems that threshold on confidence scores to make systematically wrong decisions.

average predicted confidence $\text{conf}(\text{bin}_m)$. **Expected calibration error (ECE)** (Pakdaman Naeini et al. 2015) measures the weighted average difference between confidence and accuracy in equation 12.4:

$$\text{ECE} = \sum_{m=1}^{N_{\text{bins}}} \frac{|\text{bin}_m|}{N} |\text{acc}(\text{bin}_m) - \text{conf}(\text{bin}_m)| \tag{12.4}$$

where N is the total sample count and $|\text{bin}_m|$ is the sample count in bin m. A measured $\text{ECE} = 0$ means confidence and accuracy agree within the chosen finite-sample bins. Population calibration implies agreement in expectation; a zero estimate does not prove calibration at every confidence level or on another distribution.

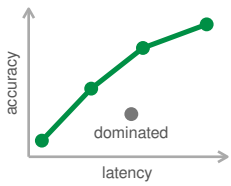
Compression frequently disrupts calibration even when preserving aggregate accuracy, a central concern when validating quantization techniques from section 10.3. When floating-point weights and activations are quantized to 8-bit integers, discrete rounding alters the numerical geometry and relative separation of final-layer logits. Often, headline top-1 accuracy barely moves, but the model becomes severely overconfident, assigning extreme probabilities to inputs where it is genuinely uncertain. Post-hoc techniques such as temperature scaling can improve calibration when fitted on separate calibration data and evaluated on an untouched representative holdout (Guo et al. 2017).

12.9.1.3 Compression benchmarks

Neural network compression (pruning, quantization, knowledge distillation, and architecture optimization) requires specialized benchmarks because compression reshapes the trade-off landscape: every byte saved or operation eliminated must be weighed against potential accuracy loss and hardware compatibility. The most basic compression metric is raw size reduction: parameter count, memory footprint in bytes, and compressed storage requirements. Size alone, however, is misleading. On ImageNet, MobileNetV2 achieves approximately 72 percent top-1 accuracy with 3.5M parameters vs. ResNet-50's 76 percent accuracy with 25.6M parameters, about 7.3× fewer parameters at comparable accuracy (Sandler et al. 2018; He et al. 2016a).

Pruning benchmarks must distinguish structured from unstructured sparsity, because they produce qualitatively different results on real hardware, as the storage and execution break-even of section 10.4.2.2 shows. Structured pruning yields smaller dense operations that conventional kernels exploit (Li et al. 2017). Unstructured pruning can reach very high sparsity but realizes speedups only with specialized sparse computation support, so protocols must specify hardware platform and software implementation (Han et al. 2015; Gale et al. 2019).

Quantization benchmarks evaluate precision reduction across data types. In the illustrative MobileNetV2 scenario, INT8 reduces raw weight storage by 4× and the assumed latency values yield the speedup in example 12.3; realized performance depends on the hardware and implementation. The precision-accuracy trade-off (Jacob et al. 2018) is worked in lighthouse 12.3 and the energy implications in section 12.7.1. Mixed-precision assignment, which keeps sensitive layers at FP16 while computation-heavy layers use INT8 or INT4, multiplies the configurations a benchmark must name. Knowledge distillation (section 10.2.3) adds a smaller student whose benchmark must verify that it generalizes rather than merely memorizing the teacher's outputs (Hinton et al. 2015).



Acceleration factors vary across hardware platforms because sparse models, reduced-precision models, and efficient architectures need compatible kernels, memory layouts, and accelerator support. Current benchmark suites like MLPerf focus primarily on standardized reference models, while production deployments often use compressed or hardware-specific variants. A compression report must therefore name its representation and execution path before an efficiency-quality comparison can establish whether the variant is deployable.

12.9.1.4 Compression validation: The efficiency-quality frontier

A compression report identifies the representation and hardware path, but deployment acceptance requires deciding whether their measured gains justify changes in model behavior. Size, latency, and energy improvements must be evaluated against the quality properties and limits the application depends on.

Pareto frontier[31] evaluation (principle 5) determines whether a compressed model represents a good trade-off. Plotting accuracy against the target efficiency metric (latency, model size, energy)

[31] **Pareto frontier**: Named after economist Pareto (1896), the frontier contains all solutions where improving one objective requires degrading another. In compression benchmarking, the trade-off between adjacent candidates must be interpreted using the named axes and units. A candidate is dominated when another is at least as good on every objective and strictly better on one; frontier membership still does not establish that deployment thresholds are met.

A dominated model is matched or beaten on both accuracy and latency by a frontier model.

reveals the trade-off frontier. Models on the Pareto frontier *cannot* improve one metric without degrading the other; models below the frontier are dominated by better alternatives.

Different compression techniques make different efficiency-quality trade-offs: quantization reduces precision while often preserving aggregate accuracy (Jacob et al. 2018), pruning induces sparsity while retaining varying levels of test performance (Han et al. 2015; Gale et al. 2019), and distillation transfers knowledge from a larger teacher or ensemble into a smaller model (Hinton et al. 2015). Because these aggregate results do not establish preserved calibration or tail behavior, validation must evaluate those properties directly (Guo et al. 2017).

Evaluating calibration during compression requires a standardized protocol. Expected calibration error (ECE) compares predicted confidence with empirical accuracy, but it has no universal thresholds. The metric depends on the binning scheme, bin count, sample size, and prediction distribution. A benchmark protocol must therefore freeze the estimator and evaluate degradation relative to the uncompressed baseline under a fixed task tolerance.

Pareto optimality identifies nondominated choices, but it does not establish that any choice clears the deployment's absolute quality floor. Acceptable degradation depends on deployment context: a 2 percent accuracy drop might be acceptable for a recommendation system where users tolerate imperfect suggestions, but unacceptable for medical diagnosis where every false negative carries severe consequences. Production acceptance gates must define absolute accuracy thresholds before compression, evaluating aggregate accuracy, calibration stability, and deployment-critical slices simultaneously. The MobileNetV2 lighthouse makes this multi-dimensional validation protocol concrete.

Lighthouse 12.3: MobileNetV2 INT8 compression

Returning to lighthouse 12.1, consider an illustrative validation protocol for INT8 quantization, grounded in MobileNetV2's architecture (Sandler et al. 2018) and post-training quantization practice (Jacob et al. 2018). The values in table 12.18 are assumed. For this example, acceptance permits less than one percentage point of loss on either top-one or top-five accuracy and requires no regression in ECE or critical edge-case accuracy under the same evaluation protocol:

Precompression baseline: MobileNetV2 achieves 71.8 percent top-1 accuracy on ImageNet at 3.5M parameters (14 MB FP32).

In table 12.18, aggregate accuracy barely changes after INT8 quantization to 3.5 MB, but calibration error and edge-case accuracy reveal substantial degradation. The INT8 model's ECE rises from 0.031 to 0.089, failing this example's no-regression criterion under the fixed ECE protocol.

Table 12.18: MobileNetV2 INT8 Postcompression Metrics: Illustrative FP32 and INT8 values for top-1 and top-5 accuracy, calibration error, and edge-case accuracy, showing how aggregate accuracy can mask calibration and tail-case degradation.

Metric	FP32	INT8	Acceptable?
Top-1 accuracy	71.8%	70.9%	✓ (0.9 pp drop; below 1 percentage-point threshold)
Top-5 accuracy	91%	90.4%	✓ (below the stated accuracy-loss threshold)
Calibration ECE	0.031	0.089	No (degraded)
Edge-case accuracy	68.2%	61.4%	No (drop of 6.8 pp)

Edge-case definition: Images with >50 percent occlusion, <100 lux lighting, or $>30°$ rotation from training distribution (approximately 5 percent of real-world inputs).

What this reveals: Under these assumptions, average-case accuracy looks acceptable (0.9 percentage-point drop), but calibration degrades and edge-case accuracy drops 6.8 percentage points. If the deployment uses confidence thresholds (for example, "only act if confidence > 85 percent") or encounters many edge cases (unusual lighting, partial occlusions), INT8 MobileNetV2 could fail despite passing aggregate benchmarks.

Fix: Evaluate temperature scaling as a post-hoc calibration candidate (Guo et al. 2017). Fit a positive scalar T_{cal} on separate calibration data to divide logits before softmax: $\text{softmax}(z_i/T_{\text{cal}})$. Validate on an untouched holdout. This rescaling preserves the top-one ranking, so edge-case classification errors require separate diagnosis of quantization and data coverage, followed by correction and testing on reserved edge-case examples.

Pruning trade-offs are also nonlinear. Iterative pruning finds subnetworks that match the dense network's accuracy up to a critical sparsity and degrade sharply beyond it (Frankle and Carbin 2019), the evidence behind the lottery ticket hypothesis of section 10.2.1.6. Compression validation must therefore establish empirical trade-off curves for each specific model and architecture, identifying where the model sits on the Pareto frontier and whether further pruning yields hardware efficiency or merely degrades accuracy.

12.9.1.5 Large language model benchmarks

The compression evaluation framework applies cleanly when the task has a stable label, such as classification accuracy, detection mAP, or segmentation IoU. Large language models break that pattern. A team can choose a model because it scores well on a public benchmark, then discover in deployment that the model recognizes multiple-choice facts but cannot generate a grounded answer, responds too slowly for an interactive product, or produces confident unsafe text that the benchmark never stressed. LLM benchmarking therefore starts by naming the deployment failure that a score is meant to rule out.

The metric taxonomy in table 12.19 organizes evaluation around those failure modes rather than leaderboard rankings. Its rows use Massive Multitask Language Understanding (MMLU),[32] HELM (Holistic Evaluation of Language Models),[33] and perplexity[34] as examples of scores that answer distinct deployment questions, while the responsiveness row is measured as time to first token and time per output token, defined with the other inference metrics in section 12.6.2.2:

Table 12.19: Failure-Oriented LLM Benchmark Taxonomy: LLM metrics are useful when each score is tied to the deployment failure it is meant to rule out. Recognition, holistic behavior, corpus prediction, and responsiveness expose different risks, so no single score establishes production readiness.

Deployment failure to rule out	Metric or benchmark family	What the score reveals	What the score cannot prove
The model recognizes facts poorly	MMLU (Massive Multitask Language Understanding)	Broad factual and disciplinary knowledge across fifty-seven subjects, with scores interpretable against chance-level multiple-choice performance	Whether the model can generate grounded open-ended answers rather than choose among multiple-choice options

[32] **MMLU (massive multitask language understanding)**: Introduced by Hendrycks et al. (2020) with 15,908 multiple-choice questions across fifty-seven subjects. MMLU's benchmarking limitation is its format: multiple-choice recognition is not the same task as open-ended generation, so an MMLU score should not be read as direct evidence that a model can produce grounded free-form answers in production.

[33] **HELM (holistic evaluation of language models)**: Stanford's 2022 evaluation framework tested a broad set of models across seven dimensions (accuracy, calibration, robustness, fairness, bias, toxicity, efficiency) (Liang et al. 2022). HELM's contribution is methodological: by evaluating models that score similarly on accuracy but diverge on calibration or toxicity, it demonstrates that single-metric leaderboards systematically hide failure modes that matter for production deployment.

[34] **Perplexity**: From Latin *perplexus* (entangled); in information theory, $2^{H(p)}$ where H is entropy. A perplexity of 10 means the model is "10-way confused" on average. The systems consequence is interpretive rather than direct memory accounting: perplexity measures held-out next-token prediction on a corpus, while serving memory pressure is governed by context length, batch size, model shape, and decoding state; KV-cache management is a separate serving problem (Kwon et al. 2023).

Deployment failure to rule out	Metric or benchmark family	What the score reveals	What the score cannot prove
The model is capable but unsafe	HELM (Holistic Evaluation of Language Models)	Accuracy alongside calibration, robustness, fairness, bias, toxicity, and efficiency	Whether one aggregate score captures the deployment risk; a model can be strong on accuracy and weak on calibration, safety, cost, or prompt stability
The model predicts its corpus well	Perplexity	Held-out next-token prediction on the same corpus; a perplexity of 10 means the model is "10-way confused" on average	Whether generated answers are helpful, safe, or grounded outside that corpus
The model feels slow in use	First-token latency, inter-token latency, and token throughput	Prompt-processing delay before generation starts and decode speed after generation begins	Whether a single throughput number hides poor interactive responsiveness, especially when batching improves throughput but worsens first-token latency

A final failure mode is that a benchmark score may reflect training-data memorization rather than general capability. Benchmark contamination is especially difficult to audit in LLMs because web-scale pretraining corpora may contain benchmark questions, inflating scores through memorization rather than skill (Xu et al. 2024). Leakage detection reframes this risk as something benchmark designers can test for rather than merely suspect. Temporal holdouts use content published after the training cutoff, dynamic benchmarks generate fresh instances continuously, and contamination tests check whether the model recalls verbatim benchmark phrasing. These techniques keep the benchmark aligned with the deployment question instead of rewarding pretraining exposure to the evaluation set.

12.9.2 Data benchmarking

Model benchmarks validate whether compression preserved model quality. Model quality, however, depends on the data alongside the architecture and training procedure, and that dependency creates a failure mode that neither system nor model benchmarks can see. A perfectly preserved model trained on biased or unrepresentative data can still fail in production. Data benchmarks validate whether the efficiency strategies from chapter 9 (active learning, curriculum design, data augmentation, and synthetic data generation) produced training sets that enable reliable deployment. This is often the last validation to fail and the hardest to diagnose: a model achieving excellent accuracy on held-out test data may collapse on production inputs that the training data never adequately represented.

Within the D·A·M taxonomy, optimizing the Algorithm and the Machine cannot compensate for structural deficiencies in the Data. An accelerator cluster operating at peak arithmetic intensity only computes incorrect representations faster when training distributions are defective. A data benchmark therefore begins with an operational protocol rather than an aggregate score. The protocol defines the deployment slice the model must serve, reserves a leakage-resistant holdout, verifies duplicate and near-duplicate separation across partitions, sets minimum coverage for rare classes and subgroups, audits label quality, and establishes drift thresholds that determine when the benchmark no longer represents production. Only after those gates are explicit do aggregate metrics become interpretable.

Coverage metrics

The first question data benchmarking must answer is whether the training distribution covers the operational domain the model will encounter in production. Generalization to poorly represented input regimes is uncertain and requires direct evaluation; the mechanisms through which training coverage fails are often subtle.

Class balance is the most apparent failure mode. In a camera-trap dataset where 99 percent of frames are empty or show common species and 1 percent show the rare species the study exists to count, a degenerate model that predicts the majority class unconditionally achieves 99 percent accuracy while failing its operational purpose. Mitigating severe class imbalance requires loss reweighting, targeted oversampling, or decision threshold calibration. More insidious is subgroup

imbalance within classes: a dataset may have balanced positive and negative classes in the aggregate, yet draw negative examples disproportionately from a specific demographic cohort or geographic region. Aggregate accuracy metrics mask these systematic localized failures. When systems interact with human populations, auditing representation across demographic dimensions (such as age, geography, or dialect) is essential, though missing or noisy demographic metadata frequently complicates detection.

Feature coverage extends beyond discrete class labels into the continuous space of operational variations. While class balance is verified directly from label statistics, feature coverage requires mapping the physical parameters of the deployment environment. A vision pipeline trained exclusively on daytime captures fails under low-light sensor noise; a voice processing pipeline trained on clean studio signals degrades under acoustic reverberation and ambient noise. These environmental variations (differing sensor hardware, lighting conditions, and rare operational edge cases) fall outside discrete label distributions. Benchmarking feature coverage therefore requires specifying concrete bounds on the input space alongside domain experts before evaluating model performance.

Quality metrics

Even when a training dataset spans the operational domain, annotation errors corrupt the supervisory signal. Label errors, which average about 3 percent across ten canonical test sets and approach 6 percent on ImageNet's validation set (Northcutt et al. 2021), do not act as benign noise. Supervised optimization treats incorrect labels as ground truth. When an evaluation set contains corrupted labels, a model that learns the true underlying distribution is penalized, while a model that memorizes the annotation artifacts receives an inflated score.

For small corpora, manual audits over stratified random samples provide baseline error estimates. At scale, confident learning identifies label errors algorithmically by estimating the joint distribution of noisy annotations and true latent labels using out-of-sample predicted probabilities. When a model consistently assigns high confidence to a class that conflicts with the assigned label, the discrepancy isolates candidate annotation errors from typical optimization uncertainty. Flagging these candidates enables targeted relabeling or filtering, circumventing the prohibitive cost of exhaustive human review.

Inter-annotator agreement measures consistency across annotators prior to model training. The statistics are the ones data engineering already uses to monitor label quality in production; a data benchmark applies them once, to certify the evaluation set itself. Cohen's kappa for two raters and Fleiss' kappa for multiple raters quantify agreement above chance expectation (Cohen 1960; Fleiss 1971). When agreement metrics fall below established thresholds on tasks with objective ground truth, the failure points to ambiguous labeling taxonomies, rater fatigue, or inconsistent guidelines. While Landis and Koch's qualitative kappa bands provide a historical reference (Landis and Koch 1977), production pipelines require agreement thresholds calibrated directly to application-specific risk tolerance.

↩ Cohen's kappa, its chance-agreement correction, and label quality drift are established in section 4.6.4.

The structural form of label noise determines its downstream impact. Random label noise dilutes gradient signals across classes, increasing sample complexity but rarely teaching coherent false representations. In contrast, systematic errors, such as consistently mislabeling an underrepresented subclass or coupling a label with an environmental artifact, inject structured bias into model weights. If images of wolves photographed against snow are consistently labeled as dogs, the model learns to associate snow with the target class. In the presence of systematic label error, collecting more training data under the same labeling protocol does not correct the bias; it merely reinforces the spurious association with higher parameter certainty.

Distribution alignment

Data benchmarking must ultimately evaluate whether a model generalizes from training conditions to deployment environments. Standard evaluation protocols assume that training, validation, and test splits are independent and identically distributed (i.i.d.). In production systems, this assumption fails routinely: temporal drift alters consumer behavior, sensor degradation shifts hardware characteristics, and geographic expansion introduces unmodeled subpopulations. When the i.i.d. assumption breaks down, held-out validation accuracy may become a poor predictor of operational performance. The direction and size of the change depend on the shifted population. A

finite evaluation certifies behavior only on the population it sampled, and only within the uncertainty its sample size allows; that limit is the verification gap (principle 9).

This train-to-production alignment gap is quantified systematically by the WILDS[35] benchmark (Koh et al. 2021), which evaluates models across distribution shifts spanning hospital systems, camera trap locations, and satellite passes. On Camelyon17-WILDS, the reported ERM baseline achieved 93.2 percent in-distribution average accuracy and 70.3 percent out-of-distribution average accuracy across unseen clinical sites. This performance drop occurs despite holding the architecture, hyperparameters, and training compute constant, demonstrating a distribution-dependent performance gap for that fixed model and training procedure. The comparison does not isolate which capacity, representation, or data changes would close it.

The same benchmark's iWildCam split is the camera trap's version of the problem. Models trained on images from one set of camera-trap locations are evaluated on traps they have never seen, where background, lighting, and the mix of species all change (Koh et al. 2021). A MobileNetV2 that meets every latency and energy gate on the board can still fail this test, and no system benchmark would reveal it.

To detect changes that warrant investigation, serving pipelines can apply the statistical shift tests and the covariate, label, and concept shift taxonomy of section 4.12.1 to incoming inference streams; the benchmarking use is to decide when the evaluation set has stopped representing production. Two-sample hypothesis tests such as the Kolmogorov-Smirnov test (Berger and Zhou 2014) for univariate features and maximum mean discrepancy (Gretton et al. 2012) for multivariate embeddings detect changes in the marginal input distribution $p(x)$. Establishing covariate shift also requires the conditional target distribution $p(y \mid x)$ to remain stable; input-only tests cannot verify that condition without label evidence. Prediction entropy and confidence distributions provide additional warning signals, but shifted inputs can still produce confident predictions. Validate alert thresholds and fallback policies against labeled deployment samples; these signals alone do not guarantee detection before quality degrades.

↪ Live covariate shift detectors feed the statistical distance monitoring and automated drift alerts developed in section 22.

Distribution alignment challenges highlight a persistent tension in ML development between two paradigms: *fixing the data and iterating on models*, or *fixing the model and iterating on data*. The side-by-side schematics in figure 12.12 isolate this divergence through the placement of the padlock and feedback path. In the model-centric panel, the dataset is locked while the feedback loop iteratively refines model parameters on the CPU; in the data-centric panel, the model architecture is locked while the loop routes back to enhance training data quality, diversity, and labeling. As the bidirectional red arrow emphasizes, the two paradigms are complementary engineering strategies rather than mutually exclusive philosophies.

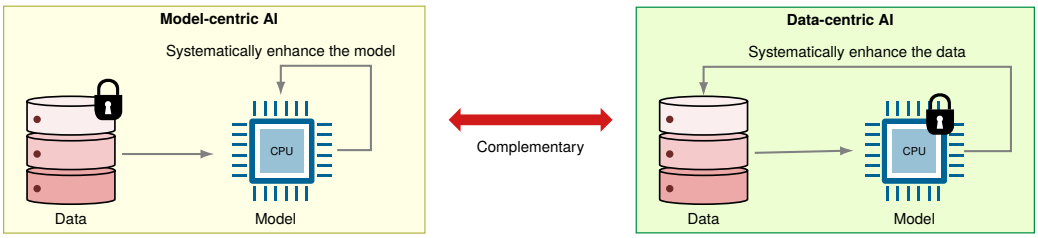


Figure 12.12: Development Paradigms: Model-centric AI iterates on architecture while holding the dataset fixed, whereas data-centric AI iterates on annotations, diversity, and bias while holding the architecture fixed. The double arrow marks the approaches as complementary.

Data-centric AI reflects an important shift in understanding that challenges the "more data is always better" assumption: dataset composition matters alongside scale. Initiatives like DataPerf (Mazumder et al. 2023) and DataComp[36] have emerged to evaluate how dataset construction affects model performance systematically. In DataComp's compute-controlled setting, a baseline that retained the top 30 percent of the candidate pool by CLIP-based filtering outperformed the unfiltered-pool baseline on aggregate downstream evaluation (Gadre et al. 2023). The result establishes the value of curation for that protocol, not a universal optimal fraction.

[35] **WILDS**: Stanford's 2021 benchmark of ten datasets with real-world distribution shifts: hospital changes (Camelyon17), wildlife camera location shifts (iWildCam), and satellite imagery temporal drift (PovertyMap). For the reported Camelyon17-WILDS ERM baseline, average accuracy fell from 93.2 percent in-distribution to 70.3 percent out-of-distribution, demonstrating that standard held-out evaluation can overestimate performance when the i.i.d. assumption fails.

[36] **DataComp**: Introduced in 2023, DataComp fixes the model family, training code, and compute budget while participants vary dataset construction. Its filtering track isolates the effect of selecting examples from a common candidate pool, making curation strategies comparable without attributing every gain to additional training compute.

Dataset saturation and dynamic benchmarks

Even when coverage, quality, and distribution alignment protocols are satisfied, static benchmarks encounter the problem of dataset saturation. As models approach empirical upper bounds on fixed test suites, leaderboard deltas compress, making it difficult to distinguish genuine capability advances from over-optimization to benchmark-specific artifacts. The capability trajectories in figure 12.13 plot this exhaustion over two decades, showing AI scores rising from normalized baselines (-100) to cross the zero line marking human performance (Maslej et al. 2024). While handwriting and speech recognition required over a decade to reach human parity (the green shaded region), reading comprehension and language understanding surged across the threshold in under two years between 2016 and 2020, rapidly exhausting the discriminating headroom of static suites.

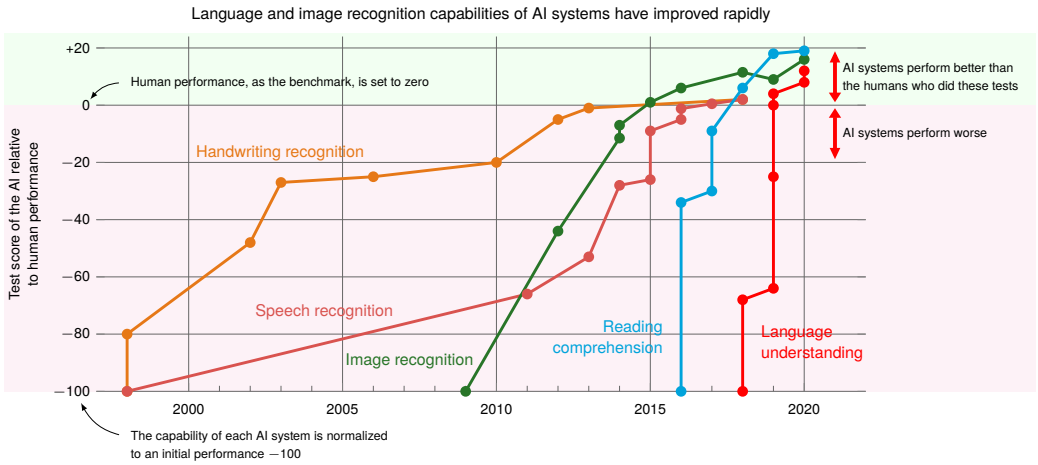

Figure 12.13: Dataset Saturation: The zero line denotes reported human performance; each curve's crossing marks a capability for which the static benchmark has less remaining discriminating headroom. The crossings do not distinguish genuine capability gains from optimization to the evaluation set. Sources: (Maslej et al. 2024; Kiela et al. 2021).

Once a static benchmark saturates, high leaderboard accuracy can mask brittle heuristics. MNIST digit recognition (LeCun et al. 1998) demonstrated early that models can exploit dataset-specific capture artifacts rather than invariant features, a concern that eventually prompted researchers to re-examine whether ImageNet had reached the end of its useful diagnostic lifetime (Beyer et al. 2020). When the evaluation distribution remains frozen, iterative model selection risks overfitting to idiosyncratic test artifacts rather than improving generalizable task capability.

Dynamic benchmarking frameworks such as Dynabench[37] (Kiela et al. 2021) address saturation by continuously evolving evaluation data. In this paradigm, human annotators generate adversarial inputs targeting the failure modes of current top-performing models, ensuring that the benchmark continues to exercise representational limits. However, dynamic benchmarks introduce a direct systems trade-off: because the evaluation distribution changes across iterations, longitudinal comparisons across model generations become difficult to calibrate. Static and dynamic benchmarks therefore serve complementary roles: static suites ensure longitudinal reproducibility on standardized tasks, while dynamic benchmarks identify newly emergent error boundaries.

37 **Dynabench**: Facebook AI Research's 2021 platform for dynamic benchmark generation, where humans craft adversarial inputs that fool current best models. Dynabench addresses the saturation problem, where very high accuracy on static benchmarks may reflect test-set familiarity rather than robust capability, but introduces its own trade-off: dynamic benchmarks are harder to compare across time because the evaluation set changes. Static and dynamic benchmarks serve complementary diagnostic roles.

12.9.3 Holistic system-model-data evaluation

Passing system, model, and data benchmarks independently is not enough. A system benchmark can validate hardware performance, a model benchmark can verify that compression preserved quality, and a data benchmark can assess training set representativeness, yet the deployed system can still fail because the three dimensions interact. Real-world AI performance emerges from that interaction, and optimizing one dimension can expose weaknesses in another.

Consider a concrete failure cascade, a composite drawn from the chapter's camera trap: an engineering team achieves target throughput on MLPerf Inference by deploying an INT8-quantized

vision model on a specialized accelerator. System benchmarks pass. However, because the quantization scale factors and zero points were fitted (quantization-range calibration) strictly against ImageNet validation samples, deploying the model in the camera trap's night-time infrared frames reveals severe accuracy degradation. Infrared frames produce activation ranges that exceed the calibrated clipping thresholds, truncating feature activations. A targeted model quality benchmark across varied exposure levels would have exposed this numerical sensitivity. Tracing the failure upstream reveals that the training pipeline contained no night-time infrared imagery, a data distribution gap that no amount of accelerator optimization or runtime kernel tuning can resolve.

Cross-dimensional coupling means that a passing benchmark in one domain can be invalidated by an unmeasured failure in another. When system benchmarks succeed alongside a model failure, the hardware delivers its promised throughput while aggressive compression degrades accuracy below deployment thresholds; when they succeed alongside a data failure, fast inference executes on benchmark inputs while training data bias causes severe accuracy disparities across demographic subgroups. Conversely, a model success paired with a system failure produces accurate predictions whose tail latency variance under concurrent load violates service-level agreements, whereas a model success paired with a data failure yields high accuracy on held-out test sets that silently degrades under production distribution shift.

These failure modes map onto the pairwise intersections of the D·A·M taxonomy (figure 1.4), though benchmark evaluation lenses do not align one-to-one with isolated physical vertices. Data benchmarks evaluate input distribution quality and coverage (D); model benchmarks assess learned algorithmic representations and numerical robustness (A); and system benchmarks expose hardware execution, kernel efficiency, and memory-interconnect traffic (M). Holistic evaluation validates the pairwise and central intersections where these domains meet, ensuring that optimizations across the Part III pipeline (data selection → model compression → hardware acceleration) do not introduce hidden cross-axis regressions.

↩ The D·A·M taxonomy and its pairwise intersections are established in section 1.5.

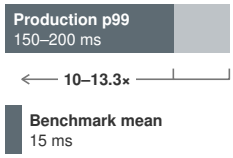
The D·A·M taxonomy provides a diagnostic framework for systematically identifying which axis limits performance. Table 12.20 formalizes this approach by crossing each D·A·M axis with compute, memory, and I/O constraints.

Table 12.20: D·A·M Bottleneck Diagnostic Matrix: Each cell suggests a constraint to investigate. Capacity limits determine whether the working set fits; bandwidth limits determine how quickly resident work can move. Activity counters alone do not identify the binding resource, and traces or controlled interventions must confirm a diagnosis.

Component	Compute Constraint	Memory Constraint	I/O Constraint
Data	Host preprocessing saturates compute	Capacity: working set exceeds RAM	Storage delivery cannot keep the accelerator fed
Algorithm	Required operations exceed the compute-time budget	Capacity: activations restrict feasible batch size	Exposed gradient synchronization limits step time
Machine	Useful operation rate approaches the compute roof	Bandwidth: traffic approaches the interface limit	Exposed transfers approach the interconnect limit

Applying this matrix organizes hypotheses when system telemetry diverges from theoretical hardware peaks. If an accelerator achieves only 30 percent GPU utilization during training, an engineer might prematurely blame the model architecture (Algorithm row) and attempt model surgery. Profiling often reveals instead that host-side data workers saturating CPU cores on image augmentation or tokenization cannot feed batches fast enough across PCIe (Data row, Compute Constraint column). The accelerator stalls not from algorithmic inefficiency, but from input pipeline starvation. The matrix guides investigation; traces and controlled interventions establish which physical subsystem is binding.

↪ A production troubleshooting matrix that maps common failure symptoms to a candidate D·A·M axis and the measurement that confirms it is collected for reference in section A.5.2.



Validation under controlled laboratory conditions differs from validation in production. A laboratory protocol may fix data, simplify arrivals, or isolate execution to answer a controlled question. In production, all three assumptions can break simultaneously: data drifts, traffic spikes unpredictably, and concurrent workloads compete for shared hardware. The recurring misconceptions that follow are the ways teams forget that difference.

12.10 Fallacies and Pitfalls

Benchmarking creates false confidence when standardized measurement obscures deployment realities. Teams assume controlled evaluations predict production performance, but real systems face variability, resource constraints, and multi-objective trade-offs that benchmarks cannot capture, wasting engineering effort on systems optimized for evaluation rather than deployment.

Fallacy: *Benchmark performance directly translates to real-world application performance.*

The apparent clarity of isolated benchmark numbers leads teams to assume that measuring a model's forward pass predicts user-facing response times. It does not. In research benchmarks, a model's raw inference pass might execute in 5–10 ms. However, inside a production serving microservice, request deserialization, tokenization, feature retrieval, and network transmission overhead expand the total response time to 50–100 ms. In an illustrative model-only test, the team reports mean latency under synthetic, evenly spaced inputs (15 ms). Under the scenario's production traffic, arrival bursts and queueing backlog raise p99 tail latency to 150–200 ms (10–13.3× gap from the model-only mean). This contrast changes the statistic, measurement boundary, and traffic conditions; quantifying a slowdown requires matched end-to-end statistics under stated workload conditions. In the same illustrative comparison, a model achieving 92 percent benchmark accuracy drops to 78–82 percent when confronted with real-world distribution shifts such as noisy text and uncurated sensor inputs. Evaluating an isolated neural network kernel cannot substitute for benchmarking the complete end-to-end serving pipeline.

In this scenario, the model-only mean understates the production tail by an order of magnitude.

Pitfall: *Optimizing exclusively for benchmark metrics without considering broader system requirements.*

Benchmark leaderboards incentivize aggressive optimization, but the optimizations that climb rankings often degrade the very characteristics production demands. This exemplifies Goodhart's Law (section 12.1), whose organizational form section 12.8.4 examined. In one illustrative scenario, a team reduces inference latency from 12 ms to 8 ms through aggressive quantization, improving MLPerf ranking by 15 positions while degrading calibration such that prediction confidence scores become unreliable for downstream decision-making. Another team improves ImageNet accuracy by 2.1 percentage points through extensive hyperparameter tuning, yet the optimized model consumes 40 percent more energy and suffers 25 percent worse performance on out-of-distribution images from production cameras.

Fallacy: *Single-metric evaluation provides sufficient insight into system performance.*

A single-number claim appears deceptively simple ("94 percent accurate" or "1,200 QPS fast"), yet production success requires balancing multiple competing objectives that any single metric obscures. Modern inference systems demand evaluation across accuracy, latency, throughput, energy, and robustness dimensions (section 12.6.2). In an illustrative trade-off, a recommendation model achieving 94 percent accuracy with 180 ms p99 latency fails service-level objectives requiring p99 < 100 ms despite excellent accuracy. Conversely, a system optimized for 1,200 QPS throughput achieves this rate while consuming 4.2 W vs. 1.8 W for a slightly slower system at 1,000 QPS (2.3× power difference). For battery-powered edge devices, the 17 percent throughput loss enables 2.3× longer operation time. Different stakeholders prioritize different metrics: ML engineers focus on accuracy, infrastructure teams on throughput and cost, product managers on latency percentiles.

Pitfall: *Using outdated benchmarks that no longer reflect deployment challenges and requirements.*

Benchmarks have inertia: teams continue reporting on established benchmarks after the results cease to provide useful discrimination. Saturation occurs when multiple approaches achieve near-identical performance, eliminating useful comparison. ImageNet top-5 classification error decreased from 28.2 percent in 2010 (Russakovsky et al. 2015) to 3.57 percent by 2015 (He et al. 2016a), sharply compressing the headroom measured by that metric. As gaps narrow, the statistical confidence intervals discussed in section 12.8.1 and the result's deployment relevance matter more than leaderboard rank. Changing deployment contexts compound the problem: benchmarks designed for server hardware become misleading for edge devices with 10× less memory and 100× lower power budgets. Effective benchmarking requires retiring saturated benchmarks and developing evaluation frameworks matching target deployment realities.

Fallacy: *Research benchmarks predict production behavior under real traffic.*

A short, isolated laboratory run can miss the thermal and architectural constraints of sustained production execution. First, laboratory runs frequently suffer from initialization errors: omitting warmup runs conflates one-time JIT compilation, GPU runtime initialization, and memory allocator page faults with steady-state execution. Second, short laboratory bursts (e.g., 30 seconds) capture transient boost clock frequencies. Under sustained production load, heat accumulates faster than cooling infrastructure can dissipate it; the hardware governor triggers dynamic voltage and frequency scaling (DVFS), downclocking silicon to protect junction temperatures. As a result, a system achieving 800 QPS throughput in short burst benchmarks sustains only 400–500 QPS under continuous load with 90 percent utilization (37.5–50 percent degradation).

12.11 Summary

Benchmarking completes Part III's optimization pipeline by validating whether the efficiency gains from data selection, model compression, and hardware acceleration deliver in practice. The three benchmark lenses examine system execution, model behavior, and data representativeness separately, then test whether their assumptions survive when the complete system runs under deployment conditions. Every row of table 12.2 began as a claim and now has a measurement: ResNet-50's INT8 claim became a test with stated conditions, its roofline ceiling met an MLPerf throughput that sits 8.0× below it, MobileNetV2's accelerator speedup narrowed once the whole frame path on the edge board was timed, and keyword spotting showed that idle power, not inference, sets a duty-cycled device's battery life.

The lenses reveal different failure modes: system benchmarks expose underdelivered throughput, tail latency, and thermal behavior; model benchmarks test accuracy, calibration, robustness, and other properties that an optimization may alter; and data benchmarks examine coverage, label quality, leakage, and alignment with deployment. Standardized suites such as MLPerf Training and Inference provide comparable system evidence, whereas model and data protocols supply the quality and representativeness evidence that a hardware result cannot establish.

Optimization claims need measured execution rather than analytical proxies: wall-clock timing captures DRAM bandwidth saturation, kernel launch serialization, and host-device transfer overhead that FLOP counts omit; percentile profiling under concurrent load exposes queuing delays and thermal throttling that arithmetic means conceal; and evaluating workloads against production-representative data reveals dynamic shape variations and memory churn that uniform synthetic inputs never trigger.

A candidate release can pass the hardware, model, and data tests yet still lack evidence for the workload it will serve. A service with bursty requests needs load validation, and a camera trap deployed under changing illumination needs labeled examples from those conditions. Laboratory benchmarks establish behavior under specified conditions; a release decision must identify which of those conditions remain valid in the target deployment and test the ones that change. Timing and memory telemetry can expose overload, while silent predictive degradation requires labels or validated quality proxies, and when labels arrive late the release protocol must name that delay. A research benchmark remains useful for comparing algorithms, but a release gate for a serving system must also include load tests, tail-latency measurements, data-quality checks, failure drills, and rollback criteria. Table 12.21 pairs each simplifying benchmark assumption with the production condition that violates it and the validation step that closes the gap.

Table 12.21: Predeployment Benchmark Checklist: Each row pairs a simplifying benchmark assumption with a production condition that can violate it and the validation step that closes the gap. Each row should be independently verified against representative operational conditions.

Benchmark Assumption	Production Reality	Validation Approach
Uniform request arrival	Bursty traffic patterns	Load test with production trace replay
Clean, preprocessed inputs	Variable quality inputs	Evaluate on production data sample
Warm system state	Cold starts, cache misses	Measure cold-start performance
Isolated execution	Resource contention	Benchmark under realistic system load

Benchmark Assumption	Production Reality	Validation Approach
Fixed model version	A/B testing, gradual rollout	Establish baseline for comparison

Once a model is live, benchmarking becomes a rolling comparison against those baselines: whether the input distribution remains close to the benchmark distribution, whether latency and throughput stay inside the measured envelope, and whether model quality moves outside its expected range. Serving systems turn this measurement loop into staged rollouts, shadow evaluation (running the new model beside production without serving its outputs), and automated rollback. Benchmarking defines the performance envelope and failure thresholds; production monitoring tests live telemetry against them.

The chapter's measurement formulas fit on one page (table 12.22). Together they let an engineer state, before running a benchmark, what it will measure and what result would refute the claim.

↪ Shadow, canary, and blue-green releases and the rollback tiers that act on these thresholds are developed in section 14.4.3.

Table 12.22: Key Equations: The chapter's measurement formulas in the notation of the sections that derive them. Each states what a benchmark must measure and over which window, so that a claim can be refuted by a measurement rather than argued.

Quantity	Formula	Where derived
Time to accuracy	$T_{\text{train}} = \inf\{t \geq 0 : \text{Accuracy}_{\text{val}}(t) \geq \text{target accuracy}\}$	equation 12.1
Training throughput	$\text{Throughput} = \frac{N_{\text{samples}}}{T_{\text{train}}}$	equation 12.2
Scaling efficiency	$\text{Eff}_{\text{scaling}}(N_{\text{GPU}}) = \frac{T(1)}{N_{\text{GPU}} \times T(N_{\text{GPU}})} \times 100\%$	equation 12.3
Hardware utilization	$\eta_{\text{hw}} = R_{\text{sustained}}/R_{\text{peak}}$	section 12.4.3
Amdahl ceiling	$1/(1-f_{\text{parallel}})$ for an accelerated fraction f_{parallel} of latency	section 12.3.4
Energy per inference	$E_{\text{inf}} = P_{\text{active}} \times L_{\text{lat,infer}}$	section 12.7
Duty-cycle average power	$P_{\text{avg}} = \alpha_{\text{duty}} P_{\text{active}} + (1-\alpha_{\text{duty}}) P_{\text{idle}}$	section 12.7.2
Energy over a window	$E_{\text{total}} = \int_{t_{\text{start}}}^{t_{\text{end}}} P_{\text{device}}(t)\, dt$	section 12.7.4
Paired-test statistic	$\chi^2 = \frac{(n_{\text{base}} - n_{\text{comp}})^2}{n_{\text{base}} + n_{\text{comp}}}$	section 12.8.1
Expected calibration error	Bin-weighted mean of the gap between confidence and accuracy	equation 12.4

Key Takeaways: Measuring what matters

- **Benchmarks validate co-design**: System, model, and data benchmarks expose hardware underdelivery, compression quality loss, and distribution mismatch. A system that passes only one axis can still fail when Data, Algorithm, and Machine constraints meet under production load.
- **A claim becomes a test only when its conditions are fixed**: Benchmark carpentry restates a claim such as "ResNet-50 is faster at INT8" as a task, dataset, model, metric, harness, specification, and run rules. A number reported without those conditions cannot be reproduced, compared, or refuted.
- **A prediction and a measurement together locate a bottleneck**: The roofline places ResNet-50 training on the compute roof, yet the measured MLPerf throughput sustains only 12.4 percent of peak. The gap says time is going somewhere other than arithmetic, and profiling attributes it.
- **Proxy numbers need boundaries**: Standardized run rules make comparisons honest, but fixed workloads are still proxies. Batch size, thermal state, input distribution, concurrency, and service-deadline windows decide whether a lab result survives the benchmark–production gap.
- **Granularity trades diagnosis for realism**: Micro-benchmarks isolate kernels, macro-benchmarks expose model-level costs, and end-to-end benchmarks capture user-visible

behavior. Effective measurement stacks all three so teams can see both the symptom and the layer that caused it.

- **Tail latency often decides pass or fail**: Interactive services with percentile-based SLOs can violate their latency target while mean latency remains acceptable. Reporting percentile latency under representative load prevents a benchmark from approving a system whose mean passes while its worst-served requests violate the SLO.
- **A component speedup is diluted across the pipeline stages it does not touch**: In the chapter's vision pipeline, unchanged preprocessing at 44.4 percent of latency turns a 5× inference speedup into 1.8× end to end, and Amdahl's law (equation 11.1) caps even an infinitely fast model at 2.25×. Benchmark the whole request path before celebrating kernel speedups.
- **Energy follows the duty cycle**: For always-on keyword spotting on a microcontroller board, the idle floor accounts for 94 percent of average power, so energy per inference alone misdescribes battery life. A power benchmark states its boundary, its window, and the duty cycle.
- **A difference is real only beyond its noise**: Paired tests on per-image outcomes and intervals over repeated run pairs decide whether a one-point accuracy gap or a measured latency reduction is a finding. A test set is a measurement instrument with finite resolution.
- **Efficiency still needs quality evidence**: INT8 may cut raw weight storage 4×; the simplified component model estimates an energy reduction of about 6.6×, but whole-device measurement, confidence calibration, subgroup robustness, and edge-case behavior decide whether the compressed model is deployable.

Each chapter in this part promised fewer FLOPs, a smaller model, or higher throughput. Benchmarking tests those promises against the complete system. The gap between a claimed improvement and a measured one reveals where Data, Algorithm, and Machine were assembled rather than matched. Applied to a measured pipeline, Amdahl's law shows why an infinitely fast model can still leave the pipeline bounded by everything outside it, while tail latency shows why an average can pass even as the worst-served requests fail.

What's Next: From lab to live

The serving protocols in this chapter specified the arrival process through a load generator. Production supplies its own changing traffic, and the serving system must respond within its declared operating envelope. Part IV leaves the controlled benchmark environment, beginning with chapter 13. Engineering for arrivals no one schedules reorders the priorities that training optimized, putting per-request latency and spare headroom ahead of raw throughput.

IV

DEPLOYMENT AND OPERATIONS

Part IV

Deployment Principles

The code can be correct and the benchmarks excellent, and yet the system may fail. Part III ended with benchmarks whose load generator decides when each request arrives and whose test data stays fixed. Part IV moves from that controlled environment to production, where ML systems face the additional threat of silent decay. A machine learning system can continue to produce outputs that are confident, well-formatted, and wrong as the world drifts away from its training distribution. At deployment, the data environment escapes the engineer's control and can stress the trained algorithm and the serving machine in ways no test set anticipated. Reliability is therefore a continuous control loop of D·A·M co-design rather than a one-time release gate. The principles here define the requirements and diagnostic models for that reliability.

Principle 9: The verification gap

Policy: Statistical verification holds only over a defined deployment population p_{deploy}, task distance d_{task}, tolerance τ_{tol}, and target error ϵ, estimated by a finite-sample procedure at a stated confidence level:

$$\Pr_{(x,y)\sim p_{\text{deploy}}}[d_{\text{task}}(f(x),y) \leq \tau_{\text{tol}}] \geq 1-\epsilon$$

Implication: Deployment is not a one-way transfer; it is a control loop. Because no test suite can cover every possible real-world input, production systems must monitor their own uncertainty and fail gracefully when they drift outside their known performance envelope.

The verification gap means finite evaluation can only estimate behavior on a defined population with uncertainty. Those bounds may erode as production data diverges from the data used to set them.

Principle 10: The statistical drift diagnostic

Fitted model: Divergence between the production and baseline distributions does not by itself determine whether accuracy changes; over a measured deployment range, labeled outcomes can fit a local linear relationship:

$$\text{Accuracy}(t) \approx \text{Accuracy}_0 - \lambda \cdot \mathcal{D}(P_t \| P_0)$$

where P_t is the data distribution at time t after deployment, P_0 is the training (baseline) distribution, Accuracy_0 is the model's performance on P_0, $\mathcal{D}(P_t \| P_0)$ is the statistical divergence between the current and baseline distributions, and λ is fitted from labeled outcomes rather than inferred from divergence alone. Consider a credit scoring model trained on 2020 borrower behavior. Two years later, inflation rises, interest rates change, and lending policies shift. The system still produces scores, but the statistical relationship between inputs and outcomes may have changed; labeled outcome monitoring determines whether real accuracy declined while conventional error logs remained quiet. Unlike many traditional software failures, which are often surfaced by crashes, exceptions, or explicit service-health signals, ML systems can fail silently because the environment changes even when the code and infrastructure remain

unchanged. This first-order linearization applies only over the measured range; the relationship is model-dependent and may be nonlinear for large drift.

Implication: Observability must extend beyond system metrics (latency, errors) to combine statistical drift signals with labeled outcomes. A system can remain operational while prediction quality changes, but drift monitoring alone does not establish degradation.

External drift is not the only threat. Even when the world holds still, the serving pipeline itself can diverge from the model validated offline.

Principle 11: The training-serving skew diagnostic

Heuristic: Training and serving code paths can diverge on identical inputs, and that divergence is measurable without labels. For scalar model scores, define training-serving divergence as the expected absolute difference between the two functions over a stated comparison-input distribution:

$$S_{\text{skew}} = \mathbb{E}[|f_{\text{serve}}(x) - f_{\text{train}}(x)|]$$

The exact relationship between S_{skew} and accuracy depends on the loss function, decision boundary geometry, and production distribution. Unexplained divergence weakens the assumption that offline validation estimates production behavior and can cause silent accuracy loss, but S_{skew} is not a universal accuracy-loss equation. This divergence arises from inconsistent preprocessing logic, different library implementations, stale feature values, or environmental state changes between the two code paths.

Implication: Feature consistency is an architectural requirement, not merely a best practice. Feature stores are more than caches; they can reduce skew by centralizing feature definitions and retrieval. Teams still need validation for freshness, point-in-time correctness, preprocessing, model-runtime, and postprocessing parity. Even subtle differences (PIL vs. OpenCV resize, FP64 vs. FP32 normalization) can compound to produce silent accuracy degradation that standard monitoring may not detect.

Time is the nonnegotiable constraint beneath all these reliability concerns. A medical imaging system that detects tumors with 99 percent accuracy but takes 30 seconds per scan may miss its workflow deadline, and an autonomous vehicle perception model that classifies obstacles correctly in 200 ms instead of 50 ms may miss its braking deadline. Latency-sensitive deployed models operate under a strict deadline: if a correct prediction arrives too late, it has no operational value and is functionally equivalent to returning no prediction at all.

Principle 12: The latency budget principle

Policy: Under serial request-path accounting, end-to-end latency is the sum of network, preprocessing, inference, postprocessing, and queueing delays, and a deployment meets its deadline only at a stated completion quantile:

$$L_{\text{lat,total}} = L_{\text{lat,network}} + L_{\text{lat,pre}} + L_{\text{lat,infer}} + L_{\text{lat,post}} + L_{\text{lat,queue}}, \qquad \Pr[L_{\text{lat,total}} \leq T_{\text{deadline}}] \geq q$$

Implication: In latency-sensitive serving, the product selects the deadline and the acceptable completion quantile, such as 0.95, 0.99, or 0.999, and throughput is optimized within that constraint. Serving systems must implement tail-latency controls (for example, bounded-delay dynamic batching or hedged requests). Serving systems must be willing to sacrifice overall throughput to meet the latency deadline of the oldest request in the queue.

A system can satisfy its latency SLOs, detect measured distributional shifts, and maintain training-serving consistency while still causing systematic harm. The previous principles address silent

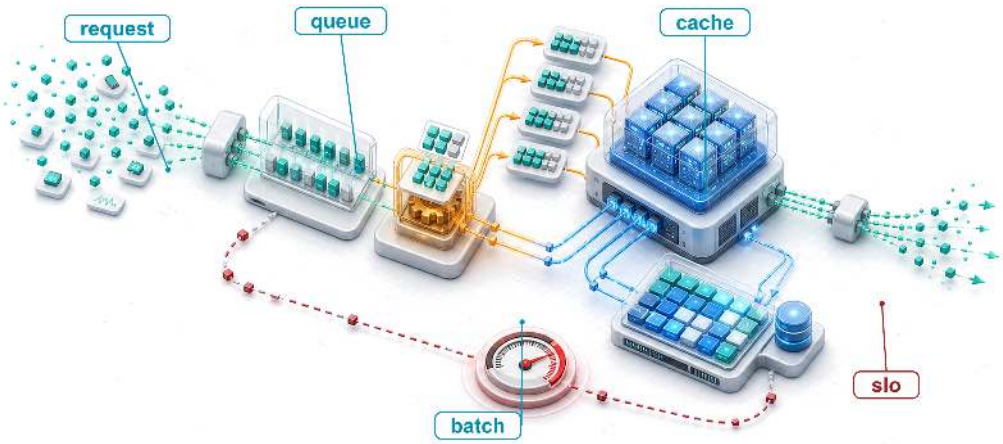
failures in correctness and service quality; this one addresses failures that degrade equity through silent amplification.

Principle 13: The bias feedback model

Fitted model: When outputs influence future inputs, today's disparity becomes an input to the next training cycle, so disparity evolves as a dynamical system rather than staying fixed. Let $\Delta_g(k) \geq 0$ denote the disparity magnitude for group g relative to a specified reference group after k fixed feedback intervals. With no effective intervention and an approximately constant dimensionless feedback factor $\alpha_{\text{fb}} > 0$, disparity may evolve as:

$$\Delta_g(k) \approx \Delta_g(0) \cdot \alpha_{\text{fb}}^k$$

where $\Delta_g(0)$ is the initial disparity magnitude relative to that reference group and α_{fb} is fitted per feedback interval. Consider a loan approval model that denies credit at higher rates to applicants from historically underserved communities. Denied applicants cannot build credit history, which makes future applications weaker, which increases future denial rates. The model's accuracy on its training distribution remains stable, but the population it serves has been reshaped by its own decisions. When $\alpha_{\text{fb}} > 1$ under these assumptions, the feedback loop is self-reinforcing; when $\alpha_{\text{fb}} \leq 1$, the modeled dynamics are stable or damped. Real deployments may also be nonlinear, saturating, or changed by intervention.



Implication: Fairness is not a postdeployment audit; it is a stability constraint on the deployment control loop. Where consequential impact warrants it and collecting or using group attributes is lawful and justified, systems must monitor disaggregated performance metrics across relevant demographic groups with the same rigor applied to latency percentiles, because a bias regression can be invisible to aggregate accuracy just as a tail-latency violation can be invisible to mean latency.

Together, the five principles define a deployment control loop that establishes what the evidence supports, observes the live system and environment, acts only when a measured failure warrants intervention, and re-evaluates the relevant service, predictive, or subgroup criterion. They separate diagnosis from response. A signal narrows the investigation but neither prescribes an automatic intervention nor proves that quality has already degraded.

Part IV makes that control loop concrete. Chapter 13 builds infrastructure that meets latency budgets under variable traffic and checks training-serving parity on the request path. Chapter 14 detects drift and skew over the model's operating lifetime while preserving the evidence needed for diagnosis and response. Chapter 15 treats fairness and feedback as measurable deployment dynamics rather than a one-time compliance check. Chapter 16 then closes the book by gathering these production controls and the quantitative bounds and models of the preceding parts into one framework for reasoning across the whole stack.

13.12 Summary

Purpose

Why does serving change the optimization priorities that made training successful?

Training and serving pursue opposing operating objectives. Training maximizes aggregate throughput across large, scheduled batches and long runs, whereas serving must answer individual, heterogeneous requests under strict latency deadlines. Training amortizes hardware initialization and weight streaming across millions of examples; serving pays its full fixed cost on every query, and small inefficiencies accumulate into machine time that must be provisioned. A system handling one billion requests a day recovers more than eleven days of machine time every day from a single millisecond saved per request. Each request also runs inside a fixed end-to-end latency budget, in which network ingress, serialization, preprocessing, queueing, and postprocessing all spend time the model cannot use. When those stages consume most of the budget, kernel optimizations barely reach the user, and a prediction that arrives after the client has timed out has no value however accurate it is. Serving is therefore a capacity problem under uncontrolled traffic as much as a latency problem. Arrival rates swing between daily peaks and troughs, so capacity provisioned for the average collapses at the peak, while capacity provisioned for the peak sits idle and costly the rest of the day. The question a serving system answers is not whether the model computes correct outputs in isolation but whether it sustains reliable, low-latency execution under production variability. In D·A·M terms, serving is where the trained algorithm meets unpredictable live data inside the machine's latency budget, and all three constraints bind on every request.

Learning Objectives

- Explain serving inversion from training throughput to per-request latency, headroom, and tail behavior
- Decompose request latency across serialization, preprocessing, inference, queuing, post-processing, and network overhead
- Apply queueing laws and simple queue models to plan capacity and admission control against percentile latency targets
- Select batching windows and inference runtimes that trade formation delay and precision for throughput within a latency budget
- Diagnose cold-start delays from weight transfer, runtime initialization, graph compilation, and warmup during model loading
- Evaluate LLM serving bottlenecks using token latency, KV-cache memory, and continuous batching constraints
- Calculate cost per inference from precision, hardware utilization, replica count, and runtime throughput

13.1 The Serving Inversion

When a user uploads a photograph and waits for its label, or a chat interface sends a prompt and waits for the first word of the reply, each request carries a strict deadline of tens to hundreds of milliseconds. Every stage between the network socket and the response draws on that single allowance: decoding the payload, waiting in a queue, moving tensors to the accelerator, running the model, and formatting the answer. Moving from offline training to live traffic triggers the **serving inversion**, a reversal of engineering priorities: training is judged by how much work the machine completes per hour, whereas serving is judged by whether each individual request returns before its deadline.

The benchmarks of chapter 12 measured models under a load generator that decided when each request arrived. Production traffic has no such scheduler. Model **serving** must sustain the operating targets that benchmarking evaluated under specified conditions while live traffic tests that operating envelope continuously, so measurement remains part of the service's lifecycle. In offline training, systems maximize aggregate throughput by packing large batches to amortize weight transfers from high-bandwidth memory (HBM) and saturate matrix arithmetic units. In online serving, requests arrive stochastically from independent clients and must return within strict service-level objectives (SLOs). The primary engineering priority therefore inverts from long-run throughput to per-request latency. The inversion restructures the balance of terms across both levels of the iron law of ML systems: shrinking a task from a large training batch to small batches or individual inputs ($B = 1$) slashes the Data factor (Samples/Task in equation 1.2) and inflates the Machine factor (Seconds/FLOP) across the unpacked terms of equation 1.3 ($T = \frac{D_{\text{vol}}}{\text{BW}} + \frac{O}{R_{\text{peak}} \cdot \eta_{\text{hw}}} + L_{\text{lat}}$). For weight-dominated operations, small batches reduce arithmetic intensity and can shift execution from compute-bound matrix multiplications toward memory-bandwidth-bound transfers (D_{vol}/BW). Simultaneously, the latency term L_{lat} expands beyond microsecond accelerator kernel launches to include network transit, request serialization, and host orchestration, often becoming the binding constraint on end-to-end response time.

↩ The multiplicative, additive, and pipelined formulations of the iron law of ML systems are established in section 1.7.

The inversion reshapes each D·A·M layer at once. In the data layer, the constraint shifts from total dataset volume to the arrival rate, payload freshness, and variable sequence dimensions of live queries, while in the algorithm layer execution becomes strictly forward-only: backpropagation state and optimizer memory vanish from the accelerator, even as dynamic input shapes introduce runtime execution variability into previously static operator graphs. In the machine layer, the operating target shifts from maximum hardware utilization to **headroom**. Whereas offline training treats an idle accelerator as wasted capital, online serving treats near-saturation as an operational hazard, because stochastic request arrivals make queue lengths and waiting times diverge nonlinearly as utilization approaches 100 percent. Maintaining adequate headroom preserves the spare capacity needed

to absorb transient traffic spikes without violating tail-latency percentiles, so serving optimizes completed requests under a strict latency deadline rather than steady-state hardware occupancy.

Meeting that latency deadline governs how engineering teams partition the end-to-end serving stack. A request's latency budget encompasses three sequential stages: host-side ingress and preprocessing (network termination, payload deserialization, and tokenization or feature transformation), accelerator kernel execution, and downstream postprocessing. Any millisecond consumed by unoptimized feature retrieval or queueing delays directly subtracts from the execution time allocated to the neural network itself. Consequently, the central engineering task in model serving is deciding which operations must remain on the synchronous request path, which tasks can be offloaded to asynchronous background pipelines, and how much headroom the system must reserve before tail-latency guarantees collapse under load. Three conditions therefore separate serving from the forward pass that a benchmark times: a per-request deadline, arrivals that no scheduler controls, and a stack in which the model is one stage among several.

Definition 13.1: Model serving

Model serving is the operational phase that provides model predictions to end-users or downstream systems under latency, throughput, availability, and cost constraints.

1. **Significance**: Online serving turns training's priority on sustained hardware efficiency (η_{hw}) into a request-latency constraint ($L_{\text{lat,total}}$), requiring a stack designed around the percentile named by its SLO.
2. **Distinction**: Unlike model training, which commonly processes scheduled batches, serving may handle stochastic online requests, synchronized streams, or offline batches.
3. **Common pitfall**: A frequent misconception is that serving is "just the forward pass." In reality, it is a systems problem: model execution is only one component of a stack that may include request routing, load balancing, and data transformation.

The SLO[1] defines the latency target that shapes every architectural decision in the serving stack, establishing the strict time budget within which all request handling must complete. When an inference server receives a request, model execution represents only one segment of an end-to-end pipeline: network ingress, payload deserialization, feature transformation, queue scheduling, and output serialization all consume time before and after the accelerator runs. The end-to-end request lifecycle partitions execution into three sequential stages (figure 13.1): input preprocessing (traditional computing), neural network evaluation (deep learning), and output postprocessing with safety validation (traditional computing). Any of these stages can become the binding latency bottleneck. Section 13.3.1 quantifies where the time goes and finds that host preprocessing can take longer than the forward pass itself.

1 **SLOs in ML serving**: An SLO is the internal target, as distinct from the contractual SLA. For ML serving, task quality and inference latency can both contribute to SLOs, creating multidimensional targets where improving one dimension (for example, deploying a larger model for accuracy) can violate another (latency).

↩ SLOs, service level agreements (SLAs), and the tail-latency percentiles they constrain are established in section 12.6.2.1.

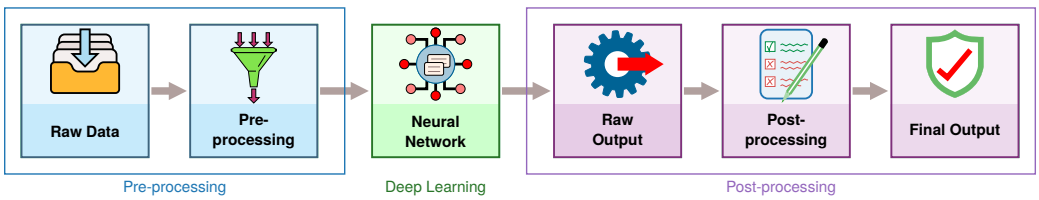

Figure 13.1: The Inference Pipeline: ML serving systems transform raw inputs into final outputs through sequential stages: preprocessing, neural network computation, and postprocessing. The neural network represents just one component; preprocessing and postprocessing make end-to-end latency depend on more than neural-network execution.

Two services carry the chapter, one per half, and each lighthouse arrives in the regime it represents. The first half follows a ResNet-50 image-classification service on one accelerator node. ResNet-50 is the book's compute-bound lighthouse. Each forward pass performs about 8.2 GFLOP of arithmetic on 102.4 MB of FP32 weights, so a large training batch keeps the matrix units busy. A served request arrives alone, however, and at batch one the same forward pass spends most of its time on weight

traffic and kernel launches rather than arithmetic. Recovering the efficiency that training enjoyed without breaking the deadline is the first half's problem, and the reference request profile introduced with the latency budget carries the service through queuing, batching, runtime selection, and replica startup. Large language model (LLM) serving then follows a GPT-2 XL chat service, the bandwidth-bound lighthouse whose decoding step section 6.7.4.2 traced. Each generated token streams all 3 GB of its FP16 weights from memory, about 0.9 ms on the book's reference H100, so memory bandwidth sets token latency and the memory each conversation holds sets concurrency. Llama 3 8B, a larger member of the same transformer family, extends that case where the per-conversation cache grows large enough to bound how many requests share the accelerator. DLRM, the capacity-bound lighthouse, appears once as a contrast in which embedding lookups rather than arithmetic dominate a request, and MobileNetV2 appears where the target device cannot hold ResNet-50 at all.

Table 13.1: Chapter Map: Each section answers one serving decision on one of the running cases and names the iron law term or resource that decision most affects. The first four rows follow a single ResNet-50 replica from its architecture to batching; the remaining rows change what the replica executes, how it starts, what it produces, and what it costs.

Section	What it decides	Running case	Iron law term or resource it targets
Serving System Architecture	How a replica turns arriving requests into accelerator work	ResNet-50 service	Fixed overhead L_{lat} (protocol, serialization, copies)
Request Lifecycle	Where one request's latency budget goes	ResNet-50 request; DLRM contrast	Every term, stage by stage
Queuing Theory	How much headroom many concurrent requests need	ResNet-50 capacity plan	Queueing delay added to L_{lat}
Throughput Optimization	How many requests share each weight read	ResNet-50 batching sweep	D_{vol}/BW and L_{lat} per request
Inference Runtime Selection	Which engine and number format execute a batch	ResNet-50 runtimes and precisions	Hardware efficiency η_{hw} and bytes D_{vol}
Node-Level Optimization	What stalls the path between network socket and accelerator	ResNet-50 node profile	Host-side L_{lat}
Model Loading and Versioning	How fast a new replica serves, and whether it computes what training computed	ResNet-50 cold start and preprocessing skew	Startup time and prediction accuracy
LLM Serving	How token streams share memory bandwidth and capacity	GPT-2 XL decode; Llama 3 8B cache	D_{vol}/BW per token; memory capacity
Economics and Planning	How many accelerators, at what cost per completed request	ResNet-50 fleet; Llama 3 8B tokens	Cost per request that meets the SLO

The architecture section (table 13.1) examines the inference server that sits between the network and the accelerator. The request lifecycle then traces one ResNet-50 request through that server and finds that the model is one slice of its latency budget. Queuing theory lets many requests arrive at once and derives the headroom that keeps their tail latency bounded, and throughput optimization raises each replica's service rate by batching, where the chapter's first half ends. The second half changes what each replica runs and how it starts: runtime and precision selection decide how fast a batch executes, node-level optimization removes the stalls between host and accelerator, and model loading decides how quickly a new replica can serve and whether it computes what training computed. LLM serving then replaces fixed outputs with token streams, and economics and planning converts the whole stack into accelerator count and cost per request. Two placement decisions precede all of these: the first is temporal, whether predictions are computed ahead of time or on demand, and the second is spatial, where the model physically runs.

13.1.1 Static vs. dynamic inference

A nightly job that precomputes product recommendations for existing users can pack thousands of items into each accelerator batch, whereas a live content-moderation API must score an uploaded image within milliseconds of arrival. Deciding whether to generate predictions before or during a user request sets the trade-off between offline hardware efficiency and online responsiveness (Google 2024b): it determines whether an accelerator runs in an unconstrained throughput regime or under the strict tail-latency deadlines of an interactive serving loop.

13.1.1.1 Static inference

Static inference (also called offline or batch inference) precomputes predictions for anticipated inputs and stores them in a retrieval store. Moving model execution entirely out of the user request path alters the underlying hardware constraints. Because batch jobs have no millisecond-level deadlines, accelerators can use large batches ($B \gg 1$) selected for throughput within memory limits. Reusing weights across samples raises arithmetic intensity for weight-dominated operations; a batch-size sweep identifies where throughput stops improving. When a client issues a request (for example, a user opening nightly generated recommendation rankings), the serving system performs a low-latency key-value lookup rather than executing a forward pass on an accelerator. The primary operational constraint shifts from accelerator latency to storage capacity and data freshness. Precomputing predictions across an entire input domain scales combinatorially ($\mathcal{O}(N_{\text{users}} \times N_{\text{items}})$ for N_{users} users and N_{items} items in recommendation systems), and stale predictions persist until the next batch refresh.

13.1.1.2 Dynamic inference

Dynamic inference (also called online or real-time inference) evaluates inputs on demand as requests arrive. On-demand execution accommodates arbitrary, previously unseen inputs within the model schema and immediately reflects newly deployed model weights without requiring precomputation. However, executing the model directly within the user request path subjects inference to the strict end-to-end latency budget set by its SLO. Because user requests arrive stochastically, the serving runtime cannot delay execution indefinitely to accumulate large batches. Serving requests individually or in small batches ($B = 1$ to $B = 4$) can expose weight traffic or launch overhead that larger batches amortize. When these costs bind execution, the device completes fewer queries per unit time, increasing provisioned cost per query. This tension between interactive response time and hardware efficiency can make dynamic serving more expensive per query than offline batching (example 13.1).

> Example 13.1: The cost of latency
>
> Latency constraints directly dictate infrastructure costs. The figures below come from the ResNet-50 reference profile that section 13.5.1 later sweeps across batch sizes. Consider a GPU server renting for $4/hour.
>
> Scenario A (low latency): Batch size 1.
>
> - Latency: 3.5 ms.
> - Throughput: 283 req/s.
> - Cost per million queries: $3.92.
>
> Scenario B (high throughput): Batch size 8.
>
> - Latency: 3.8 ms, barely above batch one, because the fixed launch cost dominates both.
> - Throughput: 2,129 req/s.
> - Cost per million queries: $0.52.
>
> **Systems insight**: Serving one image at a time saves only the difference between 3.8 ms and 3.5 ms of latency, yet multiplies the hardware cost per million queries by 8×. Engineers must quantify whether that speedup generates enough business value to justify the 8× cost increase.

Consider two contrasting deployment scenarios for a ResNet-50 image classifier. A static batch approach suits a photo management application that preclassifies every image in a user library overnight. Classifying 10,000 photos one at a time, at 3.5 ms per batch-one forward pass on the reference H100, would take 35 s; at the 89,500 images/s that MLPerf Inference (Reddi et al. 2019) measured for a compiled INT8 engine at large batch on the same accelerator, the same library takes 0.11 s, about 320× faster, and clients experience instantaneous retrieval upon browsing. Conversely, a dynamic online approach suits a content moderation service that must evaluate user-uploaded media in real time, where each image traverses the complete preprocessing, accelerator execution, and postprocessing pipeline within a 100 ms service-level objective.

These two modes optimize for fundamentally different operating regimes. Static inference maximizes accelerator utilization and amortizes memory transfers across large, offline batches, trading persistent storage capacity for zero serving latency at query time. Dynamic inference minimizes tail latency under stochastic, concurrent traffic, accepting lower compute efficiency and higher marginal cost per query to evaluate arbitrary, unpredictable inputs. Production architectures frequently synthesize both paradigms into a tiered design, in which static precomputation populates key-value caches with predictions for high-frequency queries, such as catalog items or viral media, while dynamic serving clusters evaluate the long tail of novel or personalized requests. Deciding when predictions are computed resolves only the temporal dimension of serving, however; equally binding is the spatial dimension, where the model physically executes, because physical placement dictates memory hierarchy limits, network boundaries, and the hardware budget available to the serving stack.

13.1.2 The spectrum of serving architectures

A cloud server can pool accelerators behind an HTTP endpoint at the cost of a network round trip and multi-second cold starts, whereas a hearing aid or industrial sensor microcontroller cannot afford a network hop or an operating system at all. Although "serving" often implies a networked server processing API requests, the four deployment paradigms (Cloud, Edge, Mobile, and TinyML) and the physical constraints that give rise to them—the light barrier, the power wall, and the memory wall—shape the serving stack into very different forms. Serving spans a continuum from **centralized networked microservices** (which pool accelerators to optimize throughput and cost per query at the expense of network round-trip overhead and cold-start latency) to **application-embedded edge serving** (which run models inside client processes via direct function calls, eliminating network latency and preserving privacy at the expense of strict device memory and power limits) and out to **bare-metal firmware execution** on microcontrollers. Those hardware limits do not disappear at serving time; serving adds latency SLOs and cost pressure on top of limits that training could absorb through patience. The same model may therefore require different serving strategies depending on where it runs.

↩ The light barrier, power wall, and memory wall that give rise to the four deployment paradigms are established in section 2.2.

The three architectures differ in what binds. Networked serving runs the model as a standalone service behind HTTP or gRPC, so network transfer and serialization join model execution as candidate bottlenecks; data-center accelerators support batching and concurrency, but a new replica's cold start can stretch from seconds to minutes because container startup, model loading, and warmup sit outside the steady-state request path. Application-embedded serving runs the model inside the user's application process on a phone or embedded board, behind a function call rather than a network interface. With no shared server to batch for, optimization targets energy and responsiveness (the shape that benchmarking calls SingleStream), and a passively cooled envelope of a few watts throttles sustained inference once the chassis heats. Bare-metal serving compiles the model into microcontroller firmware, often without an operating system or a dynamic allocator, so weights execute in place from flash memory, activations fit a preallocated tensor arena of a few hundred kilobytes of SRAM, and batching is impossible on a single sensor stream.

↩ The MLPerf SingleStream, MultiStream, Server, and Offline scenarios are established in section 12.4.4.1.

Embedded execution enables **zero-copy inference**. When data moves through a system, each copy consumes CPU cycles and memory bandwidth. In cloud serving, separate physical memory spaces force repeated transfers. A camera frame passes from a network socket buffer to user space, through a preprocessing buffer into page-locked host DRAM, and across PCIe into accelerator memory. A mobile pipeline can eliminate these intermediate copies when its camera, image signal processor (ISP), CPU, and NPU exchange shared buffer descriptors in unified system memory. In unified-memory system-on-chip (SoC) architectures, such as Apple A- and M-series processors or Qualcomm Snapdragon, all compute engines share a single physical DRAM pool. When software passes buffer handles rather than duplicating bytes, inference latency drops and memory bus power decreases, although format conversions may still require CPU or ISP intervention.

The deployment tiers differ first in their operating envelopes (latency targets, memory, and power), which section 2.2 derived and tabulated for each paradigm; what serving adds is the model each tier can actually run. Applying those envelopes to one image-classification workload, table 13.2 shows why cloud and mobile can adapt ResNet-50 while TinyML must substitute MobileNetV2. The cloud column runs the model through TensorRT, NVIDIA's ahead-of-time inference compiler,[2] and the

[2] **TensorRT**: TensorRT builds its engine ahead of time for one microarchitecture (such as Hopper or Blackwell) (NVIDIA 2024c). That target-specific build phase allows the compiler to generate fused kernels, select microarchitecture-specific Tensor Core execution paths, and optimize memory layouts (such as NC/32HW32). The resulting nonportable engine reduces per-request execution latency and minimizes the accelerator count needed to satisfy a target throughput.

mobile column through the TensorFlow Lite runtime; the chapter uses these engines as given until section 13.6 examines what such runtimes do to a model.

Table 13.2: Image Classification Across the Serving Spectrum: Illustrative side-by-side comparison of cloud, mobile, and TinyML serving for the same image-classification task, showing how model format, latency, throughput, memory footprint, and energy budget differ across deployment contexts.

Dimension	Cloud	Mobile	TinyML
Model format	TensorRT FP16 engine (51.2 MB)	TensorFlow Lite INT8 (25.6 MB)	Not feasible (25.6 MB); alternative: MobileNetV2 INT8 (3.5 MB)
Inference (batch-1)	0.33 ms (batch-16: 0.83 ms)	12 ms (NPU), 45 ms (CPU)	120 ms
Throughput	30,400 img/s (batched)	~80 img/s (single-stream)	~8 img/s
Memory	2 GB VRAM (batch-32)	150 MB peak (shared with app)	320 KB arena (fits in 512 KB SRAM)
Energy/inference	—	0.8 mJ (NPU), 4.2 mJ (CPU)	12 mJ

Systems Perspective 13.1: ResNet-50 across the serving spectrum

Systems insight: It is tempting to read table 13.2 as one model deployed three ways. That reading is misleading: the cloud and mobile tiers share the ResNet-50 graph but use different precision and runtimes, while the TinyML tier cannot run ResNet-50 at all and substitutes an architecture designed for its constraints. Treating these as one model hides the work that makes each deployment possible.

Whichever tier hosts it, a networked deployment runs the model inside a server process, and each such replica must turn an irregular stream of requests into work its accelerator can execute efficiently. That conversion is the job of the inference server's internal architecture.

13.2 Serving System Architecture

Inside each replica, user requests arrive in irregular bursts—milliseconds apart one moment and silent for seconds the next—whereas accelerator compute engines demand steady streams of uniform, dense batches to saturate memory bandwidth and arithmetic units. Reconciling these two incompatible rhythms at the system boundary requires a serving architecture that decouples network ingress from execution scheduling, absorbing arrival bursts and packing irregular inputs into dense batches without violating latency SLOs.

13.2.1 Internal architecture and request flow

If a web server invoked the accelerator synchronously every time a socket read completed, slow client uploads would stall the GPU and concurrent connections would contend for device memory. An inference server[3] (such as NVIDIA Triton or TensorFlow Serving) avoids this by acting as a specialized runtime scheduler that manages concurrency, device memory, and data movement between host CPUs and accelerator devices. Rather than running the model directly on the network thread, the server pipelines incoming requests through dedicated subsystems that isolate client network handling from accelerator compute. Every request traverses a six-stage runtime pipeline (figure 13.2) from network ingress and request-buffering queues through the dynamic batcher to the inference runner and hardware accelerator.

Across the stages in figure 13.2, the server handles concurrency management, request transformation, model lifecycle management, and execution scheduling. At network ingress, the server manages concurrency through asynchronous event loops (such as `epoll` or `kqueue`) and worker thread pools that handle thousands of concurrent client TCP connections without stalling accelerator execution pipelines. Decoupling network I/O from compute ensures that slow client transfers or network stalls do not starve the accelerator of ready work.

3 **Inference server**: Google's TensorFlow Serving (Olston et al. 2017) helped establish the separation of model logic from serving infrastructure; NVIDIA's Triton (NVIDIA 2024d) extends this pattern across multiple model frameworks and backends. The critical design insight is that a scheduler and dynamic batcher turn irregular single-request traffic into accelerator-friendly execution, improving utilization when latency budgets allow batching. Exact utilization gains depend on model, hardware, arrival rate, and the configured batching window.

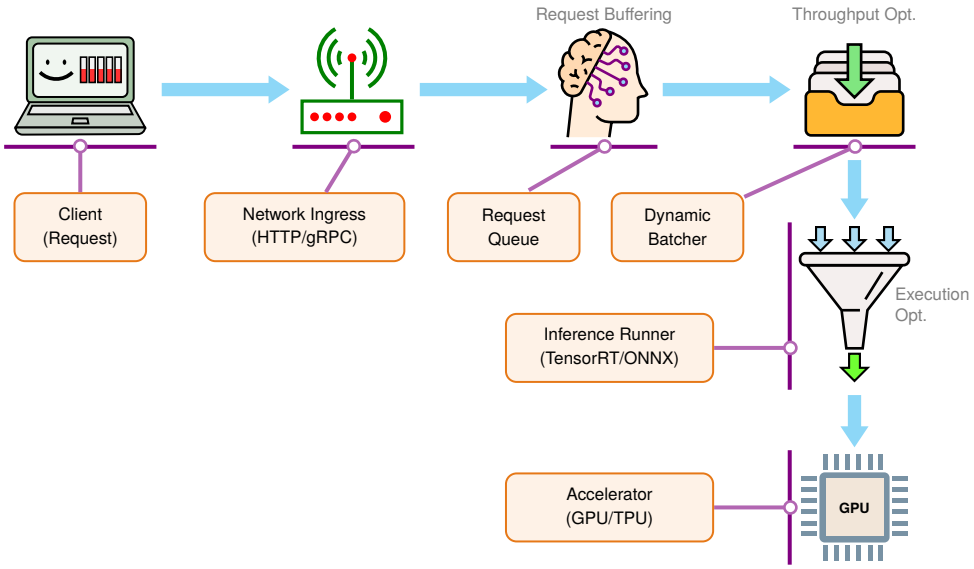

Figure 13.2: Inference Server Anatomy: A modern inference server decouples network handling from accelerator execution through a staged pipeline. Each stage isolates a concern, from absorbing bursty traffic to forming efficient batches, so the hardware accelerator stays busy despite irregular arrival patterns.

Once a payload arrives, the server transforms requests into tensors, decoding serialized network bytes into contiguous, aligned memory buffers that match the tensor layout required by the underlying execution engine. For example, four-dimensional vision tensors typically adopt NCHW[4] or NHWC formats. On modern accelerators, matrix multiplication units (such as Tensor Cores) load 8- or 16-element channel vectors using coalesced memory transactions that favor channels-last (NHWC) layout. If the execution kernel requires a different physical layout, the server must materialize that layout. Calling `torch.permute` merely creates a view with reordered strides; an explicit memory copy or transpose kernel must physically reorder the data in memory. Because such materialization performs zero arithmetic ($I \approx 0$ FLOP/byte), memory traffic and launch overhead dominate its cost. A device-local conversion consumes device memory bandwidth, whereas conversions across the host-device boundary consume PCIe bandwidth.

For those tensors to execute without startup stalls, the server also manages the model's local lifecycle. The runtime establishes the CUDA context before allocating device memory (VRAM) and streaming weights onto the accelerator, pins host memory buffers for direct memory access (DMA) transfers, and executes representative warmup passes to trigger deferred compilation and memory allocation before admitting live client traffic. While enterprise model registries, canary rollouts, and rollback policies belong to cluster-level operations (chapter 14), the serving engine governs local state, validating that active model instances are warmed, resident in accelerator memory, and ready for dispatch.

Between request buffering and the warmed model sits the execution **scheduler**, which coordinates accelerator dispatch by implementing dynamic batching (section 13.5). For weight-dominated inference at batch size $B = 1$, streaming parameters from HBM can limit execution before the arithmetic units reach peak throughput. Grouping B requests into a concurrent batch amortizes the byte transfers of reading model weights across all B inputs, increasing the arithmetic intensity ($I = O/D_{\text{vol}}$).

To balance individual request latency against batch compute efficiency, the scheduler tunes queue residency using a **batching window** (or timeout threshold). Setting the batching window to zero removes deliberate batch formation delay, but requests can still wait for an available worker. An immediately dispatched small batch may also expose too little work to use the accelerator efficiently. Conversely, setting a bounded window (such as 2 to 5 ms) allows the scheduler to buffer arriving requests until either the queue reaches a target batch size or the timeout expires. The window

[4] **NCHW and NHWC (tensor memory layouts)**: These acronyms encode the dimension order of 4D image tensors: N (batch), C (channels), H (height), and W (width). In a contiguous NCHW tensor, each channel plane is contiguous; in NHWC, channels for one spatial position are adjacent. Optimized kernels may favor either layout, and a semantic mismatch can scramble values even when the element count is correct. Serving code should therefore make both dimension meaning and any physical-layout conversion explicit.

bounds deliberate formation delay; waiting for a busy worker is a separate resource-queue delay. Batching trades that formation time for greater weight reuse and potentially higher service capacity, while total latency includes both waits and execution.

13.2.2 Interface protocols and serialization

As accelerator kernels undergo aggressive compilation (via TensorRT, TorchDynamo, or custom kernels), device execution time often drops below a single millisecond, and the host-side cost of ingesting, transporting, and deserializing payloads becomes the dominant term in end-to-end latency (the per-request overheads itemized in section 13.3.2.1). Two interface choices—the wire serialization format and the network transport protocol—determine whether that host ingress path stays in microseconds or consumes the latency budget before inference begins.

13.2.2.1 The serialization bottleneck

Machine learning payloads differ fundamentally from conventional web API payloads. They consist of multi-dimensional arrays of floating-point numbers (such as image tensors, dense embedding vectors, or token sequence logits). While text-based JSON is ubiquitous in web services, serializing dense numerical arrays into text incurs severe CPU and memory penalties. Serialization overhead manifests because JSON parsers must scan every byte sequentially, validate syntax, allocate heap nodes, and invoke string-to-float conversion routines (such as `strtod`). Each 32-bit float expands from 4 raw bytes into 7 to 15 ASCII characters including punctuation. Furthermore, raw binary data (such as compressed JPEG or raw image bytes) requires Base64 encoding to travel within JSON strings, imposing a 33 percent size inflation before parsing begins.

Binary serialization formats, such as Protocol Buffers[5] and FlatBuffers,[6] bypass this text conversion cost. Float arrays transmit directly as packed IEEE 754 byte streams with zero ASCII conversion and zero Base64 framing. Furthermore, FlatBuffers organizes serialized records with internal relative offsets, enabling zero-copy deserialization, in which the serving application reads tensor dimensions, data types, and byte offsets directly out of the network receive buffer without allocating an intermediate object graph on the heap.

13.2.2.2 REST vs. gRPC

Transport protocol selection governs connection life cycles and socket multiplexing. Conventional REST APIs typically deploy HTTP/1.1 with JSON payloads. HTTP/1.1 clients commonly use multiple persistent TCP connections for concurrency. Establishing each connection incurs handshake and, for HTTPS, TLS costs, but keep-alive reuse amortizes setup across requests. HTTP/1.1 also suffers from request-level head-of-line blocking, because responses on a single connection must return in request order. While REST APIs can adopt HTTP/2 or binary encodings, the combination of HTTP/1.1 and JSON creates significant socket overhead and CPU parsing contention when serving high-throughput tensor workloads.

In contrast, gRPC (gRPC Remote Procedure Call)[7] pairs HTTP/2 transport with Protocol Buffers serialization. HTTP/2 establishes a single long-lived TCP connection and multiplexes hundreds of concurrent request and response streams simultaneously using binary framing. This architecture multiplexes concurrent streams over a persistent connection and removes HTTP-level response-order blocking (a lost TCP packet can still stall every stream on the connection, which HTTP/3 addresses by moving to QUIC), while Protobuf enforces strongly typed contracts and serializes binary tensor payloads efficiently. Consequently, gRPC is the standard protocol for internal microservice communication in model serving clusters, where low latency, compact wire payloads, and bidirectional token streaming are primary design criteria. Even a modest embedding payload shows the gap in wire footprint and host parsing time.

> **Napkin Math 13.1: JSON vs. Protobuf serialization**
>
> Consider a request payload containing 1,000 floating point numbers (for example, an embedding vector).
>
> - **JSON**: Uses ~9 KB on the wire. Requires ~50 µs to parse.

↩ Clipper's decomposition of serving latency, in which serialization rivals model execution, is established in section 12.3.4.

[5] **Protocol Buffers (Protobuf)**: Protobuf uses a predefined schema (from a `.proto` file) to encode structured data into a compact binary format (Protocol Buffers Authors 2026). Because the schema carries field names and types, the wire payload need not repeat them as JSON does. Its wire format is still not identical to a C++ object's in-memory layout, so it requires a parsing step and does not provide the same direct zero-copy access pattern that FlatBuffers targets.

[6] **FlatBuffers**: The "flat" in the name describes the design: the binary buffer can serve as the serialized representation and the data structure being read, avoiding a separate parsing or unpacking phase for supported access patterns (FlatBuffers Authors 2026). For ML inference, this can enable zero-copy access to tensor metadata, because the serving system reads tensor shapes and offsets directly from the buffer rather than allocating a second object representation.

[7] **gRPC (gRPC remote procedure call)**: The gRPC framework pairs HTTP/2 transport with an interface definition language and message format, most commonly Protocol Buffers (gRPC Authors 2026). The size and latency benefit over REST/JSON depends on payload shape, client/server implementation, and whether serialization is a meaningful share of the end-to-end latency budget.

- **Protobuf**: Uses ~4 KB on the wire. Requires ~5 µs to parse.

Math: Switching one request to the binary payload saves 50 µs − 5 µs = 45 µs of parse time. For this illustrative system processing 10,000 requests per second, the savings compound to 10,000 × 45 µs = 0.45 s of CPU time reclaimed every wall-clock second, which is 45 percent of one core freed from serialization overhead alone.

Systems insight: This 10× scenario gain makes gRPC/Protobuf, FlatBuffers, or another binary protocol a strong candidate for high-throughput internal microservices when serialization is a visible part of the latency budget.

Architectural selection is governed by system constraints. REST over HTTP/1.1 remains practical for public-facing edge gateways where broad client compatibility and human-readable debugging take precedence over raw wire efficiency. Within cluster boundaries, gRPC over HTTP/2 with binary serialization can reduce overhead when high query volume or tensor serialization consumes a significant share of the host CPU budget; its streaming support also suits incremental token responses.

13.2.3 The load balancer layer

When traffic exceeds what a single machine can handle, adding model replicas does not prevent tail-latency spikes if requests still land on a replica that is mid-batch or still loading weights into GPU memory. Cloud and data center deployments therefore place a **load balancer** between clients and model servers to route around busy or unready replicas. A serving load balancer protects the fleet by coupling request distribution with readiness checks and traffic shifting. It routes incoming requests across replicas using policies such as round-robin or least-connections so that traffic steers around slow or saturated workers before queues build, and it backs that routing with health monitoring that inspects both process liveness and model initialization state—confirming that weights are loaded and warmup passes are complete before a replica receives live queries. The same routing control also supports progressive rollouts, shifting traffic gradually between model versions rather than cutting over abruptly.

↪ Shadow, canary, and blue-green release strategies that build on this traffic shifting are developed in section 14.4.3.

On a single machine running several model instances, such as several Open Neural Network Exchange (ONNX) Runtime sessions, the serving framework and the operating system queue requests without a separate balancer; a dedicated balancer becomes necessary once replicas span machines, and its distribution algorithms belong to that distributed setting. This chapter therefore plans capacity one node at a time. The unit of capacity is the sustained model throughput of one node, and the queueing analysis in section 13.4 determines the utilization at which that node can no longer meet its latency target and a second replica must be added behind the balancer. Protocol selection, process architecture, and the balancer in front of the replicas establish the structural skeleton of a serving deployment; evaluating actual operational performance requires tracing how latency accumulates as one request traverses each stage of a replica's runtime pipeline.

13.3 Request Lifecycle

A single HTTP request carrying a 224×224 JPEG image arrives at an inference server. Between the moment the first byte enters the network stack and the moment the classification payload departs, the request traverses a sequence of pipeline stages, grouped below into preprocessing, inference, and postprocessing, with data transfer between them. Each stage consumes a slice of the end-to-end latency budget, making granular phase decomposition essential for targeted performance tuning.

13.3.1 The latency budget

A serving system that completes thousands of inferences per second still fails its users if individual requests take two seconds to return and miss their interactive deadlines. For dynamic inference systems, the serving inversion established in section 13.1 therefore imposes a strict latency budget that shapes system design (Gujarati et al. 2020).

Relevant metrics expand from aggregate throughput and mean latency to the latency distribution. Mean and p50 describe the center, while p95 and p99 expose the slow tail. If mean latency is 50 ms

but p99 is two seconds, the p99 threshold is 40× the mean, so about 1 percent of requests are at or beyond two seconds. Whether that tail matters depends on the service and its users, which is why percentile targets should come from the SLO rather than convention.[8] Managing these percentile constraints requires decomposing the total allowed response time into a **latency budget** that allocates time across each processing phase, the serial accounting that the latency budget principle (12) states formally.

[8] **Tail latency**: Unlike averages, percentile latencies reveal the performance impact of system outliers common in ML serving, such as model cache misses or garbage collection pauses. These rare, high-latency requests can disproportionately harm user satisfaction and business outcomes. Because the magnitude is workload-specific, services validate percentile targets (p95, p99) against their own users and SLOs.

Definition 13.2: Latency budget

Latency budget is the time allocated to request stages under an end-to-end deadline; the SLO also specifies the required completion quantile.

1. **Significance**: It acts as a zero-sum constraint system where any milliseconds consumed by serialization or network overhead directly reduce the latency budget ($L_{\text{lat,total}}$) available for model inference.
2. **Distinction**: The budget allocates time across stages, while the latency SLO of section 12.6.2.1 couples the deadline (for example, < 50 ms) with a completion quantile (p99 or p99.9). A service-level indicator (**SLI**) is the measured quantity used to evaluate that objective. Tail latency spikes can stem from queueing, batch formation, cache state, interference, or data movement.
3. **Common pitfall**: A frequent misconception is that the "model" has the entire budget. In the illustrative breakdown in table 13.3, the remainder is consumed by host preprocessing and data movement (JPEG decode, resize, normalization, and PCIe transfer), while upstream network and serialization overheads (table 13.5) consume further margin.

Every serving request traverses three sequential phases that share this latency budget: preprocessing converts raw input such as image bytes or text strings into model-ready tensors, inference executes the model computation over those tensors, and postprocessing turns the resulting device outputs into user-facing responses. Accelerating model execution alone yields diminishing returns when host-side preprocessing and response formatting consume the majority of the latency budget, an immediate manifestation of Amdahl's law. As hardware compilers compress accelerator kernel runtimes into sub-millisecond durations, host-device coordination and memory transfers emerge as the primary latency bottlenecks.

Inference is one slice of the latency budget; preprocessing rivals it.

13.3.2 Stage-by-stage latency breakdown

An engineer who measures only total request duration in a vision service sees a single millisecond number that lumps together CPU-bound JPEG decompression, host-to-device PCIe transfers, accelerator kernel execution, and response formatting, making it easy to spend weeks optimizing GPU kernels that account for less than half of total response time. Timing each pipeline boundary independently isolates the actual bottleneck before optimization begins.

Example 13.2: ResNet-50: Latency budget breakdown

Table 13.3 details the per-phase latency breakdown for one ResNet-50 serving request on the reference H100, with the forward pass taken from the chapter's modeled profile and the host phases as stated assumptions.

Table 13.3: ResNet-50 latency budget: Per-phase breakdown of a single serving request on the reference H100 (modeled forward pass, assumed host phases), showing that host preprocessing alone takes longer than the ResNet-50 forward pass. The percentages expose where engineering effort pays off in this scenario. Per-phase percentages are rounded to the nearest whole number and may not sum to exactly 100.

Phase	Operation	Time	Percentage
Preprocessing	JPEG decode	3 ms	35%
Preprocessing	Resize to 224×224	1 ms	12%
Preprocessing	Normalize (mean/std)	0.5 ms	6%
Data Transfer	CPU→GPU copy	0.5 ms	6%
Inference	ResNet-50 forward pass	3.5 ms	41%
Postprocessing	Softmax + top-5	0.1 ms	~1%
Total		**8.6 ms**	**100%**

Systems insight: In this ResNet-50 serving budget, preprocessing consumes 52 percent of latency even though the forward pass performs nearly all of the arithmetic. If a compiled TensorRT engine reduces the forward pass to the modeled 0.33 ms, preprocessing would dominate at 83 percent.

Laid on the node's hardware, the same budget occupies three resources in turn, and the accelerator is busy for less than half of the request (figure 13.3). While a host CPU core decompresses the JPEG, resizes the image, and normalizes pixel values before copying the tensor across PCIe, the GPU waits completely idle for work to arrive.

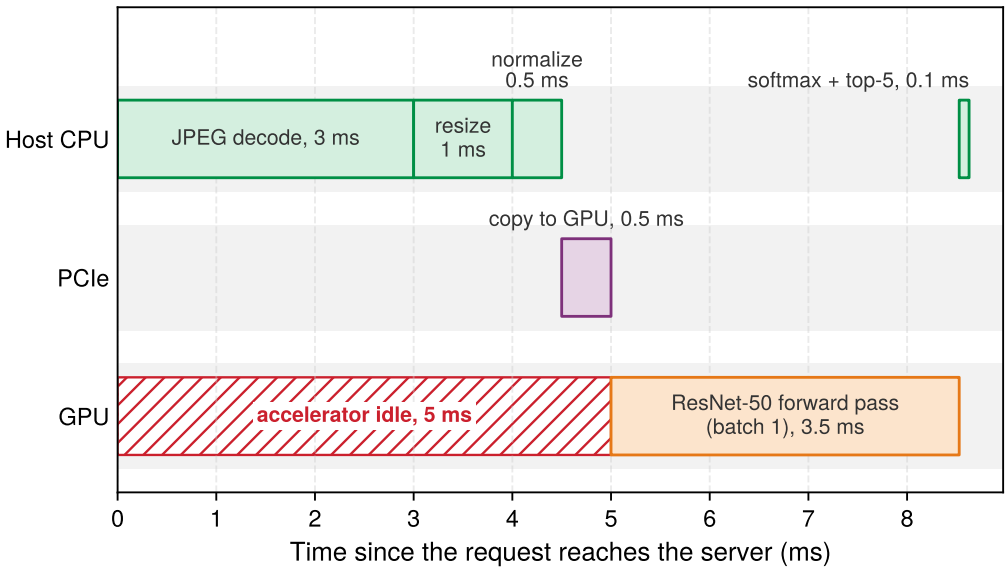

Figure 13.3: One Request on One Node: The reference ResNet-50 request drawn on the three resources it crosses. JPEG decode, resize, and normalization occupy a host CPU core, the input crosses PCIe, and the forward pass occupies the accelerator; softmax and top-5 selection are drawn on the host. Durations follow table 13.3, so the accelerator is busy for 41 percent of the 8.6 ms request and idle while the host prepares the input. Network transfer, serialization, and batching delay lie outside this budget and are not drawn.

The 3.5 ms batch-one forward pass in table 13.3 is the chapter's reference profile for ResNet-50: an eager framework running FP16 on the reference H100, modeled from the iron law's terms rather than measured, and the later ResNet-50 examples derive from it. The framework issues 174 kernels, one per operation, and each pays 10 µs of Python dispatch and 5 µs of driver launch, the per-operation costs of section 7.3.4. Each kernel also occupies the accelerator for at least an assumed 5 µs, and the arithmetic itself, at the 25 percent of peak that ResNet-50 sustains in section 8.4.2, takes about 33 µs

per image. A compiled INT8 engine anchors the other end of the range: MLPerf Inference measured 89,500 images/s on one H100 at large batch (Reddi et al. 2019). The capacity plan in section 13.4.3 uses the reference profile as the service time, the batching sweep in section 13.5.1 starts from it at batch one, and the cold-start timeline in section 13.8.1 assumes its warm steady state. The runtime and precision comparisons in section 13.6 change one term of the same model at a time, so the effect of each change is visible.

In the ResNet-50 scenario, dense convolutional arithmetic dominates the model stage's work. That does not make the stage compute bound at every batch size. At batch size one on the reference H100, issuing the kernels takes 2.6 ms, 74 percent of the forward pass, so the stage is overhead-bound and runs far below peak arithmetic throughput; batching amortizes that fixed cost and fills the machine (section 13.5.1). Changing the model architecture can move the dominant cost out of dense arithmetic entirely, and recommendation systems make this shift concrete.

Lighthouse 13.1: Lighthouse example: DLRM serving

Scenario: Serving DLRM with a 10 ms p99 latency budget.

Analysis: While ResNet-50's model stage is dominated by convolutional neural network compute, DLRM's dominant model-stage cost is embedding-table memory access. End-to-end serving bottlenecks still require measuring the full path: preprocessing, inference, postprocessing, and data movement. Table 13.4 breaks the recommendation request down by phase.

Table 13.4: DLRM serving latency: Illustrative per-phase breakdown of a recommendation request under a 10 ms p99 budget, contrasting DLRM's memory-bandwidth-bound embedding lookups against ResNet-50's convolution-dominated forward pass. Adding compute to the inference stage does not help once embedding-table bandwidth is the binding constraint.

Phase	Operation	Time	Bottleneck
Input Parsing	Request parsing	0.5 ms	CPU
Embedding Lookup	Fetch 100+ dense vectors	6 ms	memory bandwidth
Inference	MLP forward pass	1.5 ms	Compute
Postprocessing	Ranking & Filtering	1 ms	CPU
Total		**9 ms**	

Systems insight: In DLRM, the "Inference" multilayer perceptron stage is only ~17 percent of the latency. The majority of time is spent in embedding lookups, retrieving 128-dimensional embedding vectors from tables that hold about 100 GB in the reference model and reach terabytes in production. This is a memory-bandwidth and capacity-bound workload where adding more compute does not help unless the embedding tables can be served faster.

Together, table 13.3 and table 13.4 expose the same general failure mode: optimization effort goes where ML expertise applies (model quantization, pruning) while the binding constraint sits elsewhere (image decoding on CPU for ResNet-50, embedding-table memory bandwidth for DLRM). For an isolated serial request with other stage times held fixed, model-only optimization is bounded by the time spent outside the model, the Amdahl ceiling that section 12.3.4 derives for a request path. Serving modifies that familiar result in two ways. Accelerator progress tightens the ceiling, because each hardware generation shrinks the model term while the host stages stay where they were; the perspective below quantifies this for the reference request. Under load, a faster model also shortens the queue, an effect the fixed-fraction calculation cannot see and the first fallacy in section 13.11 develops.

Systems Perspective 13.2: The quantitative approach to serving

Analysis: Amdahl's law (principle 8) sets this ceiling (section D.2.3.1 provides the formal derivation). Preprocessing (4.5 ms) and data transfer (0.5 ms) consume 58 percent of total latency. Optimizing the model 10× faster (3.5 ms → 0.35 ms) yields only a 1.6× end-to-end

speedup (reducing latency from 8.6 ms to 5.5 ms). Focusing exclusively on model optimizations like quantization or pruning yields diminishing returns when non-model stages dominate execution time.

Mechanism: Domain-specific accelerators, such as the Tensor Processing Unit (TPU) and Tensor Cores, replace complex control logic with dense multiply-accumulate arrays, which shrinks the model term. The host-side stages stay on general-purpose CPUs and I/O buses, so the faster the accelerator, the larger their share of end-to-end latency.

Systems insight: Profile before optimizing. If preprocessing dominates, GPU-accelerated pipelines (NVIDIA DALI) that move preprocessing next to the accelerator may outperform model quantization, although the end-to-end gain is pipeline-specific.

13.3.2.1 Per-request overheads outside the model

Beyond model forward-pass execution, every request pays fixed overheads to the host system and network stack. When an inference query arrives, it traverses the network interface, moves across kernel and user space, deserializes from wire protocols into memory buffers, queues for batch assembly, and copies across the PCIe interconnect to accelerator device memory. These host-side operations run on general-purpose CPUs and I/O buses, which is why their share grows as the model term shrinks. Each overhead has a representative cost, a scaling behavior, and a design choice that reduces it (table 13.5).

Table 13.5: Per-Request Overheads Outside the Model: A representative breakdown of noninference latency sources. While individual components like serialization can be below 1 ms, they compound. Under the upper ends of the displayed ranges, these overheads together can rival the reference ResNet-50 forward pass. The engineering goal is to measure the actual request path and reduce the binding costs through choices such as binary payloads, persistent connections, and fewer copies.

Overhead	Typical Cost	Scaling Behavior	Reduction Strategy
Network I/O	1–5 ms	Linear with payload	Compression, Region Colocation
Serialization	50–500 µs	Linear with payload	gRPC/Protobuf (vs. JSON)
Queuing	0.1–10 ms	Diverges near capacity	Dynamic Batching, Autoscaling
Dispatch	10–50 µs	Constant per batch	Kernel Fusion (reduce launches)
Data Copy	100–500 µs	Linear with tensor	Zero-Copy/Shared Memory

13.3.2.2 The killer microseconds problem

Barroso, Patterson, and colleagues identified a critical gap in how computer systems handle latency across time scales (Barroso et al. 2017). Nanosecond-scale stalls (such as cache misses) are hidden by hardware instruction-level parallelism, while millisecond-scale delays (such as disk I/O or network RPCs) are hidden by operating system thread context switching. Operations in the microsecond range (1–100 µs) fall into the gap between these two mechanisms. They are too long to spin-wait on a CPU core without wasting compute cycles and power, yet too short for the operating system to context-switch to another thread without paying scheduling overheads that exceed the wait time itself.

Serving infrastructure operates directly in this killer microseconds regime. Using the representative ranges in table 13.5, serialization at 50–500 µs, dispatch at 10–50 µs, and data copy at 100–500 µs are each individually small, but for the 3.5 ms reference forward pass, these named microsecond-scale overheads collectively add about 5 percent to 30 percent of the latency budget before network and queuing delays are counted. No single overhead justifies optimization in isolation, yet together they determine whether the system meets its SLO.

Tackling this compound overhead demands systematic architectural intervention across the software-hardware interface. When microsecond delays accumulate across serialization, kernel dispatch, and memory copies, isolated optimizations to individual functions yield negligible improvements. Instead, high-performance serving runtimes remove the boundaries themselves by employing zero-copy memory buffers between networking and execution runtimes, maintaining persistent CUDA streams to bypass driver dispatch latencies, and migrating preprocessing kernels directly onto the accelerator to avoid intermediate host-device transfers.

13.3.3 Resolution and input size trade-offs

Bigger inputs cost more to decode and more to run, so input resolution is a serving control as well as a model property. Model architectures are often evaluated at fixed resolutions, but the serving runtime must ingest variable client inputs and rescale them before kernel execution. In convolution-dominated vision networks, floating-point operations scale quadratically with spatial dimensions ($\mathcal{O}(H \cdot W)$), whereas static costs (such as weight streaming from accelerator memory and kernel launch overheads) remain invariant. Varying input resolution therefore shifts the operational arithmetic intensity across the roofline boundary. Compute-bound stages slow down quadratically as pixel count expands, whereas memory-bound stages scale with activation memory footprint.

For convolution-dominated, compute-bound models, equation 13.1 gives a first-order approximation in which throughput scales inversely with resolution squared, comparing two input resolutions r_1 and r_2 (image side lengths in pixels):

↩ The roofline boundary and arithmetic intensity ridge points that separate compute-bound from memory-bound stages are established in section 11.6.

$$\frac{\text{Throughput}(r_2)}{\text{Throughput}(r_1)} = \left(\frac{r_1}{r_2}\right)^2 \tag{13.1}$$

Doubling resolution from 224 to 448 gives a 4× compute-scaling estimate, whereas the illustrative 3.6× scenario includes fixed overhead. Table 13.6 shows the mechanism behind that gap. Each step up in resolution reuses the same weights across more pixels, so the modeled arithmetic intensity rises and the fixed weight traffic becomes a smaller share of the work. That amortization is why the illustrative slowdown falls short of the pure compute estimate. The model counts only weights and one pass over a scaled activation term, so it establishes the direction of the effect; a profiler decides whether the executed kernels are compute or memory bound.

Table 13.6: Resolution and Modeled Arithmetic Intensity: This estimate divides FLOPs by weight bytes plus one assumed read/write of a scaled activation term. It omits aggregate intermediate-tensor, cache, and workspace traffic, so crossing a ridge point does not establish the executed-kernel bottleneck.

Resolution	Assumed Activation Term	Modeled Arith. Intensity
224×224	12.5 MB	64.4 FLOP/byte
384×384	36.7 MB	137 FLOP/byte
512×512	65.3 MB	183.9 FLOP/byte
640×640	102.0 MB	218.4 FLOP/byte

13.3.3.1 Resolution strategies in production

Different deployment contexts choose resolution according to which constraint binds first. A mobile application may accept 224×224 inputs because latency and battery life outweigh marginal accuracy gains, whereas medical-imaging workloads often step up to 512×512 or higher because diagnostic detail justifies the extra compute. Between those fixed choices, a perception pipeline may run a wide field at low resolution and reserve high-resolution crops for fine-grained recognition, while a public API that receives arbitrary user uploads can either normalize every image to a single input size or route each request to one of several validated resolution profiles.

13.3.3.2 Adaptive resolution

Adaptive resolution lets production systems select resolution dynamically based on content. One approach runs a lightweight classifier at 128×128 to categorize content type, then selects task-appropriate resolution with documents at 512×512, landscapes at 224×224, and faces at 384×384. In this illustrative scenario, the policy provides 1.4× throughput improvement with 99.2 percent accuracy retention vs. fixed high resolution. This pattern trades preprocessing cost from running the lightweight classifier for inference savings on the main model. While resolution sets the cost of the stages before the model, the stage after it is usually far cheaper, though it still crosses the device boundary and spends host CPU time and therefore belongs on the same budget.

13.3.4 Postprocessing

When a model finishes a forward pass, its raw output logits sit in accelerator memory that client applications cannot read directly; copying thousands of unreduced floats across the PCIe bus and

formatting strings on the CPU can stall the worker thread between batches. Postprocessing turns those device tensors into structured application responses across the physical boundary between the accelerator and the host CPU, and how the serving engine splits computation across that boundary determines whether the final stage finishes in microseconds or blocks the pipeline.

13.3.4.1 From logits to predictions

Classification models emit unnormalized logits across the label space, and turning those raw scores into application-ready predictions requires a chain of reduction, filtering, and calibration steps. When only the single most likely label matters, argmax selection extracts the index of the highest logit, whereas applications that present ranked alternatives use top-k extraction to keep the k largest scores alongside their class indices. Before returning those candidates, probability calibration (such as temperature scaling) rescales raw logits so that output confidences reflect empirical accuracy, allowing thresholding to discard predictions that fall below a required certainty cutoff.

Executing reduction operations on the accelerator can reduce host-device transfer volume when the saved transfer cost outweighs the device execution and launch overhead. Performing softmax, argmax, or top-k selection in device memory prunes the payload before it crosses the PCIe bus. In ResNet-50 classification, for example, running top-k on the GPU reduces the transfer payload from 1,000 float32 logits (4,000 bytes) to five values and five integer indices. For ResNet-50 image classification, listing 13.1 traces this execution path from GPU tensor operations to host CPU label lookup and response formatting.

Listing 13.1: ResNet-50 Postprocessing: Normalizes raw logits into probabilities, extracts top-k predictions, and formats the API response.

```
# Normalize raw logits into probabilities
# Input: logits tensor of shape (1, 1000), one score per ImageNet
# class
probs = torch.softmax(logits, dim=-1)  # Normalize to sum=1 on GPU

# Extract top-5 predictions for multi-class response
# topk returns (values, indices) sorted by probability
top5_probs, top5_indices = probs.topk(5)  # GPU operation
top5_probs = top5_probs.squeeze(0).tolist()
top5_indices = top5_indices.squeeze(0).tolist()

# Map class indices to human-readable labels
# imagenet_labels: list of 1000 class names from synset mapping
labels = [imagenet_labels[i] for i in top5_indices]  # CPU lookup

# Format response with predictions and metadata for API contract
response = {
    "predictions": [
        {"label": label, "confidence": float(prob)}
        for label, prob in zip(labels, top5_probs)
    ],
    "model_version": "resnet50-v2.1",  # Client-side version tracking
    "inference_time_ms": 5.2,  # Observability for latency monitoring
}
```

In listing 13.1, total postprocessing time is approximately 0.1 ms, negligible compared with preprocessing and inference. The GPU handles the normalization and top-5 reduction, so the subsequent `.tolist()` call transfers only tens of bytes across PCIe. However, `.tolist()` forces a synchronous device-to-host copy, blocking the host thread until the GPU stream finishes. In high-throughput pipelined servers, such synchronization barriers must be scheduled carefully to avoid stalling the CPU thread while it feeds subsequent requests. Fitting a calibration mapping is an offline task; applying a simple fitted mapping online is usually inexpensive, but it is valuable only when downstream decisions require confidence scores whose empirical meaning has been validated.

13.3.4.2 Output formatting

Production systems package predictions to satisfy application-level API contracts. These contracts govern JSON serialization schemas, floating-point formatting, error codes, and fallback defaults when thresholding rejects all candidates. In Python-based runtimes, repetitive JSON serialization and string allocation can consume unexpected host CPU cycles under heavy concurrency, turning a microsecond-scale formatting step into a CPU bottleneck. High-throughput servers address this by delegating serialization to native C++ runtimes or binary protocols like Protocol Buffers. Response metadata, including model version and inference execution time, completes the payload to enable downstream observability. Characterizing postprocessing closes the individual request's latency budget, though analyzing these stages strictly in isolation assumes sequential evaluation, where each transaction completes its entire lifecycle before subsequent work begins.

13.3.5 Hardware utilization and request pipelining

Executing each request in lockstep isolation leaves specialized accelerators heavily underutilized. Because network termination, payload preprocessing, neural network evaluation, and response serialization bind on distinct physical subsystems (host network interfaces, CPU cores, PCIe interconnects, and accelerator matrix units), strict serial processing forces the accelerator into idle bubbles while the host prepares incoming tensors. The central systems objective is to maximize the accelerator's **duty cycle**, the proportion of wall-clock time spent actively executing arithmetic kernels, without violating request tail-latency deadlines. Serving runtimes achieve this through **request pipelining**, overlapping asynchronous host preprocessing of forthcoming queries with concurrent accelerator execution on previously staged batches.

13.3.5.1 Overlapping I/O and compute

↩ Asynchronous host-accelerator transfer and double buffering mechanisms are established in section 11.5.4.2.

Figure 13.4 sequences execution across CPU preprocessing and GPU inference to demonstrate how request pipelining recovers lost compute capacity. In serial execution (A), each request must complete its entire lifecycle (Network → CPU Preprocessing → GPU Inference → Postprocessing) before the next request begins, leaving the GPU idle for more than 50 percent of wall-clock time. Pipelining concurrent requests (B) overlaps CPU preprocessing of upcoming requests with active GPU inference on earlier inputs, eliminating the idle bubbles and maximizing accelerator duty cycle.

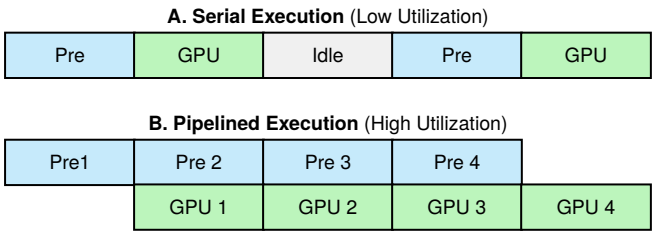

Figure 13.4: Request Pipelining: Pipelining hides latency by overlapping independent operations across different hardware resources. In pipelined execution (B), the CPU processes the next request's data while the GPU executes the current request's inference. This can increase accelerator duty cycle and throughput without changing the model.

Pipelining relies on non-blocking hardware queues and asynchronous execution streams. Instead of blocking until a GPU kernel completes, the host CPU thread enqueues memory transfers and kernel launches into an accelerator stream and immediately begins preprocessing the next incoming request. The accelerator's DMA engine and compute cores execute those queued operations independently, overlapping host preprocessing with device execution.

13.3.5.2 The systems metric: Hardware duty cycle

System efficiency here measures accelerator duty cycle rather than the fraction of peak arithmetic throughput or bandwidth achieved. In equation 13.2, compute time is the union of useful kernel-active intervals on each resource, summed across resources; overlapping kernels on one GPU are not counted twice.

$$\text{System Efficiency} = \frac{\sum T_{\text{compute}}}{\text{Wall Clock Time} \times \text{Resource Count}} \tag{13.2}$$

The reference ResNet-50 request spends 4.5 ms preprocessing on a host CPU core and 3.5 ms on the accelerator, so a serial system keeps the accelerator busy only 41 percent of the time. With at least two requests in flight in a sustained stream, the accelerator works on one request while the host prepares the next, and duty cycle rises to 78 percent after pipeline fill. It cannot reach 100 percent with one preprocessing worker, because the host stage is the slower of the two; a second worker removes that cap. A finite pair still pays pipeline fill and drain time, and stochastic service must retain enough capacity headroom to meet its tail-latency objective. If the CPU is too slow to feed the GPU, the system becomes CPU-bound, and further model optimization provides zero throughput gain; this is the Amdahl ceiling of section 13.3.2 seen from the throughput side. Hardware upgrades tighten it, because accelerator compute throughput has grown far faster than CPU single-thread performance across successive generations. A system that was compute-bound on an older accelerator may become CPU-bound after a hardware upgrade, not because preprocessing got slower but because the model got dramatically faster while the CPU did not.

Checkpoint 13.1: The latency budget

A request's latency is spent across every stage of its path, not only in the model. Use this checkpoint to locate where the budget goes before choosing an optimization.

- ☐ **Amdahl ceiling**: in the reference ResNet-50 request, why does a 10× faster model yield far less than a 10× faster response, and why does a faster accelerator make the ceiling tighter rather than looser?
- ☐ **Tail vs. mean**: can you explain why mean latency cannot demonstrate compliance with a p99 SLO?
- ☐ **Latency budget**: given a 50 ms request deadline and a combined upper bound of 18 ms for all other stages, including network transit, preprocessing, transfer, and postprocessing, how much remains for inference and queueing? Why would a measured 18 ms mean for those stages be insufficient to certify a p99 SLO?
- ☐ **Pipelining**: explain how overlapping CPU preprocessing with GPU inference raises accelerator duty cycle without changing the model, and what happens to throughput when the CPU stage is slower than the GPU stage.

Tracing an isolated request reveals the intrinsic execution time of each pipeline phase. In production, however, multiple requests arrive concurrently and contend for shared accelerators, CPU cores, and memory buses, introducing queuing delays that dwarf raw computation time.

13.4 Queuing Theory

An inference service that responds in a few milliseconds at moderate load can suffer sudden, tenfold latency spikes when traffic climbs toward capacity, even though no hardware has failed and the model's execution time has not changed. Because requests arrive in irregular bursts and contend for shared accelerator queues, host-to-device PCIe links, and memory buses, queuing theory governs how waiting times grow and why latency explodes nonlinearly as utilization approaches capacity.

13.4.1 Little's Law

Before deciding how many accelerators to provision, an engineer must know how many requests will sit inside the server at the same time; underestimating that in-flight population exhausts host request buffers, worker threads, and device activation memory under load. Given an expected arrival rate and mean response time, Little's Law determines this average concurrency directly from throughput, while queuing models predict how response times climb as utilization nears saturation.

↪ The derivation of Little's Law from conservation of requests is collected for reference in section D.2.5.

Systems Perspective 13.3: Notation alert: L vs. latency

Classical queueing texts write Little's law with single letters for the in-system count and the time in system; this book writes Q_{req} for the count and T_{lat} for the time, because the classical count letter would collide with the loss $\mathcal{L}$ and with the iron law's fixed-latency term L_{lat}. In queuing theory, T_{lat} denotes the *response time* or *time in system per request*; queue-only waiting time is W_q. Here, Q_{req} denotes the average in-system request count, λ_{arr} the arrival rate, μ the service rate of a server that handles one request at a time, and $\rho_{\text{serv}} = \lambda_{\text{arr}}/\mu$ the serving utilization. The subscripts distinguish queueing notation from the degradation equation's λ sensitivity parameter and keep serving utilization from occupying bare ρ. Section 13.5.2 adds the few symbols that batching needs.

Formulated by John D. C. Little (Little 1961), **Little's law** establishes an exact relationship among three macroscopic metrics in any stable queuing system:

$$Q_{\text{req}} = \lambda_{\text{arr}} \cdot T_{\text{lat}} \tag{13.3}$$

where Q_{req} is the average number of requests residing in the system, λ_{arr} is the arrival rate (requests per second), and T_{lat} is the average time each request spends from arrival to completion.

Little's law holds regardless of the arrival distribution, service-time distribution, or scheduling discipline; it requires only that the system is stable and that requests are neither created nor destroyed internally. For an inference service targeting 1000 QPS with a mean response time of 50 ms, Little's law dictates the average in-flight request population that host memory buffers and worker threads must sustain.

Napkin Math 13.2: Little's Law capacity sizing

Problem: How many requests are in the system on average at 1,000 QPS?

Math: Little's Law gives $Q_{\text{req}} = \lambda_{\text{arr}} T_{\text{lat}}$, so average population equals throughput multiplied by mean time in system.

Given:

- **Arrival rate** (λ_{arr}), equal to throughput in a stable system: 1,000 QPS.
- **Mean time in system** (T_{lat}): 50 ms (0.05 s).

Math: Q_{req} = 1,000 QPS $\times$ 0.05 s = 50 concurrent requests on average

Systems insight: The system holds 50 requests on average across batch and queue state. That population is a memory and concurrency requirement, not a limit on the accelerator. A server whose GPU executes at most 32 requests per batch can still sustain this load, because the requests not currently executing wait in host memory; service rate, queueing behavior, and the tail distribution, not the population itself, determine whether the load is feasible.

Because equation 13.3 binds these three variables, constraining any two dictates the third. If an inference service averages 10 ms per request ($T_{\text{lat}} = 0.01$ s) and holds 50 concurrent requests on average ($Q_{\text{req}} = 50$), the sustainable arrival rate must be $\lambda_{\text{arr}} = Q_{\text{req}}/T_{\text{lat}} = 5000$ requests per second. Conversely, if host memory limits concurrency to an average of 10 requests while average time in system remains 10 ms, the system cannot exceed a throughput of 1,000 requests per second without dropping traffic.

13.4.2 The utilization-latency relationship

Little's Law describes average system inventory under steady-state conditions, but it does not reveal how latency behaves as traffic approaches system capacity. The M/M/1 queuing model (in Kendall's notation: Markovian, that is Poisson, arrivals; Markovian, that is exponential, service times; and one server) quantifies the headroom required to prevent latency collapse (Harchol-Balter 2013).[9] For a system with Poisson arrivals[10] and exponential service times, equation 13.4 gives the average time

[9] **M/M/1 queue**: Queuing theory originated with Agner Krarup Erlang's 1909 analysis of the Copenhagen Telephone Exchange, where call arrivals were modeled as memoryless (Poisson).

[10] **Poisson process**: Named after French mathematician Simeon Denis Poisson (1781–1840), this stochastic model describes events occurring continuously and independently at a constant average rate, so counts in disjoint intervals are independent.

in system:

$$T_{\text{lat}} = \frac{1}{\mu - \lambda_{\text{arr}}} = \frac{\text{service time}}{1 - \rho_{\text{serv}}} \tag{13.4}$$

where λ_{arr} is the arrival rate, μ is the service rate (requests per second the server can handle), and $\rho_{\text{serv}} = \lambda_{\text{arr}}/\mu$ is the utilization (the fraction of time the server is busy).

Because the denominator contains $1 - \rho_{\text{serv}}$, latency grows nonlinearly as utilization approaches unity, and small incremental increases in traffic near saturation trigger severe backpressure and queuing delays. The standard M/M/1 formulation assumes exponentially distributed service times. For compiled neural networks processing fixed-size batches and static tensor dimensions, execution times are nearly constant, making an M/D/1 queue a tighter model of mean queuing delay. The analysis here retains the M/M/1 model because it yields closed-form solutions and predicts greater mean queueing delay than M/D/1 under matched arrival rate and mean service time. In production environments, variable input lengths, dynamic batch formation, CPU preprocessing, and key-value cache lookups introduce runtime variance that quickly breaks deterministic assumptions.[11] Under this model, average time in system multiplies rapidly as utilization approaches 100 percent (table 13.7).

[11] **Kendall notation**: Kendall's A/S/c (arrival/service/servers) shorthand (Kendall 1953) is the one already used for $M/M/1$, where "M" signifies a Markovian (memoryless) process; the "D" in M/D/1 denotes deterministic service. Neither model replaces measurement of a production workload's arrival process, service-time variance, or tail behavior.

Table 13.7: Utilization-Latency Relationship: Average time in system (wait + service) as a multiple of service time for an M/M/1 queue. At 50 percent utilization, time in system is 2× service time; at 90 percent, it reaches 10×. This nonlinear growth explains why systems that perform well at moderate load suddenly violate SLOs when traffic increases: moving from 80 percent to 90 percent utilization doubles latency.

Utilization (ρ_{serv})	Latency Multiple	Example (3.5 ms service)
50%	2×	7.1 ms
70%	3.3×	11.8 ms
80%	5×	17.6 ms
90%	10×	35.3 ms
95%	20×	70.6 ms

Plotted against the serving utilization ρ_{serv}, the fraction of time the server is busy, the same $M/M/1$ model shows why the knee matters (figure 13.5). Latency stays nearly flat at low utilization and then climbs without bound as the server approaches 100 percent busy, because each new arrival is increasingly likely to find work already waiting. The 99th percentile curve rises even faster in absolute terms, staying a fixed multiple above the mean that section 13.4.3 derives next. The green zone below 50 percent utilization and the red zone above 70 percent illustrate a planning policy, not universal operating limits. This rapid compounding near saturation is why latency-sensitive systems reserve headroom rather than planning for permanently high accelerator occupancy.

13.4.3 Tail latency

↪ Why long-tailed latency distributions make high percentiles, rather than the mean, govern what users experience is collected for reference in section B.2.1.

A serving cluster running at 70 percent utilization can report a comfortable mean latency while its slowest 1 percent of requests wait more than four times as long in the queue. Because averages hide this tail contention, production SLOs specify percentile targets (p95, p99) that bound experience for the slowest requests (Dean and Barroso 2013).

The M/M/1 model that produced the mean in equation 13.4 also yields the full latency distribution, and the tail follows from it. Total request latency (queue wait plus service) is exponentially distributed with cumulative distribution function $F(t) = 1 - e^{-t/T_{\text{lat}}}$, where $T_{\text{lat}} = \frac{\text{service time}}{1-\rho_{\text{serv}}}$ is that mean response time. To derive the 99th percentile latency (p99), we solve for the time t_{99} where 99 percent of requests have completed ($F(t_{99}) = 0.99$):

$$1 - e^{-t_{99}/T_{\text{lat}}} = 0.99 \implies e^{-t_{99}/T_{\text{lat}}} = 0.01 \implies -\frac{t_{99}}{T_{\text{lat}}} = \ln(0.01) = -\ln(100) \approx -4.605$$

Solving for t_{99} and substituting the mean latency T_{lat} yields the governing expression for tail latency:

$$T_{\text{lat,p99}} \approx \frac{\text{service time}}{1 - \rho_{\text{serv}}} \cdot \ln\left(\frac{1}{1 - 0.99}\right) \approx \frac{4.6 \cdot \text{service time}}{1 - \rho_{\text{serv}}} \tag{13.5}$$

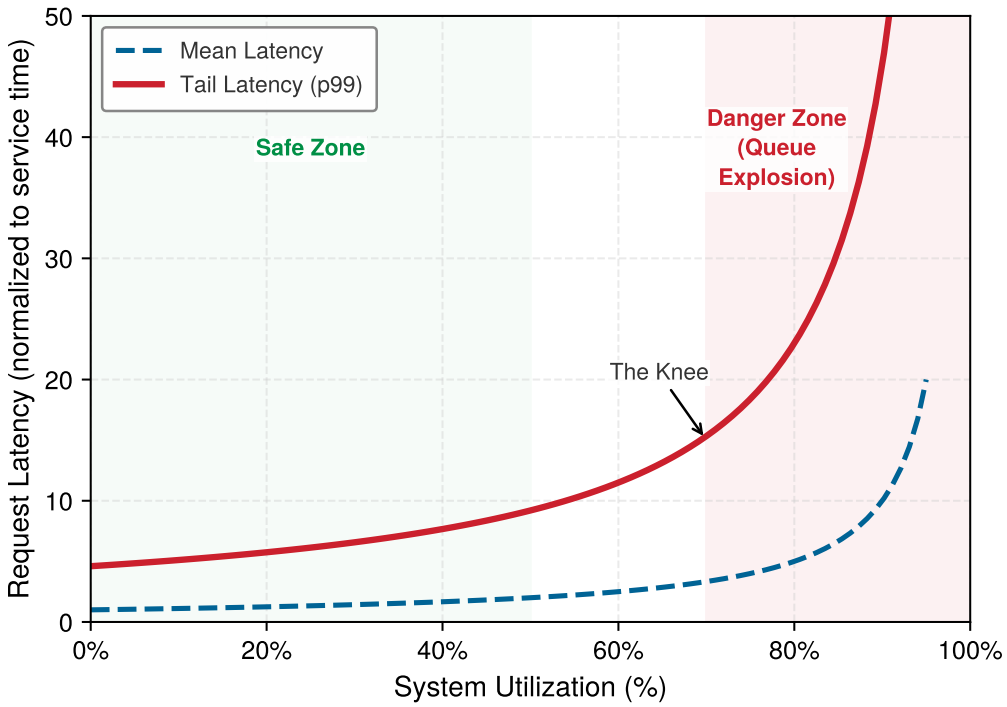

Figure 13.5: The Tail Latency Explosion: Request latency vs. serving utilization ρ_{serv}. Mean latency (blue) and the p99 approximation (red) both grow nonlinearly as utilization approaches saturation; the 70 percent marker is an illustrative planning knee rather than a model-derived breakpoint. In an $M/M/1$ queue, the 99th percentile latency scales as $-\ln(0.01) \approx 4.6\times$ mean latency, illustrating why tail delays compound violently near saturation.

At 70 percent utilization, average latency is only 3.3 times service time, while p99 latency reaches 15.3 times service time $(4.6/0.3 \approx 15.3)$. Evaluating a serving cluster by average latency therefore conceals severe tail degradation. Before exploring software mitigations like hedging, systems engineers must first provision sufficient accelerator capacity to satisfy tail-latency SLOs under peak load. For a ResNet-50 deployment, the M/M/1 tail-response-time model turns provisioning into a short sequence of steps.

Napkin Math 13.3: ResNet-50 capacity planning

Consider designing a ResNet-50 serving system with these requirements:

- **Queue-plus-GPU p99 subbudget**: 50 ms
- **Peak expected traffic**: 5,000 QPS
- **GPU service time** (batch one, the chapter's reference ResNet-50 profile): 3.5 ms

Step 0: Define the modeled request boundary. The worker model covers waiting for the GPU and the GPU forward pass only. This scenario allocates 50 ms to that portion of the request and separately assumes a combined 18 ms upper bound for network transit, serialization, preprocessing, transfer, and postprocessing. The end-to-end deadline must accommodate both allowances. A 50 ms end-to-end deadline would instead require subtracting the outside-worker allowance before applying the queue model; the arithmetic below would no longer apply. An outside-stage mean or p99 cannot substitute for the stipulated combined upper bound.

Step 1: Find safe utilization. From equation 13.5, $T_{\text{lat,p99}} \approx 4.6 \times$ service time $/ (1 - \rho_{\text{serv}})$. Setting $T_{\text{lat,p99}} \leq 50$ ms with 3.5 ms service time gives $\rho_{\text{serv}} \leq 1 - (4.6 \times 3.5\,\text{ms})/50\,\text{ms} = 0.68$

(68 percent maximum utilization). This is an M/M/1 p99 estimate under the stated arrival and service assumptions; a load test must validate the tail.

Step 2: Calculate required service rate. $\mu_{\text{required}} = 5,000\,\text{QPS}/0.68 = 7402.9\,\text{req/s}$

Step 3: Determine GPU count. In this M/M/1 model, the single-GPU rate is 283 req/s.

GPUs needed = 7402.9 req/s / 283 req/s = 26.1 $\rightarrow$ 27 GPUs

This single-GPU rate is the batch-1 service rate. Each request holds the GPU for the full service time, which keeps the M/M/1 model closed-form. Dynamic batching (section 13.5) amortizes fixed overhead across requests and raises the per-GPU rate several-fold, so a batched deployment may need fewer GPUs after its own latency distribution is validated; section 13.10.2 compares the two regimes.

Step 4: Add headroom for variance. This scenario adds 30 percent headroom for traffic spikes and variance: final count = 27 $\times$ 1.3 = 35.1, rounded up to 36.

Step 5: Verify fault tolerance. The 30 percent headroom addresses traffic variance, but production systems also need fault tolerance. With 36 GPUs, losing one leaves 35 GPUs handling 5,000 QPS. The postfailure utilization is 5,000 QPS / (283 req/s $\times$ 35) = 50.4%.

This remains well below the 68 percent safe utilization threshold, confirming N+1 redundancy is satisfied. For stricter fault tolerance requirements, N+2 redundancy (tolerating two simultaneous failures) would require 29 GPUs under the same safe-utilization threshold, or about 38 GPUs if the 30 percent headroom must remain after two simultaneous failures.

Result: Under the batch-1 M/M/1 assumptions, 36 H100 GPUs supply the modeled queue-plus-GPU capacity for 5,000 QPS within the 50 ms p99 subbudget, including one failed replica. End-to-end acceptance still requires validating the tail under load and the separately reserved outside-worker allowance.

The queuing analysis explains the capacity planning approach detailed in section 13.10.2 and connects directly to the MLPerf Server scenario. The Server scenario (section 12.4.4.1) is defined as Poisson arrivals scored by throughput against a tail-latency target. A Server result is therefore valid only when the run satisfies its percentile-latency constraint; otherwise, the target QPS must be reduced and the run repeated.

13.4.4 Tail-tolerant techniques

A capacity plan built on stationary Poisson arrivals holds only while traffic stays near the planned rate. Production traffic instead arrives in bursty, uncoordinated surges driven by user behavior, scheduled jobs, and daily cycles; when a surge pushes arrivals past the reserved headroom, accelerator service times cannot shrink to absorb the excess, so queries pile up in host and device queues and clients begin timing out.

Example 13.3: The 'Black Friday' traffic spike

Scenario: An e-commerce recommendation serving system experiences a 10× traffic surge (10,000 QPS) during Black Friday sales events.

Diagnosis: A fleet sized for normal traffic now receives more requests per second than it can complete. Utilization pins at 100 percent, and every second of the surge adds the excess arrivals to a queue that the servers cannot drain, so waiting time grows for as long as the surge lasts. In this scenario, latency reaches 10 s and clients time out. Section 13.4.2 showed why the queue starts growing sharply well before utilization reaches 100 percent.

Systems lesson: High average throughput does not prevent queueing collapse under traffic surges. Depending on the service, preserving a tail-latency objective may require load shedding, graceful degradation, or autoscaling before utilization reaches the workload's queueing knee.

Eliminating all sources of latency variability is often impractical. Production systems instead employ techniques that tolerate variability while still meeting SLOs (Dean and Barroso 2013; Dean

2012). For one serving node, the first distinction is between an isolated straggler and overload. Racing an isolated slow request can reduce its latency when spare capacity exists. When the node is overloaded, however, racing requests injects duplicate work and deepens the queue, so the system must instead protect the latency of admitted requests through graceful degradation or admission control. **Graceful degradation** returns lower-fidelity results to preserve throughput: classification pipelines fall back to cached approximations, generative models truncate decoding lengths, and model ensembles evaluate only a subset of members. Dynamically reducing active ensemble members shortens the service time $T_{\text{svc}}(B)$ of each batch of B requests, which increases the effective service rate $\mu_{\text{eff}}(B) = B/T_{\text{svc}}(B)$ and lowers utilization $\rho_{\text{serv}} = \lambda_{\text{arr}}/\mu_{\text{eff}}(B)$ toward a workload-appropriate operating point with more headroom, as illustrated by figure 13.5, trading a controlled accuracy reduction for SLO survival instead of an uncontrolled latency collapse. **Admission control** enforces an even stricter boundary. When the ingress queue exceeds a designated threshold, the server immediately rejects excess queries with HTTP 503 status codes rather than admitting work doomed to violate its latency deadline.

Setting this rejection threshold requires accounting for the work ahead of the arriving request. Consider a warmed, isolated worker that serves requests sequentially in first-in-first-out (FIFO) order, without batching or preemption. Assume known upper bounds on each request's service time and on every remaining stage outside the worker, including the response path. Subtract time already spent since the request began from its end-to-end latency allowance, then subtract the remaining outside-worker bound and the arriving request's service bound. The result is its waiting allowance. The worker's outstanding-work bound is the sum of the current request's residual service bound and the service bounds of queued requests. Admission passes the deadline screen only when that sum fits within the waiting allowance; a negative allowance rules out admission even to an idle worker. A request-count limit approximates this comparison only when service costs are sufficiently uniform. When they are, a practical starting point bounds the ingress queue at two or three requests per worker, the backlog a worker clears within two or three further service times, and the deadline screen and measured tails then tighten or relax that bound.

Suppose the outstanding work exceeds the full model's waiting allowance but fits the allowance obtained with a validated, faster model that is already resident and warmed. The server can admit the request through that fallback if its prediction quality meets the application's minimum requirement. Shortening the new request's service time frees waiting allowance, but does not remove work already queued ahead of it. If neither acceptable model fits, rejection avoids spending accelerator time on a result that would arrive too late. Rejection reduces availability, while fallback can reduce prediction fidelity; both outcomes must be counted alongside latency so that shedding difficult requests does not make the service appear successful merely by shrinking its measurement population.

The deadline screen is a deterministic bound only under the stated service, isolation, and scheduling assumptions. Mean service time or a per-stage p99 cannot replace those upper bounds. Variable input lengths, batch formation, and shared memory-bus contention require empirical calibration against the joint request-latency distribution. Completed-request tails must be reported together with rejection rates and fallback quality over offered traffic. Adaptive admission control can tighten the admissible backlog as measured tail latency approaches the SLO, but neither a fixed queue count nor the simplified screen certifies a production p99 target.

13.4.5 Scaling across multiple replicas

Once traffic outgrows a single node's safe utilization knee, no single-machine tuning can prevent queue build-up; higher aggregate volume requires **horizontal replication**, placing identical model replicas behind a load balancer so that each holds a complete model copy and serves disjoint queries without inter-node synchronization. (Model parallelism, which shards one large model across accelerators linked by a fabric such as NVLink, solves a different problem: fitting a model that exceeds one device's memory or latency budget.) The $M/M/c$ queuing model extends the single-server analysis to c parallel workers; pooling requests in one shared queue absorbs arrival bursts better than isolated single-server queues, provided dispatch is balanced (least-loaded routing, for example) and each replica keeps its own headroom.

13.4.5.1 The tail at scale problem

Dean and Barroso's analysis reveals why tail latency becomes critical as systems scale beyond single machines (Dean and Barroso 2013). When requests fan out to m parallel backends (querying an ensemble of models, searching sharded embedding indices, or parallelizing pipeline stages), the overall user request completes only when the slowest sub-task finishes. If sub-task completion events are independent and each has a 99 percent probability of finishing within latency threshold $L_{\text{lat,SLO}}$, the probability that all m backends finish within $L_{\text{lat,SLO}}$ is $(0.99)^m$. For a fan-out of $m = 10$, only $0.99^{10} \approx 90.4\%$ of requests meet the target; at $m = 100$, that probability drops to $0.99^{100} \approx 36.6\%$, meaning nearly two-thirds of user requests experience a tail delay. This "tail at scale" effect makes controlling single-node tail variance essential for overall system performance.

Hedging and tied requests limit the damage from a straggler replica. Under hedging, a request that has not completed within the expected time is duplicated to another server, and the client keeps whichever response arrives first.[12] With a stable latency distribution, a threshold at the historical 95th percentile duplicates about 5 percent of requests; correlated slowdowns raise that fraction and can make hedging amplify overload instead of reducing the tail. Tied requests instead enter several server queues at once and cancel the other copies when one server begins processing, which avoids waiting to detect a slow response. Both techniques create duplicate work. Cancellation before dispatch prevents a losing copy from consuming accelerator time, whereas cancellation after dispatch only discards its result, so either needs spare capacity and an explicit duplicate-work budget. Canary requests apply the same idea to fan-out, sending the request first to one or two servers and committing to the full fan-out only if they answer within the expected time.

Replicas or streams on one machine can also race requests, but sharing an accelerator or memory bus can correlate their slowdowns and exhaust the same headroom. The local admission decision remains the foundation; fleet coordination is an extension of it. Retries across a fleet obey the same duplicate-work constraint, because load balancers that retry rejected requests at other overloaded replicas amplify the overload, so replicas should share load information and shed the same fraction of requests rather than each rejecting independently. Production frameworks may use shortest-job-first or deadline-aware scheduling rather than FIFO, changing which queued work lies ahead of an arrival and requiring a corresponding admission analysis (Harchol-Balter 2013).

[12] **Hedging**: The term is borrowed from finance, where an offsetting position reduces risk; here, the redundant request insures against a slow server. The insurance is not free. For ML systems, the losing hedged request may still occupy accelerator time if inference has already launched, because ordinary GPU kernels are not cheaply canceled mid-execution. Thus, a hedging policy must budget duplicate work as well as the latency benefit.

Checkpoint 13.2: Queuing and SLO headroom

Latency SLOs are not enforced by *fast inference* alone; they are enforced by *headroom*.

- ☐ **Little's Law**: at a fixed stable throughput, can you use $Q_{\text{req}} = \lambda_{\text{arr}} T_{\text{lat}}$ to explain why a higher average in-system population implies a higher mean response time, even if per-request compute time is unchanged?
- ☐ **Utilization cliff**: can you explain why latency grows nonlinearly as utilization ρ_{serv} approaches one, and why production systems target a conservative ρ_{serv} rather than "100 percent busy"?
- ☐ **Queue behavior**: use the mean and p99 curves in figure 13.5 to explain nonlinear latency growth near saturation. Why is the marked 70 percent knee an illustrative planning choice rather than a model-derived breakpoint?
- ☐ **Capacity planning**: can you explain why a throughput number is only "real" if requests still meet the percentile latency SLO under load?
- ☐ **Admission decision**: for the isolated FIFO worker, how does increasing the arriving request's service bound change its waiting allowance? If a faster fallback fits behind the outstanding work, what quality and availability conditions distinguish admitting it from rejecting the request? Why would substituting measured mean times invalidate the deterministic bound?
- ☐ **Headroom estimate**: a stable service handles 2,000 requests per second and measures a 10 ms mean response time. Use $Q_{\text{req}} = \lambda_{\text{arr}} T_{\text{lat}}$ to estimate its average in-flight population. Why does this result alone not establish compliance with a 50 ms p99 SLO?

Headroom keeps the queue stable by leaving capacity idle, and adding replicas creates headroom by adding accelerators. The other way to keep utilization below the knee is to raise each replica's service rate, and for an accelerator that executes one request at a time the largest lever is to execute several at once.

13.5 Throughput Optimization

Consider the reference ResNet-50 classifier on an H100 GPU operating at batch size one. Each forward pass reads the model's weights from high-bandwidth memory to serve a single image and issues a long sequence of small kernels whose fixed launch cost is paid once per image, leaving neither weight traffic nor launch overhead shared across inputs. Processing requests continuously at 280 images/s, each pass spends 99 percent of its time on those fixed costs. Processing 32 images at once delivers 7,000 images/s, a 25× throughput improvement on identical hardware, because one kernel sequence and one weight read now serve thirty-two inputs. The fixed-cost share must not be confused with serving utilization. A single worker processing batch 1 at 280 requests/s is 100 percent busy in queueing terms ($\rho_{\text{serv}} = 1.0$) with zero spare serving capacity, yet nearly all of its time goes to work that a larger batch would share. **Batching**[13] is the primary lever for improving serving economics, but its operational constraints differ sharply between training and serving (Crankshaw et al. 2017). *Training* batches maximize throughput by grouping hundreds or thousands of samples together with no constraint on individual sample latency. *Serving* batches must balance accelerator saturation against individual request deadlines, ensuring that no early-arriving input waits excessively for a batch to form. An inference server resolves this tension through **dynamic batching**, adjusting batch size at runtime to match incoming request arrivals.

[13] **Batch**: From Old French *bache* (a quantity baked at one time), entering computing in the 1950s for jobs processed together without human interaction. The ML serving usage preserves the original trade-off: grouping requests amortizes fixed costs (kernel launch, weight movement) across multiple inputs, but an online request may wait for a batch to form.

> Definition 13.3: Dynamic batching
>
> ***Dynamic batching*** is the ML serving optimization that trades latency for throughput under stochastic arrival patterns.
>
> 1. **Significance**: By buffering requests into a batching window, the scheduler amortizes fixed overheads (L_{lat}) across multiple inputs, pushing the system away from the bandwidth-bound regime (BW) toward the compute-bound regime (R_{peak}).
> 2. **Distinction**: Unlike fixed-size serving batches, dynamic batching adjusts the realized batch size at inference time according to arriving traffic, a timeout, and a maximum-batch limit.
> 3. **Common pitfall**: A frequent misconception is that batching "always helps." In reality, there is a latency-throughput Pareto frontier: if the batching window is too large, the increased queuing delay may violate the system's SLO before the throughput gains are realized.

13.5.1 Why batching helps

A single request often leaves an accelerator's compute units idle because its operations expose too little parallel work to hide kernel launch overhead or reuse weights streamed from memory (though large spatial inputs or smaller edge accelerators may already saturate at batch one). For workloads that underuse the device at small batches, increasing the batch size improves hardware efficiency (Shen et al. 2019) by amortizing fixed costs across multiple requests and running inputs in parallel across the batch dimension.

Two fixed costs dominate at small batch sizes. Kernel launch overhead is the time for the CPU to prepare and submit work to the GPU. The number of launches depends on graph lowering and fusion rather than the layer count. For each launch, the CPU must assemble kernel parameters, copy them to GPU-accessible memory, and signal the GPU to begin execution. The cost per kernel does not depend on batch size. The reference ResNet-50 profile issues 174 kernels at 15 µs of host time each, 2.6 ms per forward pass. At batch size 1, this overhead far exceeds the actual compute time; at batch size 32, the same overhead is amortized across thirty-two images. Weight loading reads model parameters from GPU memory (VRAM) to the compute units. In a weight-streaming

approximation, batch size 1 reads the weights for one image; batch size 32 reuses that weight stream across thirty-two images, increasing weight-only operational intensity by 32×. Activation traffic, caches, and workspace determine the executed operation's full intensity.

↩ Per-kernel launch overhead, and why fusion and graph execution attack it, are established in section 7.3.7.2.

Larger batches improve hardware efficiency but inflate per-request latency. The engineering objective is to identify the operating point that maximizes sustainable throughput while satisfying the request deadline. For the reference ResNet-50 profile quantified in table 13.8 below, serving batch size 8 with a 10 ms batching window requires a mean formation-plus-inference budget of approximately 8.8 ms: an arriving request waits on average half the window (5 ms, as derived in section 13.5.4.1) and requires 3.8 ms of inference. If the service must meet a 20 ms SLO, the remaining 11.2 ms provides headroom for worker backlog and auxiliary pipeline stages, while delivering 7.5× higher service throughput than batch 1 on identical hardware. On this accelerator the batching window, not the computation, is most of the batch-8 budget. Batch size cannot grow indefinitely, and figure 13.6 shows why by modeling this relationship across batch sizes on a logarithmic axis. To isolate the planning knee under worst-case scheduling conditions, the figure assumes a strictly serialized single worker that waits out the full batching window before executing each batch, without pipelined overlap (Latency $= T_{\text{window}} + T_{\text{svc}}(B)$). Under this unpipelined assumption, batch-1 throughput is 74 requests/s rather than the 280 images/s sustained when inference runs back to back. Throughput rises almost in proportion to batch size while the fixed overhead dominates each batch, because each added image costs only 33 µs of device time. The planning knee sits where the batch's total per-image work equals the fixed part of its latency, the window plus the fixed cost, near batch 410: there latency is twice that of batch one and throughput is half its ceiling, and beyond it each doubling of the batch roughly doubles latency while throughput gains less and less. In this model throughput never declines; it saturates, so latency, not throughput, sets the largest useful batch.

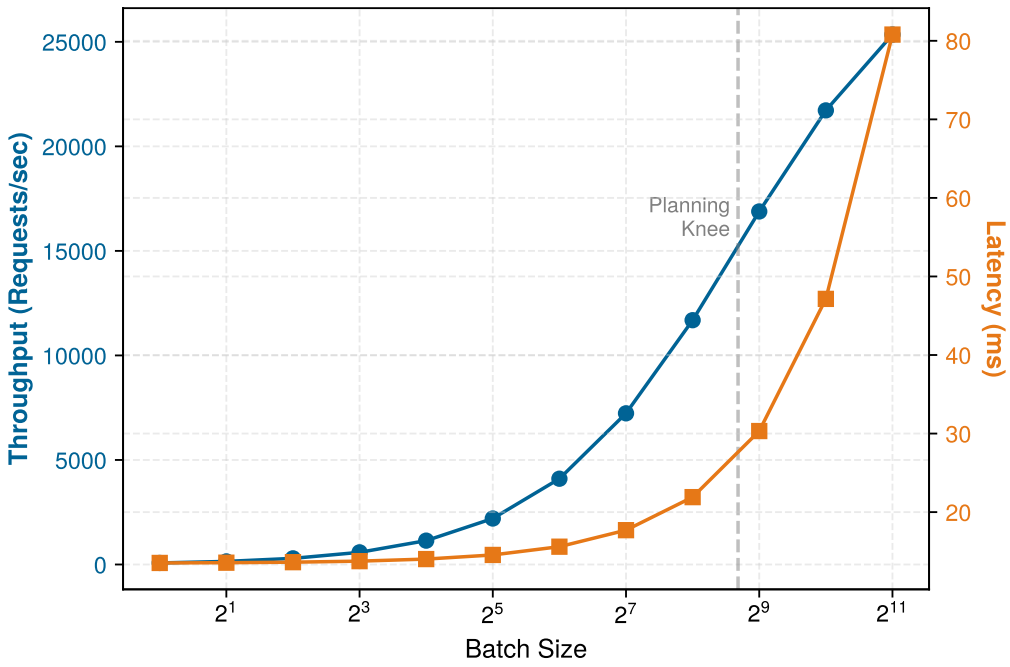

Figure 13.6: The Throughput-Latency Knee: Batch size vs. throughput (blue) and latency (orange) for the reference ResNet-50 profile on the H100. Throughput rises nearly in proportion to batch size while fixed overhead dominates, then flattens toward its ceiling. Latency grows slowly at first and roughly in proportion to batch size beyond the marked planning knee, where it is twice the batch-one latency and throughput reaches half its ceiling. Each throughput value is batch size divided by the plotted formation-plus-service latency, for a single worker that waits out a 10 ms window and then serves each batch; pipelined serving sustains higher throughput. Values are modeled, not measured.

The vertical dashed marker near batch size 410 in figure 13.6 marks the point where per-image work equals the fixed part of a batch's latency. The knee illustrates a general systems trade-off rather than a fixed operating setting. Under unpipelined serial dispatch, throughput is bounded by $B/(T_{\text{window}} + T_{\text{svc}}(B))$. In contrast, when the serving runtime pipelines batch formation with accelerator execution, saturated throughput depends solely on accelerator service time ($\mu_{\text{eff}}(B) = B/T_{\text{svc}}(B)$), achieving the higher capacities documented in table 13.8.

Napkin Math 13.4: ResNet-50 batching efficiency

Table 13.8 illustrates the throughput-latency trade-off for the reference ResNet-50 profile on the H100 across batch sizes one through thirty-two. The last column is the *fixed-cost share*, the fraction of each batch's time spent on costs that do not grow with batch size: kernel issue, the per-kernel device floor, and the weight read. This share must be distinguished from the server's queueing utilization ($\rho_{\text{serv}} = \lambda_{\text{arr}}/\mu$, section 13.4.2) and its wall-clock duty cycle (equation 13.2). For example, a dedicated worker executing batch size 1 continuously operates at 100 percent queueing utilization with zero idle time between requests, yet spends 99 percent of each forward pass on fixed costs that a larger batch would share.

Math: For the batch-8 row, dividing batch latency by batch size yields per-image compute: 3.76 ms ÷ 8 images ≈ 0.47 ms per image. Dividing batch size by batch latency yields throughput: 8 images ÷ 3.76 ms ≈ 2,130 img/s. The same two relations apply to every derived row.

Table 13.8: ResNet-50 batching sweep: Modeled per-image time, throughput, and fixed-cost share across batch sizes one through thirty-two for the reference profile on the H100. Throughput grows 25× from batch one to batch thirty-two as the fixed-cost share falls from 99 percent to 77 percent, while pure inference time stretches only from 3.5 ms to 4.5 ms. The window-plus-inference column adds the full 10 ms batching window and excludes worker queueing; because the window and the fixed cost dominate it, it rises only modestly across the sweep. The fixed-cost share is distinct from server queueing utilization and wall-clock duty cycle.

Batch Size	Inference Time	Window + Inference	Per-Image Compute	Throughput	Fixed-Cost Share
1	3.53 ms	13.5 ms	3.53 ms	280 img/s	99%
4	3.63 ms	13.6 ms	0.91 ms	1,100 img/s	96%
8	3.76 ms	13.8 ms	0.47 ms	2,130 img/s	93%
16	4.02 ms	14.0 ms	0.25 ms	3,980 img/s	87%
32	4.55 ms	14.5 ms	0.14 ms	7,040 img/s	77%

The inference times exclude queue wait. The window-plus-inference column is the unpipelined worst case for a request that waits out the whole window, and section 13.5.4.1 derives the average wait a request actually sees.

Systems insight: Batch size 32 achieves 25× higher throughput than batch size 1. However, user-perceived latency includes both queue wait and inference time. With a 10 ms batching window and 4.5 ms inference, formation plus inference reaches 14.5 ms, excluding resource backlog and other request stages, vs. 3.5 ms at batch size 1.

The sweep reports seconds; the same batches look different in bytes and joules. At batch one each image carries the entire 102.4 MB FP32 weight read by itself, and at batch thirty-two it carries one thirty-second of it, while the 25 MB of activations each image writes and reads stays fixed (table 13.9). Arithmetic intensity rises from 64 FLOP/byte to 291 FLOP/byte. With the energy constants that accompanied the iron law in section 1.7, 160 pJ/byte of DRAM traffic and 2.3 pJ/FLOP of FP32 arithmetic, the energy of one classification falls from 39.2 mJ at batch one to 23.4 mJ at batch thirty-two. Data movement accounts for 52 percent of that energy at batch one and 19 percent at batch thirty-two. Past that point arithmetic dominates, and a larger batch saves almost nothing per image while still lengthening every request's wait.

Table 13.9: Memory and Compute per Image Across Batch Sizes: ResNet-50 forward pass counted in FP32 bytes and FP32 operation energy, the precision of the book's energy constants. Weight bytes divide by the batch size while activation bytes do not, so arithmetic intensity and energy per image improve until activations and arithmetic dominate. Activation traffic uses the same assumed 12.5 MB footprint, written once and read once, as the resolution estimate; time per image comes from the FP16 reference profile of table 13.8.

Batch Size	Weight Bytes per Image	Activation Bytes per Image	Arithmetic Intensity	Time per Image (Sweep)	Energy per Image	Movement Share
1	102.4 MB	25 MB	64 FLOP/byte	3.53 ms	39.2 mJ	52%
8	12.8 MB	25 MB	217 FLOP/byte	0.47 ms	24.9 mJ	24%
32	3.2 MB	25 MB	291 FLOP/byte	0.14 ms	23.4 mJ	19%

13.5.2 Formation delay and the latency-throughput frontier

The throughput gains demonstrated in table 13.8 incur a deliberate systems cost. Every request in a batch pays a latency penalty, an engineered queueing delay introduced to elevate hardware utilization. The performance gain arises from parameter reuse across inputs. Evaluating B independent queries simultaneously converts memory-bound matrix-vector products into compute-dense general matrix multiplications (GEMM), raising arithmetic intensity toward the hardware roofline ceiling (Principle 6). Conversely, the latency penalty accumulates in the queue, because assembling B distinct queries forces earlier arrivals to sit idle while waiting for subsequent requests to appear.

Formalizing this trade-off requires extending the single-server queuing notation. Let $T_{\text{svc}}(B)$ denote the execution duration for a batch of size B. The unbatched service rate is $\mu = \mu_{\text{eff}}(1) = 1/T_{\text{svc}}(1)$, while batching B inputs yields an effective aggregate throughput of $\mu_{\text{eff}}(B) = B/T_{\text{svc}}(B)$. In a request-triggered fixed-batching system, end-to-end response time decomposes into two distinct penalties: **batch formation delay** ($L_{\text{lat,form}}$), the time earlier requests wait while the batch accumulates to capacity, and **inference inflation**, the modest increase in kernel execution duration $T_{\text{svc}}(B)$ as batch size expands from 1 to B. Under stationary Poisson arrivals at rate λ_{arr}, the first request in a batch waits an average of $(B-1)/\lambda_{\text{arr}}$ seconds while the final arrival waits zero, yielding an average formation delay of $(B-1)/(2\lambda_{\text{arr}})$. Assuming an execution worker is immediately available upon batch assembly, equation 13.6 models the resulting latency-throughput Pareto frontier:

$$L_{\text{lat,batch}} \approx \underbrace{\frac{B-1}{2\lambda_{\text{arr}}}}_{\text{Formation delay}} + \underbrace{T_{\text{svc}}(B)}_{\text{Inference time}} \tag{13.6}$$

Equation 13.6 formalizes the component trade-off between accelerator throughput and individual request latency, assuming an idle worker is immediately available upon batch assembly. Increasing B raises arithmetic intensity and amortizes memory bandwidth across inputs, but introduces formation delay for early arrivals. Evaluated as a formation-plus-service component comparison using the service times from table 13.8 at 500 QPS, moving from batch 1 to batch 32 increases formation wait from 0 ms to 31 ms, a 10× increase in isolated stage latency (3.5 ms to 36 ms). However, batch-one service cannot sustain 500 QPS on a single worker whose peak service rate is only 280 requests/s; without batching, worker backlog diverges toward infinity, so 3.5 ms does not represent a viable steady-state response time at this arrival rate. Batching is what makes 500 QPS feasible on that hardware in the first place, demonstrating that grouping requests can lower loaded end-to-end response time even while adding formation delay. Sizing B is therefore an operational stability screen before it is an economic optimization: operators first enforce queue stability ($\lambda_{\text{arr}} < \mu_{\text{eff}}(B)$) and then select the batch size that maximizes throughput within the memory ceiling and latency SLO ($L_{\text{lat,SLO}}$). Because equation 13.6 assumes the batcher waits for a full count of B requests before launching, how serving systems relax that count-only assumption when traffic fluctuates separates the two batching policies below.

13.5.3 Static vs. dynamic batching

If an inference server holds execution until its queue accumulates a fixed batch of B requests, a lull in traffic can leave early arrivals waiting indefinitely until enough subsequent queries arrive to fill

the batch. **Static batching** (where *static* describes the batch dimension rather than the precomputed predictions of static inference) fixes the batch size at compile time so compilers can allocate static memory buffers and emit specialized compute kernels—a natural fit for offline processing and model training, where inputs are already staged, but a liability when interactive requests arrive stochastically. Conversely, setting a small fixed batch size to cap waiting time leaves accelerator compute units underutilized and fails to amortize weight transfers from high-bandwidth memory when traffic spikes.

Dynamic batching decouples batch formation from arrival determinism by buffering incoming requests behind a dual-trigger scheduler (Olston et al. 2017; NVIDIA 2024d). Rather than waiting indefinitely for a fixed tensor shape, the serving runtime makes a batch eligible for dispatch when either of two thresholds is satisfied: the queue accumulates a maximum batch size B_{max}, or a timeout window T_{window} expires relative to the oldest buffered request. When traffic bursts, the queue fills to B_{max} almost instantaneously, achieving high arithmetic intensity with minimal queuing delay. When arrival rates drop, the timeout window forces the dispatch of an undersized batch ($B < B_{\text{max}}$), bounding formation time at the expense of per-request compute efficiency. If the accelerator is busy, the ready batch can still wait for service. The timeout window T_{window} and maximum batch size B_{max} form the primary operational levers. Shorter windows limit formation delay, whereas longer windows allow larger batches when enough requests arrive. A longer window is useful only when the resulting throughput gain remains within the latency and memory constraints.

13.5.4 Dynamic batching latency-throughput trade-offs

Setting those two levers (T_{window} and B_{max}) requires accounting for what happens to the latency budget while the batcher waits: a wide window can spend a large share of the SLO accumulating requests before a single kernel launches. Because latency under load grows in the queue before it grows on the accelerator (section 13.4.4), configuring a dynamic batcher starts by separating time spent waiting from time spent in service.

Equation 13.7 decomposes the modeled batching-and-service portion of request latency into two components. Its total excludes network transit and any host stages outside the service interval:

$$L_{\text{lat,batch}} = L_{\text{lat,wait}} + T_{\text{svc}}(B) \tag{13.7}$$

where $L_{\text{lat,wait}}$ is the time spent waiting in the batching queue (corresponding to $L_{\text{lat,queue}}$ in the latency budget of principle 12) and $T_{\text{svc}}(B)$ is the service time for a batch of size B (encompassing $L_{\text{lat,infer}}$ plus portions of $L_{\text{lat,pre}}$ and $L_{\text{lat,post}}$). This wait includes formation and any subsequent wait for a worker. The batching window T_{window} bounds formation time alone; $L_{\text{lat,wait}} \leq T_{\text{window}}$ holds only when no additional resource backlog delays dispatch. Batch size affects service time through weight reuse, parallel work, and execution overhead.

13.5.4.1 Quantitative analysis of batching

Configuring a dynamic batching policy requires balancing batch formation delay against accelerator execution time and pending queue backlog. In a pure count-triggered batcher (equation 13.6), average formation delay $(B-1)/(2\lambda_{\text{arr}})$ contracts as arrival rate λ_{arr} grows, but diverges under light traffic. Conversely, a pure timer-triggered batcher dispatches on a periodic schedule of length T_{window}, decoupling formation delay from instantaneous arrival fluctuations.

To evaluate how time-based batching impacts latency budgets, consider a baseline fixed calendar window where batches dispatch periodically every T_{window} seconds and an idle execution worker is available at the boundary. Under stationary Poisson arrivals, query arrival times distribute uniformly across the interval $[0, T_{\text{window}}]$. A request arriving at offset t within the window experiences a formation wait of $T_{\text{window}} - t$. Integrating across the uniform distribution yields an expected waiting time equal to exactly half the batching window (equation 13.8):

$$\mathbb{E}[L_{\text{lat,wait}}] = \frac{T_{\text{window}}}{2} \tag{13.8}$$

A 20 ms batching window adds 10 ms average wait (up to 20 ms for the first arrival in a window; later arrivals wait less) regardless of batch size achieved. For a 50 ms mean latency SLO with 3.5 ms inference, the average wait consumes 20 percent of the latency budget before any computation begins, about 3× the forward pass itself; tail SLOs must budget the full window.

13.5.4.2 Batch size distribution

For fixed calendar windows, the number of requests collected during T_{window} follows a Poisson distribution with mean $\lambda_{\text{arr}} T_{\text{window}}$. Equation 13.9 formalizes this relationship:

$$\Pr(\text{batch size} = k) = \frac{(\lambda_{\text{arr}} T_{\text{window}})^k e^{-\lambda_{\text{arr}} T_{\text{window}}}}{k!} \tag{13.9}$$

where k is a nonnegative integer count of arrivals in the window.

With a fixed 10 ms window, the count a window collects fluctuates most at low traffic. At 50 QPS the mean batch is 0.5 with a standard deviation of 0.7, and 61 percent of windows contain no request at all, so no GPU batch launches. At 200 QPS the mean is 2 and the standard deviation 1.4, so realized batches still swing widely around the mean. At 1000 QPS the mean reaches 10 and the spread narrows relative to it, so the probability that a window collects at least twice the mean falls from 39 percent at the lowest traffic level to 0.3 percent at the highest, the law of large numbers at work.

13.5.4.3 Throughput maximization strategy

Throughput optimization requires separating per-request latency from saturated service capacity. A request waits for batch formation, then pays the service time of the formed batch. Under sustained load, however, batch formation can overlap with the previous batch's execution, so capacity is governed by the ready-batch service time:

$$\mu_{\text{eff}}(B) \approx \frac{B}{T_{\text{svc}}(B)}, \qquad \text{throughput} = \min(\lambda_{\text{arr}}, \mu_{\text{eff}}(B)) \tag{13.10}$$

In equation 13.10, λ_{arr} is the offered arrival rate and $\mu_{\text{eff}}(B)$ is the saturated service capacity for batch size B. The numerator increases linearly with batch size while service time often increases sublinearly over a useful range because larger batches amortize fixed kernel-launch overheads and DRAM weight transfers, shifting execution from memory-bandwidth-bound matrix-vector operations toward compute-bound matrix-matrix multiplication. The batching window still appears in request latency and in low-traffic regimes, where the expected batch size is limited by arrivals during the window, roughly $\lambda_{\text{arr}} T_{\text{window}}$.

To analytically evaluate batching strategies across arbitrary batch sizes without interpolating discrete benchmark tables, the reference ResNet-50 profile is affine in batch size, $T_{\text{svc}}(B) = 3.50\ \text{ms} + (0.033\ \text{ms})\,B$: 3.50 ms of fixed kernel issue, per-kernel device floor, and weight read, plus 0.033 ms of device work per image. It is the same model that produced the batching sweep (table 13.8), so the sweep and the model describe one service. This analytical service model unifies the queueing, window screening, and dispatch calculations throughout the remainder of this section. The sweep's window-plus-inference column already evaluates it for a 10 ms batching window T_{window}, pairing formation-plus-service latency with saturated pipelined capacity. The sweep's throughput gains trace directly back to the fixed-overhead term L_{lat} of the iron law (principle 3), which batching amortizes across requests.

The sweep, the formation wait, and the arrival statistics compose a calendar-window planning model. Average formation wait is half the window, Poisson arrivals make the window count fluctuate around $\lambda_{\text{arr}} T_{\text{window}}$, and saturated service capacity $\mu_{\text{eff}}(B)$ grows as batching amortizes fixed costs. An oldest-request timer, a maximum-batch trigger, or a busy worker changes the observed wait and batch distributions. Mean-latency screening can narrow candidate configurations; a percentile SLO requires their tail behavior under the intended dispatch policy and load.

13.5.4.4 Latency-constrained optimization

When latency is the binding constraint, a mean-latency approximation provides an initial screen of candidate batch sizes. For the portion of a mean latency SLO allocated to batching and service, $L_{\text{lat,budget}}$, and average wait time $T_{\text{window}}/2$, equation 13.11 defines the maximum allowable batch size B_{SLO} using a first-order average latency approximation. Other request stages require separate budget allocations. This is a feasibility bound, not a throughput optimum, and it screens a mean budget rather than certifying a p95 or p99 target:

$$B_{\text{SLO}} = \max\left\{B : \frac{T_{\text{window}}}{2} + T_{\text{svc}}(B) \le L_{\text{lat,budget}}\right\} \tag{13.11}$$

Applying equation 13.11 to the affine service model for a 50 ms mean budget shows how the choice of batching window shapes the feasible configuration space. A conservative 5 ms window adds 2.5 ms of average formation wait (up to the full 5 ms for the first request in a window) and leaves 47.5 ms for inference, enough by equation 13.11 for a batch of about 1,340 images. The configured engine maximum batch of 128, an assumed setting, binds first, so the batch is capped at 128 images and the worker sustains about 16,600 img/s when saturated. An aggressive 25 ms window adds 12.5 ms of average wait and leaves 37.5 ms, still enough for about 1,030 images, so the same engine cap binds and saturated capacity does not change. A tail SLO, unlike this mean-latency plan, must budget the full window rather than its average.

This comparison quantifies the diminishing returns of expanding the batching window. Widening the window by 20 ms buys no saturated capacity while increasing average formation wait by 10 ms. On an accelerator this fast relative to its fixed cost, the latency budget stops being the binding constraint on batch size; the engine's maximum batch and the arrival rate are. However, this initial screen relies on mean formation wait and deterministic batch sizing. In production, stochastic arrivals introduce batch-size variance that can breach tail deadlines even when the mean latency appears well within the budget, requiring the percentile envelope analysis developed next.

13.5.4.5 SLO violation analysis

Batch size variability can cause SLO violations even when mean latency appears safe. A request in a fixed window sees itself plus the other arrivals, so $B_{\text{req}} = 1 + \text{Poisson}(\lambda_{\text{arr}} T_{\text{window}})$. With an available worker at dispatch, combining the full window with the request-seen p99 batch size gives the conservative formation-plus-service envelope in equation 13.12:

$$L_{\text{lat,envelope}} = T_{\text{window}} + T_{\text{svc}}(B_{\text{req,p99}}) \tag{13.12}$$

For λ_{arr} = 500 QPS and T_{window} = 10 ms, the mean request-seen batch size is 6 and its p99 is 12. The mean latency is 8.7 ms; the conservative envelope is 13.9 ms.

The envelope is 1.6× the mean, and a configuration whose mean sits comfortably inside the SLO can still breach it when a full window coincides with an unusually large batch. Under the available-worker calendar-window assumptions, the envelope conservatively screens formation plus service because the longest window wait and largest batch need not hit the same request. A passing configuration clears only this screen; acceptance still requires evaluating worker backlog and the other request stages under the intended traffic and dispatch policy. A failing configuration can be rejected conservatively or investigated with a more faithful model and load test. Neither outcome alone establishes compliance with the end-to-end SLO.

13.5.4.6 Adaptive batching windows

Static batching windows impose a rigid trade-off that penalizes both traffic extremes. Under heavy traffic surges, a static timeout window holds early arrivals unnecessarily long after sufficient queries have already accumulated, consuming latency budget without enlarging the batch. Conversely, during off-peak periods, a fixed window frequently dispatches tiny, inefficient batches, failing to exploit accelerator arithmetic intensity. To navigate this tension, serving runtimes employ **adaptive batching** policies that dynamically modulate window duration based on instantaneous queue backlog, observed arrival rates, and the residual latency margin before the service-level objective expires. An adaptive window contracts during surges and expands during lulls, so it can lower average latency and raise realized batch size at the same time, within the remaining latency budget. Listing 13.2 implements one such heuristic.

Listing 13.2: Adaptive Batching Window: Heuristically adjusts batch timeout based on queue depth, arrival rate, and the remaining latency budget.

```
def adaptive_batching_window(
    queue_depth, arrival_rate, slo_ms, service_ms, fixed_overhead_ms
):
    """Compute a heuristic batching window.

    Based on current system state.
    """
    target_batch_size = 16  # Deployment-tuned target batch

    # Fast path: batch ready, close immediately to minimize latency
    if queue_depth >= target_batch_size:
        return 0

    # Compute maximum allowable wait from the remaining p99 budget.
    max_wait_ms = max(0, slo_ms - service_ms - fixed_overhead_ms)

    # Estimate time to accumulate target batch at current arrival
    # rate.
    # arrival_rate is requests/second, so convert seconds to
    # milliseconds.
    if arrival_rate > 0:
        requests_needed = target_batch_size - queue_depth
        estimated_wait_ms = requests_needed / arrival_rate * 1000.0
        # Return minimum of estimated wait and SLO-constrained maximum
        return min(estimated_wait_ms, max_wait_ms)

    return max_wait_ms  # Low traffic: use remaining budget to accumulate batch
```

The heuristic selects a candidate formation timer. Its inputs omit time already spent by the oldest request and work queued ahead of the batch, so the returned window does not establish a remaining deadline allowance. Deadline-aware dispatch must account for both quantities and validate the service and outside-worker budgets under load.

The nondominated batching configurations form a Pareto frontier where improving throughput requires accepting higher latency. Across five window and batch-cap configurations on the reference profile, from a 2 ms window capped at batch 8 to a 50 ms window capped at batch 128, modeled throughput rises from 2,100 img/s to 16,600 img/s, a gain of 680 percent, while the modeled p99 envelope rises from 5.8 ms to 57.7 ms, 10× its initial value. Average latency over the same range grows from 4.8 ms to 32.7 ms.

13.5.4.7 Practical configuration guidelines

The frontier, like the knee of figure 13.6, shows why configuration must work backward from the latency budget. Past the knee, widening the window buys diminishing throughput for sharply rising tail latency. In the worked scenario, reserving 30 percent of the SLO for batching wait gives $T_{\text{window}} \leq 0.3 \times L_{\text{lat,SLO}}$; another workload may allocate a different fraction after accounting for network, preprocessing, inference, and postprocessing. The traffic estimate should include peaks and burst duration rather than rely only on the mean. GPU memory supplies a separate ceiling on batch size through activations and runtime workspace. Finally, monitoring the realized batch-size and wait-time distributions reveals whether the assumed arrival model holds and whether a fixed or adaptive window is appropriate.

For an illustrative ResNet-50 serving system with a 50 ms SLO and 500 QPS traffic, the calculation provides starting estimates for two configuration knobs: the batching window and maximum batch size. Table 13.10 summarizes the resulting configuration and modeled operating point. The batch statistics and tail envelope use the calendar-window model without worker backlog; an oldest-request timer and maximum-batch trigger require a load test of their actual distributions. Its saturated-capacity row derates the ideal batch-32 rate by an assumed efficiency factor of 0.89, standing in for scheduling gaps and batches that dispatch before they fill.

Table 13.10: Practical Batching Configuration: A 30 percent allocation sets a 15 ms maximum window; this illustrative scenario selects a 12 ms window below that bound and assumes a batch-32 cap. The reported latency is a conservative envelope, not the request-latency p99.

Quantity	Value	Engineering role
Latency budget for batching	15 ms	Portion allocated to batch formation.
Maximum window	15 ms	Upper bound implied by the latency budget.
Expected request-seen batch	7	Average batch seen by an arriving request.
Request-seen p99 batch	13	Tail batch size under Poisson arrivals.
Assumed memory-limited batch	32	Scenario cap for accelerator memory.
Selected configuration	$T_{\text{window}} = 12$ ms, $B_{\max} = 32$	Candidate knob setting for load testing.
Conservative tail envelope	15.9 ms	Full window plus request-seen p99 batch service time.
Illustrative saturated capacity	6,300 img/s	Ideal batch rate derated by the efficiency factor.
Offered throughput	500 img/s	Offered load; acceptance requires load validation.

Example 13.4: From a batching window to a dispatch decision

Problem: In a hypothetical trace of the selected dual-trigger configuration, four requests arrive at 0, 2, 5, and 9 ms. No further requests arrive before dispatch. The worker becomes available at 18 ms, and the remaining response path takes 4 ms. Does the oldest request meet the 50 ms deadline under the planning service-time model?

Analysis: The batch remains below the maximum count, so the oldest-request timer makes it eligible after 12 ms. The worker is still busy, adding 6 ms of resource-queue wait. The four-request batch then takes 3.6 ms under the same linear service model used for the window analysis. Adding the remaining response path gives 25.6 ms from the oldest arrival to completion.

Result: Dispatching the four-request batch meets the oldest request's deadline with 24.4 ms of slack; the later arrivals finish with more slack. Waiting for the maximum batch would leave these requests stalled because the trace supplies no further arrivals. The timeout therefore determines eligibility, while worker availability determines actual dispatch.

Systems insight: The selected window passes this complete trace, including backlog and the response path. Establishing a percentile SLO requires repeating the accounting over the intended traffic, service-time variation, and input mix, with rejected requests and fallback quality reported alongside completed-request latency.

Working backward from the budget can also conclude that the right window is zero, because schedulers and dynamic memory allocators add coordination and synchronization overhead that hurts latency-critical or resource-constrained deployments. Under an ultra-low p99 target, even a brief formation delay consumes an unacceptable fraction of the latency budget, while in runtimes without ragged (variable-length) tensor support, batching variable-length inputs pads every sequence to the longest item in the batch—waste that single-request execution avoids completely. Memory capacity can rule out batching as well: when model weights already occupy most of the accelerator's physical memory, concurrent batch activations and dynamic KV-cache allocations risk out-of-memory aborts, forcing the runtime to serve one request at a time.

13.5.5 Traffic patterns and batching strategy

A timeout window tuned for independent web API calls will stall a multi-camera robotics rig whose frames arrive in synchronized bursts, and it is useless on a smartphone that processes one user photo at a time. Because the right batching policy depends on how requests arrive, the MLPerf inference benchmark supplies four standardized scenarios that approximate common production arrival patterns.

13.5.5.1 Server traffic (Poisson arrivals)

The MLPerf Server scenario models cloud/API-like inference traffic with Poisson arrivals (Reddi et al. 2019), the arrival model behind the window statistics of section 13.5.4.2. A fixed calendar window collects $\lambda_{\text{arr}} T_{\text{window}}$ requests on average, and that count fluctuates most, relative to its mean, at low traffic. Higher traffic can fill a desired batch sooner, permitting a shorter formation window. An oldest-request timer also includes the request that starts the window. Increasing the arrival rate therefore allows the same expected batch count with less deliberate waiting. The scheduler may instead target a larger batch if the latency and memory budgets permit it. Neither choice creates service capacity. The formed batches must complete fast enough to keep up with sustained arrivals, or resource backlog grows despite the shorter window. Window tuning must jointly check the arrival count, the service rate at the realized batch sizes, and the full request-latency distribution.

13.5.5.2 Streaming traffic (correlated arrivals)

Video analytics, robotics, and other multi-sensor systems receive inputs from several synchronized sensors, so arrivals are correlated rather than independent. The batch size equals the number of sensors and the deadline equals the frame period, both fixed outside the server, and the binding quantity becomes arrival jitter. Inference cannot start until the last frame of a set lands, so jitter consumes the frame budget before any computation runs. Such pipelines bound latency with an explicit synchronization deadline, the latest batch start that still meets the frame deadline, and a fallback, such as reusing a sensor's previous frame, when a frame misses it. The MultiStream scenario (section 12.4.4.1) approximates this shape for benchmarking.

13.5.5.3 Single-user traffic (sequential arrivals)

Synchronized sensors fix batch size and deadline outside the server. At the opposite end of the spectrum, interactive mobile and edge applications process one request stream at a time, leaving no opportunity to batch independent queries. The MLPerf SingleStream scenario captures this sequential-serving shape. Here, the optimization target shifts from a synchronization budget under a frame deadline to per-request latency and energy consumption under a rigid thermal envelope. For the smartphone vision pipeline modeled below, the primary engineering objective is not batch formation, but minimizing per-phase latency and energy dissipation.

13.5.5.4 Mobile serving constraints

Cloud services often emphasize fleet cost and latency; mobile serving adds three closely coupled constraints. The first is an energy budget that throughput alone does not capture, because each inference consumes battery. In the modeled pipeline, 2.98 mJ at 22 FPS draws about 66 mW for the inference path alone, before camera, display, ISP, and OS overhead add to that total in a full photo app. Thermal throttling can compound this limit when sustained system power reaches a device-specific thermal boundary. Memory constraints close the set because the model shares RAM with the application and operating system. Reload time depends on device storage, runtime, and model state; quantization and memory-mapped loading (section 13.8.2) can reduce footprint and startup work but do not eliminate those dependencies.

Example 13.5: ResNet-50: Mobile serving

Table 13.11 decomposes per-phase latency and energy for a single-user mobile vision inference:

Table 13.11: Mobile ResNet-50 pipeline: Illustrative per-phase latency and energy for a single-user mobile vision inference, showing that JPEG decode on the CPU dominates the energy budget even though the NPU inference stage carries the model's compute. Optimization targets shift from throughput to energy-per-inference at the edge.

Phase	Duration	Energy	Notes
Camera buffer read	8 ms	0.08 mJ	System API
JPEG decode (CPU)	15 ms	1.5 mJ	Single-threaded
Resize + Normalize	5 ms	0.4 mJ	CPU preprocessing
NPU inference	12 ms	0.8 mJ	82% utilization
Postprocess + UI	5 ms	0.2 mJ	Result rendering
Total	**45 ms**	**2.98 mJ**	22 FPS sustained

The mobile serving node is governed by four metrics:

- **Energy per inference**: 2.98 mJ enables ~12.1M inferences per 10 Wh battery (typical smartphone)
- **Modeled inference power**: 2.98 mJ / 45 ms = 66 mW, excluding the rest of the device and therefore not a guarantee of indefinite operation
- **NPU vs. CPU trade-off**: CPU fallback replaces the 12 ms, 0.8 mJ NPU inference stage with a 45 ms, 4.2 mJ CPU stage; the full pipeline would rise from 45 ms and 2.98 mJ to about 78 ms and 6.4 mJ before additional system overhead.
- **Memory footprint**: 150 MB peak (model + activations), competing with app memory

Systems insight: In this illustrative pipeline, the mobile NPU reaches 82 percent utilization at batch size one while the chapter's batch-one ResNet-50 request keeps the H100 busy only 41 percent of the time even before its tiny per-image arithmetic is counted. The contrast is workload- and hardware-specific, but it shows why a mobile accelerator designed for single-stream execution can operate efficiently without the batches used to amortize a large server GPU.

These physical constraints make edge serving optimization fundamentally different from data-center optimization. Rather than maximizing aggregate batch throughput, the objective is to sustain real-time execution within a tight thermal and battery envelope without triggering hardware throttling or starving foreground applications of system memory.

13.5.5.5 Traffic pattern summary

Traffic-adaptive batching adjusts the batching window as queue depth and request rate change. The four MLPerf inference scenarios that section 12.4.4.1 defines map onto these traffic shapes and the batching strategy each favors (table 13.12). These scenarios are benchmark abstractions rather than deployment prescriptions, so the operative batching policy must still follow the service's current concurrency, deadline, and power constraints.

Table 13.12: Traffic Patterns and Batching Strategies: The four MLPerf inference scenarios approximate distinct deployment contexts. Server traffic (cloud APIs) uses dynamic batching with a timeout; MultiStream evaluates grouped queries under its version-specific latency rules, while a production sensor deadline requires separate validation; SingleStream processes requests individually; Offline uses large batches subject to memory capacity to maximize throughput.

Scenario	Context	Strategy	Focus
Server	Cloud APIs, web services	Dynamic batching with timeout	Window tuning, utilization-latency curve
MultiStream	Grouped sensor-like inputs	Joint query processing	Group latency under benchmark rules

Scenario	Context	Strategy	Focus
SingleStream	Mobile apps, embedded devices	No batching ($B = 1$)	Preprocessing, power efficiency
Offline	Batch processing, data pipelines	Maximum batch size	Throughput, hardware utilization

The examples developed here (cloud API traffic under the Server scenario, grouped sensor inputs motivated by MultiStream, and throughput-dominated pipelines under Offline inference) all decide how requests share the accelerator. Together with the latency budget and the queueing model, they complete one replica of the ResNet-50 service, which is where the chapter's first half ends. None of them decides how efficiently the accelerator executes each batch once it forms. The same batch of the same model can run several times faster or slower depending on the engine that compiles and schedules its kernels and on the number format it computes in, and those choices are the next lever.

Checkpoint 13.3: Batching and traffic patterns

Batching is the primary lever for serving economics, but the optimal strategy depends on context.

- ☐ **Throughput-latency trade-off**: Explain why batch size 32 achieves 25× higher throughput than batch size 1, yet a production system with a 20 ms SLO might still choose batch size 8.
- ☐ **Wait vs. compute**: Given an end-to-end latency budget, can you separate batch formation, waiting for an available worker, and batch service time $T_{\text{svc}}(B)$? Which wait does a batching timeout control?
- ☐ **Dynamic vs. static batching**: Describe why static batching fails under variable traffic arrival rates, and how dynamic batching with an adaptive time window resolves queue starvation.
- ☐ **Traffic pattern matching**: Map deployment scenarios (cloud API, synchronized multi-camera stream, mobile app) to corresponding MLPerf scenarios, identifying the batching strategy suited to each operational constraint.
- ☐ **Adaptive windows**: For a desired expected batch count, explain why higher traffic permits a shorter formation window. How would you check whether the realized batches can keep up with arrivals, and what must a load test verify before accepting the configuration?
- ☐ **When not to batch**: Name a latency target, runtime limitation, or memory condition under which a batching window of zero is the right configuration.
- ☐ **Bytes and joules per image**: Using table 13.9, explain why energy per image falls steeply from batch 1 to batch 8 but only slightly from batch 8 to batch 32.
- ☐ **The first half in one request**: For one ResNet-50 request arriving at 500 QPS, name the stage that sets its latency floor, the quantity that sizes the queue's headroom, and the two things the scheduler's batch changes, and explain how each depends on the one before it.

13.6 Inference Runtime Selection

Running an unchanged ResNet-50 model through a compiled C++ engine rather than an eager Python interpreter cuts batch-one latency on the reference H100 by more than fivefold, without altering a single weight. Dynamic batching and request scheduling govern how requests are grouped and queued, but an execution engine still has to map the resulting tensor operations onto physical execution units and memory hierarchies. The **inference runtime**, the software layer that schedules tensor operations and manages device resources, therefore changes both latency and throughput for a fixed model architecture. Runtime engineering proceeds in two steps: selection chooses the execution engine that fits the deployment target, and configuration tunes that engine for the model, hardware, input shapes, and latency budget.

13.6.1 Runtime constraint map

Attempting to deploy a Python-based server runtime onto a 256 KB microcontroller fails before the first request arrives, and exporting a model with custom operators to a mobile neural processing unit (NPU) delegate can silently push unsupported layers back onto the CPU. The deployment target narrows the viable runtime family before any speed comparison matters, and each tier in table 13.2 rules out entire classes of software. The keyword-spotting microcontroller in section 7.3.8 requires a fixed memory arena and a compact C/C++ runtime, whereas a smartphone can host an application runtime that routes supported operators to accelerator delegates and falls back to another path when an operator is missing. Within each target envelope, table 13.13 lists the candidate runtime families and the conversion or execution condition each candidate must pass before latency or memory numbers can be compared.

Table 13.13: Runtime Constraint Map: Read each row left to right as one trade, in which a family gives up flexibility, gains an optimization path, and acquires a new way to fail. The middle column records where a family sits relative to an untuned eager baseline rather than a measured result, so latency, memory use, energy, and utilization still have to be measured for the specific model, hardware, precision, batch size, and compiler configuration.

Runtime family	Where it fits	Constraint anchor	Optimization path	Constraint to test
PyTorch eager	Research and iteration	Baseline latency; full Python/runtime footprint	Dynamic graphs, eager debugging	Dispatch overhead and missing graph view
Compiled PyTorch/TensorFlow	Server training and serving	Workload-dependent gains when graph capture is clean	Graph capture, fusion, layout planning	Operator coverage and graph breaks
TensorFlow Lite/Core ML	Mobile and edge inference	Target-specific mobile latency and package-size budgets	Quantization, static graphs, NPU delegates	Target-specific conversion constraints
TF Lite Micro/microTVM	Microcontroller inference	Target-specific microcontroller RAM and flash budgets	Static allocation, INT8 kernels	Selected operators and constrained memory
ONNX Runtime	Cross-framework serving	Backend-dependent; can match native runtimes for supported graphs	Standard graph format, execution providers	Export gaps and custom-operator fallbacks
TensorRT/TVM	Hardware-specialized inference	Target-dependent gains over untuned eager baselines	Kernel fusion, precision lowering, autotuning	Narrower target and conversion assumptions

A runtime can fit the device and still fail to execute the exported model. Specialized inference runtimes such as TensorRT and Apache TVM require compatible operators and conversion paths; a mobile delegate may support only part of a graph. Unsupported regions can introduce fallback execution and extra transfers. Portability therefore requires an agreement about the graph and operator semantics on both sides of the export boundary.

13.6.2 Runtime ecosystem and configuration

Serving a model directly from the Python interpreter used to train it is the fastest path to a working endpoint, but under production load the interpreter itself becomes the bottleneck: threads contend for the Global Interpreter Lock (GIL), operators launch one by one without whole-graph fusion, and dynamic allocations fragment memory. Engine selection therefore starts with the binding system constraint rather than the training framework. When rapid iteration and full support for dynamic Python control flow or custom operators matter most, PyTorch and TensorFlow models can serve directly through their native runtimes. When interpreter overhead limits throughput, serialized graph formats such as `torch.export` and TensorFlow SavedModel (with TorchScript supporting legacy deployments) capture a static operator graph for ahead-of-time optimization and multi-threaded C++ execution. Framework-native runtimes prioritize developer flexibility and broad operator coverage, whereas specialized inference engines trade that generality for whole-graph rewrites and lower launch overhead.

13.6.2.1 General-purpose optimization

The development framework and deployment runtime need not be the same system, but they must exchange a representation both can interpret. The **ONNX** format addresses this fragmentation by

standardizing model exchange across runtimes (ONNX Contributors 2019). A pipeline can train an architecture in PyTorch, export the computation graph to an ONNX intermediate representation, and execute the serialized graph in ONNX Runtime or compile it for a target accelerator. In contrast, TensorFlow Lite relies on its own conversion path, translating TensorFlow SavedModels into FlatBuffers rather than routing through ONNX. Although standard interchange formats reduce manual model conversion between development and production environments, they do not eliminate compatibility testing, operator coverage gaps, or custom-kernel fallback overhead.

The exchange is hub-and-spoke around the common ONNX intermediate representation (figure 13.7). Training frameworks such as PyTorch, TensorFlow, Keras, Caffe2, MXNet, and CNTK export inward to the shared representation, and ONNX Runtime and other target frameworks load the serialized computation graph outward without reimplementing model code.

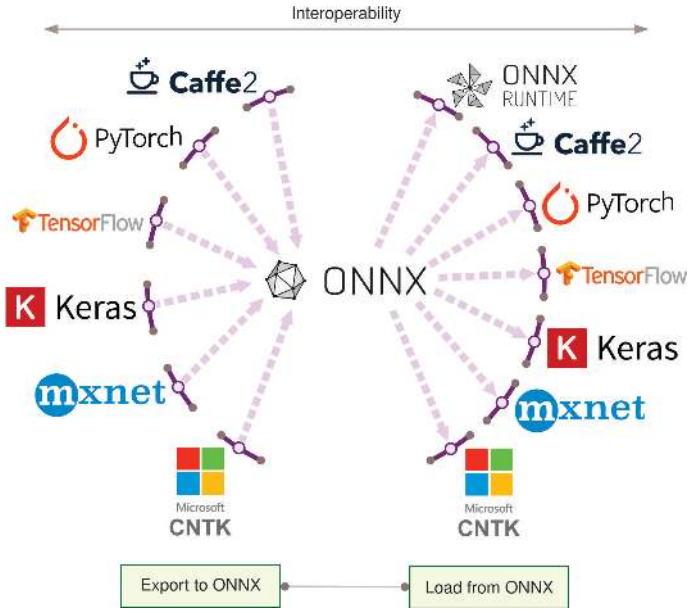

Figure 13.7: Framework Interoperability: The inward spokes represent exports into the shared ONNX format, while the outward spokes represent loads into compatible tools and runtimes; portability requires support on both sides of that boundary.

Interchange formats mitigate framework fragmentation, but an export boundary cannot salvage an architecture that violates the target's physical limits. Converting a graph to ONNX or an embedded runtime after development completes cannot resolve an excessive memory footprint, missing hardware operators, or unsupported dynamic control flow. Treating deployment as an afterthought guarantees costly rewrites, which is why hardware and runtime trade-offs need evaluating before the first line of model code is written.

When cross-hardware portability is the binding constraint, ONNX Runtime[14] provides an intermediate, hardware-agnostic execution layer (Microsoft 2024). Models export to the ONNX format, after which ONNX Runtime applies target-independent graph optimizations and delegates subgraphs to hardware-specific execution providers. This architecture enables single-format deployment across CPUs, GPUs, and custom accelerator application-specific integrated circuits (ASICs).

Portability still demands profiling operator placement across execution boundaries. If an operation is unsupported by the preferred execution provider, placement depends on the configured provider order and available implementations. A CPU fallback can introduce host-accelerator transfers and synchronization that erode the expected latency advantage; if no provider supports the operation, execution may fail. Profiling must therefore verify provider assignment and operator coverage across the entire graph, not merely confirm that the exported artifact executes without errors.

14 **ONNX Runtime**: Microsoft's inference engine applies graph optimizations such as constant folding, redundant-node elimination, and kernel fusion before handing subgraphs to execution providers. Performance relative to a tuned target-specific engine such as TensorRT depends on the workload, execution provider, and hardware.

13.6.2.2 Specialized inference engines

When latency budgets or serving costs bind more tightly than portability, specialized engines such as TensorRT for NVIDIA GPUs and OpenVINO[15] for Intel hardware optimize graphs specifically for target microarchitectures (NVIDIA 2024c; Intel Corporation 2026b; Chen et al. 2018). Rather than maintaining portable abstractions, these compilers specialize kernels directly to the hardware's register files, cache hierarchies, and matrix execution units. A specialized engine such as TensorRT or TVM offers no advantage unless its backend supports the target and its conversion path supports the model (NVIDIA 2024c; Chen et al. 2018), and ONNX reduces the exchange burden without proving either condition (ONNX Contributors 2019).

Layer fusion[16] is kernel fusion (also called operator fusion) applied when the engine is built. For the convolution → batch normalization → ReLU block, whose folding section 10.4.1 derives, the serving compiler performs the fold once, at engine build time, because batch normalization is a fixed affine transform once training ends. It absorbs the normalization into the convolution weights and bias, then fuses the ReLU into the same kernel, so the input feature map is read from HBM once and only the activated result is written back.

Kernel auto-tuning benchmarks and selects the optimal algorithm for each operation on the target microarchitecture. A single 2D convolution can be evaluated through direct convolution, GEMM transformation (im2col), Winograd minimal filtering (efficient for small 3×3 filters), or Fast Fourier Transforms (efficient for large spatial filters), alongside dozens of tile-size variations. Because the winning strategy depends on filter dimensions, batch size, and the accelerator's register and shared memory capacity, the compiler benchmarks candidate implementations against target hardware and caches the lowest-latency kernel, trading ahead-of-time compilation time for predictable serving latency. Together with operator fusion, these optimizations produce substantial speedups over an untuned framework-native baseline, though they require explicit graph compilation and may restrict dynamic tensor dimensions.

Example 13.6: ResNet-50: Runtime comparison

Table 13.14 applies the chapter's profile to each engine at batch one on the reference H100, changing one term at a time. The eager row is the reference profile. TorchScript runs the same kernels from a graph executor, removing the per-operation Python dispatch; ONNX Runtime also fuses each convolution with its normalization, activation, and residual add, cutting 174 kernels to 56; TensorRT replays the whole fused pass as one captured graph and then varies only the number format.

Table 13.14: Inference runtime comparison: Modeled batch-one latency and speedup for ResNet-50 on the reference H100 across PyTorch eager, TorchScript, ONNX Runtime, and TensorRT, from the chapter's serving profile.

Runtime	Latency	Speedup	Notes
PyTorch (eager)	3.53 ms	1×	Reference profile
TorchScript	1.79 ms	2×	No per-op Python dispatch
ONNX Runtime	0.61 ms	5.8×	Fused kernels
TensorRT FP32	0.38 ms	9.3×	One graph launch; TF32
TensorRT FP16	0.33 ms	10.6×	FP16 Tensor Cores
TensorRT INT8	0.30 ms	11.6×	Requires calibration

Systems insight: Removing per-operation overhead, not lowering precision, produces most of the batch-one speedup. TensorRT FP32 is already 9.3× faster than eager execution, and INT8 adds only 1.3× over FP32, because once host overhead is gone the per-kernel floor dominates a single image. Precision pays at large batch, where per-image work dominates; INT8 also requires calibration data and NVIDIA-specific deployment.

This optimization-compatibility trade-off governs engine selection. Higher specialization can improve hardware efficiency for supported operations and shapes but increases deployment com-

15 **OpenVINO (open visual inference and neural network optimization)**: An Intel-oriented inference toolkit that converts, optimizes, and runs models across Intel CPU, GPU, and NPU targets (Intel Corporation 2026b). Specializing for direct hardware execution departs from the portable execution guarantees of general-purpose frameworks, enabling the compiler to emit architecture-tuned vector instructions (such as AVX-512 or AMX) and exploit low-precision integer execution units. While speedups depend on the specific operator mix and target processor, this specialization can make CPU or edge serving economically viable for latency-sensitive models.

16 **Layer fusion**: The term parallels loop fusion in compiler optimization, where adjacent loops over the same array are combined into one pass to reduce memory traffic.

↩ Kernel fusion, which merges adjacent operations so intermediates stay in registers and on-chip memory instead of round-tripping through HBM, is established in section 7.3.2.

plexity, restricts dynamic control flow, and may introduce numerical deviations from the training baseline. The engineering choice depends on latency budgets, operational constraints, and how frequently model architectures evolve.

Once an execution engine is selected, configuration tunes its resource allocation to the hardware envelope. For CPU inference, thread pool sizes must match physical core counts: too few threads leave execution units idle, while too many cause CPU cache thrashing, OS scheduling delays, and lock contention across non-uniform memory access (NUMA) domains. For accelerators, static memory preallocation reserves fixed-size activation workspaces during initialization, removing runtime memory allocations (`cudaMalloc`) and page-table faults from the latency-critical request path. Execution provider priority determines which hardware backend handles each operator subgraph, while graph optimization levels balance build times against constant folding and algebraic simplification. Production deployments must benchmark these configurations across full latency distributions (p50, p99) rather than relying on framework defaults.

13.6.3 Precision selection for serving

On the reference H100, Tensor Cores execute FP16, FP8, and INT8 matrix operations, and each halving of the bytes per value doubles the dense peak rate. For ResNet-50, moving from FP32 to INT8 multiplies large-batch throughput several times over while sacrificing less than 0.4 percentage points of top-1 accuracy. Numerical precision is therefore coupled directly to infrastructure economics. At the serving layer, precision engineering introduces operational constraints: calibration data fidelity, layer sensitivity under live inputs, and dynamic precision dispatch.

↩ The quantization techniques this selection draws on, from numerical formats through calibration and quantization-aware training, are established in section 10.3.

13.6.3.1 Precision-throughput relationship

For memory-bandwidth-bound operations, reducing precision raises throughput by cutting the byte volume transferred across the memory bus. Equation 13.13 gives the bandwidth-only upper bound from precision reduction:

$$\frac{\text{Throughput}_{\text{INT8}}}{\text{Throughput}_{\text{FP32}}} = \frac{32}{8} = 4\times \text{ (theoretical maximum)} \tag{13.13}$$

Actual speedup depends on the compute-to-memory ratio, operator mix, hardware instruction throughput, and matrix alignment, falling below the bandwidth-only bound whenever arithmetic throughput or memory alignment binds. Low-precision kernels achieve peak arithmetic efficiency only when matrix dimensions align with the accelerator's warp-level execution tiles (for example, multiples of 8 or 16 elements). When dimensions do not align with hardware tiles, libraries such as cuBLAS and cuDNN pad tensors or fall back to slower execution paths.

↩ Tensor Core tile architectures and their matrix-dimension alignment constraints are established in section 11.4.2.

Example 13.7: ResNet-50: Precision trade-offs on the H100

Table 13.15 compares FP32, FP16, and two INT8 paths for ResNet-50 on the reference H100: batch-one latency for each TensorRT engine of the chapter's profile, throughput at large batch, weight bytes, and assumed accuracy:

Table 13.15: Precision trade-offs on the H100: Modeled batch-one latency for each TensorRT engine of the chapter's profile; large-batch throughput modeled at the sustained fraction for FP32 (on TF32 Tensor Cores) and FP16, and measured by MLPerf Inference for INT8; weight bytes from the registry; assumed top-1 accuracy.

Precision	Batch-1 Latency	Large-Batch Throughput	Weights	Accuracy	Calibration
FP32	0.38 ms	15,200 img/s	102.4 MB	76.13%	None
FP16	0.33 ms	30,400 img/s	51.2 MB	76.13%	None
INT8 (PTQ)	0.30 ms	89,500 img/s	25.6 MB	75.80%	1,000 samples
INT8 (QAT)	0.30 ms	89,500 img/s	25.6 MB	76.05%	Additional training

Systems insight: At batch one, INT8 is only 1.3× faster than FP32, because the fixed per-kernel cost dominates a single image. At large batch it sustains about 6× FP32's throughput and loses 0.33 percentage points of accuracy with PTQ. QAT recovers most of that loss but requires retraining.

Integer formats are not the only 8-bit option. On the reference H100, an 8-bit floating-point format (FP8, whose E4M3 layout for weights and activations section 10.3 introduced) is the natural serving default for transformer workloads. The H100's dense FP8 peak of 1,979 TFLOP/s is 2× its FP16 peak of 989 TFLOP/s, and each value occupies one byte instead of two. For the chapter's GPT-2 XL service, FP8 weights shrink from 3 GB to 1.5 GB, which lowers the bandwidth floor on a batch-one decode step from 0.9 ms to 0.45 ms. Because the format keeps a floating-point exponent, it tolerates the wide activation ranges of transformers better than INT8, though it still needs per-tensor scale factors and an accuracy check before deployment.

13.6.3.2 Precision selection constraints

Quantizing every layer of a network to INT8 indiscriminately, or calibrating scale factors on daytime studio photos before serving nighttime camera feeds, can cost several percentage points of accuracy. Precision selection is constrained by layer sensitivity, calibration data, and runtime policy. Not all layers tolerate reduced precision equally. The error bound of the uniform quantizer, half a quantization step inside the calibrated clipping range plus saturation error outside it (section 10.3, with the step from equation 10.1), limits what each layer must absorb. Layer-level output or task error depends on activation distributions and downstream sensitivity, so it must be measured rather than inferred from a universal norm law. This mechanism explains why first convolutional and final classification layers are commonly retained at FP16, while intermediate layers tolerate INT8. Initial layers process low-dimensional raw inputs (such as 3 RGB channels) before representations expand into overcomplete feature spaces that can absorb quantization noise, whereas final classification layers produce raw logits where small numerical perturbations directly shift decision boundaries and alter top-1 predictions.

Post-training quantization adds a data dependency. The calibration dataset determines the clipping thresholds $[\alpha, \beta]$ and scale factors s used for INT8 conversion, requiring it to match the statistical profile of live serving traffic rather than arbitrary training or validation splits. A calibration-serving distribution mismatch causes excessive clipping or underflow, degrading end-to-end task accuracy, an operational pitfall analyzed in section 13.11.

Production serving architectures can also turn precision from a static compilation setting into a dynamic runtime policy. When request queues are shallow and the system operates with ample latency headroom against its service level objective (SLO), the engine can dispatch requests at FP16 to maximize task accuracy. During traffic spikes that threaten queue saturation, the engine can dynamically switch execution to INT8 to preserve latency bounds. Similarly, requests that yield low classification confidence under INT8 can be selectively re-evaluated at FP16, trading a small accuracy margin for lower latency when traffic spikes.

Precision selection carries direct infrastructure sizing consequences. Under the large-batch throughput gain of table 13.15, 10 GPUs at INT8 offer the same aggregate saturated capacity as about 59 GPUs at FP32. Equal capacity does not establish equal queueing latency; service-time distributions, batching policy, and failure reserve must still satisfy the same SLO. Precision engineering

is therefore an infrastructure sizing discipline, directly coupling numerical representation to cluster capital expense and energy consumption. Yet configuring the runtime and numerical bit width addresses only the model level; achieving low-latency serving in production requires optimizing the host-to-device boundaries within the physical server node itself.

13.7 Node-Level Optimization

The reference ResNet-50 request spends 3.5 ms in the forward pass and 8.6 ms end to end. Once a compiled engine shrinks the forward pass to the modeled 0.33 ms, preprocessing alone accounts for 83 percent of what remains. An isolated model benchmark hides exactly these costs, because they sit on the host: JPEG decoding on CPU cores, copies across the PCIe bus, and the driver work that launches each kernel.

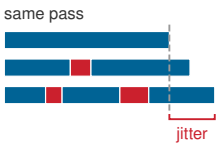
Runtime selection and precision tuning operate at the model level, determining what computation runs and what numerical format it uses. Between the model graph and the silicon, however, lies an execution layer encompassing graph compilation, bus transfers, and CPU-accelerator coordination. Node-level optimization targets this complete end-to-end request path on concrete hardware, eliminating overhead between the network socket and accelerator execution units across four primary physical boundaries:

- **Graph-to-kernel boundary**: Translating computation graphs into numerous fine-grained kernel launches incurs driver serialization overhead and forces intermediate tensors through device HBM. Graph compilers fuse adjacent operations into composite kernels that preserve intermediate activations in on-chip SRAM or register files.
- **Host-accelerator boundary**: Accelerators sit idle when the host processor fails to enqueue work ahead of execution. Unpipelined copies across host-device interconnects (such as PCIe) and blocking synchronization calls stall accelerator compute pipelines.
- **CPU execution boundary**: Host preprocessing pipelines and CPU-based inference degrade when executed through interpreted scalar code rather than vectorized single instruction, multiple data (SIMD) instruction units and NUMA-local memory allocations, and when operating-system noise preempts the threads that feed the accelerator.
- **Storage and deserialization boundary**: Initializing serving replicas requires streaming weight tensors from persistent storage into host memory. Formats requiring recursive object deserialization bottleneck CPU execution, creating cold-start latency spikes that impede autoscaling. This boundary governs how quickly a replica starts rather than how fast it serves, so section 13.8.2 develops it with the rest of model loading.

Each boundary represents a distinct physical constraint where execution stalls on memory bandwidth, bus transit, or control overhead rather than peak arithmetic throughput. The subsections that follow cross these boundaries from the accelerator outward—from runtime graph compilation and host-to-accelerator execution pipelines to CPU locality, model loading, and multi-model memory sharing.

13.7.1 Runtime graph compilation

Crossing the first of those boundaries—the graph-to-kernel interface—without compilation leaves the host CPU submitting tiny kernels one operator at a time across a 32-layer transformer or 50-layer convnet, often spending more time in the driver than the GPU spends on the math. Specialized inference engines (section 13.6) beat eager framework baselines because serving workloads run fixed operator graphs over bounded input shapes. When the operator sequence and tensor dimensions are known before live traffic arrives, compilers move graph optimization from the per-request critical path to offline deployment preparation.



The whole-graph rewrites that make this shift pay are the ones the specialized engines apply at build time. Kernel fusion and the batch-normalization fold of section 13.6.2.2, the canonical case of compile-time constant folding, remove launches and intermediate-memory traffic from every request. Static memory planning (section 11.8.2.3) reuses one preallocated arena for tensors whose lifetimes do not overlap, which keeps allocator calls off the request path. In a serving trace, repeated launch overhead and intermediate-memory traffic point to missing fusion, and allocation stalls on the request path point to a missing memory plan.

Beyond memory planning and kernel fusion, static execution paths can use CUDA Graphs, the replay of a captured sequence of kernel launches that section 7.3.6 developed. Each eager submission pays the 5–20 µs of host launch work quantified in section 13.5.1, and total submission cost depends on the executed kernel count, not the number of layers. A decode step launching 8 to 10 sub-kernels across each of 32 transformer layers can accumulate several milliseconds of host submission work, longer than the accelerator needs for the tensor math at small batch sizes. Serving systems therefore capture the graph during warmup, once per supported batch size because replay requires static shapes and fixed buffer addresses, and dispatch it during live inference with a single driver invocation (illustratively $\sim 5\,\mu s$, depending on the graph, driver, and hardware). Replay removes repeated host submission work without eliminating device execution costs.

> **Systems Perspective 13.4: Compilation timing trade-off**
>
> Just-in-time compilation defers graph optimization until the runtime engine observes concrete input shapes and execution paths. This runtime visibility enables aggressive kernel specialization for dynamic control flow and variable sequence lengths, but it injects compilation overhead directly into the serving path, generating multi-second latency spikes on early requests.
>
> Ahead-of-time compilation executes graph analysis, kernel fusion, and hardware-specific auto-tuning prior to deployment. Pre-building removes the covered compilation work from the request path, but weights, device contexts, allocations, and representative execution paths still require loading and warmup. The compiled engine remains constrained to its supported shape profiles and may require padding or multi-profile compilation to accommodate dynamic input sizes.

13.7.2 Deterministic latency and resource isolation

Compilation fixes what the accelerator executes; it does not control how steadily the host feeds it. The server shares its host with other work. On a single host, the operating system multiplexes hardware across background telemetry daemons, logging agents, and kernel worker threads. When these unisolated processes contend for execution resources, they intermittently preempt the inference pipeline. These noisy neighbors are a primary source of **latency jitter**, where the physical time required to execute identical forward passes fluctuates unpredictably. This contention inflates 99th percentile (p99) tail latency even when average hardware utilization remains low. Resource contention thus widens tail latency through service-time variance, a physical degradation distinct from the queuing-delay accumulation along the saturation knee plotted in figure 13.5.

Noisy neighbors stretch identical forward passes unevenly, widening the tail.

Keeping latency predictable requires isolating the serving process from the operating system's default time-sharing scheduler. Serving systems such as Clockwork demonstrate that deep neural network (DNN) inference execution times can be predictable down to sub-millisecond tolerances under their controlled workload and hardware conditions (Gujarati et al. 2020). CPU affinity (thread pinning) establishes the baseline compute boundary by binding inference worker threads to designated physical cores. Without pinning, the OS scheduler periodically migrates threads between cores, losing access to warm private L1 and L2 cache contents and requiring lines to be refetched from shared L3 cache or DRAM. On multi-socket architectures, thread migration across NUMA boundaries is even more penalizing. Accesses to memory left on the previous socket cross inter-socket interconnects, adding tens of nanoseconds of latency per transaction. Pinning threads to specific cores and binding their memory allocations to local NUMA nodes reduces migration-related cache misses and remote-socket memory traffic.

Even with pinned CPU cores, memory access latency remains vulnerable to the virtual memory subsystem. Under host memory pressure, the kernel can page inactive address ranges out to disk. When the CPU touches a paged-out address, execution can stall for milliseconds while the page returns to DRAM. Host buffers used for PCIe DMA also need resident, registered backing pages during the transfer. Memory locking (`mlock`) instructs the kernel to pin specified virtual address ranges into physical host RAM, preventing page eviction for host-resident weights, input staging buffers, and offloaded key-value (KV) cache blocks. This removes eviction-related page faults at the cost of host memory flexibility; locked pages remain resident until unlocked, while cache misses

and memory contention can still delay access. Because `mlock` operates strictly on host page tables, it does not apply to accelerator HBM, which is allocated directly by the accelerator driver.

Beyond scheduled processes, asynchronous hardware interrupts introduce another source of sub-millisecond preemption. When a network interface card (NIC) receives packet bursts, it triggers hardware interrupt requests (IRQs) that force the handling CPU core to immediately suspend user-space execution and process kernel interrupt handlers. If the OS routes these interrupts to cores running the inference engine's submission loop, the CPU pauses command dispatch to the accelerator. Because GPUs process short inference layers in microseconds, even brief CPU submission stalls drain the accelerator's hardware command ring buffer, causing pipeline bubbles where compute units sit idle waiting for the next kernel descriptor. Interrupt shielding restricts IRQ affinities to dedicated housekeeping cores, reducing preemption of the GPU dispatch thread by those device interrupts.

Isolating physical cores, locking host memory, and shielding interrupt lines reduce specific sources of operating system noise, though the resulting service-time distribution still needs measurement under the intended load. Thus far, isolation has treated the host as a predictable partner that feeds a discrete accelerator; when deployment constraints or workload profiles dispense with the accelerator altogether, the host CPU becomes the executor itself.

13.7.3 CPU inference optimization

For a small fraud-detection or ranking model evaluated at batch size one, copying a single request across PCIe and launching GPU kernels through the driver can take longer than running the forward pass directly on the host processor. Deploying inference on CPUs therefore remains practical for lightweight models, sparse or bursty request streams that cannot saturate an accelerator, and services where host-to-device transfer time exceeds the math time. Yet an untuned Python CPU path leaves most of the processor's silicon idle. Modern server CPUs[17] (such as Intel Xeon and AMD EPYC) include wide SIMD vector registers and matrix units (AVX-512 and AMX), which specialized runtimes such as OpenVINO target by tiling matrix operations across L1/L2 caches and emitting packed fused multiply-add (FMA) instructions (Intel Corporation 2026b).

[17] **SIMD**: From Michael Flynn's 1966 taxonomy of computer architectures, SIMD enables one instruction to operate on multiple data elements simultaneously. Intel's AVX-512 can process sixteen FP32 values in a 512-bit vector, while AMX adds matrix tile operations. The attainable fraction of peak depends on data type, matrix shape, memory behavior, and implementation, but optimized vector kernels provide multiple-fold speedups over scalar execution.

The NUMA boundaries that thread pinning respects matter more when the CPU itself runs the model. Memory controllers are physically distributed across CPU sockets and linked by coherent interconnects (such as Intel UPI or AMD Infinity Fabric). Accessing memory attached to a remote socket incurs substantially higher latency and lower bandwidth than local channel access. An inference server must maintain NUMA awareness. Worker threads must be pinned to dedicated physical cores, and the weight tensors and request buffers those threads touch must reside in memory nodes local to that socket. Because model weights, at hundreds of megabytes to tens of gigabytes, routinely exceed per-socket L3 cache capacities, every forward pass streams weights from main RAM. Mismatched socket allocations force continuous weight streaming across the slower inter-socket interconnect, creating severe tail-latency degradation.

For lightweight models evaluated at batch size one, a CPU frequently outperforms a discrete GPU. When an accelerator processes an isolated request, the fixed overhead of transferring inputs across the host PCIe bus (several microseconds), driver queue serialization, and kernel launch overhead (5–20 µs per kernel) can easily surpass the arithmetic execution time. The CPU processes the request directly in local cache without bus transfers or driver queue delays. Determining the operational crossover requires empirical measurement across model architecture, arithmetic intensity, batch size, and latency constraints.

13.7.4 Profiling the serving node

Finding that crossover—or diagnosing why an accelerator-backed node misses its p99 target while average GPU utilization sits below 30 percent—requires inspecting where each request actually waits across the host and device. The top-down profiling method of section 8.5 applies unchanged to a serving node, where the objective is useful throughput that meets the latency SLO. The duty-cycle metric defined in equation 13.2 helps locate idle intervals, but active time alone does not measure arithmetic efficiency or prove adequate queueing headroom. Timeline profilers, such as PyTorch Profiler and NVIDIA Nsight Systems (`nsys`), record concurrent CPU threads, OS runtime calls, memory transfers, and GPU hardware queues along a synchronized timeline.

Serving traces show three recurring signatures:

- **Idle compute bubbles**: White space on the GPU execution track indicates hardware starvation. Compute warps idle while waiting for the host CPU to complete request preprocessing (e.g., tokenization or image decoding), page faults during on-demand weight paging, or blocking inter-thread synchronization.
- **Kernel launch fragmentation**: A sequence of micro-kernels, each executing in under 5–10 µs, suggests launch overhead as a candidate. Host launch timing and gaps between device kernels reveal whether submission starves the GPU; if so, graph capture or legal fusion may help.
- **Interconnect transfer stalls**: Synchronous `MemcpyHtoD` blocks on the primary CUDA stream indicate unpipelined host-to-device data movement. Overcoming this stall requires allocating page-locked (pinned) host memory and executing asynchronous transfers on dedicated copy streams to overlap bus transit with concurrent accelerator execution on preceding requests.

Example 13.8: The profiling loop

Scenario: An inference serving node reports high p99 tail latency despite low average GPU compute utilization.

Diagnosis: Timeline profiling (Nsight Systems/PyTorch Profiler) reveals large idle gaps between tiny GPU kernels caused by CPU host-side preprocessing bottlenecks and kernel launch overhead.

Systems lesson: Serving node optimization requires empirical timeline profiling. Iteratively identifying trace bottlenecks (kernel launch overhead, host-device copy stalls) guides targeted optimizations like kernel fusion and pinned memory.

Table 13.16 summarizes representative node-level optimization techniques alongside their primary target metrics and engineering costs. The table serves as a decision matrix rather than an exhaustive checklist. Engineering effort should be directed exclusively to the row that addresses the binding bottleneck identified on the measured execution trace.

Table 13.16: Node-Level Optimization Impact: Illustrative ranges for matching techniques to measured bottlenecks. Realized gains and implementation cost depend on the model, runtime, hardware, and workload.

Technique	Target Metric	Illustrative Gain	Implement. Cost	Best For
Kernel Fusion	Latency & Throughput	2–5×	Medium (Compiler)	Memory-bound layers
INT8 Quantization	Throughput	3–4×	High (Calibration)	Inference-heavy nodes
Graph Compilation	Latency	1.5–3×	Low (One-line)	Static graph models
Zero-Copy Loading	Startup Time	10–50×	Low (File format)	Autoscaling/Cold Start
CPU Pinning	Tail Latency (p99)	20–50% reduction	Low (Config)	Latency-critical apps

This diagnostic hierarchy ensures engineering resources address structural bottlenecks along the entire request path rather than applying isolated micro-optimizations. A four-level audit checkpoint structures this prioritization from external service boundaries down to device kernels.

Checkpoint 13.4: The optimization hierarchy

Optimizing inference follows the request path from the outside in across four structural levels:

- ☐ **System budget**: Partition the end-to-end latency budget between network transit, host application processing, queueing delay, and kernel execution using distributed tracing tools to verify compliance.
- ☐ **Application level**: Determine whether the arrival stream and latency budget permit batching, and test whether the gain in service capacity outweighs formation and resource-queue waiting.

- ☐ **Model level**: If dispatch or operator placement binds the request path, evaluate a compatible compiled engine or graph configuration and recheck quality across supported input shapes.
- ☐ **Kernel level**: Where intermediate traffic or launch overhead is measured, assess legal fusion candidates and verify their numerical behavior and end-to-end benefit.

A node tuned this way runs each request near its physical limit, but only once it is running. The compiled engine that makes the steady state fast took tens of seconds to build, its weights must cross storage, host memory, and the PCIe bus before the first request arrives, and its preprocessing must match what training used. How a replica reaches that steady state, and whether it computes what training computed once there, decides whether the fast node is also a correct and available one.

13.8 Model Loading and Versioning

In a representative deployment, a newly provisioned replica needs 35 seconds before it can answer its first request, most of them spent compiling a TensorRT engine, while a subtle PIL-to-OpenCV preprocessing discrepancy silently costs five percentage points of classification accuracy. Every optimization so far assumed a replica that is already running and that computes the function training produced; both assumptions fail at the edges of a replica's life. Cold start delays the moment a new replica becomes useful, so it is controlled by how weights are loaded, cached, and shared across the models and versions that occupy one machine. Skew corrupts every prediction a correctly running replica makes, so it is prevented by keeping training and serving transformations identical; serving is where its symptom appears. The path below follows a replica from storage to a warmed engine, then to the several models and versions one machine may host, and ends with that symptom.

13.8.1 Cold start and initialization dynamics

When an autoscaler spins up a new serving container during a traffic surge, that replica cannot answer a single request until its weights are loaded into memory, its execution graph is compiled, and its device buffers are initialized (Romero et al. 2021). This startup delay, known as cold start, governs how quickly a service recovers from node failures or scales out into a spike.

Definition 13.4: Cold start

Cold start is the initialization latency incurred when starting a new model replica.

1. **Significance**: It represents the fixed startup cost of loading weights, compiling graphs, and allocating buffers, which can take seconds or minutes and block elastic scaling during traffic bursts.
2. **Distinction**: Unlike inference latency ($L_{\text{lat,infer}}$), which is a per-request cost, cold start is an initialization cost paid when a replica or model instance is created, including deployment, scale-out, recovery, and on-demand model loading.
3. **Common pitfall**: A frequent misconception is that cold start is "just loading weights." In reality, it includes graph compilation and memory allocation, which can often take longer than the bandwidth-limited data transfer itself (D_{vol}/BW).

Total cold-start latency compounds across four physical operations along the initialization path: weight loading streams serialized parameters from persistent storage across the network or host I/O subsystem into host memory and then across the PCIe bus into GPU HBM, after which graph compilation lowers the framework computational graph into device-specific machine code by fusing operators and auto-tuning matrix multiplication kernels for the target accelerator. Once the compiled graph is ready, memory allocation reserves device arenas for activation scratchpads and intermediate buffers, and warmup[18] execution runs synthetic inferences to populate kernel caches, prime framework memory allocators, and complete any remaining lazy initialization before live traffic arrives.

[18] **Warmup**: Borrowed from just-in-time (JIT) compilation, where initial executions compile hot paths into optimized machine code; for ML serving, warmup inferences trigger CUDA kernel compilation, cuDNN algorithm auto-tuning, and memory pool allocation that frameworks defer until first use.

Establishing a CUDA context represents the first fixed cost on the device initialization timeline. Before launching any GPU kernel or allocating device memory, the runtime must instantiate a driver-level context: an internal control structure that manages virtual address spaces, loaded kernel binaries, and hardware event queues. Creating this context requires synchronous communication with the kernel-mode driver and allocates tens to hundreds of megabytes of device memory for bookkeeping. The 0.3–0.5 s range in table 13.17 reflects a typical data center environment; while CUDA lazy loading defers kernel module loading to shorten this initial pause, it merely defers that latency penalty to the first executed inference (NVIDIA 2026a).

In multi-process serving deployments where multiple worker processes share a single accelerator, replicating individual CUDA contexts wastes both memory capacity and initialization time. CUDA Multi-Process Service (MPS) coordinates concurrent work from multiple client processes, reducing scheduling overhead when individual processes underuse the device (NVIDIA 2026d). Its isolation behavior depends on the architecture. Pre-Volta clients shared a GPU address space; Volta clients retain separate GPU address spaces and contexts while their kernels can execute concurrently. Separate address spaces do not provide hard fault containment. A fatal GPU fault can affect other clients sharing the affected GPU, so the serving design must budget for correlated replica failures.

Example 13.9: ResNet-50: Cold start timeline

Table 13.17 traces the per-phase duration of a ResNet-50 cold start:

Table 13.17: ResNet-50 cold start timeline: Illustrative per-phase durations for weight loading, CUDA context creation, TensorRT compilation, and warmup, with totals for the optimized local case and the first-deploy cloud case showing where the dominant cost lives.

Phase	Duration	Notes
Weight loading (SSD)	0.5 s	98 MB FP32 weights from local storage
Weight loading (S3)	3–5 s	Network latency dominates for cloud storage
CUDA context	0.3–0.5 s	GPU driver initialization and memory setup
TensorRT compilation	15–30 s	Converts PyTorch model to optimized engine
Warmup (10 inferences)	0.2 s	Triggers remaining lazy initialization
Runtime overhead	0.4 s	Process startup, framework hooks, and runtime setup
Total (local, optimized)	**~1.5 s**	With precompiled TensorRT engine, warm container
Total (cloud, first deploy)	**~35 s**	Including compilation from cold state

Systems insight: Precompiling models and storing the optimized engine eliminates the 30-second compilation phase on subsequent deployments.

Without warmup, the first live request absorbs deferred JIT compilation, driver memory allocation, and kernel launch overhead. A request whose steady-state forward pass takes 3.5 ms can stall for hundreds of milliseconds during an unmitigated cold start, violating strict SLOs. Controlling this initialization overhead requires systematic selection among storage, memory, and runtime loading strategies.

13.8.2 Loading strategies and serialization formats

Once precompilation removes the 30-second compiler step from table 13.17, weight loading becomes the largest remaining term in the startup budget, and how the server schedules that read trades cold-start duration against first-request latency and memory footprint. The simplest approach, full loading, reads the entire model into memory before the server marks itself ready. This maximizes steady-state inference speed because all weights are resident in memory, but it stretches cold-start time and restricts model size to available memory. A second strategy, lazy initialization, defers compilation and allocation until first use. This minimizes startup time but shifts latency to the first request, so production systems often combine lazy initialization with synthetic warmup requests to trigger initialization before real traffic arrives.

Autoscaling systems operate as closed-loop controllers that provision or deprovision serving replicas in response to traffic demand. During demand surges, cold-start latency governs how rapidly new replicas become ready to serve traffic. For multi-gigabyte models, cold-start duration is heavily dominated by streaming serialized model weights from persistent storage into host memory. The architectural choice of serialization format determines whether this stage is bounded by storage read bandwidth or by CPU parsing overhead.

Legacy PyTorch checkpoints loaded via `torch.load()` package weights within a zip archive containing pickle-encoded object metadata. Deserializing a pickle file forces the CPU to interpret a stream of serialization opcodes sequentially, allocating individual Python objects (dictionaries, metadata wrappers, and tensor headers) and potentially copying tensor bytes into newly allocated memory. Restricted loading modes reduce arbitrary code execution risks, while memory-mapped options can avoid some eager copies. Whether parsing or storage dominates depends on the checkpoint, loading path, and hardware.

A tensor-oriented format[19] bypasses interpreter-driven object construction. Safetensors organizes checkpoints with a lightweight header containing tensor metadata followed by contiguous, uncompressed tensor byte buffers aligned to memory boundaries. Because the on-disk binary layout mirrors the in-memory array layout, the runtime can use memory mapping (`mmap(2)`), which maps file blocks directly into the process's virtual address space. Virtual memory pages fault into host RAM on access or are prefetched sequentially by the operating system, reducing Python object reconstruction and avoiding eager user-space tensor copies on the mapped path. Mapping shortens apparent startup, but a dense model eventually touches nearly all of its weights, so deferred page faults can move loading latency into early requests. The benefit is greater for sparsely accessed components or model repositories that load subsets on demand; latency-sensitive services still prefault or warm the pages needed on the request path. On systems with discrete accelerators, transferring these tensors across PCIe or NVLink is still required before computation begins, so memory-mapped host loading reduces CPU reconstruction costs without eliminating page faults, storage reads, or device initialization.

[19] **Safetensors**: The name emphasizes safety: unlike unrestricted pickle deserialization, the format does not encode executable Python objects (Hugging Face 2026). It stores tensors as contiguous raw bytes with a small header and supports memory-mapped loading. In the local benchmark example, that path is 10× faster than the compared PyTorch checkpoint path; the result is workload- and storage-specific and does not include transfer to a discrete accelerator.

Example 13.10: Loading speed: Safetensors vs. Pickle

Scenario: A serverless inference replica loads a 5 GB model checkpoint during cold-start scaling events.

Diagnosis: PyTorch `torch.load()` (Pickle) requires CPU object reconstruction, taking 15 s to initialize. Safetensors memory-mapping bypasses CPU parsing, loading weights in 1.5 s (10× faster).

Systems lesson: Tensor-oriented, memory-mapped formats can reduce CPU reconstruction and eager-copy overhead during cold start. Storage throughput, page faults, runtime initialization, and accelerator transfer still remain in the scale-out budget.

13.8.3 Model caching infrastructure

Production systems also cache model weights at the infrastructure level to shorten cold start, and the right cache follows how often the model changes. Embedding the weights in the container image yields a single deployment artifact with no network fetch at startup, but images of 10–50 GB slow every container pull, so the approach suits models that rarely update. A shared filesystem of versioned weights lets many replicas read one copy without rebuilding images, at the price of network latency in every cold start and a new availability dependency; it still requires an explicit, atomic version switch so that files never change underneath a live replica. Node-local SSD caching prepopulates Non-Volatile Memory Express (NVMe) drives on inference nodes with frequently used models and loads at several GB/s without the network, but it needs its own refresh policy as models update. Which versions those caches hold, and how a new version replaces an old one in production, belongs to the release process of section 14.4.3.

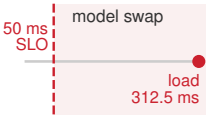
13.8.4 Multi-model serving

Dedicating an entire GPU to each regional model, A/B candidate, or ensemble stage leaves most of the fleet idle whenever traffic to individual models is uneven, yet packing several models onto one GPU without coordination risks out-of-memory crashes and noisy-neighbor latency spikes. Production systems therefore share a single machine across multiple models, making GPU memory capacity and bandwidth isolation the primary constraints. How a server manages that shared memory depends on whether models fit in VRAM simultaneously. When the combined footprint exceeds device capacity, time-multiplexing loads one model at a time and swaps weights on demand as routing changes, keeping implementation simple at the cost of swap latency. When several models fit together, memory sharing partitions GPU memory among them so that more models remain resident without swapping, even though each model receives a smaller concurrency budget. Across both regimes, model virtualization—as implemented by frameworks like Triton—decouples model lifecycle from application code by exposing repository and control APIs that load, unload, and version models dynamically (NVIDIA 2024d, 2026c, 2026b). Which policy wins depends on the arrival mix: steady traffic across models favors keeping them concurrently resident, whereas bursty, model-specific traffic favors time-multiplexing with explicit preloading to balance average latency against GPU utilization.

13.8.4.1 Partitioning one GPU across models

When multiple models or multiple instances of the same model must run concurrently on a single GPU, the hardware must partition resources between them. NVIDIA's Multi-Instance GPU[20] technology enables hardware-level isolation, dividing a data-center GPU such as the H100 into up to seven independent GPU instances, each with dedicated memory and compute resources (NVIDIA 2026e). On GPUs without MIG, CUDA stream scheduling permits overlapping or time-multiplexed work without hardware partitioning. The choice depends on whether consistent latency with MIG or maximum utilization with shared streams is the priority.

13.8.4.2 Model swapping and host memory



When the aggregate size of all models exceeds GPU memory capacity, the serving system must swap models between host dynamic random-access memory (DRAM) and device memory (VRAM) on demand. This introduces a new latency component determined by the PCIe bus bandwidth. For a 10 GB model on PCIe Gen4 x16 (32 GB/s theoretical bandwidth), loading takes at least 312.5 ms before deserialization, graph setup, or warmup. This raw transfer latency dwarfs a tight service-level objective such as a 50 ms deadline by more than $6\times$, rendering on-demand model swapping unviable on the interactive request path.

To accelerate this transfer path, systems keep the weights in pinned memory (page-locked host RAM). The GPU's DMA copy engines require the source pages to stay at fixed physical addresses for the whole transfer, but ordinary heap memory is pageable, and the operating system may relocate or swap its pages at any time. A transfer from a pageable buffer therefore takes two stages: the CPU first copies the data into a pinned staging buffer, and the DMA engine then moves that buffer across PCIe. Allocating model weights with `cudaHostAlloc` removes the CPU staging copy; achieved bandwidth still depends on transfer size, memory locality, and contention. What serving adds is a capacity trade-off. Pinned memory cannot be paged out or reclaimed by the OS under memory pressure, so every pinned model holds its share of physical host RAM until it is released. High-throughput serving systems therefore pin active model weights and I/O ring buffers while leaving standby model checkpoints in pageable memory.

13.8.5 Training-serving skew

Loading the exact checkpoint that training produced still does not guarantee that the server computes the same function if the host pipeline transforms raw inputs differently before those weights ever run. A model that performed well during validation degrades silently in production whenever training-serving skew causes the two paths to compute different features from the same raw input while every latency and error-rate dashboard stays green. The consistency requirement belongs to the data pipeline; serving is where a violation surfaces, and because the divergence is measurable on identical inputs without labels (principle 11), it is also one of the most preventable failures. Section 7

[20] **MIG (multi-instance GPU)**: Introduced with NVIDIA's A100 (NVIDIA Corporation 2020a) and documented across supported data-center GPUs (NVIDIA 2026e), MIG partitions a single physical GPU into independent instances, each with dedicated compute and memory resources; unlike software sharing (MPS or time-slicing), MIG provides hardware-level isolation between partitions. The trade-off is granularity, because partitions must follow fixed profiles, so resources cannot be divided arbitrarily. For multi-model serving, MIG reduces noisy-neighbor risk on shared hardware, while per-model SLO guarantees still depend on scheduler policy, load, and the selected partition profile.

Model loading lands far outside a tight serving SLO.

↩ Pinned memory and the DMA staging copy it avoids are established in section 7.5.2.1.

↩ Training-serving skew and the consistency imperative it violates are established in section 4.7.1.

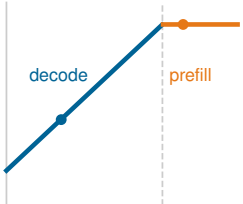
catalogs the skew categories and the method that detects each. The serving-specific manifestation of skew is **preprocessing divergence**: the real-time inference pipeline processes raw data differently than the batch training pipeline, a common failure mode when training uses Python/Pandas while serving uses C++/Java or optimized inference servers.

> Example 13.11: ResNet-50: Image preprocessing skew
>
> **Scenario**: ResNet-50 vision serving models experience silent prediction accuracy degradation between offline training and online serving pipelines.
>
> **Diagnosis**: The serving pipeline implemented C++/OpenCV preprocessing (`cv2.INTER_LINEAR`, BGR order) while training used Python/PIL (`PIL.BILINEAR`, RGB order, different normalization constants).
>
> **Systems lesson**: Preprocessing divergence causes silent training-serving skew without raising runtime exceptions. Standardizing data transformation pipelines across training and serving environments prevents input distribution corruption.

A replica that loads quickly, runs predictably, and computes what training computed completes fixed-output serving. Every workload so far, however, has treated a request as one completed prediction. The fastest-growing category of serving workloads violates this assumption entirely. Large language models generate outputs token by token, with each token depending on every previous one. A single request may produce hundreds or thousands of tokens over seconds of elapsed time, yet must feel responsive from the first token onward. The shift from *fixed-output* to *variable-length, streaming-output* serving reopens each tool developed so far, from the latency budget to the runtime.

13.9 LLM Serving

An image classifier returns a single class vector in a few milliseconds and immediately frees its activation buffers, whereas a conversational LLM streams hundreds of tokens over several seconds while holding a growing key-value cache in GPU memory. LLMs make three properties far more prominent than in fixed-output serving: *autoregressive generation*[21] (each token depends on all previous tokens, making output inherently sequential), *variable-length output* (response length is unknown at request time, complicating fixed-batch assumptions), and *stateful memory* (the key-value cache grows with each generated token, creating dynamic memory pressure). Each property strains a different tool from the preceding sections: sequential generation splits the latency budget into phases, unknown output length breaks fixed-batch scheduling, and the growing cache makes memory capacity, not arithmetic, the limit on concurrency. The p50, p95, and p99 metrics used for classification serving still matter, but they apply separately to the initial prompt processing and to the subsequent token generation. The same principles of queuing theory, batching trade-offs, and latency budgets remain applicable; LLM serving adds domain-specific techniques atop them.



The chapter's second service carries the section. GPT-2 XL, the bandwidth-bound lighthouse, anchors the metrics, the decode floor, speculative decoding, and the energy per generated token, because its weight stream sets each of them. Llama 3 8B, introduced with the running cases, carries the cache budget, paging, and prefix reuse, because its longer contexts make memory capacity rather than bandwidth the constraint that binds first.

13.9.1 Performance metrics: TTFT and TPOT

A single end-to-end latency number cannot distinguish a chat response that begins streaming in 100 ms and flows at reading speed from one that leaves the user staring at a blank screen for two and a half seconds before dumping the entire paragraph at once. Because generative models emit a stream of tokens rather than a single output tensor, serving systems split latency into time to first token (TTFT) and time per output token (TPOT), the average of a request's inter-token latencies (ITL), as defined in section 12.6.2.2. In serving, each metric belongs to one phase. *Prefill* (processing the prompt and populating its KV cache) sets TTFT and is often compute-bound, while *decode* (generating output) sets TPOT and is often bandwidth-bound at small batches. A low TTFT therefore does

[21] **Autoregressive**: From Greek *auto-* (self) and Latin *regressus* (a going back), since the output "regresses" on itself; George Udny Yule introduced autoregressive models in 1927 for analyzing sunspot cycles. In language modeling, each output token conditions on all previously generated tokens, creating a serial dependency that prevents the parallelism exploited during training. Decode is often weight-bandwidth-bound at small batches; larger batches amortize the weight stream and can shift the bottleneck toward compute or KV-cache traffic (Pope et al. 2023).

↩ Prefill, small-batch autoregressive decode, and the KV cache that every decode step reads are established in section 6.7.4.2.

Prefill and low-batch decode often face different resource limits.

not mean a fast model. A model can have a fast TTFT but a sluggish TPOT (if the memory wall (BW) is the bottleneck), leading to a frustrating user experience where the answer starts quickly but "stutters" thereafter. Because these metrics capture distinct aspects of the user experience, interactive services set separate targets for TTFT, TPOT or ITL, and aggregate throughput.

> **Systems Perspective 13.5: LLM serving latency targets**
>
> Interactive LLM services usually need separate SLOs for responsiveness, generation fluidity, and fleet throughput. The following values are illustrative targets rather than universal requirements:
>
> - **TTFT**: $<$ 500 ms (for a 1000-token prompt)
> - **TPOT**: $<$ 50 ms (equivalent to ~20 tokens/s, faster than human reading speed)
> - **Throughput**: $>$ 1000 tokens/s aggregate across active serving replicas
>
> A single "latency" number therefore hides the prefill/decode split. TTFT is the blank-screen budget, TPOT is the reading-flow budget, and aggregate service throughput, measured as tokens/s summed across active serving replicas, determines whether those targets hold under shared load.

13.9.2 The decode floor

The chapter's bandwidth-bound lighthouse puts numbers on both phases. A GPT-2 XL chat request with a 512-token prompt performs about 1.5 TFLOP of prefill arithmetic, which an H100 sustaining 40 percent of its FP16 peak completes in about 3.9 ms, the model's share of TTFT. Each decode step then reads all 3 GB of FP16 weights to produce one token per active sequence. At batch one that read takes 0.9 ms, so the model-side TPOT can be no shorter, however many arithmetic units the accelerator adds. The floor assumes the step is launched as one captured graph. Issued operation by operation from an eager framework, the same step spends about 8.6 ms on the host submitting 576 kernels, roughly 10× the weight read, which is why every decode floor in this chapter assumes the CUDA Graph capture that section 7.3.6 developed.

Batch-one decode with FP16 weights runs at the weight-only arithmetic intensity of about 1 FLOP/byte that section 6.7.4.2 derived. The H100's ridge point sits near 295 FLOP/byte, so the step is memory-bandwidth bound by more than two orders of magnitude (Pope et al. 2023), and equation 13.14 gives its floor per token, where D_{vol} is the bytes the step reads and $\text{BW}_{\text{accelerator}}$ is the accelerator's memory bandwidth:

$$T_{\text{token}} \approx \frac{D_{\text{vol}}}{\text{BW}_{\text{accelerator}}} \tag{13.14}$$

While decode remains bandwidth bound, every step pays to move every weight, in energy as well as in time, and adding compute cores yields little latency improvement; faster memory (Machine), fewer bytes per parameter or a smaller model (Algorithm), or better batching and cache management change the bound.

Batching changes which bytes dominate. Each sequence also reads its own KV cache on every step. GPT-2 XL's attention heads each keep their own keys and values, with no grouped-query sharing, so its cache holds 307.2 KB per token of context, or 314.6 MB for a full 1,024-token context. Batching shares the weight read across sequences but not the cache reads. At batch one with a full context, a step moves 3.3 GB and takes 1.0 ms. At batch 32 it moves 13.1 GB, 77 percent of it cache, and takes 3.9 ms. Aggregate throughput rises from about 1,010 tokens/s to 8,200 tokens/s, while each sequence's TPOT stretches by 3.9×. The same trade between per-sequence cadence and aggregate throughput governs every scheduling technique that follows.

13.9.3 Decoding strategies

Switching a chat endpoint from greedy decoding to four-way beam search quadruples both the arithmetic per step and the KV-cache memory each active user holds. The sampling algorithm executed at each step therefore shapes serving cost directly. Greedy decoding takes the highest-scoring token and needs one forward pass per token, though it can fall into repetitive output because

it never revisits an early choice. Beam search keeps several candidate sequences and multiplies both computational work and KV-cache footprint by the beam width. Stochastic sampling scales the logits by a temperature and truncates the vocabulary with top-k or top-p nucleus sampling before drawing a token (Holtzman et al. 2020). For the serving system, beam width multiplies the state each request holds, while the sampling variants add only a small per-step reduction whose cost depends on its kernel implementation and on the sequence-length distribution that continuous batching must absorb.

Interactive LLM services commonly return tokens as they are produced rather than waiting for complete generation. This streaming response transforms the user experience. A two-second total generation feels responsive when tokens stream continuously, but feels broken when users stare at a blank screen for two seconds. Streaming requires infrastructure support for incremental responses and client-side rendering. Once generation streams token by token, the serving unit changes from one fixed-output prediction to a stateful sequence whose length is unknown when it is admitted and whose memory footprint grows on every step. The unknown length breaks the fixed-batch scheduling developed for fixed-output models, and the growing state turns accelerator memory into the next constraint.

13.9.4 Continuous batching

An autoregressive request finishes only when it emits an end-of-sequence token, so its length is revealed one step at a time. Extending the request-level dynamic batching of section 13.5 to an entire generation cycle keeps batch membership fixed until every sequence finishes. When sequence lengths vary, this static commitment degrades accelerator efficiency. If one sequence in a batch of eight finishes after ten tokens while others require 100 tokens, 90 percent of the compute and memory bandwidth allocated to that sequence slot is wasted on padding tokens or masked dummy operations while awaiting the slowest sequence (Yu et al. 2022).

Continuous batching[22] (also called iteration-level batching) eliminates this idle-slot waste by rescheduling batch composition at each decoding iteration (Yu et al. 2022; Kwon et al. 2023). Rather than committing to a static batch that persists across hundreds of forward passes, the serving engine re-evaluates batch membership at every token-generation step. When a sequence emits its end-of-sequence token, the scheduler immediately reclaims that execution slot, admitting an arriving request into the batch for the subsequent forward pass. Active sequences continue decoding without interruption, maintaining high accelerator utilization across variable-length workloads.

Serving runtimes such as vLLM[23] and TensorRT-LLM improve throughput via two mechanisms: reclaiming wasted compute from completed sequences and shortening queue wait times for new arrivals (Kwon et al. 2023; NVIDIA 2026g). However, admitting new requests dynamically creates a systems collision between prompt prefill and token decoding. Long-prompt prefill often exposes high arithmetic intensity and can occupy the GPU for tens of milliseconds. Low-batch decoding often has less weight reuse and is memory-bandwidth bound, advancing one token per active sequence at a time. When an engine executes a prefill in the same iteration as active decodes, the ongoing decode streams stall, causing severe spikes in inter-token latency. Sarathi-Serve resolves this interference through chunked prefill and stall-free batching (Agrawal et al. 2024). By splitting long prompts into fixed-size chunks (e.g., 512 tokens) and co-scheduling a single chunk alongside active decode requests per step, the scheduler limits the prefill work admitted per iteration, reducing interference with active decodes; measured iteration times determine the resulting token cadence.

13.9.4.1 Speculative decoding

Continuous batching and chunked prefill keep decode batches full and their cadence steady, but at small batch each generated token still pays for one full weight stream. Speculative decoding[24] attacks that bound directly. A small draft model proposes several tokens, and the target model verifies the whole proposal in one parallel pass, so a single weight stream can yield more than one accepted token. Evaluated T5-XXL workloads achieved roughly 2–3× speedups (Leviathan et al. 2023), though the gain depends on how often the target model accepts the draft.

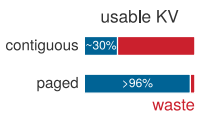
If the draft proposes γ tokens and the target accepts each with probability α, independently of the others (Leviathan et al. 2023), one verification pass yields on average the number of tokens

[22] **Continuous batching**: NVIDIA TensorRT-LLM calls the same technique "in-flight batching" (NVIDIA 2026g). Request-level batching commits to a fixed batch for an entire generation sequence (potentially hundreds of iterations), while continuous batching reschedules at every token-generation step, a contrast that parallels preemptive OS process scheduling versus run-to-completion.

[23] **vLLM (virtual large language model (LLM))**: An open-source serving system that enables continuous batching via its PagedAttention algorithm (Kwon et al. 2023). Keeping KV-cache waste low lets it serve larger effective batches on the same hardware.

[24] **Speculative decoding**: Parallel verification is possible because the draft has already committed to all γ candidate tokens, so the target can score the whole block in one causal-attention forward pass, as it scores a prompt during prefill, rather than in γ sequential steps (Leviathan et al. 2023). The technique removes serial steps at the runtime layer without changing the model architecture.

in equation 13.15, which counts the accepted draft tokens plus the one token the target always contributes:



$$\mathbb{E}[\text{tokens per target pass}] = \frac{1-\alpha^{\gamma+1}}{1-\alpha} \tag{13.15}$$

Verifying $\gamma+1$ positions costs the target about one weight stream, because at batch one the pass remains bandwidth bound rather than compute bound. For the GPT-2 XL service, a GPT-2 Small draft with 248 MB of FP16 weights proposes 4 tokens per round, spending 0.30 ms on draft reads against 0.90 ms for the target's verification pass. At an assumed acceptance rate of 70 percent, a round yields 2.8 tokens on average, so the time per generated token falls from 0.90 ms to 0.43 ms, a 2.1× speedup. The gain shrinks as acceptance falls or as the batch grows. A full batch already shares each weight stream across many sequences, and verifying several positions per sequence then consumes arithmetic that a batch-one step left idle but a full batch does not.

13.9.4.2 PagedAttention

Keeping decode batches full, however, shifts the primary serving bottleneck to memory management. Because transformer generation appends attention states at every step, the KV cache for each active request grows dynamically in accelerator HBM. When sequences of varying lengths share memory, contiguous allocation produces severe external fragmentation. If a completed 100-token sequence releases its cache, an arriving 150-token request cannot occupy that freed memory because it requires a larger contiguous address range. Over time, physical memory fractures into small, noncontiguous gaps, preventing new sequences from launching even when total unallocated capacity appears sufficient. Together with the over-reservation of contiguous allocators, this memory fragmentation can waste 60 to 80 percent of KV-cache memory in naive implementations (Kwon et al. 2023), severely limiting the concurrent batch size that determines serving throughput.

PagedAttention,[25] introduced in vLLM, resolves this fragmentation by applying operating system virtual memory paging to accelerator memory (Kwon et al. 2023). In static contiguous allocation, reserving maximum sequence length memory up front causes internal waste, while freed regions may be too small or poorly placed to satisfy a new contiguous reservation. Instead of allocating one contiguous region per sequence, PagedAttention divides the KV cache into fixed-size blocks mapped through a block table. A sequence's cache can therefore occupy noncontiguous physical blocks. When a sequence completes, its blocks return to a free pool for reuse. Rather than copying noncontiguous blocks into a temporary contiguous buffer before computing attention, a specialized PagedAttention CUDA kernel traverses the block table directly, staging noncontiguous blocks into on-chip SRAM during query-key multiplication. By eliminating external fragmentation and bounding internal waste to each sequence's last, partially filled block, PagedAttention reduced KV-cache waste below 4 percent in the reported evaluation and enabled substantially higher batch concurrency on the same accelerator hardware (Kwon et al. 2023). Paging decides where cache blocks live, however; it does not reduce how many blocks each sequence needs, and that number grows with every generated token.

PagedAttention recovers the KV-cache waste of contiguous allocation.

[25] **PagedAttention**: The name directly references OS virtual memory paging, first implemented on the Atlas computer at Manchester (1962) to solve the same class of allocation problem, in which programs needed more memory than physically available, and contiguous allocation wasted space (Kilburn et al. 1962). Introduced at SOSP 2023, PagedAttention applies this six-decade-old abstraction to GPU KV-cache memory; in its evaluation, the recovered memory enabled 2–4× higher throughput on the same hardware (Kwon et al. 2023).

13.9.5 Memory and KV cache

Even after PagedAttention eliminates fragmentation waste, thirty-two long-context conversations can exhaust an 80 GB GPU's memory when the quantized model weights themselves occupy less than half the device. The KV cache, the per-sequence store of attention keys and values defined in section 6.7.4.2, grows linearly with sequence length: prefill creates cache entries for every prompt token, and each decoded token appends another entry, so a request's footprint is set by its prompt length plus the tokens it has generated so far. Summed across concurrent variable-length sequences, this dynamic state can exceed the model weights and dominate available accelerator memory, which is why the remaining memory levers either reuse cache state across requests or move it off the accelerator.

13.9.5.1 KV budget

Once contexts grow, the cache rather than the weights sets how many conversations one accelerator can hold, and Llama 3 8B makes the budget concrete. Each token stores a key vector and a value vector in every layer for every key-value head. Storing 16-bit Key and Value tensors across $N_L = 32$

layers with $H_{\text{KV}} = 8$ grouped-query attention heads of dimension $d_{\text{head}} = 128$ requires $2 \times 32 \times 8 \times 128 \times 2$ bytes $= 131{,}072$ bytes ≈ 131 KB per token per sequence. Grouped-query attention (Dubey et al. 2024) lets the model's 32 query heads share those key-value heads, which cuts the cache by 4× relative to full multi-head attention. An 8,192-token conversation therefore holds 1.07 GB. With 16.1 GB of FP16 weights resident on an H100 whose 80 GB datasheet capacity is 85.9 GB in the decimal units used for tensor footprints, about 69.8 GB remains for caches before runtime workspace, room for about 65 such conversations at once. The weights are a fixed cost; every additional conversation, and every additional thousand tokens of context, draws on the same remainder.

Larger models make the cache the binding constraint sooner. For a 70-billion-parameter-class model with grouped-query attention, 4-bit weights consume 35.3 GB of the same H100, leaving 50.6 GB for FP16 cache before runtime workspace. A batch of 32 conversations exhausts that budget at roughly 4,800 tokens of context, so serving engines trade concurrent batch size against context length to avoid out-of-memory failures (figure 13.8).

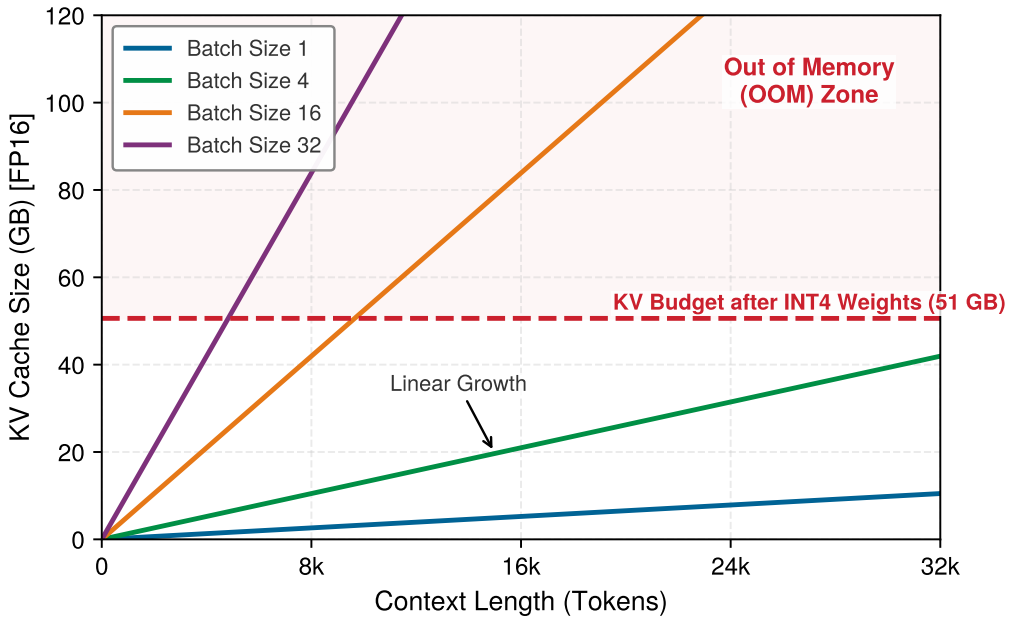


Figure 13.8: The KV-Cache Explosion: FP16 KV-cache usage vs. context length for a 70-billion-parameter-class model with GQA. On the modeled H100's 80 GB of HBM (85.9 GB decimal), 35.3 GB of INT4 weights leave 50.6 GB for KV cache before runtime overhead. Batch size 32 reaches that cache budget at roughly 4.8k tokens, forcing a trade-off between batch size and context length.

A model whose weights and cache do not fit one accelerator, even at reduced precision, can still be served from one machine by splitting it across the node's accelerators with the model parallelism of section 8.7.1.2. Serving usually favors tensor parallelism. Pipeline stages also fit, but every decoded token must pass through each stage in turn, which adds latency to every step. Tensor parallelism instead puts every accelerator to work on every layer, and each accelerator holds a slice of the weights and of the KV cache, so a 70-billion-parameter-class model at 16-bit precision, whose weights alone exceed one H100's memory, fits across the accelerators of one node with room left for cache. The cost is a collective operation after each layer's matrix multiplications. On NVLink that exchange is small next to the layer's compute; over PCIe or a network it would dominate each decode step. A serving engine therefore keeps one model's tensor-parallel group inside a single node and meets higher volume by replicating whole groups across machines rather than stretching one group across them.

13.9.5.2 Prefix caching and memory offloading

Many requests carry identical prefixes, and recomputing their cache entries wastes both prefill compute and memory. **Prefix caching** stores the KV states of common instruction prefixes (such as a

2,000-token system prompt or a shared retrieval-augmented generation (RAG) context), allowing independent requests to reuse the prefill result for an identical prefix. For n_{req} requests sharing a prefix of S_{prefix} tokens, the avoided prefill work is roughly $(n_{\text{req}} - 1)S_{\text{prefix}}$ token steps, subject to cache hits, eviction, and implementation overhead. For multi-turn conversations, the same principle lets a subsequent turn process only the new suffix after reusing compatible prior state.

When the aggregate KV cache exceeds GPU VRAM, systems can employ **KV cache offloading**. This strategy spills inactive or low-priority context windows to host CPU RAM or NVMe SSD, freeing VRAM for active generation. The reload cost is bounded below by bytes moved divided by PCIe or NVMe bandwidth, before software overhead and queueing are added. Offloading therefore prevents OOM failures and enables larger context windows, but it also creates affinity, invalidation, and hot-decode latency risks that must be budgeted explicitly.

13.9.6 Session affinity constraints

Prefix reuse and offloading both assume that the next turn of a conversation reaches the replica that holds its cache. Session affinity, routing successive requests from a client to the same physical replica, arises whenever serving state resides in local accelerator memory rather than being reconstructed on every invocation. In conversational models, this resident state is dominated by the KV cache. When turn i executes on a replica, that replica's HBM retains the projected keys and values across all prior prompt and generation tokens. Routing turn $i+1$ to a different replica discards that local memory footprint, forcing the new node to recompute the entire prefix sequence from scratch. This redundant prefill consumes memory bandwidth and tensor-core cycles that would otherwise advance active decode iterations, directly inflating time-to-first-token.

A parallel physical constraint governs personalized serving using fine-tuned Low-Rank Adaptation (LoRA) modules: small per-user adapters, each a pair of low-rank matrices whose product is added to a frozen base weight matrix. While base-model weights remain pinned in device HBM, individual user adapters must be dynamically staged into memory. If incoming requests for a user scatter across multiple replicas, each node must repeatedly transfer adapter tensors over the host-to-device PCIe bus or fetch them across the network, displacing other active working sets in memory. Stateful preprocessing pipelines, such as tokenizer vocabularies and per-session normalization state, impose the same penalty, requiring redundant CPU-side allocations and cache rebuilds whenever execution moves across node boundaries.

Strict affinity creates a direct conflict with dynamic batching. Continuous batch schedulers maximize accelerator throughput by packing concurrent requests into unified matrix multiplications, raising operational arithmetic intensity in proportion to batch size ($I \propto B$). When requests are pinned to designated replicas, the scheduler's pool of batchable candidates fragments across the cluster. A replica assigned to an idle or low-concurrency user session must either process underfilled batches, collapsing arithmetic intensity back into the memory-bandwidth-bound regime, or stall waiting for affinity-matched tokens. To prevent this collapse in utilization, production routers use soft affinity. Under soft affinity, the ingress gateway prioritizes the cache-holding replica when capacity allows, but sheds requests to alternate nodes when local queue delays exceed the physical latency required to transfer adapter weights or recompute prefix tokens.

↩ Products of two low-rank matrices, and the storage and memory traffic they save relative to a full matrix, are established in section 10.2.2.1.

> **Systems Perspective 13.6: LLM serving: Beyond the fundamentals**
>
> Each LLM serving technique answers one of two physical limits. The first is the decode bound, in which every generated token pays for a full weight stream at small batch. Continuous batching keeps decode batches full so each stream serves many sequences, chunked prefill keeps prompt processing from stalling that stream, and speculative decoding extracts more than one accepted token per stream. The second is the KV cache, which grows with sequence length and batch size and often exceeds the weights themselves; PagedAttention, prefix caching, offloading, and session affinity decide where it lives and how much of it can be reused. Weight-only quantization (such as INT4 weights with FP16 activations), the precision lever of section 13.6.3 applied to the weight stream, addresses both at once, because it shrinks the bytes streamed per token and frees capacity for cache (Lin et al. 2024).

These LLM-specific optimizations build directly on core serving mechanics: queueing models govern scheduling timeouts, batching dynamics determine throughput-latency curves, and reduced precision bounds memory traffic. Advanced treatments extend these mechanics to multi-tenant prefix sharing across fleets and multi-node tensor-parallel execution.

Every technique above changes how many sequences share each weight stream and how long each one holds its cache. Because an accelerator draws power whether a decode pass serves one sequence or a full batch, that same sharing directly governs the energy each generated token costs. Dividing node power by aggregate token throughput converts batching and prefix-caching gains into joules per token.

Napkin Math 13.5: The energy cost of a chat

Problem: How much energy does an H100-backed chat service spend per generated token and for a response with 500 tokens?

As LLMs scale, joules per token becomes a first-class operational metric alongside latency. Assuming the H100 draws its 700 W thermal design power (TDP), this scenario estimate follows from throughput and power (Choquette 2023):

1. **Throughput**: 114 concurrent requests $\times$ 8 tokens/s per request $\approx$ 912 tokens/s.
2. **Power**: 700 W (GPU) + 300 W (Host/Overhead) = 1000 W.
3. **Energy per token**: 1000 W / 912 tokens/s $\approx$ 1.0965 J/token

Systems insight: Under these assumptions, a response of 500 tokens consumes $\approx$ 548.2 J. A measured production figure is of the same order. Google reports $\approx$ 864 J (0.24 Wh) for the median Gemini text prompt, counting host, idle-reserve, and facility energy, although the study does not state how long that prompt was (Elsworth et al. 2025).

- For comparison, charging a smartphone consumes $\approx$ 40000 J.
- Boiling a cup of water consumes $\approx$ 100000 J.

The primary way to reduce J/token is to increase hardware utilization and eliminate redundant compute. If the GPU sits at 10 percent utilization due to poor batching, it still draws ~300 W and the host adds 300 W, causing energy per token to rise to 6.6 J/token (approximately 6× the baseline). Architectural optimizations like prefix caching also skip the energy-intensive prefill phase for shared context, directly reducing the energy footprint of retrieval-augmented generation (RAG) and chat applications. The serving lesson is that efficiency is not only a latency or cost metric; it also determines how much energy each useful token consumes.

Systems Perspective 13.7: Looking ahead: Spending more compute per query

Every lever so far takes the number of tokens a request generates as given, and fixed-output serving minimizes latency ($L_{\text{lat,total}} \to 0$) for a fixed amount of work per request. Reasoning models and other inference-time-compute systems make that token count a choice: they deliberately spend more computation per query to improve answer quality, generating intermediate reasoning or search tokens before the visible answer. The optimization target then expands to include answer quality, and every extra reasoning token pays the decode costs this section derived: one more step of decode work at the batch's cadence, one more KV-cache entry held until the response ends, and its share of the joules per token. Answer quality now trades directly against TPOT, cache capacity, and energy per query.

Checkpoint 13.5: LLM serving fundamentals

LLM serving introduces constraints absent from traditional model serving.

- ☐ **TTFT vs. TPOT**: Contrast the distinct user experiences captured by TTFT and TPOT, explain why long-prompt prefill often exposes more arithmetic intensity than low-batch decode, and convert a 50 ms TPOT target into its tokens-per-second equivalent.
- ☐ **Continuous batching and PagedAttention**: Contrast static batching waste under variable sequence lengths against iteration-level scheduling, and explain how PagedAttention eliminates external fragmentation in the KV cache and bounds internal waste to a single partially filled block per sequence.
- ☐ **Memory wall**: Explain why adding compute units yields negligible latency improvement when token generation is bandwidth-bound, and identify how higher-bandwidth memory, model quantization, or batching alters the operating regime.
- ☐ **Prefix caching and offloading**: Explain how caching key-value activations for shared prompt prefixes eliminates redundant prefill compute, and evaluate the latency trade-offs that govern offloading KV caches to host system memory.
- ☐ **Joules per token**: Explain why energy consumption scales with generated sequence length, and how low hardware utilization inflates the energy cost per useful token.

Every LLM serving optimization ultimately decides how many sequences share each weight stream and how much accelerator memory each sequence holds. The chat-energy calculation showed that the same sharing sets the joules spent per useful token, because each decode step streams the weights once for the whole active batch, so a well-filled batch divides that energy across sequences. Unlike fixed-output inference, LLM energy also grows with response length. Carbon accounting additionally requires an emissions factor and a defined boundary. These per-token bounds describe one accelerator. Deciding how many accelerators a service needs, and what each generated token costs, requires carrying them, together with the fixed-output results of the earlier sections, into capacity planning and unit economics.

13.10 Economics and Planning

A team that has raised an H100's ResNet-50 throughput several-fold through batching still faces a fleet-level question: does serving a 5,000 QPS target within the same p99 latency SLO cost less on a few H100s or on several times as many lower-cost T4s? Batching, precision tuning, kernel fusion, graph compilation, and the LLM levers that share each weight stream across sequences all improve single-node performance, but production deployment requires choosing how many machines to rent, of what type, and at what total bill. Serving infrastructure cost grows continuously with request volume (Zhang et al. 2019), while training cost follows a one-time dataset, model, and optimization budget. The bitter lesson sharpens this asymmetry. The methods that win are the ones that scale, so successive models grow larger, and while training pays for that scale once, serving pays for it on every request.

Tail latency dictates the technical design of a serving system, but economics dictates its operational scale. As specialized accelerators and runtime optimizations reduce the compute cycles required per forward pass, the marginal cost per inference declines.[26] Counterintuitively, reduced unit cost does not shrink aggregate serving expenditures. In accordance with Jevons paradox, lower marginal costs stimulate disproportionately higher query volumes, integrating model evaluation deeper into user-facing product loops. At hyperscale, recurring operational inference costs quickly eclipse one-time offline training investments, shifting the primary systems bottleneck toward sustained per-query efficiency.

↩ The bitter lesson, that general methods which scale with computation keep outperforming hand-engineered ones, is established in section 1.4.

[26] **Jevons paradox**: William Stanley Jevons observed in 1865 that efficiency improvements in coal-powered steam engines increased total coal consumption by making steam power economically viable for applications previously too costly (Jevons 1865); the same dynamic can apply to AI inference, where each 10× cost reduction opens application classes that were economically infeasible at the previous price point, expanding aggregate demand by more than the efficiency gain.

Example 13.12: Inference cost at Facebook

Scenario: Production ML serving systems at Meta execute tens of trillions of inferences daily across global user-facing services (Hazelwood et al. 2018).

Diagnosis: Recurring inference serving compute and energy costs dwarf initial offline model training expenses. Live request arrival patterns and strict latency bounds constrain GPU batching.

Systems lesson: Model architectures cheap to train can prove unviable to serve at fleet scale. Production serving infrastructure requires hardware-software co-design to balance tail latency, batch size, and recurring operational total cost of ownership.

The same serving-economics pressure appears in public API prices. Figure 13.9 tracks this cost collapse across representative public API list-price snapshots from 2023 through 2025 on a logarithmic scale. The steep downward trend line isolates how prompt token pricing fell by multiple orders of magnitude, from thirty dollars per million tokens for original GPT-4 down to several cents for Gemini 1.5 Flash and DeepSeek-V3. Vendor prices change frequently, so these points should be read as historical provenance for the trend rather than as current purchasing guidance (OpenAI 2023b, 2023a, 2024; OpenAI Developer Community 2024; Anthropic 2024; Google Developers Blog 2024; DeepSeek 2024). Each order-of-magnitude drop changes which applications are economically viable, and a provider can sustain such prices only if its serving stack extracts more completed requests from each accelerator-hour. Converting engineering efficiency into unit cost draws on the latency, batching, and memory mechanisms of the preceding sections.

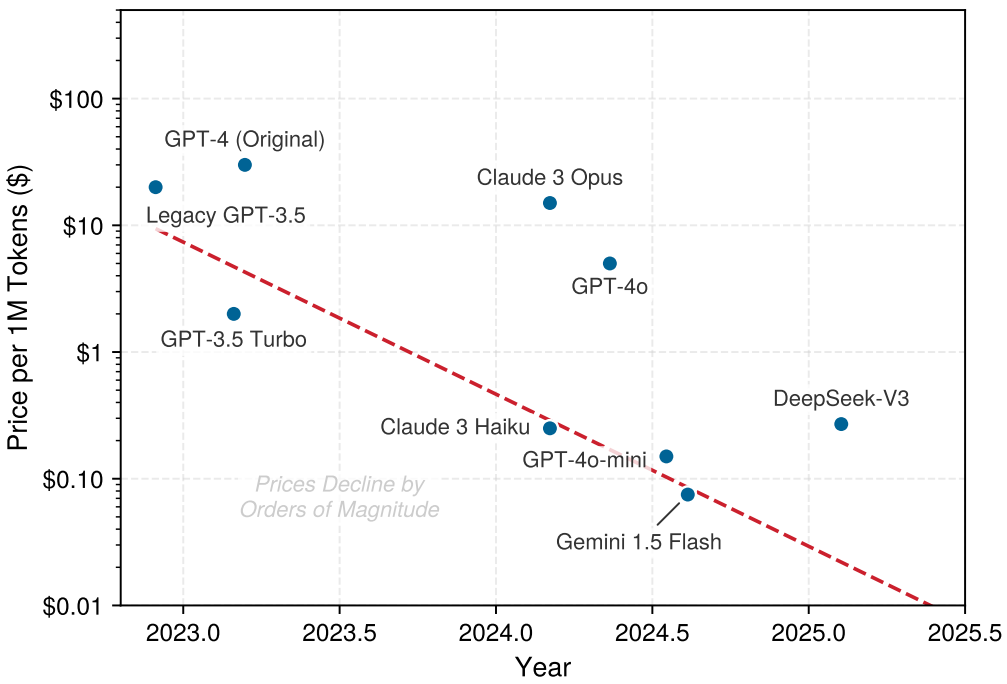

Figure 13.9: Intelligence Deflation: Representative public API input-token list prices per 1M tokens ($) over time (Log Scale). Nine model-version list prices come from the launch and pricing announcements of OpenAI, Anthropic, Google, and DeepSeek between late 2022 and 2025; the dashed line is a log-linear fit through the price floor, the points that each set a new low. The series is intended as a market trend indicator, not a controlled or current-price comparison. API token-processing prices have collapsed by multiple orders of magnitude, transforming the economics of automated AI workflows.

13.10.1 Cost per inference across hardware

Choosing serving instances by hourly rental price alone, or by peak throughput alone, misleads whenever traffic fluctuates: an H100 that costs several times as much per hour as a T4 delivers the lowest cost per million images when traffic keeps it full, but becomes the more expensive option when overnight traffic drops and the GPU sits mostly idle. The **cost per inference** divides the allocated serving cost by the number of completed inferences that satisfy the service objective. The numerator can include provisioned CPU or accelerator time, memory capacity, data transfer, storage, and orchestration. At high utilization, useful throughput spreads that provisioned cost across many requests. At low utilization, paid capacity sits idle, so the same hourly cost is divided among fewer successful inferences.

Hardware selection for model serving trades hourly rental price against parallel throughput. Although GPU instances cost several times as much per hour as commodity CPU instances, their matrix units can process enough requests per second to cut the cost per completed query by an order of magnitude. Whether CPUs or dedicated accelerators win economically depends on arithmetic intensity, batchability, and the latency deadline.

Host CPU execution is cheaper for small models, services with relaxed latency deadlines (hundreds of milliseconds), and sparse or unpredictable traffic that leaves dedicated accelerators idle. Conversely, GPU acceleration wins when models perform dense matrix operations, when service-level objectives require response times of tens of milliseconds or less, and when sustained traffic lets dynamic batching amortize kernel launch and memory transfer costs.

Beyond steady-state costs, startup time affects scaling economics. Instance launch, image pull, driver initialization, model loading, compilation, and warmup can make accelerator replicas slower to become ready than CPU replicas, although exact times depend on the platform and deployment artifact. If traffic rises faster than useful capacity can come online, latency SLOs can fail despite sufficient eventual capacity.

When accelerator replicas have a long readiness delay, predictive scaling or a warm pool may be more reliable than purely reactive scaling. For a model that runs acceptably on both device types, a hybrid design can use always-on accelerator capacity for baseline load and CPU overflow for spikes, trading a different unit cost and latency profile for faster reserve capacity. Whether this GPU+CPU hybrid works depends on model compatibility and identical output semantics across runtimes.

Example 13.13: ResNet-50: Cost analysis

Table 13.18 gives an illustrative scenario for hourly cost, throughput, and per-million-image cost when serving ResNet-50; the H100 row uses the batch-32 rate of the chapter's batching sweep:

Table 13.18: Illustrative ResNet-50 cloud inference cost comparison: Assumed hourly cost and saturated throughput, with derived cost per one million images for CPU, T4, and H100 instances.

Instance Type	Cost/Hour	Throughput	Cost per 1M Images
c5.xlarge (CPU)	$0.17	50 img/s	$0.94
g4dn.xlarge (T4 GPU)	$0.53	400 img/s	$0.37
One H100 GPU	$4	7,040 img/s	$0.16

Systems insight: At full utilization the H100 has the lowest unit cost, but its hourly rate is 7.5× the T4's, so it wins only while traffic keeps it busy. Below about 3,000 img/s of sustained traffic, T4 capacity sized to the load costs less per image than one partly idle H100. Cloud pricing varies by region and changes over time; consult current pricing for production planning.

13.10.2 Capacity planning

The unit-cost comparison in table 13.18 evaluates each instance at its saturated throughput, but a live fleet cannot run at 100 percent utilization without pushing every arrival burst past the knee of the latency curve (figure 13.5). Determining how many replicas to provision therefore combines

those per-device service rates with the queueing bounds from section 13.4. **Capacity planning** translates three inputs into replica counts: traffic patterns (peak request rate, daily and weekly cycles, growth projections), latency SLOs (p50, p95, p99 targets), and model service times across batch sizes (Harchol-Balter 2013).

The ResNet-50 capacity notebook in section 13.4.3 ran this workflow for batch-one service, deriving an M/M/1 utilization threshold of 68 percent from equation 13.5 and arriving at 36 H100s with headroom for a 5,000 QPS target. The plan extends to batched service by the same arithmetic. Applying the same utilization factor to the saturated batched rate of 7,040 img/s in table 13.18 gives 2 H100 before headroom and 3 after; the batch-1 plan needed 27 and 36.

This arithmetic compares assumed capacities under different service models; it does not establish equal p99 latency. Batching changes service times, realized batch sizes, and waiting distributions, so the factor derived for unbatched M/M/1 service cannot by itself certify the batched plan. The throughput opportunity is the batching gain of section 13.5; its usable capacity requires a load test including formation delay and worker backlog. This scenario provisions peak load plus 30 percent headroom; production margins depend on the workload and policy. Autoscaling can reduce costs during low-traffic periods while meeting latency objectives during peaks; section 14.4.1 develops the operational policy layer around these serving calculations. Capacity must be sized for requests that meet the SLO, not for raw request volume.

13.10.3 Production case study: Serving 8-billion-parameter Llama 3

When a team deploys an 8-billion-parameter Llama 3 chat service on a single H100 under a 200 ms TTFT and 20 ms TPOT budget, does GPU memory capacity, prefill compute, or decode bandwidth cap the number of requests per hour, and what does each million tokens cost? The serving bounds of section 13.9 become a dollar figure only when they meet a concrete workload, an SLO, and an hourly rental rate. This case study costs out that single-H100 deployment, reusing the decode floor and the cache budget derived earlier rather than re-deriving them. Unlike the 70-billion-parameter scale-up in figure 13.8, the 8-billion-parameter model fits on one GPU with substantial memory headroom, so batching, prompt prefill, and autoregressive decoding can be balanced on a single device without multi-node sharding.

13.10.3.1 Workload profile

The following fixed workload assumptions define the reference case used throughout the latency, memory, and economics calculations; together, they bound the analyses that follow:

- **Model**: 8-billion-parameter Llama 3 (quantized to 4-bit using activation-aware weight quantization (AWQ); see section 10.3 for quantization techniques) (Dubey et al. 2024; Lin et al. 2024).
- **Hardware**: 1× NVIDIA H100 SXM5 GPU (80 GB HBM3 device capacity, equivalent to 85.9 GB on the decimal basis used for tensor footprints, 3.35 TB/s bandwidth) (Choquette 2023).
- **Request characteristics**: 1,000-token input prompt (Prefill), 256-token generated response (Decode).
- **Target SLOs**: TTFT $<$ 200 ms, TPOT $<$ 20 ms.

13.10.3.2 Latency deconstruction

The end-to-end request latency is governed by the two-phase execution model of autoregressive transformers, applying the TTFT and TPOT metrics defined in section 13.9.1. Prefill determines whether the user sees a prompt response quickly; decode determines whether the generated stream keeps moving after it starts.

Prefill phase (time to first token) The model processes the 1,000-token prompt in parallel. Assuming 40 percent of peak compute efficiency during prefill, the model-side TTFT estimate is 41.9 ms, comfortably within the 200 ms SLO and leaving the remaining budget for network ingress, tokenization, and queueing.

Decode phase (time per output token) The model generates 256 tokens sequentially. At batch one, this phase is memory-bandwidth bound: each step streams the 4 GB weight tensor from VRAM. A batched step amortizes that stream across its active sequences.

Dividing the 4 GB weight tensor by the 3.35 TB/s bandwidth yields the theoretical floor: $T_{\text{token}} \approx$ 1.2 ms. Adding an assumed residual per-layer dispatch cost after graph capture gives a modeled TPOT of 1.57 ms. This dispatch overhead reflects the cumulative cost of launching 8–10 discrete GPU kernels (RMSNorm, RoPE, projections, attention, multilayer perceptron (MLP)) across each of the model's 32 layers. At batch size one, launching $ $250–300 small kernels adds several milliseconds of CPU-GPU submission and driver overhead, which serving engines mitigate by capturing the decode graph into a single CUDA Graph. Generating all 256 tokens therefore takes 256 tokens $\times$ 1.57 ms = 0.40 s.

13.10.3.3 Memory and throughput

With 4-bit weights occupying 4 GB, the remaining ~81.9 GB is available for the KV cache and runtime workspace, and the case study sets aside the cache reserve below while leaving the rest as workspace headroom. AWQ compresses the weights to 4 bits but leaves the KV cache in 16-bit precision, so each token still costs the approximately 0.131 MB of FP16 cache derived for this model in section 13.9.5.1. Dividing the 77.3 GB reserve by that per-token cost yields capacity for ≈ 0.6 million tokens, so at 1,256 tokens the GPU can hold a concurrent batch size of ~469 requests.

13.10.3.4 Unit economics

Consider a representative H100 SXM5 rental cost of approximately $3/hour and an assumed isolated prefill rate of 10,000 prompt tokens/s, deliberately below the rate implied by the model-side TTFT estimate above to allow for scheduling and kernel inefficiency. Dividing that rate by the 1,000-token prompt gives the prefill request capacity. For this calculation, each completed request counts both prompt and generated output tokens, totaling 1,256 tokens. Multiplying the limiting request rate by this token count and the seconds in an hour gives 45.2 million tokens/hour; dividing the hourly rental cost by that throughput gives $0.066/million tokens.

The comparison also converts KV residency into a request rate by dividing the resident request count by the modeled time to complete prefill and decode. It assumes that all those resident requests can advance at the modeled per-request pace, which is an optimistic concurrency assumption rather than a measured decode capacity. Under these assumptions, isolated prefill supplies the smaller rate and sets the displayed cost floor. Shared prefill/decode contention, batched decode timing, runtime workspace, and SLO-qualified throughput determine whether the service realizes that rate; memory fit alone does not establish it. The resulting cost floor is a bound for this workload, and a load experiment must supply the missing service capacity before the same arithmetic can price an accepted deployment configuration.

Checkpoint 13.6: Complete the LLM capacity decision

- ☐ **Define acceptance**: For the case study's 200 ms TTFT and 20 ms TPOT targets, state the required completion quantiles, availability requirement, and memory reserve before evaluating a configuration. Why do latency thresholds alone leave the SLO incomplete?
- ☐ **Measure the missing capacity**: Hold runtime, precision, hardware, and prompt/output lengths fixed. Increase offered request rate across several concurrency limits below the residency ceiling. For each warmed configuration, record TTFT and TPOT distributions, completed request rate, rejection rate, and peak allocated memory. Identify the configurations that satisfy all acceptance conditions.
- ☐ **Close the economic decision**: Recompute cost using each qualifying configuration's completed request rate and the case study's prompt-plus-output token convention. Select the lowest-cost qualifying setting for the required load. If none qualifies, identify whether lower offered load, a different batching/runtime policy, or different hardware is the next experiment. Explain why the KV-residency ceiling cannot supply the missing throughput observation.

For large language models, memory capacity (the size of the unallocated VRAM dedicated to the KV cache) determines maximum concurrent residency, while prefill compute and decode bandwidth determine realized token throughput and cost under a specific traffic mix. Memory bandwidth bounds low-batch decode latency; larger batches amortize parameter movement and shift the limit toward compute or KV-cache traffic. Physical constraints govern serving economics across the entire stack: latency budgets partition into prefill and decode phases, queueing theory dictates batch sizing and capacity headroom, and memory bandwidth bounds decode throughput. Misinterpreting these interactions leads directly to the operational fallacies and pitfalls that follow.

13.11 Fallacies and Pitfalls

Serving inverts training priorities in ways that violate intuitions from batch processing. The nonlinear relationship between utilization and latency, the hidden costs of preprocessing, and the silent failure modes of training-serving skew cause violated SLOs, wasted optimization effort, and accuracy degradation invisible to standard monitoring.

Fallacy: *Reducing model inference latency proportionally reduces user-perceived latency.*

Engineers who optimize model inference expect proportional improvement in user-perceived latency, but serving systems introduce latency sources absent from offline benchmarks. Under load, queuing delay dominates: equation 13.4 shows that at 80 percent utilization with 3.5 ms service time, average wait time is 14.1 ms before inference even begins. Reducing inference from 3.5 ms to 1.8 ms changes service time but also shifts utilization from 80 percent to 41 percent, reducing queuing wait from 14.1 ms to 1.2 ms, a 12× queuing improvement that dwarfs the 1.7 ms inference gain.

This nonlinear interaction between inference speed and queuing behavior produces an apparent paradox: the system-level speedup (17.6 ms $\rightarrow$ 3.0 ms, or 6×) far exceeds the model-level speedup (3.5 ms $\rightarrow$ 1.8 ms, or 2×). At first glance, this superlinear improvement appears to contradict Amdahl's law, which states that total system speedup is strictly bounded by the enhanced execution fraction. However, the fixed-fraction Amdahl calculation holds other stage costs unchanged; serving is a dynamic queueing system. Average queue waiting time scales nonlinearly with server utilization: $W_q \propto \frac{\rho_{\text{serv}}}{1-\rho_{\text{serv}}}$, where $\rho_{\text{serv}} = \lambda_{\text{arr}} \cdot T_{\text{svc}}(1)$ for unbatched service. When kernel optimization cuts service time $T_{\text{svc}}(1)$, it does not merely accelerate execution; it simultaneously lowers server utilization ρ_{serv}. Pulling utilization away from saturation collapses queue waiting times nonlinearly. A kernel optimization therefore shortens the request twice, once in the service time and again in the queue that the lower utilization drains. Conversely, profiling inference latency in isolation without modeling arrival load conceals the primary driver of user-perceived performance.

Pitfall: *Running serving infrastructure at high utilization to maximize cost efficiency.*

Teams target 90 percent utilization to minimize idle capacity. In production, latency degrades nonlinearly as utilization approaches capacity. Equation 13.4 shows that at 90 percent utilization, average time in system reaches 10× service time. Moving from 70 percent to 90 percent utilization cuts modeled infrastructure cost by 22.2 percent but triples average latency. For a 3.5 ms inference service, modeled p99 latency rises from ~54.1 ms to ~162 ms under the M/M/1 assumptions. In this scenario, operating at 60 to 70 percent utilization preserves substantially more latency headroom than 90 percent. A production target must instead be selected from the measured arrival process, service-time distribution, SLO, failure reserve, and cost objective.

Fallacy: *Training accuracy guarantees serving accuracy.*

Engineers assume identical model weights preserve validation-set performance. In production, preprocessing differences can shift inputs outside the training distribution. Section 13.8.5 explains how resize interpolation, numerical precision, and feature timing can create skew despite identical weights. Validation accuracy holds only over the population it sampled (principle 9), and a serving path that transforms inputs differently presents the model with a different population. The illustrative scenario here drops from 95 percent to 90 percent, a 5 percentage-point loss; these values are not a reported production incident. Production systems require consistent preprocessing and task-quality monitoring because latency and exception checks cannot detect this failure.

Pitfall: *Using average latency to evaluate serving system performance.*

Engineers monitor average latency because it trends smoothly and is simple to compute. An average, however, cannot show whether the percentile named by an SLO is failing. As section 13.4.3 demonstrates, at 70 percent utilization with 3.5 ms service time, average latency is 11.8 ms but the modeled p99 reaches 54.1 ms, a 4.6× gap invisible to mean-based monitoring. Services therefore report the relevant latency distribution and SLO percentile rather than the mean alone.

Fallacy: *Larger serving batches always improve throughput without affecting latency SLOs.*

Engineers maximize batch size assuming GPU saturation improves cost efficiency under production load. In serving systems, however, batching introduces a latency-throughput trade-off governed by queuing dynamics absent from offline benchmarks. Accumulating requests into larger batches increases wait time for early arrivals. An oldest-request window of 10 ms can add up to 10 ms of formation wait if the batch-size trigger does not fire first. Waiting for an available worker can add further delay; the combined distribution determines p99 latency. For the chapter's ResNet-50 profile on the H100 (section 13.5.5), increasing batch size from 16 to 32 raises saturated throughput by 77 percent and per-batch inference time only from 4.0 ms to 4.5 ms; at 500 QPS, however, filling the larger batch raises mean formation wait from 15 ms to 31 ms, and variable input sizes within a batch can create padding overhead that wastes compute on padding tokens. Section 13.5.4 shows why, for tight p99 targets, larger batch sizes can violate SLOs when batch formation delay plus increased per-batch inference time exceeds the latency budget. Serving batch optimization requires jointly tuning batch size, batch timeout, and concurrency against latency SLOs under realistic traffic patterns, not maximizing throughput in isolation.

Pitfall: *Calibrating quantization ranges with unrepresentative data.*

Teams may calibrate with a convenient sample even when it does not represent the supported deployment distribution. Post-training quantization determines INT8 scale factors from activation ranges in calibration data, so representative coverage matters. The illustrative scenario here drops from 76.1 percent to 72.9 percent, a 3.2 percentage-point loss; it is not a reported production incident. Effective quantization requires calibration and validation on data representative of the inputs the service is expected to handle.

Fallacy: *Cold start latency only matters for the first request.*

Engineers optimize steady-state latency assuming most requests hit warm instances. Cold starts compound during traffic spikes, deployments, and recovery, which is exactly when capacity is most needed. In this illustrative scenario, 10 instances each require 30 s of compilation, totaling 300 instance-seconds; parallel warming makes capacity useful after about 30 s, and a request that reaches a replica before warmup completes waits about 500 ms instead of 5 ms. Autoscaling policies that count only steady-state replicas therefore underestimate the capacity a spike requires. The scale-out budget must include compilation, weight loading, cache initialization, and health-check time (section 13.8.1), and warm pools of pre-initialized spare replicas, precompiled engines, staged model loading, or admission control keep new replicas from becoming another source of tail latency.

13.12 Summary

Serving moves a validated model into an operating workload. Online requests add a latency distribution, queueing, traffic variability, and failure reserve to the throughput concerns familiar from training. Little's Law relates stable long-run population, arrival rate, and response time; M/M/1 supplies an intentionally simple model of nonlinear latency growth near saturation. Neither replaces measurement, but together they turn headroom and capacity into explicit hypotheses that a load test can validate.

Effective serving optimization measures the complete request path rather than model inference alone. Protocol and serialization choices matter when transport is a visible fraction of the budget; preprocessing matters when it feeds an accelerator too slowly; batching matters only when arrivals and the SLO permit waiting. Training-serving skew adds a different failure mode. The service can remain fast and error-free while inconsistent transformations silently change its predictions.

The chosen deployment paradigm changes the feasible request path. A cloud API may use dynamic batching under a measured arrival process, synchronized sensors impose a frame deadline,

and a single-stream mobile workload may choose batch one to protect responsiveness and energy. The MLPerf scenarios provide standardized approximations of these shapes; production design still begins with the service's own traffic, hardware, and objective.

Node-level optimization connects the model's operations to the machine that executes them. Profiling reveals whether compilation, kernel fusion, precision, locality, serialization, or loading actually binds the request path. Gains matter only when they survive production input shapes, accuracy checks, and latency variation. Token-streaming language models stretch the whole toolkit at once. On the chapter's GPT-2 XL service, a batch-one decode step can be no faster than the 0.9 ms an H100 needs to read the model's weights. Latency splits into time to first token and time per output token, batching must reschedule at every generated token, and the KV cache, not arithmetic, bounds how many requests can share an accelerator. Capacity planning converts that valid throughput into replica count and unit cost, while the Llama 3 case study in section 13.10.3 separates calculable capacity bounds from the load experiment needed to establish valid throughput. A faster kernel that neither reduces provisioned capacity nor improves the SLO has not produced an economic gain.

Every row of the chapter map (table 13.1) reduces to a few counting rules, collected in table 13.19. Each formula links an observable workload parameter—arrival rate, service time, batch window, weight volume, or hourly node rate—to the operational metric it governs. Together they let an engineer estimate a service's latency budget, headroom, batch size, decode floor, and cache budget before a load test confirms them.

Table 13.19: Key Equations: The chapter's counting rules in the notation of the sections that derive them. The queueing rows assume Poisson arrivals and a single server, the batching rows assume an available worker at dispatch, and the decode floor assumes batch-one decode launched as one captured graph; each is a planning estimate that a load test must confirm.

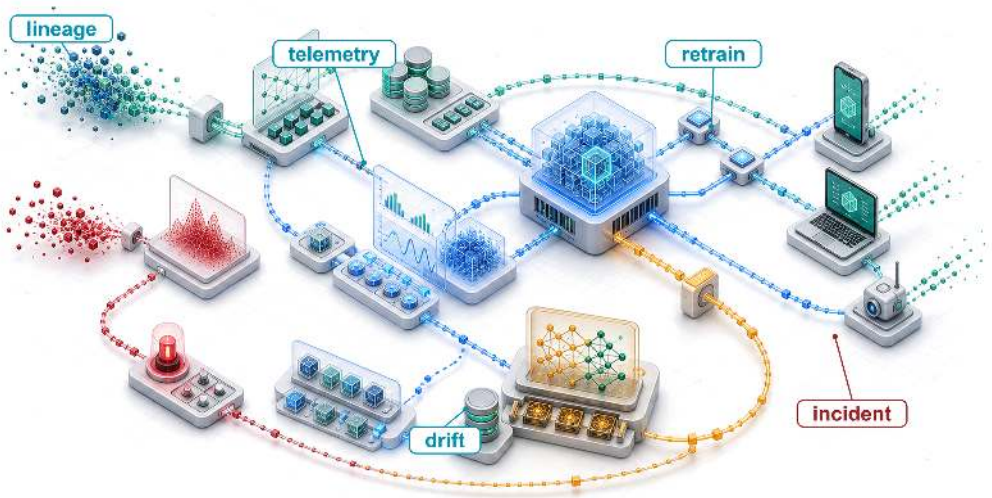
Quantity	Formula	Where derived
Requests in the system	$Q_{\text{req}} = \lambda_{\text{arr}} \cdot T_{\text{lat}}$	equation 13.3
Mean time in system (M/M/1)	$T_{\text{lat}} = \frac{\text{service time}}{1-\rho_{\text{serv}}}$	equation 13.4
p99 time in system (M/M/1)	$T_{\text{lat,p99}} \approx \frac{4.6 \cdot \text{service time}}{1-\rho_{\text{serv}}}$	equation 13.5
Count-triggered batch latency	$L_{\text{lat,batch}} \approx \frac{B-1}{2\lambda_{\text{arr}}} + T_{\text{svc}}(B)$	equation 13.6
Mean wait in a fixed window	$\mathbb{E}[L_{\text{lat,wait}}] = \frac{T_{\text{window}}}{2}$	equation 13.8
Saturated batched capacity	$\mu_{\text{eff}}(B) \approx \frac{B}{T_{\text{svc}}(B)}$	equation 13.10
Tail batch envelope	$L_{\text{lat,envelope}} = T_{\text{window}} + T_{\text{svc}}(B_{\text{req,p99}})$	equation 13.12
Decode floor per token	$T_{\text{token}} \approx \frac{D_{\text{vol}}}{\text{BW}_{\text{accelerator}}}$	equation 13.14
Tokens per speculative round	$\frac{1-\alpha^{\gamma+1}}{1-\alpha}$	equation 13.15
KV cache per token	$2\, N_L\, H_{\text{KV}}\, d_{\text{head}}\, s_{\text{elem}}$ bytes	section 13.9.5.1
Cost per inference	Allocated hourly cost divided by completed inferences per hour that meet the SLO	section 13.10.1

Key Takeaways: Inverting every training priority

- **Serving is latency economics**: Training rewards throughput over long runs, but serving spends a fixed per-request budget across serialization, preprocessing, queuing, inference, postprocessing, and the network. Optimizing only model latency misses the stages users actually wait on.
- **Utilization turns into waiting**: In the chapter's M/M/1 approximation, average time in system rises from 5× service time at 80 percent utilization to 10× at 90 percent. Headroom keeps modest traffic surges from becoming SLO failures.

- **Fast models expose the rest of the pipeline**: Once inference is fast, image decode, tokenization, and other preprocessing can dominate total latency. The binding optimization becomes the request path, not the neural network kernel.
- **Batching follows traffic, not habit**: Poisson-modeled web arrivals can use dynamic batching, synchronized sensors need aligned batches, and single-stream mobile workloads may have little batching opportunity. A useful window converts available latency slack into throughput without violating the SLO.
- **Skew breaks accuracy without errors**: Resize methods, color-channel order, normalization constants, or feature definitions that differ between training and serving can change the model's effective input distribution. Shared transformations, parity tests, and production-slice monitoring reduce this risk.
- **Runtime choices become infrastructure cost**: Precision, graph compilation, kernel fusion, and serving runtime translate directly into replica count and cost per inference. Quantization and specialized runtimes can materially reduce required serving capacity when they preserve accuracy and fit the target hardware.
- **LLM serving is memory management**: Decode often reads weights from VRAM for every generated token, so token latency is bandwidth-bound unless batching changes the constraint. KV-cache layout, PagedAttention, continuous batching, precision, and runtime choice determine both concurrency and cost per token.

Training is judged by useful work completed; an online service is judged by whether requests meet their latency objective. Each stage draws on the same latency envelope: serialization, preprocessing, the queue, the model, and the response. Data determines input size and arrival shape, the algorithm determines compute and state, and the machine determines service rate and movement costs. Queueing couples all three nonlinearly, so a system within budget at moderate traffic can breach it after a small surge. Serving engineering therefore allocates the budget across the request path, preserves headroom for variability and failure, and verifies that the required fraction of requests finishes before the deadline, which is the latency budget principle (12) in operational form.



What's Next: From fast to still correct

This chapter evaluates the request path under a specified workload: latency within budget, headroom preserved, and useful throughput converted into cost. Those performance checks do not establish whether the answers are still right. Training-serving skew showed that a service can stay fast and error-free while its predictions change, and drift produces the same silence when the world moves rather than the pipeline. Chapter 14 widens the unit of concern from request-path performance to the model's operating lifetime. Monitoring tracks prediction quality alongside system health, feature stores and model registries keep serving aligned with training, and staged rollout with rollback lets a replacement model reach users without turning a bad release into an outage.

Purpose

Why can an ML system be perfectly available and perfectly wrong at the same time?

Conventional monitoring often detects crashes, latency regressions, and availability failures quickly, but semantic errors can remain silent in any software system. ML systems add another silent failure mode. A model experiencing data drift can continue serving ordinary-looking predictions while accuracy degrades, triggering no alerts because every health check (latency, throughput, uptime) remains green. A fraud model can keep answering in milliseconds for months after the patterns it learned have moved elsewhere, and the first alarm may be the losses themselves. Model quality can degrade because the world changes. Customer behavior shifts, new product categories appear, seasonal patterns evolve, and the distribution the model learned from diverges from the one it now faces. Drift is not a certainty but a persistent risk for deployed models. Unlike latency or uptime, correctness may become observable only after labels or downstream outcomes arrive, so detecting degradation often requires imperfect signals and explicit investigation rather than a single threshold. Managing it requires continuous monitoring that tracks prediction quality alongside system health, drift signals that trigger investigation, retraining when outcome evidence supports it, and deployment strategies that validate new model versions against production traffic before full rollout. The gap between development and production is not a hurdle cleared once but a condition managed indefinitely, for as long as the model makes decisions that someone relies on. Machine learning operations exists because uptime without measured accuracy may still deliver wrong answers at scale. In D·A·M terms, operations makes co-design continuous, because the data environment can remain a moving target long after initial deployment.

Learning Objectives

- Explain why ML systems can remain available while prediction quality silently degrades under distribution shift
- Diagnose technical debt across data-model, model-infrastructure, and production-monitoring interface boundaries
- Design model registries, parity tests, and CI/CD pipelines that preserve training-serving consistency and reproducible rollback
- Compare canary, blue-green, shadow, and rollback strategies by the release risk they contain and the accelerator memory they hold
- Design the operations loop's layered monitoring and incident response to trace drift, skew, and degradation to a data, model, or infrastructure cause
- Apply the retraining staleness model to choose cost-aware retraining triggers and intervals
- Evaluate operational maturity and investment using model criticality, operational risk, and organizational readiness

14.1 Silent Failure in Production

A serving cluster can return HTTP 200 on every request, stay well inside its tail-latency budget, and pass every infrastructure health check while the recommendations it serves lose relevance week after week. A **silent failure** is a production model that keeps answering every request on time, raises no error, and passes every health check while its answers grow worse. Any deployed model is exposed to it, because a model is a fit to the data it trained on and the world it serves keeps moving after training ends. Chapter 13 built the request path that delivers those answers, a service that meets its latency budget, holds headroom for bursts, and turns throughput into cost per inference. A benchmark establishes performance at a point in time, and serving infrastructure verifies that the required fraction of requests finishes within the latency budget. Neither check asks whether the answers are still right. Operations is the stage of the lifecycle (chapter 3) that has no finish line. It keeps a model correct for as long as anyone relies on its decisions. The team deploys to production, and week one looks excellent. The challenge begins in week two.

Data distributions shift, user behavior changes, and the world moves on from the conditions under which the model was trained. ML models that succeed in development can fail to achieve sustained production use when postdeployment ownership and monitoring are absent. The root cause is an operational mismatch. Availability-focused monitoring tracks server uptime, request latency, and request success rates, while ML monitoring must also track statistical health, including accuracy over time, input-distribution shift, and per-segment prediction quality. A model can degrade substantially while throwing no exceptions, triggering no infrastructure alarms, and maintaining perfect uptime.

The degradation is measurable. In the Wild-Time benchmark, Yao et al. (2022) train a model on data from one period and test it both on held-out data from that period and on data from later years, across six real datasets that span yearbook portraits, satellite imagery, hospital records, news, and scientific papers. Figure 14.1 shows the result. On every dataset the same model scores lower on the later data, by 4 to 18.5 points of accuracy or of area under the curve (AUC), although nothing about the model or its serving path changed. The loss comes entirely from the world moving away from the training data, and only monitoring that compares predictions against fresh outcomes can see it.

The discipline that makes these invisible failures visible is **machine learning operations (MLOps)**. It inherits the automation and operations lineage of DevOps (Kreuzberger et al. 2023), but addresses a different failure mode. Conventional services can often be tested against deterministic code paths, while ML systems depend on training data distributions, learned parameters, and environmental conditions that shift continuously. Data distributions, learned parameters, slice-level evaluations, and runtime feedback loops therefore all function as release artifacts that govern production behavior, and a release extends far beyond an executable binary or code diff.

The operational mismatch connects directly to the book's analytical foundations. If benchmarking provides the *sensors* for the system, MLOps is the complete *control system*, and the degradation equation (equation 1.1) names the quantity it controls. Accuracy falls by a fitted sensitivity λ times

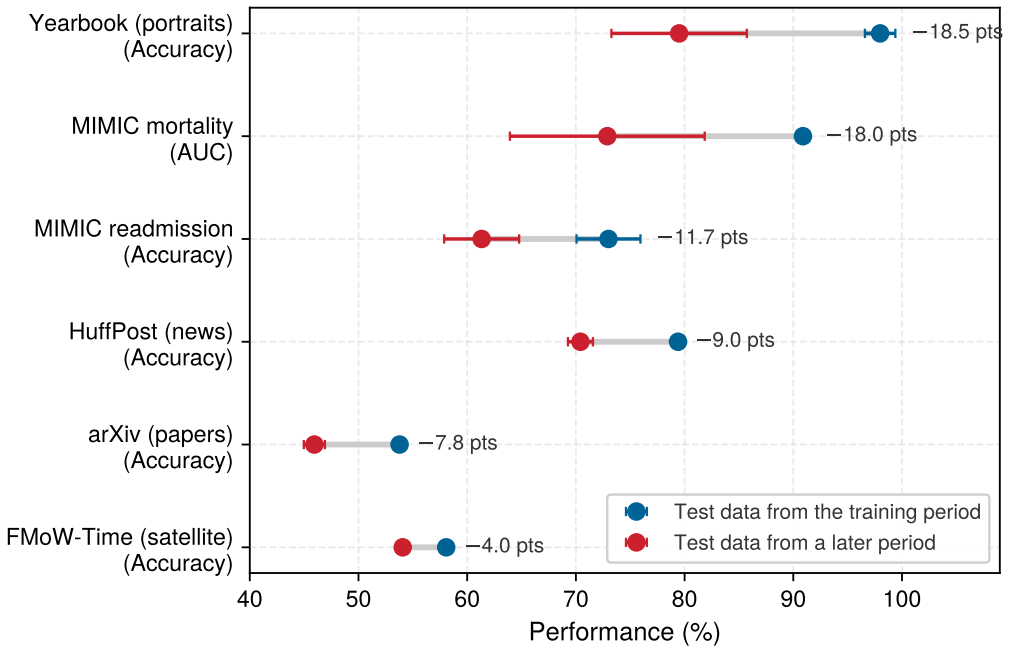

Figure 14.1: Measured Accuracy Loss over Time: For six datasets, performance of the same trained model on held-out test data from its training period (blue) and on data from a later period (red), with error bars showing one standard deviation over three training seeds. The label gives each drop in percentage points. MIMIC mortality is scored by AUC; the others by accuracy. Data from Yao et al. (2022).

the divergence between the serving and training distributions, so operations must measure that divergence continuously and estimate λ from paired drift and outcome data, because divergence alone does not prove that accuracy will fall. MLOps also formalizes interfaces and responsibilities across traditionally isolated domains (data science, machine learning engineering, and systems operations (Amershi et al. 2019)) through continuous retraining, A/B evaluation, graduated rollout, and standardized artifact tracking that supports reproducibility and auditability.

Definition 14.1: MLOps

Machine learning operations (MLOps) is the engineering practice of productionizing ML systems through CI/CD, workflow orchestration, reproducibility, versioning, collaboration, continuous training and evaluation, monitoring, and feedback loops (Kreuzberger et al. 2023).

1. **Significance**: Leaving the loop open shows up as stale predictions, silent accuracy degradation, and prolonged recovery times. Drift thresholds, retraining triggers, and mean time to recovery (MTTR) targets are deployment-specific, calibrated from prediction value, label delay, validation risk, and retraining compute expense. A retraining run is justified only when the expected accuracy gain outweighs its execution cost and rollout risk.
2. **Distinction**: DevOps monitors functional correctness, throughput, and availability. MLOps adds statistical controls for *predictive correctness*, which can decay while uptime, latency, and HTTP status codes stay healthy.
3. **Common pitfall**: A frequent misconception is that retraining on new data automatically resolves distribution shift. Retraining without diagnosing what shifted (the inputs the model receives, the relationship between those inputs and the correct answers, or both) preserves the underlying failure or amplifies collection bias. Reweighting the training

data can correct a change in input mix, but only new outcome evidence shows whether a changed input-output relationship requires adaptation; section 14.5.2 separates the two cases formally.

The loop has three stages (design, model development, and operations), but its defining feature is the return path. Runtime telemetry and retraining triggers carry live performance signals from operations back into requirements and data engineering, so deployment feeds the next design cycle instead of ending the project (figure 14.2).

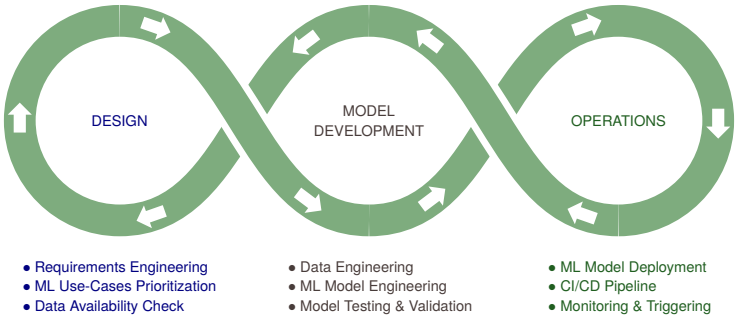

Figure 14.2: Iterative MLOps Loop: Monitoring and triggering feed production evidence back into design and model development, turning requirements, engineering, testing, and deployment into a continuous operating cycle.

The operations stage of that loop runs on every production model as five steps, which together form the **operations loop**. It detects a change in inputs, outputs, or outcomes; diagnoses which layer of the system caused it; decides whether retraining, rollback, or waiting is worth its cost; releases a replacement under controlled exposure; and recovers to a known-good version when a release misbehaves. Each step is a control that a team must build and pay for, and each consumes a concrete machine resource: telemetry bytes for detection, logged requests for diagnosis, accelerator-hours for a retraining run, and a second resident copy of the model for a safe release.

Deploying, monitoring, and maintaining one production ML system defines the fundamental operational unit: the **ML node**, a complete system comprising data pipelines, feature computation, model training, serving infrastructure, and monitoring for a single machine learning application. Platform operations at larger scale (managing hundreds of models, cross-model dependencies, multi-region coordination, and organization-wide ML platform engineering) constitute advanced topics that build on these single-model foundations.

Keeping one ML node correct decomposes into three interfaces that follow the artifact from data ingestion to live traffic and back again. At the start of the pipeline, the **data-model interface** governs the handoff between data infrastructure and model training, where the goal is feature consistency so that training and serving pipelines compute features the same way. Once a checkpoint is trained, the **model-infrastructure interface** carries those weights into a scalable service; its challenge is environment parity, because a model that works in a notebook can fail in production when versions, dependencies, or runtimes differ. Closing the loop, the **production-monitoring interface** returns statistical telemetry[1] from live serving back to training, enabling self-correction when distribution shift degrades accuracy without crashing the service.

These three interfaces determine how operational infrastructure partitions responsibility across the lifecycle. Feature stores stabilize feature computation at the data-model boundary, model registries and deployment pipelines preserve the model-infrastructure handoff, and drift monitors, retraining triggers, and governance policies connect production evidence back to a controlled response, shortening the window in which degradation goes unaddressed.

Two of the book's lighthouse workloads (section 1.7.1) carry the chapter, one for each end of the deployment spectrum. The cloud half follows a ranking service built on DLRM, the recommendation model that chapter 13 set against ResNet-50's compute-bound service. DLRM's home regime is capacity-bound. Its 100 GB of embedding tables exceed the 80 GB of one H100, so even its smallest

[1] **Telemetry**: The feedback path that can make model degradation visible before it becomes a business failure; crashes and error codes expose some software failures, but semantic errors can remain silent in any application. ML systems add distribution shift, which can go undetected without statistical telemetry such as feature distributions, prediction confidence, and drift indicators.

deployment spans two accelerators before throughput enters the calculation, and every operational control that needs a second copy of the model pays for it in memory. A ranking model is also the workload whose world moves fastest. User interests and the item catalog change daily, click labels arrive within hours, and the model's own rankings shape the clicks it later trains on. The edge half follows the keyword spotter, whose home regime is power-bound. Its 200 KB INT8 model listens continuously on a microcontroller with 4 MB of flash, where every radio transmission and flash write draws on a small energy budget. Section 4.12 left that spotter six months after launch with a detection rate four percentage points below its target, and the edge sections of this chapter pick up the drop. The device cannot be reached by hand, its audio cannot leave it, and a failed update must not disable it.

The week-two problem takes concrete shape on the ranking service in an illustrative scenario. Initial measurements show 94 percent click-prediction accuracy, p99 latency inside the service's budget, and strong performance across test segments. By week four, accuracy has dropped to 88 percent, but the infrastructure metrics show nothing wrong. By week eight, a product manager notices that recommended items convert poorly; investigation reveals the model has not adapted to a competitor's new promotion that shifted what users click. The model needed investigation six weeks ago, but no system was watching for this degradation. MLOps provides the framework to detect such changes, assess whether retraining addresses them, and validate replacement models while limiting the impact on users.

The chapter builds the operations loop in the order a team needs it (table 14.1). Technical debt explains why ML systems accumulate the hidden coupling that makes silent failure likely. Development infrastructure builds the pipeline that can rebuild and trace any model exactly, and releasing models moves a candidate onto live traffic with a tested path back. Production monitoring then watches the deployed model for the evidence the loop runs on, and retraining decisions turn that evidence into a choice to retrain, roll back, or wait. Incident response and governance handle the failures that monitoring surfaces, operational maturity decides which control a team should add next, and two case studies carry the loop to the edge and into the clinic.

Table 14.1: Chapter Map: Each section builds one step of the operations loop and names the machine resource that step consumes on the DLRM ranking service.

Section	Loop step	Question it answers	Machine cost on the ranking service
Technical Debt	Why the loop exists	Where hidden coupling accumulates	Glue code and unused features that still move bytes
Development Infrastructure	Release (prepare)	How a model is rebuilt and traced exactly	Versioned copies of data, features, and 100 GB of tables
Releasing Models	Release, recover	How a candidate reaches traffic and how it is withdrawn	A second resident copy of the tables for each release control
Production Monitoring	Detect	Whether predictions are still right	Telemetry bytes per second and their retention
Retraining Decisions	Decide	Whether a new model is worth its run	Accelerator-hours that contend with serving
Incident Response and Governance	Diagnose, recover	Which layer failed, and who acts	Replay and slice queries over logged requests
Operational Maturity	All steps	Which control to add next	Operational spend matched to the model's value
Case Studies	All steps	How the loop changes at the edge and in the clinic	Flash banks, radio energy, and clinician review time

Operating this feedback path requires adding statistical controls to the release and reliability practices of DevOps. Technical debt accumulates wherever one of the three interface boundaries erodes. Feature stores, versioning, and CI/CD pipelines restore the reproducibility needed to isolate a fault at those boundaries, while monitoring, drift detection, and staged rollout protect predictive quality once inputs begin to shift. A small set of foundational principles decides which of these controls a given model needs and when each should act.

14.1.1 Five operational principles

Without clear operating rules, a team cannot tell whether an accuracy drop came from an unrecorded data change, a mismatched serving feature, or an overdue retraining run. Five operational principles prevent these blind spots by anchoring each boundary of the ML node to a measurable quantity, from a complete artifact hash for reproducibility to net retraining value for automation (table 14.2). The sections that follow build the controls that enforce them.

Table 14.2: MLOps Principles Summary: Quick reference for the five foundational principles that guide all MLOps tooling and practice decisions.

Principle	Core Insight	Key Metric
Reproducibility	Version all artifacts	Complete artifact hash
Separation of concerns	Independent layer evolution	Layers touched per change
Consistency	Training equals serving	Feature skew rate
Observable degradation	Make failures visible	Time to detection
Cost-aware automation	Optimize total cost	Net retraining value

14.1.1.1 Reproducibility

Reproducibility requires every artifact[2] that influences model behavior to be versioned and traceable. This principle extends beyond code repositories to encompass input datasets, feature schemas, hyperparameter configurations, and execution environments. Equation 14.1 expresses this dependency formally:

$$\text{Model Output} = f(\text{Code}_v, \text{Data}_v, \text{Config}_v, \text{Environment}_v; \xi) \tag{14.1}$$

where v identifies an immutable version hash and ξ captures execution nondeterminism. Exact reproduction requires freezing all four versioned inputs alongside random seeds, dataloader sample ordering, deterministic GPU reduction kernels, and identical accelerator hardware architectures.

Fixing random seeds (such as `torch.manual_seed(42)`) still fails to guarantee bitwise reproducibility across training runs on accelerator hardware. The root cause is finite-precision arithmetic. In exact arithmetic, addition is associative, so $(a+b)+c = a+(b+c)$. Floating-point formats such as FP32, FP16, and BF16 break associativity because each intermediate sum is rounded to fit a finite mantissa width. Because concurrent atomic updates on an accelerator reach memory in an order that varies from run to run, the rounded sums differ in their least significant bits, and these differences compound over thousands of optimization steps. Two runs with identical seeds and code can therefore diverge into measurably different weights unless deterministic reduction algorithms, which fix the summation tree at the cost of parallel throughput, are enabled (section 12.8.2 develops this trade-off between reproducibility and performance).

[2] **Artifact**: Model weights are realized training outputs; the inputs and randomness that produced them cannot generally be inferred from the parameters. Versioning only code is therefore insufficient, and even versioning code, data, configuration, and environment may not guarantee exact replay when kernels or training are nondeterministic.

↩ The floating-point formats, their dynamic ranges, and where accumulated rounding error matters in training are established in section 8.6.3.

14.1.1.2 Separation of concerns

Separation of concerns decomposes MLOps systems into distinct functional layers that can evolve independently. Because data schemas, training algorithms, traffic patterns, and business rules change on different schedules, isolating each layer lets a team update one without rebuilding the others, as table 14.3 summarizes:

Table 14.3: MLOps Separation of Concerns: Each layer addresses a distinct responsibility and evolves at different rates across the data, training, serving, and monitoring layers. This separation enables independent scaling and updates, reducing blast radius when changes are required.

Layer	Responsibility	Stability
Data Layer	Feature computation, storage, serving	Changes with data schema evolution
Training Layer	Model development, hyperparameter optimization	Changes with algorithm research
Serving Layer	Inference, scaling, latency management	Changes with traffic patterns
Monitoring Layer	Drift detection, performance tracking	Changes with business requirements

14.1.1.3 Consistency imperative

The architectural boundaries in table 14.3 allow teams to upgrade serving runtimes without retraining models, adjust alert thresholds without redeployment, and modify data ingestion pipelines while preserving interface contracts. That architectural independence remains safe only when training and serving environments process features identically, establishing training-serving parity as the consistency imperative of section 4.7.1. A violation of that parity is training-serving skew, and the training-serving skew diagnostic (principle 11) detects it without waiting for labels by comparing what the training and serving code paths compute, from features through model scores, for the same inputs. The financial consequence of this discrepancy is captured in equation 14.2:

$$\text{Skew Cost} = \text{Rate}_{\text{skew}} \times Q_{\text{day}} \times C_{\text{error}} \tag{14.2}$$

where $\text{Rate}_{\text{skew}}$ is the fraction of queries with erroneous predictions caused by training-serving skew, Q_{day} is the daily query volume, and C_{error} is the average business cost incurred per erroneous prediction.

For a system serving 1,000,000 queries/day with 1 percent skew-induced errors costing $0.10 each, annual skew cost reaches $365,000. The loss recurs every year until consistency mechanisms remove its cause. Shared feature stores, unified C++ or Rust feature-extraction libraries invoked identically during offline training and online serving, and automated schema validation tests support consistency at the system boundary; matched-input tests must still verify feature values and semantics.

14.1.1.4 Observable degradation

Observable degradation requires ML systems to make silent failures visible through continuous measurement. Model accuracy degrades along a continuous statistical spectrum rather than failing as a discrete binary crash. An observed failure's time signature (an acute drop, gradual drift, or localized cohort decay) governs both the detection mechanism and the operational response. The ranking service's four-week slide from 94 to 88 percent was a gradual signature, the kind that trend analysis on accuracy catches and that no uptime or latency alert can see. Making degradation observable therefore means pairing each failure signature with the telemetry that can see it and the countermeasure it calls for, as table 14.4 outlines.

Table 14.4: Degradation Detection Strategies: Four failure signatures map to detectors and operational responses. Sudden drops require immediate diagnosis and may call for rollback, while gradual or subgroup degradation calls for diagnosis before retraining or targeted data collection.

Degradation Type	Detection Mechanism	Response Strategy
Sudden accuracy drop	Threshold alerts	Diagnose; roll back if release-related
Gradual drift	Trend analysis	Diagnose, then retrain if warranted
Subgroup degradation	Cohort monitoring	Targeted data collection
Latency increase	Percentile tracking	Infrastructure scaling

14.1.1.5 Cost-aware automation

Cost-aware automation balances computational costs against accuracy improvements. Let ΔAccuracy be the expected gain in accuracy percentage points, Value per Point the monetary value of one percentage-point gain over the decision horizon, Training Cost the compute and labor cost of a retraining run, and Deployment Risk the expected cost of validation and rollout failure. Equation 14.3 models this trade-off:

$$\text{Retrain if: } \Delta\text{Accuracy} \times \text{Value per Point} > \text{Training Cost} + \text{Deployment Risk} \tag{14.3}$$

The inequality acts as an operational decision gate rather than an unconstrained trigger. An automated pipeline should initiate retraining only when empirical evidence indicates that expected accuracy gains surpass execution cost and rollout risk. This economic trade-off governs retraining triggers, validation thresholds, and rollout gates; section 14.6 formalizes this model to calculate optimal retraining cadences. The margin by which the left side of equation 14.3 exceeds the right is the *net retraining value*, the quantity that a retraining trigger should test.

How these principles manifest in practice depends on the workload. The ranking service drifts daily as user preferences shift, while the keyword spotter may run unchanged for months between updates. The monitoring strategy must match the workload's regime and, more decisively, the labels its deployment can observe.

Lighthouse 14.1: Monitoring strategy by archetype

The dominant failure modes and monitoring priorities differ across workload archetypes. Table 14.5 compares four representative archetypes by drift pattern, monitoring metric, and example retraining trigger:

Table 14.5: Monitoring Strategy by Workload Archetype: Illustrative starting points for monitoring strategy. Real thresholds must be calibrated to the deployment's label delay, traffic volume, business risk, and alert-fatigue budget.

Archetype	Dominant Drift Pattern	Primary Monitoring Metric	Example Retraining Trigger
Compute-bound (ResNet-50)	Visual distribution shift (lighting, camera, new object classes)	Accuracy on holdout set (ground truth available)	Accuracy drops > 2% from baseline (∼monthly for stable domains)
Bandwidth-bound (GPT-2)	Vocabulary drift, topic shift, emerging entities	Perplexity on live traffic (no ground truth needed)	Perplexity increases > 10%; new vocabulary detected (∼weekly for news domains)
Capacity-bound (DLRM)	User behavior shift, item catalog churn, cold-start items	CTR/CVR delta vs. historical cohorts	Engagement drops > 5%; catalog refresh (∼daily for e-commerce)
Power-bound (KWS DS-CNN)	Acoustic environment change (noise floor shift)	Duty cycle (wakeups/hour) + false positive rate	False wake rate > 1%; battery drain exceeds spec (∼quarterly OTA update)

Systems insight: Ground-truth availability governs monitoring design. A workload's binding regime sets its cost and capacity but does not determine which quality signal is observable. Vision tasks with labels (ResNet-50) track holdout accuracy; language and recommendation services (GPT-2, DLRM) rely on perplexity or implicit clicks; microcontroller models without labels (the keyword spotter's DS-CNN) monitor duty cycles, while estimating false-wake rates requires a reference signal or reviewed examples. Retraining cadence is constrained by label delay, deployment access, validation cost, and the rate of observed change.

These principles respond to three recurring operational failures: concept drift,[3] data-quality defects (Schelter et al. 2018), and silent postdeployment degradation. Addressing them changes both what a team versions and who must coordinate alongside what it monitors: MLOps brings a broader stakeholder ecosystem together around data versioning,[4] model versioning, and continuous statistical monitoring that extend beyond traditional software engineering. By treating datasets and pipeline state as first-class versioned artifacts alongside source code, this expanded operational scope turns deployment from a linear release pipeline into a continuous, evidence-driven feedback loop.

Checkpoint 14.1: The MLOps loop

The operations loop feeds production evidence back into design.

The feedback cycle

- ☐ **Loop closure**: Explain how production telemetry returns evidence to the model lifecycle and why an alert does not by itself authorize retraining.
- ☐ **Retraining trigger**: Distinguish a distribution change from a measured quality regression, and explain why either requires diagnosis before selecting a remedy.

The artifacts

[3] **Concept drift**: Concept-drift and data-stream research formalized the problem that a model's target relationship can change after deployment (Widmer and Kubat 1996; Gama et al. 2014). In adversarial domains such as spam, fraud, and abuse detection, the distribution can actively adapt in response to the model, making continuous monitoring and retraining a structural requirement rather than an operational luxury.

[4] **DVC (Data Version Control)**: DVC brings Git-like versioning to datasets and model artifacts (Iterative 2024), closing the artifact gap that equation 14.1 formalizes. Without data versioning, the Data_v term is unrecoverable, and no combination of code commits can reconstruct the model that was deployed.

- ☐ **Artifact versioning**: Identify the data, code, configuration, weights, and environment versions needed to trace a deployed model, and explain why versioning alone does not guarantee exact replay.

Each iteration through the operational loop introduces data dependencies, model interactions, and configuration state invisible to traditional compilation and testing. When left unmanaged, these hidden dependencies accumulate into systemic technical debt that slows releases and degrades predictive accuracy. Understanding the architectural patterns of this debt is the prerequisite for designing the infrastructure that pays it down.

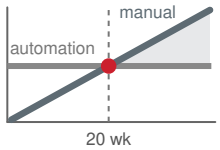
14.2 Technical Debt

A team that ships a model by copying feature scripts, skipping schema checks, and wiring predictions directly into downstream services gets to production quickly and then spends the next year debugging silent regressions that no unit test catches. In traditional software systems, technical debt[5] represents the future rework created by choosing expedient shortcuts over disciplined architecture (Cunningham 1992). In machine learning systems, that debt compounds through statistical coupling and data dependencies that code review and unit tests cannot detect (Sculley et al. 2015). A codebase can remain clean while the external world shifts, rendering trained parameters stale and breaking downstream consumers. The ML Test Score rubric (Breck et al. 2017) quantifies this debt; it returns with the maturity audit near the end of the chapter.

5 **Technical debt**: Ward Cunningham's 1992 WyCash experience report introduced the debt metaphor for expedient code and delayed consolidation (Cunningham 1992).

Definition 14.2: Technical debt in ML

Technical debt in machine learning is the accumulating maintenance and change cost created by implicit data dependencies, entangled features, and undeclared consumers in ML systems, where the resulting liabilities may also appear as silent accuracy degradation.



1. **Significance**: Google's analysis of production ML systems argues that model code is only a small fraction of the surrounding system; the larger operational surface includes data collection, feature extraction, configuration, serving infrastructure, monitoring, and process management (Sculley et al. 2015). ML-specific debt drivers compound this: changing one input feature can silently shift the learned representation of every other feature (entanglement), a model trained to correct another model's errors creates a fragile dependency chain (correction cascades), and downstream systems consuming model outputs without explicit contracts become undeclared consumers that break silently when the model is updated.
2. **Distinction**: ML technical debt includes system- and data-level dependencies that code review and ordinary code-focused tests may miss. It can slow development and degrade prediction quality even while availability metrics remain healthy.
3. **Common pitfall**: A frequent misconception is that "better code" solves technical debt in ML. In reality, it is a systems architecture problem: the debt accumulates when the assumptions of the training distribution (feature ranges, label meanings, data freshness) are not enforced as runtime contracts at the system boundary.

A break-even calculation makes the cost dynamics of technical debt concrete. Teams often resist automation investment because manual processes seem faster in early development, but that advantage disappears once recurring manual interventions exceed the up-front automation cost.

Napkin Math 14.1: The cumulative cost of manual operations

Problem: Why build automated pipelines when manual retraining is faster?

Physics: Manual work accumulates over time.

Cumulative manual work overtakes the one-time automation investment near week 20.

- Manual retrain: 4 hours of engineering per week.
- Pipeline build: 80 engineering hours (one-time).

Math:

- **Result**: 80 engineering hours ÷ 4 hours per week = 20 weeks.
- **Assumption**: This simplified calculation sets pipeline upkeep to zero, so automation removes the weekly task entirely.
- **Upkeep**: Real pipelines need maintenance and new features. Each week then recovers only the difference between the manual load and the upkeep, which pushes break-even later; automation still pays back whenever its weekly upkeep stays below the manual work it replaces.
- **Consequence**: After 1 year, manual teams still spend 4 hours per week on maintenance, while pipeline teams spend only their upkeep (0 recurring hours under this calculation's assumption).

Context: Over a system's lifetime, the cost of *maintaining* it can exceed the cost of *building* it. In ML, technical debt is often *data-driven* rather than *code-driven*, because correct code can still fail when the data it processes shifts. Without telemetry, the team cannot tell whether maintenance work is reducing debt or merely hiding it.

Systems insight: A team that retrains by hand eventually has no time left to ship new models, provided automation upkeep stays below the manual load it removes. Without monitoring that makes silent failures visible, the team also accumulates debt in a system that grows harder to manage.

The debt is larger than manual retraining alone, because modeling code constitutes only a small fraction of a real-world deployment. Core modeling code is one peripheral component among ten around the ML system, alongside nine supporting subsystems spanning data verification, feature extraction, configuration, and machine resource management (figure 14.3). Their presence broadens the maintenance surface; the diagram does not measure each component's cost.

Figure 14.3: Hidden Infrastructure of ML Systems: ML code is one of ten components arranged around the ML system at the center, alongside data collection, data verification, feature extraction, configuration, machine resource management, serving infrastructure, monitoring, analysis tools, and process management tools. Modeling occupies one circle and the remaining nine identify the operational surface a deployment must also carry; circle counts do not measure code volume or maintenance cost. Source: (Sculley et al. 2015).

While automation addresses the recurring operational overhead of manual retraining, it cannot prevent architectural decay. Deployed systems accumulate hidden complexity through systemic failure modes that emerge from statistical coupling rather than deterministic logic. The patterns group by where the coupling hides: in eroded boundaries and the correction cascades they invite, in interface dependencies that no import statement declares, in feedback and configuration that accumulate as the system evolves, and in the code and architecture around the model.

14.2.1 Boundary erosion

When an upstream pipeline changes how missing ages are filled or rescales a price column, every unit test in the repository can pass while the downstream model's predictions quietly shift. Statistical software loses its modular boundaries more easily than conventional software does because component behavior depends on the distribution of incoming data rather than on type signatures alone. In conventional software, modular encapsulation and typed APIs make dependencies explicit, though changes can still violate behavioral contracts. Machine learning systems blur these boundaries because an upstream formatting change or a new normalization rule can satisfy every syntactic check while shifting feature distributions and degrading downstream model accuracy. This implicit coupling through data pipelines creates unmonitored dependencies among feature engineering, training pipelines, and serving endpoints.

This erosion produces **entanglement**, where dependencies between features and components become so intertwined that local changes demand global coordination. The resulting failure mode reflects the CACE principle: *Change Anything Changes Everything*. When systems lack strict statistical checks at their boundaries, adjusting a feature encoding or data filtering threshold can shift learned weights throughout the model during retraining. With frozen weights, the same change leaves the learned parameters alone but alters the inputs the model sees, and potentially its predictions. For example, changing the binning strategy of a continuous feature shifts the feature's variance and covariance structure, causing a previously calibrated model to underperform and forcing downstream recalibrations across dependent services.

Defending against boundary erosion requires architectural modularity enforced at runtime. Components require explicit data contracts that govern statistical invariants, including allowed feature ranges, null tolerances, and drift thresholds. Enforcing separation between data ingestion, feature generation, and inference logic creates verification boundaries where data distributions can be validated before reaching model weights. Because boundary erosion remains silent during initial prototyping, schema contracts and invariant checks are the earliest point at which statistical coupling can be detected and managed.

14.2.2 Correction cascades

When boundary erosion goes unaddressed, engineering fixes frequently trigger a **correction cascade**: patching a specific model defect with an auxiliary post-filter introduces secondary errors elsewhere, requiring further patches that destabilize the entire pipeline. In ML systems, these cascades are severe because changes propagate through statistical dependencies rather than deterministic code branches. Retraining a model to correct a specific false-positive cluster may degrade accuracy across previously stable cohorts. Adding an auxiliary model to override edge-case predictions introduces uncalibrated scores that confuse downstream consumers. Repeated dependent patches can demand coordinated revalidation, with maintenance costs that may exceed those of revising the base model.

Figure 14.4 traces this failure propagation along a four-stage dependency chain (Models A through D), where each downstream component compensates for the residual errors of its predecessor. When an upstream patch alters Model A, the dashed red arcs mark every downstream correction that requires revalidation and may need retraining.

A cascade requires dependent correction models; fine-tuning or reusing an established model does not create one by itself, although reuse does inherit representations and assumptions that require evaluation on the new task. Over time, those inherited properties become rigid architectural constraints that complicate future updates.

For example, fine-tuning an existing customer churn model for a new product line inherits the base model's feature encodings and calibration thresholds. If the new product has different user engagement patterns, patching prediction errors with auxiliary post-processing rules creates a

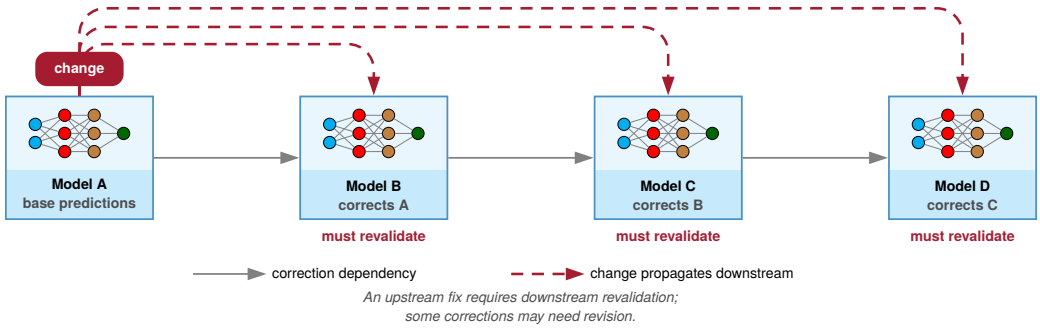


Figure 14.4: Correction Cascades: Each model is trained to correct the errors of the model before it, forming a chain of dependencies. Changing an upstream model can invalidate downstream corrections, turning one local fix into revalidation across the chain and potentially several retraining cycles.

fragile multi-stage pipeline. When accuracy degrades, engineering teams discover that the root failure lies several layers upstream in the original labeling conventions.

Mitigating correction cascades requires balancing component reuse against redesign. While fine-tuning reduces initial compute and data collection costs, training a replacement base model can remove dependencies on a chain of auxiliary corrections, while data and labeling assumptions still require validation. The architectural decision depends on task similarity, covariate alignment, and the ongoing maintenance cost of chained models. Where dependent models are unavoidable, systems must decouple them through version-pinned model artifacts and frozen intermediate representations.

14.2.3 Undeclared consumers and data dependencies

When Model A writes its predictions to a shared warehouse table and Model B later reads that column as a training feature, neither repository's import graph records the connection. Boundary erosion and correction cascades both stem from interface dependencies that bypass formal software contracts. Traditional software dependencies are declared through import statements, package managers, and RPC schemas, allowing static analysis tools to map dependency graphs. In machine learning systems, dependencies hide inside data streams, invisible to static code analysis.

Hidden coupling frequently manifests as **undeclared consumers**, where downstream services consume model predictions without formal registration or service-level agreements. When the upstream model is retrained or its output distribution shifts, these untracked consumers fail silently. For example, a credit risk score consumed by an automated marketing system can alter applicant pools, feeding shifted distributions back into future training runs, so the model increasingly trains on the applicants its own scores favored. This vulnerability is compounded by **data dependency debt**, which accumulates when ML pipelines ingest unversioned tables, unstable upstream features, or signals with volatile distributions. Eliminating this interface debt requires infrastructure-enforced boundaries: strict authentication and registration for model prediction endpoints, machine-readable schema contracts for feature stores, and automated data lineage tracking that registers consumers before granting read access.

14.2.4 Feedback loops and configuration sprawl

As an ML system evolves, even with documented interfaces, the most dangerous dynamic is the feedback loop, where a deployed model shapes the data distribution that trains its successors. In the ranking service, suggested content dictates user engagement, clicks generate subsequent training sets, and the model reinforces its own historical selections while starving unselected content of exposure. In production, this failure mode often surfaces as a widening performance gap across demographic cohorts: underrepresented groups receive worse recommendations, generating sparse engagement logs that further weaken cohort representation in subsequent retraining runs, the self-reinforcing loop that the bias feedback model (principle 13) describes. Detecting feedback loops requires cohort-stratified monitoring that tracks error distributions across user segments rather than relying on aggregate validation metrics.

↪ A worked example that fits the bias feedback factor from two audits and treats fairness as a stability property of the retraining loop is developed in section 15.3.4.

Evolution also degrades the workflows around the model. Over repeated deployment cycles, they accumulate **pipeline and configuration debt**, growing into sprawling collections of ad hoc glue scripts and divergent hyperparameter files. When pipelines lack modular interfaces, teams copy existing scripts rather than refactor brittle data loaders, producing redundant pipelines that process the same raw inputs with subtle inconsistencies. Compounding this, rapid prototyping frequently embeds business logic directly into feature preparation scripts. Controlling pipeline evolution requires workflow orchestration engines with immutable directed acyclic graph (DAG) definitions, strict parameter validation, and configuration versioning managed under the same source control as model code.

14.2.5 Code and architecture debt

Production ML repositories are rarely dominated by model definitions; instead, they fill with **glue code**, the integration wrappers written to shuttle tensors and records between general-purpose ML frameworks, feature pipelines, and low-latency serving engines (Sculley et al. 2015). Sculley et al. (2015) observe that a mature system can end up at most 5 percent machine learning code and at least 95 percent glue code. The proportion varies by system, but the asymmetry explains why integration code, not the model, dominates the maintenance surface. The resulting tight coupling to framework-specific APIs is a maintenance liability, because minor upstream framework updates force extensive rewrites of the surrounding integration scaffolding. Isolating third-party libraries behind stable internal interfaces prevents external API churn from propagating throughout the serving stack.

Rapid experimentation further burdens codebases through **dead experimental codepaths**. Research iterations leave behind legacy branches, alternative feature transforms, and abandoned scoring logic. Unlike traditional dead code that static analyzers flag and compilers prune, experimental ML codepaths often remain executable at runtime because they are guarded by dynamic configuration flags. These dormant branches expand the test matrix, complicate regression verification, and obscure the precise execution graph operating in production. Enforcing deprecation schedules and pruning retired feature flags prevents experimental residue from destabilizing the serving runtime. The same residue accumulates in data as well as code, where a retired feature can keep flowing through the pipeline long after anyone remembers why it exists.

> **Systems Perspective 14.1: Zombie features**
>
> Long-lived production models often accumulate features whose original owners, semantics, or intended use have faded. A feature can be deprecated in application code while still flowing through a feature store, training dataset, or serialized model input contract. The model may learn to ignore it, split signal across a duplicate, or depend on a preprocessing artifact that nobody still owns. Removing such a feature is therefore no longer a local cleanup. It becomes a compatibility change that can affect retraining, serving, monitoring, and downstream analysis.
>
> Features in ML systems do not disappear just because code owners stop thinking about them. Unused feature payload volume D_{vol} inflates serialization overhead and consumes memory bandwidth BW without improving accuracy. Without explicit deprecation policies and feature-store governance, models accumulate "dead code" that degrades D_{vol}/BW and complicates debugging (Sculley et al. 2015).

Underlying both patterns is **abstraction debt**. Traditional software engineering relies on mature abstractions such as objects, interfaces, and modules, whereas ML engineering lacks universal abstractions for concepts such as a feature, a training dataset slice, or a model lifecycle state. Without standardized primitives, teams frequently reinvent bespoke abstractions or abandon encapsulation altogether. Infrastructure components such as feature stores, model registries, and standardized prediction services mitigate this debt by providing uniform abstractions for feature transformation, artifact lineage, and inference routing.

Sculley et al. (2015) also list three system smells that signal mounting debt: the *Plain-Old-Data Type Smell* (passing unvalidated raw floats and string arrays rather than domain types with invariant checks), the *Multiple-Language Smell* (stitching Python, SQL, C++, and shell scripts across the training-

serving boundary), and the *Prototype Smell* (promoting throwaway research notebooks directly into production serving without re-engineering). Treating debt paydown as a routine operational discipline rather than an emergency intervention keeps these code smells from accumulating.

14.2.6 Technical debt in practice

When statistical dependencies, undeclared consumers, and unversioned configurations go unchecked in production, they surface not as compiler warnings but as commercial losses and operational incidents. Examining how those failures unfold in live systems clarifies why code-level testing alone cannot contain them.

14.2.6.1 Production debt patterns

Four documented cases show these patterns in production. The first pair shows coupling through model behavior. YouTube's recommendation system learns from noisy user-behavior signals, so its ranking objectives, per-user weighting, and live A/B evaluation are part of the system design rather than offline details (Covington et al. 2016). Its own rankings shape what users watch, which makes today's recommendations tomorrow's training signal, the feedback loop that evaluation on fixed historical logs can miss. Zillow's iBuying venture exposes the decision-coupling version of a cascade, in which a forecast drives purchases that cannot be undone when the forecast is later corrected (war story 14.1).

War Story 14.1: The Zillow Offers wind-down (2021)

Context: Zillow, a real-estate marketplace, ran Zillow Offers, an iBuying business that bought homes directly on the strength of forecasts of home prices and resale economics (Zillow Group 2021).

Mechanism: The valuation forecast did not remain a prediction. It set purchase prices, purchases became inventory, and inventory carried the forecast's error onto the balance sheet. Zillow reported that it had bought homes at prices above its revised estimates of future selling prices, while resale-capacity constraints delayed some closings (Zillow Group 2021). Revising the forecast corrected the model's view of the market but could not reverse commitments made on the earlier view, so the correction propagated downstream as losses rather than as a repair.

Impact: In November 2021 Zillow announced that it would wind down Zillow Offers, reported a $304 million third-quarter inventory write-down, and cut about 25 percent of its workforce (Zillow Group 2021).

Response: A safer design caps the inventory exposure any one forecast can create, keeps manual override between prediction and purchase, and places circuit breakers that halt purchasing when forecast uncertainty exceeds the accepted risk budget.

Systems lesson: The case does not show a chain of residual-correction models, and retraining alone would not have removed the business risk. It shows the hazard that correction cascades share: a fix applied at one stage cannot undo the state that downstream stages already built on its earlier output. When predictions trigger irreversible actions, the dependency chain runs through the physical world, and the operational controls must sit on that chain.

The second pair exposes coupling through ownership and configuration. In safety-critical driving automation, automated-control outputs, driver expectations, and subsystem responsibilities that are not specified clearly enough let operational failures cross component boundaries rather than stay local (National Transportation Safety Board 2017). Facebook's News Feed iterations show the configuration version of the same problem, in which rapid ranking changes without traceable settings and explicit objectives become hard to audit after deployment (Engineering 2016; Mosseri 2018).

In every case the remedy is structural. Mitigating technical debt requires end-to-end MLOps infrastructure: feature registries that enforce runtime schemas, metadata stores that track model-data lineage, automated CI/CD pipelines that validate statistical properties, and observability platforms that detect distribution shift before silent errors propagate downstream.

Silent interface decay, untracked consumers, and unversioned pipeline dependencies can each make a model unsafe to serve while its offline validation metrics look acceptable. Table 14.6 collects the debt patterns of this section with their root causes, failure symptoms, and mitigation strategies, the catalog of failure modes that a production-readiness rubric must detect.

Table 14.6: Technical Debt Patterns: Machine learning systems accumulate distinct forms of technical debt from data dependencies, model interactions, and evolving operational contexts. Primary debt patterns, their causes, symptoms, and recommended mitigation strategies guide practitioners in recognizing and addressing these challenges systematically.

Debt Pattern	Primary Cause	Key Symptoms	Mitigation Strategies
Boundary Erosion	Tightly coupled components, unclear interfaces	Changes cascade unpredictably, CACE principle violations	Enforce modular interfaces, design for encapsulation
Correction Cascades	Sequential model dependencies, inherited assumptions	Upstream fixes break downstream systems, escalating revisions	Careful reuse vs. redesign trade-offs, clear versioning
Undeclared Consumers	Informal output sharing, untracked dependencies	Silent breakage from model updates, hidden feedback loops	Strict access controls, formal interface contracts, usage monitoring
Data Dependency Debt	Unstable or underutilized data inputs	Model failures from data changes, brittle feature pipelines	Data versioning, lineage tracking, leave-one-out analysis
Feedback Loops	Model outputs influence future training data	Self-reinforcing behavior, hidden performance degradation	Cohort-based monitoring, canary deployments, architectural isolation
Pipeline Debt	Ad hoc workflows, lack of standard interfaces	Fragile execution, duplication, maintenance burden	Modular design, workflow orchestration tools, shared libraries
Configuration Debt	Fragmented settings, poor versioning	Irreproducible results, silent failures, tuning opacity	Version control, validation, structured formats, automation
Prototype Debt	Rapid prototyping shortcuts, tight code-logic coupling	Inflexibility as systems scale, difficult team collaboration	Flexible foundations, intentional debt tracking, planned refactoring

The mitigation column reads as a requirements list for the rest of the chapter. Shared feature definitions, versioned artifacts, and automated pipelines are development infrastructure; cohort monitoring belongs to production monitoring; and the rubric that scores a system against the whole catalog, the ML Test Score, is taken up with operational maturity (section 14.8.1), once the controls it audits have been built. Development infrastructure comes first, because a fault cannot be traced to a boundary that was never versioned.

14.3 Development Infrastructure

When a production model fails an accuracy check, an engineer who cannot recover the exact training dataset, feature transformation code, and container image that produced it can only guess which input changed. Development infrastructure turns the debt patterns diagnosed in section 14.2 into concrete enforcement points. A feature schema that drifts upstream cannot be repaired by a dashboard alone; it needs a shared contract, a versioned artifact, and a deployment path that rejects incompatible changes before they reach production. Table 14.7 maps each component directly to a foundational principle (section 14.1.1) and a specific failure mode. CI/CD pipelines also carry versioned artifacts, but the table assigns them cost-aware automation because the pipeline is where the retraining and promotion gates of equation 14.3 actually execute, automating only the changes that pass them.

Table 14.7: MLOps Infrastructure as Debt Remediation: Each infrastructure component responds to a class of technical debt observed in production ML systems. Feature stores can reduce training-serving skew by reusing feature definitions and values; versioning systems support reproducibility; CI/CD pipelines automate rollout controls; monitoring systems can surface silent degradation before users do.

Infrastructure Component	Principle Implemented	Debt Pattern Addressed
Feature stores	Consistency	Data dependency debt, training-serving skew
Versioning systems	Reproducibility	Configuration debt, correction cascades
CI/CD pipelines	Cost-aware automation	Pipeline debt, boundary erosion
Monitoring systems	Observable degradation	Feedback loops, silent failures

These operational components sit between the framework and the hardware and track what neither of them tracks, the data lineage and the cluster state. MLOps occupies the middle of the five-tier stack of figure 14.5 (ML models, frameworks, orchestration, infrastructure, and hardware). Model orchestration, which runs from data management to serving, and operational infrastructure, which runs from job scheduling to monitoring, together bridge mathematical frameworks and physical accelerator clusters and enforce the remediations of table 14.7. The tiers say *where* a component sits in the implementation stack, while the four layers of table 14.3 say *who* owns an operational responsibility; the rest of the chapter reasons with the layers and the three interfaces.

Inside the orchestration and infrastructure tiers, four architectural mechanisms execute these operational responsibilities. At the data boundary, a feature storage and retrieval layer serves a unified schema across two disparate access patterns: high-throughput analytical scans over immutable columnar files for offline training, and low-latency point lookups against key-value stores for online serving (section 14.3.1.1). To keep every transformation and checkpoint traceable, an artifact and lineage store records content-addressed hashes for dataset snapshots, code commits, container images, and model weights so that any live prediction can be audited back to its exact training inputs (section 14.3.1.2). Workflow orchestration then sequences the pipeline stages, from ingestion and validation through training and evaluation, as declared dependency graphs with retry semantics and automated triggers (section 14.3.2.1), while a compute runtime underneath schedules accelerator hardware, host memory, and processor cores across training jobs and serving endpoints under strict resource isolation (section 14.3.2.2). Specific frameworks implement pieces of this decomposition, but the underlying mechanisms and interface boundaries outlast any particular tool.

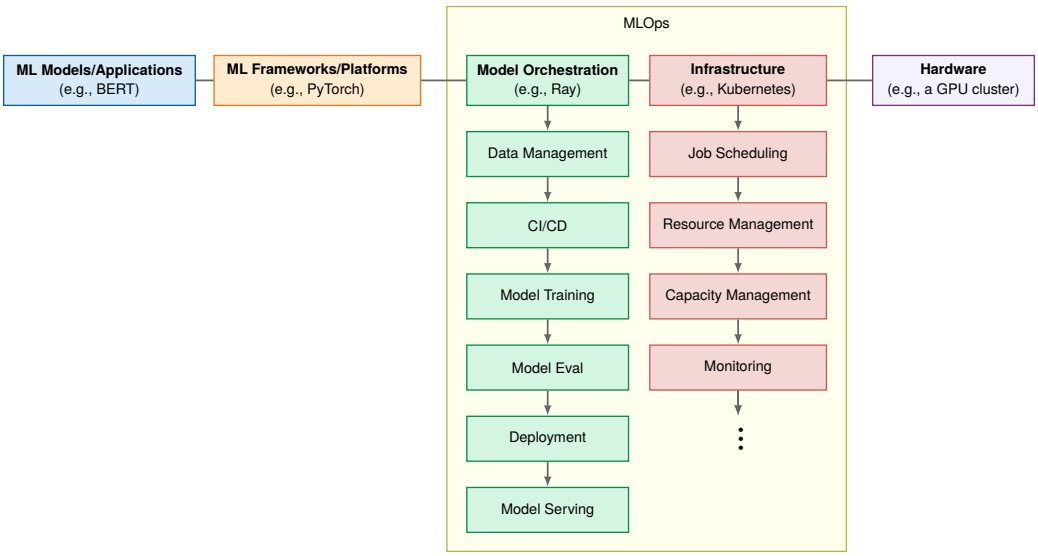

Figure 14.5: MLOps Stack Layers: Five columns organize the ML system stack: ML Models/Applications, ML Frameworks/Platforms, Model Orchestration, Infrastructure, and Hardware. MLOps spans orchestration tasks from data management through model serving and infrastructure tasks from job scheduling through monitoring, supporting automation, reproducibility, and scalable deployment.

14.3.1 Data infrastructure and preparation

If the offline training pipeline reads a backfilled warehouse table while the online serving path reads a live event stream with different null defaults, the deployed model evaluates inputs it never learned to score. Machine learning technical debt stems largely from unmanaged data boundaries: unversioned datasets erode system boundaries, inconsistent feature computation triggers correction cascades, and undocumented data dependencies create hidden downstream consumers. Data engineering built the collection, preprocessing, and feature-transformation pipelines, together with the validation and dataset versioning that make one pipeline correct and reproducible. Operations turns those pipelines into versioned interfaces that it enforces across every pipeline touching a model. Where data engineering optimizes single-pipeline correctness and ingestion throughput, MLOps data management governs cross-pipeline consistency, ensuring that offline training and online serving compute identical features.

Operations holds those interfaces to three properties: consistency, freshness, and quality. Consistency requires every artifact that influences model behavior, from raw records to engineered feature tables, to remain addressable by version, so that a checkpoint can be traced to the dataset snapshot that produced it (section 14.3.1.2), and requires training and serving to share one feature definition (section 14.3.1.1), with content-addressed dataset versioning tools such as DVC (Iterative 2024) supplying the first half of that guarantee. Because consistent definitions still degrade if inputs arrive late, freshness requires scheduled pipelines, declared in workflow orchestrators such as Apache Airflow (Apache Software Foundation 2024), to deliver current data on a known cadence so that a late run becomes a visible failure rather than a stale feature. Even timely, versioned pipelines can ingest corrupted values, so quality requires the validation checks of section 4.5.3 to run as gates that reject a corrupted batch before it reaches training or serving, while annotation platforms such as Label Studio (HumanSignal 2024) keep label corrections under version history.

↩ The collection, preprocessing, and feature-transformation pipelines that MLOps formalizes are established in chapter 4.

On the ranking service, the three properties operate in concert. Click and session events are ingested and joined with the item catalog through a scheduled pipeline (freshness). The resulting features, such as session length and rolling click rates, are stored in a feature store for both offline retraining and low-latency online lookup (consistency). Schema validation, range checks, missingness tests, and label audits reject corrupted event records before they enter the training set (quality), while dataset versioning and model-registry integration maintain traceability from raw event logs to deployed predictions.

14.3.1.1 Feature stores

The data dependency debt and training-serving skew analyzed in section 14.2 share a common root cause, inconsistent feature computation across pipeline stages. Without a unified feature layer, feature definitions are typically implemented twice: on the ranking service, a data scientist computes `user_session_length` in Python using batch aggregations over historical logs, whereas a systems engineer reimplements the calculation in Java or C++ to satisfy real-time serving latencies. Because one implementation measures wall-clock time between raw events while the other tracks server processing time and filters idle timeouts, the model trains on one definition and serves with another, degrading accuracy silently in production. Feature stores[6] address this divergence by providing an abstraction layer between data engineering and machine learning, implementing the consistency imperative through a single source of truth for feature transformations. In pipelines lacking this abstraction, duplicated feature logic across environments introduces training-serving skew, temporal data leakage, and distribution drift.

Feature stores resolve the tension between batch throughput and online latency by keeping two synchronized storage tiers behind one API, an offline store for high-throughput training scans and an online store for point lookups under a tail-latency service-level objective (SLO), both reading from the same versioned transformation logic. Historical retrieval must also be point-in-time correct, so that each training example sees only the feature values that existed at its observation time. Section 4.7.5 develops both mechanisms, including the as-of join that enforces point-in-time correctness. Operations depends on them because a ranking model trained on leaked features looks excellent offline and fails on live traffic.

Beyond consistency, feature stores support versioning, metadata management, and feature reuse across models. A ranking model and a fraud model built on the same user activity frequently

6 **Feature store**: Uber's Michelangelo platform described a centralized feature store for sharing and serving features across production models (Hermann and Del Balso 2017). At that scale, the consistency guarantee must hold under an online latency budget. A feature store differs from a shared library of feature code because its shared feature path must also serve fresh features fast enough for real-time inference.

↩ Training-serving skew, a violation of the consistency imperative, is established in section 4.7.1.

depend on overlapping features that can be centrally maintained, validated, and shared. Integration with data pipelines and model registries preserves lineage. When an upstream feature definition is updated or deprecated, downstream models can be automatically identified and scheduled for retraining.

Training-serving skew: Diagnosis and prevention Training-serving skew manifests operationally through feature store inconsistencies and pipeline divergence. Table 14.8 summarizes common causes and their detection methods:

Table 14.8: Training-Serving Skew Categories: Each category requires different detection and prevention strategies. Preprocessing and missing-data skew emerge from divergent transformation code and require parity validation, which shared feature logic, including a feature store where appropriate, can reduce. Time-dependent features need timestamp checks that both paths apply the same cutoff, and library version drift needs environment comparison because identical code can compute different values under different library versions.

Skew Type	Example	Detection Method
Feature preprocessing	Normalization uses different statistics	Same-input replay and value comparison
Missing data handling	Training fills NaN with mean; serving uses 0	Schema validation with explicit null handling
Time-dependent features	Features computed with different time cutoffs	Timestamp validation in feature pipelines
Library version drift	NumPy or Pandas version differences	Environment hash comparison

Training-serving skew case study The ranking service shows how feature divergence manifests in deployment. After a later release of the serving path, the model loses 8 percent of its accuracy despite zero alterations to model code or weights. Comparing feature distributions reveals that `user_session_length` has an empirical mean of 45 minutes in the training set but only 12 minutes in online inference. That difference starts the investigation; different user populations could produce it even with identical feature logic. Replaying the same recorded sessions through the versioned training and serving transformations, with the same available events and cutoff, reveals different durations for the same requests. Inspection of those artifacts then identifies feature-definition skew. The offline training pipeline calculated wall-clock duration from the initial event to the final event in a session, whereas the online serving path counted only foreground-active time after filtering idle periods. The model learned decision boundaries against a feature distribution that the serving infrastructure never delivers.

Feature stores resolve this discrepancy by centralizing feature logic into a single versioned definition, extending upstream data pipelines. In listing 14.1, training materializes historical features with point-in-time correctness, serving performs real-time point lookups, and both pipelines bind to the identical versioned definition hash rather than independent code paths.

Listing 14.1: Feature Store Consistency: Unified retrieval reduces training-serving skew by sharing versioned feature definitions across both pipelines.

```
feature_definitions = registry.load(version="2026-06-01")

training_features = feature_definitions.materialize_historical(
    entities=training_entities,
    at_event_time=True,
    names=["user.session_length", "user.purchase_history"],
)

serving_features = feature_definitions.lookup_online(
    entities=[{"user_id": 12345}],
    names=["user.session_length", "user.purchase_history"],
)

assert training_features.schema == serving_features.schema
assert (
    training_features.definition_hash
    == serving_features.definition_hash
)
```

By centralizing the definition of `session_length`, both offline and online pipelines execute identical transformation logic, though automated integration tests must still verify value parity. Centralized registries also record metadata and lineage, enabling rapid diagnosis when feature definitions evolve (Hermann and Del Balso 2017; Gojek and Google 2019).

The consistency imperative (section 14.1.1.3) put a number on this failure. A 1 percent skew error rate on 1,000,000 queries/day already costs $365,000 a year, while the `user_session_length` divergence above produced an 8 percent accuracy degradation. Centralized feature stores amortize the engineering cost of this infrastructure across multiple models and services, translating architectural consistency into measurable operational savings.

Skew detection in CI/CD Continuous integration pipelines must validate feature consistency before deployment. A parity test replays recorded inputs through the versioned training and serving transformations, aligns results by request identifier, and compares each feature using its declared semantics and numerical tolerance. Both paths must receive the same events available at the prediction cutoff; otherwise the test confounds implementation differences with differences in information. For a duration feature, the contract specifies the time unit and whether idle periods count. Categorical values and missingness must agree exactly; floating-point values may use a feature-specific tolerance.

A small counterexample shows why distributions cannot replace this check. Suppose the training transformation returns session durations of 12 and 45 minutes for requests A and B, respectively, while serving returns 45 and 12 minutes for those same requests. The marginal distributions are identical, so a KS comparison finds no difference, but request-keyed comparison detects both mismatches. Conversely, a new population of shorter sessions can shift the marginal distribution while both paths still agree for every replayed request. Point-in-time correctness remains a separate requirement; agreeing paths can both use information unavailable at prediction time.

Listing 14.2 supplies a complementary distribution screen using the two-sample Kolmogorov-Smirnov (KS) test that the data pipeline already uses to watch for drift (section 4.5.3). The KS statistic is the largest vertical gap between the empirical cumulative distribution functions (eCDFs) of the training and serving samples. Setting the threshold to 0.1 asserts that cumulative probabilities do not diverge by more than 10 percentage points at any value across the feature's support. In this illustrative release policy, exceeding the threshold pauses promotion for review rather than diagnosing skew. The threshold must be calibrated against sample size and feature sensitivity. Passing the screen establishes only limited marginal divergence at that threshold; it does not establish per-request parity.

Listing 14.2: Feature Distribution Screen: This function compares training and serving feature distributions using the Kolmogorov-Smirnov test, pausing promotion for review under an illustrative threshold policy.

```
def screen_feature_distributions(
    training_features, serving_features, threshold=0.1
):
    """Pause promotion for review if distributions diverge."""
    for feature in training_features.columns:
        ks_stat = ks_2samp(
            training_features[feature], serving_features[feature]
        )
        if ks_stat.statistic > threshold:
            raise DistributionReviewRequired(
                f"{feature}: KS={ks_stat.statistic:.3f}"
            )
```

14.3.1.2 Versioning and lineage

Lineage tracking and versioning implement the reproducibility principle formalized in section 14.1.1. Software artifact provenance already depends on source code, build tools, dependencies, and configuration. In machine learning systems, model behavior is the joint product of code, hyperparameter configuration, and the training dataset snapshot. Changing any single dependency produces an

entirely distinct model artifact. Each artifact gets a content hash, so any model can be traced to its inputs.

Data versioning addresses dataset mutability by retaining raw data snapshots and intermediate feature tables under content-addressable hashes, so the recorded inputs to historical runs remain retrievable. Hashes identify artifacts but cannot reconstruct missing content or remove execution nondeterminism. Model versioning registers trained weights as immutable artifacts alongside training hyperparameters, evaluation metrics, and environment dependency manifests. A **model registry**[7] is the store that holds these immutable artifacts under lifecycle states (such as staging, production, or retired) and exposes lineage graphs tracing the complete dependency chain from raw ingested records to deployed prediction endpoints (MLflow Project 2026; Google Cloud 2024).

The registry is also what lets the release machinery promote, hold, or roll back the exact artifact that was evaluated. It stores immutable version tags, links evaluation metrics to artifact hashes, and governs which checkpoint each serving tier runs (Google Cloud 2024). This distinguishes a registry from an exploratory model catalog, which indexes candidate architectures for experimentation; a model enters the registry only when it becomes a versioned candidate for deployment. Experiment tracking frameworks such as MLflow[8] (Databricks 2024) and unified distributed runtimes such as Ray[9] record the surrounding execution state, training parameters, and lineage. Together, registry governance and lineage tracking turn experimental validation into controlled release, so a tested candidate can be promoted to production, monitored under live traffic, and reversed without losing provenance.

These mechanisms construct the lineage graph of the machine learning system. This graph establishes the audit trail required to diagnose production failures: determining whether an incoming request distribution diverged from training baselines, whether upstream feature calculations changed, or whether the serving environment loaded an unvalidated weight checkpoint. By recording provenance as a required, queryable artifact, systems engineering gives incident triage a verifiable record against which to test root-cause hypotheses.

14.3.2 Continuous pipelines and automation

Feature stores and versioning systems lock down data and artifact consistency at a single point in time, whereas production models must repeat preprocessing, training, evaluation, and release without an engineer running scripts by hand and risking a skipped validation check or a mismatched dataset path. Continuous automation binds those static controls into integrated workflows that respond to new data, shifting objectives, and operational constraints (Orr et al. 2021; Google Cloud 2026a).

14.3.2.1 CI/CD pipelines

CI/CD pipelines carry that consistency from the *data* side to the *process* side, ensuring that changes flow through validated stages rather than ad hoc deployments. ML CI/CD pipelines must handle complexity absent from traditional software: data dependencies, model training workflows, and artifact versioning that couple code changes to statistical behavior changes.

A typical ML CI/CD pipeline consists of coordinated stages: checking out updated code, preprocessing input data, training a candidate model, validating performance, packaging the model, and deploying to a serving environment. In some cases, pipelines also include triggers for automatic retraining based on data drift or performance degradation. By codifying these steps, CI/CD pipelines[10] reduce manual intervention, enforce quality checks, and support continuous improvement of deployed systems.

ML-focused CI/CD layers two tiers of tooling for one reason. A general-purpose CI/CD orchestrator (GitHub Actions (GitHub, Inc. 2024b), for example) manages version-control events and execution logic, but the ML layer must additionally version data, gate on model metrics, and trigger retraining. Teams therefore add an ML platform or workflow orchestrator (Kubeflow (Authors 2024), for example) that supplies higher-level abstractions for those tasks.

Without this automation, model deployment degrades into a manual, error-prone process in which an engineer retrains locally, copies artifacts to a staging server, and promotes to production with no guarantee that the data, code, or hyperparameters match what was validated. The cost of such ad hoc workflows compounds with team size and deployment frequency, producing configuration drift and silent regressions that surface only after the model has served incorrect predictions.

[7] **Model registry**: Prevents "registry bypass," the failure mode where the undocumented production model diverges from the trained artifact through different preprocessing, stale serialization formats, or manual hotfixes applied directly to the serving endpoint. Without a registry enforcing versioned, immutable artifacts with queryable metadata and state, rollbacks require locating the correct weights from an ad hoc artifact store under incident pressure.

[8] **MLflow**: An open-source MLOps framework that couples artifact storage (S3/GCS) with metadata DBs (PostgreSQL) to record hyperparameter runs, model binary hashes, and deployment stage transitions. The systems trade-off is centralizing lineage tracking vs. incurring database connection bottlenecks during massive parallel hyperparameter sweeps.

[9] **Ray**: A distributed computing framework from UC Berkeley (Moritz et al. 2018) that provides a unified task and actor interface, backed by a distributed scheduler and fault-tolerant store. The broader MLOps lesson is that fragmented infrastructure creates translation points where preprocessing logic, normalization constants, tokenizer versions, or artifact formats can diverge silently. Shared execution abstractions can reduce that fragmentation, but training-serving skew still requires explicit consistency checks across data, features, and serving code.

A continuous training pipeline runs seven sequential stages, from dataset ingestion, data validation, and data transformation through training, evaluation, validation, and registry promotion (figure 14.6). Driven by dedicated processing, training, and evaluation engines beneath the pipeline, the workflow coordinates with surrounding dataset, model, and metadata repositories whenever an external trigger initiates retraining.

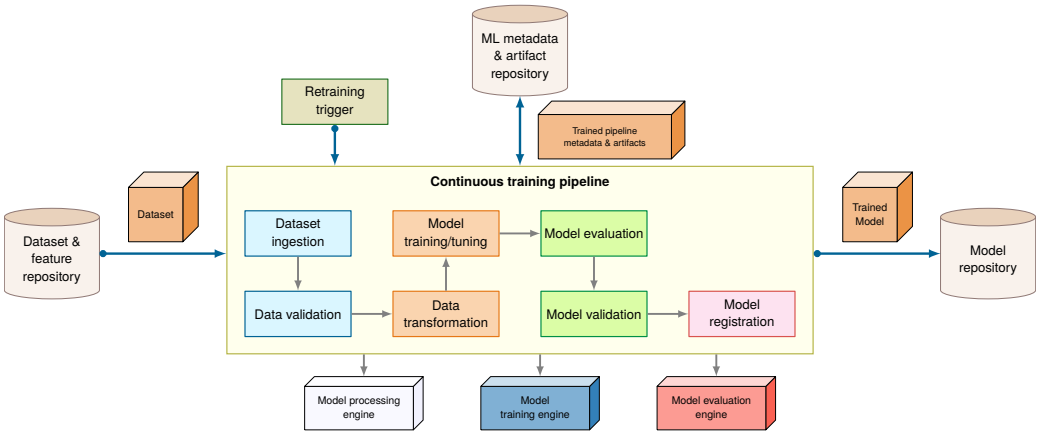

Figure 14.6: ML CI/CD Pipeline: Read the enclosed stages in execution order; the retraining trigger starts a new run, while connected repositories preserve the dataset, model, metadata, and artifacts needed to reproduce and govern it. Adapted from Google Cloud's MLOps continuous delivery and automation pipeline guidance (Google Cloud 2026a).

Consider the ranking model under active development. When a developer commits code changes, the CI pipeline pulls the specified dataset version, performs feature preprocessing, and initiates model training. Experiments are tracked in a registry such as MLflow (Databricks 2024), which logs loss curves and registers model artifacts. After passing automated offline validation, the model is containerized and deployed to a staging cluster. If the candidate satisfies staging validation, the pipeline executes a canary rollout (section 14.4.3), gradually shifting production query traffic to the new model while monitoring inference latency and error rates. If a performance regression emerges, traffic automatically rolls back to the previous model checkpoint.

CI/CD becomes foundational when systems release models repeatedly or carry meaningful production risk, turning ad hoc experimentation into structured, repeatable deployment. Scaling beyond one pipeline requires reusable components and explicitly specified artifact schemas.

> Example 14.1: Google TFX production ML pipelines
>
> **Scenario**: Google's production experience motivated TensorFlow Extended (TFX), a set of reusable components for production ML pipelines (Baylor et al. 2017). As pipelines multiply, ad hoc handoffs make validation, lineage, and reproducibility difficult.
>
> **Diagnosis**: Each stage needs explicit validation and metadata so a deployed model can be traced to the data, transformations, code, and evaluation that produced it.
>
> **Systems lesson**: Directed acyclic graph orchestration alone does not establish reproducibility. Standardized components and ML Metadata (MLMD), a store that records the inputs and outputs of every pipeline component run, preserve lineage through recorded inputs and transformations.

14.3.2.2 Training pipelines

CI/CD pipelines orchestrate the overall workflow, but training itself requires specialized compute infrastructure. Model training builds on the single-node parallel execution primitives that training systems already provide. Within MLOps, training activities become components of a reproducible pipeline supporting continual experimentation and production deployment.

[10] **Idempotency**: This property ensures that retrying a pipeline stage does not create duplicate externally visible effects, conflicting registrations, or repeated deployment actions. Producing identical models from identical inputs is a separate property (determinism and reproducibility), and the `training` stage may violate it due to randomness such as weight initialization. Production systems therefore combine stable run identifiers and atomic publication for idempotency with fixed random seeds, deterministic kernels, fixed library versions, and controlled data ordering for reproducibility.

↩ The single-node data- and model-parallel execution that training pipelines schedule is established in section 8.7.1.

Frameworks such as TensorFlow (Martín Abadi et al. 2016), PyTorch (Paszke et al. 2019), and Keras (Chollet et al. 2024) supply modular components for model architectures and optimization routines. Operational discipline determines which exploratory training routines graduate into versioned, tested retraining jobs, and under what execution triggers.

↩ The criteria for selecting a framework are established in section 7.9.1.

Training scripts and environment configurations are version-controlled with Git (Torvalds and Hamano 2024) and hosted on GitHub (GitHub, Inc. 2024a). Interactive Jupyter (Project Jupyter 2024) notebooks accelerate prototyping by coupling code, inline visualizations, and execution state, but running them unaltered in production pipelines introduces severe operational liabilities.

Notebooks in production Automated CI/CD pipelines assume deterministic and reproducible code execution, but Jupyter notebooks violate this assumption through persistent kernel state. In an interactive session, cells can be executed out of linear order, creating hidden memory dependencies that cannot be reproduced from a clean interpreter restart. A common production failure occurs when development relies on cells executed in sequence 1-3-2; a scheduled batch runner executing top-to-bottom (1-2-3) fails due to undefined variables or altered intermediate tensors.

Testing difficulties compound this state vulnerability. Standard unit-testing harnesses and mocking frameworks do not interface cleanly with interactive notebook documents. Cell-level assertions are rarely parameterized or wired into test runners, leaving notebooks significantly less tested than modular Python code.

Two tools help. Papermill enables parameterization and headless execution of notebooks, injecting runtime configurations and executing cells top-to-bottom as discrete pipeline stages (Papermill Project 2026). The nbconvert tool converts validated notebooks into static executable Python scripts for production environments (Project Jupyter 2026), exposing exported code to linters and CI test runners. Teams must still select or refactor exploratory cells and verify clean, ordered execution.

Extracting code from notebooks into tested modules introduces refactoring overhead, but it prevents hidden state assumptions from causing training-serving skew in production, a silent failure whose cost grows with every day it goes undetected, as the silent-failure calculation in the monitoring discussion shows (notebook 14.3).

Modular training logic also allows a pipeline to schedule repeatable experiments within the node's resource budget. Concurrent runs compete for accelerator memory, host preprocessing capacity, and storage bandwidth; enforcing resource limits recorded alongside each run's configuration keeps experiments within the capacity reserved for them. If execution can be interrupted, checkpoint-and-resume (section 8.4.5) preserves completed training work without requiring the entire run to restart.

How often to run this pipeline depends on evidence that only production monitoring supplies, so section 14.6 takes up the decision after monitoring. A pipeline that can run on demand still produces only candidates, and validation decides which of them may ship.

14.3.2.3 Model validation

Training pipelines produce model candidates; model validation determines which candidates merit production deployment. Unlike research evaluation, where a model that beats a benchmark on a static test set may be considered successful, production validation must assess operational readiness under representative conditions and establish the monitoring and rollback controls needed after the distribution changes. This is where MLOps manages the verification gap (principle 9) rather than closing it. No test suite covers the deployment population, so validation keeps re-estimating performance as that population changes.

The evaluation process begins with performance testing against a holdout test set sampled to represent the current production population and refreshed as that population changes. Core metrics such as accuracy, AUC, precision, recall, and F1 score (Rainio et al. 2024) are computed and tracked longitudinally to detect degradation from data drift (IBM 2024), the shift of the input distribution away from the one the model trained on. Section 14.5.2 shows how such drift appears in live telemetry.

Beyond static evaluation, production pipelines expose candidate weights to live traffic in controlled stages (shadow, canary, and blue-green deployment) while bounding the blast radius, and section 14.4.3 develops each. Validation defines the evidence every stage must produce before a candidate advances. Evaluating candidates under identical operational conditions is the prerequisite

for a sound promotion decision; a candidate that shows apparent metric gains simply because it was evaluated against a differing traffic slice or temporal window confounds model quality with data variance. Cloud ML platforms support controlled evaluation through request replay, shadow serving, and synthetic load testing. The comparison must also be recorded: experiment trackers such as Weights & Biases (Weights & Biases, Inc. 2024) log the data slice, time window, configuration, and metrics used for each candidate, so a promotion decision can be audited and repeated under the same conditions.

While automated validation gates protect against regressions on primary aggregate metrics, production validation also requires auditing slices and long-tail behavior. Automated test suites often mask severe performance drops on underrepresented subpopulations or safety-critical edge cases. Production architectures combine automated gating with policy reviews, particularly for models deployed in regulated domains. This multi-stage validation discipline bridges offline evaluation with live production monitoring, ensuring that candidate models satisfy accuracy, latency, and safety invariants before receiving unconstrained serving traffic.

14.3.3 Infrastructure integration

A versioned model checkpoint is still unsafe to deploy if the serving cluster runs a different feature definition or lacks a tested path back to the previous weights. Development infrastructure locks these pieces together across two of the three critical system interfaces: feature stores and data versioning reduce inconsistency at the data-model interface by centralizing and tracking feature access across training and serving, while CI/CD pipelines, model registries, and validation gates stabilize the model-infrastructure interface by automating the transition from trained weights to containerized services with rollback capability. Together, these controls prepare an artifact for release; the third interface, production monitoring, closes the operational loop by tracking whether predictive quality holds as inputs and operating conditions change, though the release must come first.

14.4 Releasing Models

A model that passes every offline gate has still not made a single production decision. Between the validated checkpoint and the first user-facing prediction lie packaging, conversion to a serving runtime, staged exposure to live traffic, and a path back if the new version misbehaves, and at each step the artifact users see can drift from the artifact that was evaluated. Deployment transforms a static checkpoint into a versioned, reproducible execution artifact. Serving then allocates accelerator memory, stages input batches, and schedules compute kernels to satisfy latency SLOs under dynamic request loads. Operations owns the seams between the two: proving that what ships is what was validated, limiting how much traffic a bad version can reach, and keeping rollback fast enough to use. On the ranking service each of those seams also costs memory, because any control that keeps two versions alive must hold two copies of the embedding tables.

14.4.1 Infrastructure as code

Holding two copies of the ranking tables across a staged release only works if staging and production provision the same accelerator hardware, memory limits, and scaling quotas. When teams manage clusters through manual commands or tickets instead of code, environments drift apart: a model that passed staging fails in production because an operator provisioned a different GPU type, a training job crashes because a colleague's experiment exhausted shared memory, or an inference service fails to scale because its resource quotas were set in an informal message six months earlier.

Infrastructure as code (IaC) treats infrastructure configuration as software (version-controlled, reviewed, tested, and automatically executed) rather than something configured through graphical interfaces or command-line tools. Changes are tracked, configurations can be tested before deployment, and environments can be reliably reproduced.

The specific tool matters less than the property it enforces. Infrastructure-as-code tools such as Terraform (HashiCorp 2014) version infrastructure definitions alongside application code, so a team can reproduce the accelerator type, network policy, storage permissions, and scaling limits of a training or serving environment on any cloud provider or on-premises hardware, and can audit and test those definitions in the same CI/CD pipelines as the model. Containerization provides the same reproducibility boundary for runtime dependencies. Docker (Merkel 2014) packages the model,

libraries, and serving code into an isolated unit, and orchestration systems such as Kubernetes (Cloud Native Computing Foundation 2024a) deploy that unit repeatedly while keeping resource allocation, scaling, and health management explicit.

To absorb spikes during hyperparameter tuning and surges in prediction traffic, teams use autoscaling[11] (Amazon Web Services 2024b), which adjusts compute capacity from usage metrics to balance performance and cost. The same infrastructure definitions must also cover on-premises and edge targets when latency, privacy, or regulation keeps part of a deployment off the cloud.

Infrastructure as code addresses how to provision resources reproducibly, but operators must still decide when and how much capacity to allocate. ML workloads break the assumptions of conventional web provisioning. Training jobs demand high-concurrency bursts across distributed accelerator topologies, creating friction between cluster utilization efficiency and time-to-solution. Inference services require sustained baseline allocations with rapid elastic scale-out to absorb request spikes under strict tail-latency SLOs. The utilization targets in section 14.5.1.1 turn these competing demands into measurable provisioning goals.

11 **ML autoscaling**: Autoscaling adjusts capacity based on demand signals (Amazon Web Services 2024b), but ML serving adds constraints absent from stateless web services. Autoscaling decisions must account for model loading time (cold-start overhead), GPU memory fragmentation, and batching behavior in addition to CPU utilization. Scaling up too slowly violates latency SLOs; scaling down too aggressively forces repeated cold starts that degrade p99 latency.

14.4.2 Validating the serving artifact

The artifact that reaches the serving fleet is rarely the checkpoint that passed evaluation. Before deployment, the model is usually compiled from eager framework code into a static graph for a specific runtime and often lowered in precision. Each conversion trades portability for speed, and each can change what the model computes, so the operational obligation is to prove that the converted artifact still behaves like the model that was validated.

↩ Inference runtimes and the precision choices they support for serving are established in section 13.6.

That proof must target the failure modes that conversion introduces silently. Consider a team that deploys an INT8-quantized model after verifying only throughput improvement. Classification accuracy drops on rare but high-value edge cases, and the degradation goes undetected for weeks because aggregate metrics remain within SLO bounds. The first validation layer is numerical equivalence, comparing optimized outputs against the original model on a representative test set with application-specific divergence thresholds. That check is necessary but insufficient, because a static calibration slice is not live traffic. Rare inputs, out-of-distribution examples, and subgroup-specific cases can expose quantization artifacts that aggregate test metrics hide, so the comparison must be disaggregated by the same cohorts that production monitoring tracks (section 14.5).

The second layer is operational validation. Memory footprint must be measured at peak runtime utilization, including dynamic allocations during inference, since some optimizations trade increased runtime memory for computational speed. Warm-up behavior varies by runtime: Accelerated Linear Algebra (XLA) may JIT-compile kernels during initial execution, whereas TensorRT selects tactics and builds an engine before deployment; loading that engine can still add startup latency. Runtime version compatibility then closes the loop. Deployment configurations need explicit version pinning, because even a minor runtime upgrade can change kernel selection, and with it both latency and numerical results, in an artifact whose weights never changed. An unpinned runtime is an untracked input to equation 14.1.

14.4.3 Model deployment

Consider a new version of the ranking model that beats its predecessor offline. An engineer exports the weights, copies them to a production server, and discovers that the model scores nearly every item the same, because the production server runs a different version of the feature extraction library and produces inputs the model has never seen. This scenario illustrates why deployment is a systems engineering problem rather than a simple file transfer. Packaging, testing, and tracking ML models for reliable production deployment requires treating the model weights, runtime dependencies, and preprocessing configuration as a single deployable unit. Containerizing the model artifact and serving runtime[12] packages user-space dependencies, runtime libraries, and environment variables into an immutable image, enforcing environment parity between development and cluster nodes.

Production deployment requires frameworks that handle model packaging, versioning, and integration with serving infrastructure. Tools like MLflow and model registries manage these deployment artifacts (A. Chen et al. 2020), while serving-specific frameworks handle the runtime optimization and scaling requirements. Before full-scale rollout, teams deploy updated models to staging or QA environments[13] to rigorously test performance.

12 **Containerization for ML deployment**: Docker (Merkel 2014) packages code with dependencies into portable units; Kubernetes (Burns et al. 2016) orchestrates those units across clusters. Containerization addresses the Environment_v term in equation 14.1 partially by capturing user-space dependencies as a versioned artifact; host kernels, drivers, and hardware remain external dependencies.

13 **Staging validation**: ML staging adds statistical quality checks to conventional functional and operational validation. A model can pass unit tests and still fail in production because the test data does not reflect the deployment distribution, so rollout gates must compare prediction statistics, evaluation slices, and business guardrails against calibrated thresholds rather than rely on unit tests alone.

A **staged rollout** carries that staging validation into live traffic in steps, widening a candidate's exposure only after the previous step shows no regression. Three release strategies put it into practice. **Shadow deployments**[14] duplicate live production traffic asynchronously to a candidate model without returning its inferences to users, enabling latency and output comparison without direct user exposure; accuracy still requires labels or another ground-truth reference. **Canary deployments**[15] route a small share of user traffic to the candidate and keep ramping that share toward full traffic as long as no regression appears under live load. **Blue-green deployments**[16] maintain parallel environments for router-level cutover and rapid rollback. Each strategy reduces a different release risk, but none removes the need for tested rollback procedures and production monitoring.

Release carries the canary stage of that staged rollout onto live traffic (Fowler 2014). During the limited rollout, telemetry pipelines monitor inference latency, system stability, and prediction distributions. On the ranking service, a candidate receives 5 percent of live queries while the team compares click-through rate, p99 latency, and prediction drift against the baseline model. Only after the candidate demonstrates statistical stability without latency regressions is it promoted to serve full production traffic.

> War Story 14.2: The Knight Capital error (2012)
>
> **Context**: Knight Capital Group was a major market maker in US equities handling over 17 percent of NYSE volume. In August 2012, an operational deployment updated SMARS, the firm's automated order-routing software, on seven of eight production servers but omitted the eighth (U.S. Securities and Exchange Commission 2013).
>
> **Mechanism**: The deployment repurposed a binary feature flag that, on the un-updated eighth server, activated Power Peg, an obsolete order-handling routine that had been left in the code. The stale server entered an un-throttled loop, transmitting parent order requests at $\sim 1{,}400$ orders/sec.
>
> **Impact**: In 45 minutes, the router executed over 4 million unauthorized transactions covering more than 397 million shares, incurring a $460 million loss. The firm survived only on emergency rescue financing raised days later, and lost its independence in an acquisition within months.
>
> **Response**: The incident motivates verifying that every production node runs the intended version before it receives traffic, explicit feature-flag lifecycle controls, and circuit breakers that limit the damage a faulty release can cause.
>
> **Systems lesson**: One server running the wrong version was enough to cause a $460 million loss. ML deployments share this vulnerability: a model registry version mismatch, un-synchronized feature schemas, or partial canary routing can flood production with corrupted inference requests before telemetry alerts fire.

Knight Capital shows why every node must be verified to run the intended version before traffic reaches it. Staged rollouts add a complementary protection by limiting how much traffic a bad version sees, but they can also expose load-dependent behavior. When canary deployments reveal anomalies at elevated traffic shares (such as memory exhaustion, queue spillover, or p99 tail latency inflation appearing at 30 percent traffic that remained undetectable at 5 percent), isolation requires systematic debugging across the stack. Effective diagnosis requires correlating multiple signals: performance benchmarking metrics, data distribution analysis to detect drift, and feature importance shifts that might explain degradation. Teams maintain debug toolkits including A/B test analysis frameworks, feature attribution tools, and data slice analyzers that identify which subpopulations are experiencing degraded performance. That diagnosis loop must connect directly to the release pipeline, because CI/CD integration automates deployment and rollback only when rollback is designed as part of the rollout mechanism rather than treated as an emergency script.

14.4.3.1 Rollback strategies and safety mechanisms

Without reliable rollback[17] capability, teams become deployment-averse and slow their iteration

[14] **Shadow deployment**: Economically justified when its expected reduction in rollout loss exceeds the cost of shadow infrastructure for duplicated inference without serving results.

[15] **Canary deployment**: The ML-specific challenge is that a "failure" is statistical degradation, not a deterministic crash: detecting a small accuracy difference with high confidence can require thousands of inferences, creating a tension between decision speed and statistical power that determines minimum canary duration.

[16] **Blue-green deployment**: Maintains two comparable production environments, "blue" (serving current traffic) and "green" (running the candidate), then switches traffic in a routing change once the green environment passes validation. Because rollback is a traffic flip rather than a staged drain, recovery can be faster than a gradual canary for stateless services. The trade-off is extra infrastructure during the switch, so blue-green wins over canary when brief duplicate capacity is acceptable and per-segment statistical validation is expensive.

↩ Staged rollout as the lifecycle's last validation gate, extending offline evaluation to live traffic, is established in section 3.8.2.

[17] **Rollback (from database transaction management)**: This "undo" action for deployments is complicated in ML by model-dependent state (for example, cached embeddings), which may be incompatible between model versions. This mismatch can prolong recovery and contribute to deployment aversion and slower iteration.

velocity, so effective rollback plans for three distinct scenarios. The fastest tier, **immediate rollback**, addresses critical failures detected right after deployment, such as serving errors, latency spikes, or obvious prediction failures, keeping the previous model version loaded and warm to switch traffic without cold-start delay. **Rapid rollback** handles performance degradation detected through canary metrics soon after deployment and relies on model registry integration to redeploy previous versions with minimal configuration changes. Once a release has ramped to full traffic, **delayed rollback** addresses subtler regressions that surface later in business metrics or user feedback, where reverting must also handle model-dependent data such as personalization state or cached embeddings accumulated under the new version. Table 14.9 summarizes implementation patterns for each rollback type:

Table 14.9: Rollback Patterns by Scenario: Each rollback type requires different infrastructure support and state handling strategies. Immediate rollback demands always-warm standbys; delayed rollback may require data migration procedures.

Rollback Type	Trigger	Implementation	State Handling
Immediate	Serving errors, crashes	Hot standby with fast routing switch	Verify state compatibility
Rapid	Canary metric degradation	Registry-based redeployment	Clear caches, restart sessions
Delayed	Business metric decline	Full redeployment with migration	Migrate state, replay if needed

Rollback testing Rollback procedures that have never been exercised often fail during an active incident, when cognitive load and time pressure are highest, because configuration dependencies, incompatible state, or unclear ownership only surface when a revert is actually attempted. Periodic rollback drills expose those gaps beforehand, while step-by-step runbooks ensure that the on-call responder can execute the revert without having designed the deployment. Automated rollback triggers shorten reaction time further, provided their thresholds are calibrated to the service with safeguards against flapping and the restored model is checked against live caches rather than serving predictions corrupted by incompatible feature state.

Stateful vs. stateless rollback ML systems vary in statefulness, which directly governs rollback complexity. For stateless workloads like tabular classification and static regression, rollback requires only swapping model weights or routing traffic back to the prior container, because individual inferences share no execution context. In contrast, stateful models (including sequential recommenders, session-based search rankers, and conversational systems) accumulate transient user state. Reverting such workloads can demand session resets, schema shims for cached context vectors, or explicit state migration; capturing versioned checkpoints at deployment boundaries mitigates this friction, but clean restoration remains an architectural property that requires empirical validation rather than assumption. The ranking service is the stateful case. It precalculates dense user and item embeddings and holds them in low-latency caches, so if version 2 rotates the latent vector space or changes the embedding dimension, the cached vectors become meaningless to a rolled-back version 1. A stateful rollback must therefore orchestrate atomic cache invalidation or dual-version namespace switching alongside weight redeployment to prevent scoring queries against incompatible vector spaces. In systems with feedback loops, the most complex failure mode arises when bad predictions pollute downstream feature logs or clickstream training sets during the degraded window, reverting the serving binary leaves contaminated data in the retraining corpus that must be expunged or quarantined before previous behavior is restored.

14.4.3.2 A/B testing for model validation

A/B testing provides the statistical foundation for deployment decisions by comparing model versions under controlled conditions. Unlike canary deployments (which validate operational stability), A/B tests measure whether a new model improves business outcomes with statistical confidence.

Experiment setup and decision rules A valid A/B test establishes four controls to ensure deployment decisions remain statistically sound. First, the **randomization unit** specifies whether traffic is split by user ID or individual request: user-level hashing preserves consistency across sessions

at the expense of larger sample requirements, whereas request-level splitting maximizes sample throughput but risks exposing a single user to alternating model variants. Second, the statistical power envelope determines the traffic volume required to resolve meaningful differences. Under a common-variance Normal approximation, let n be the required users per variant, δ_{MDE} the minimum detectable effect, σ the outcome standard deviation (for a conversion metric, each user's outcome is a yes-or-no event, so σ^2 is the baseline conversion rate times one minus that rate), and $z_{\alpha/2}$ and z_{β} the positive standard-Normal critical values for the chosen two-sided confidence and power. The worked scenario uses 95 percent confidence and 80 percent power. Equation 14.4 translates those design targets into required traffic before launch.

$$n = \frac{2(z_{\alpha/2} + z_{\beta})^2 \sigma^2}{\delta_{\text{MDE}}^2} \tag{14.4}$$

For a 2 percent relative lift on a 5 percent baseline conversion rate (5 percent to 5.1 percent) and 80 percent power, the experiment requires roughly 745,644 users per variant. If traffic limits the test to 25,000 users per variant instead, solving equation 14.4 for δ_{MDE} shows that the test can detect only a much larger lift, about 0.5 percentage points absolute.

Third, **guardrail metrics** define operational and behavioral boundaries that must not degrade even if the primary metric improves; a recommendation model improving click-through rate by 10 percent while increasing p99 response latency by 500 ms violates system guardrails and risks cascading timeouts across downstream services. Fourth, a fixed evaluation horizon runs the test until the preregistered sample size and a minimum duration covering weekly seasonality are reached. Stopping the moment significance first appears inflates false positive rates through repeated peeking; sequential designs permit early stopping but need specialized analysis.

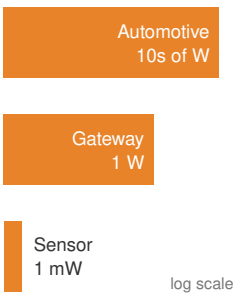
Those controls establish the statistical envelope, yet ML systems add failure modes that ordinary web experiments can hide. Conversion events may arrive days after prediction, creating delayed feedback: a recommendation shown Monday can drive a purchase Friday, so the attribution window must be part of the test design. Novelty effects can also inflate early performance as users engage with fresh recommendations, which is why mature experiments include a burn-in period before measurement. Ranking systems add interference effects, because showing an item to one user can change what remains available to another, violating the independence assumption behind standard A/B analysis, and segment heterogeneity creates a further problem when an overall neutral result hides opposite effects in different cohorts. Guardrails, segment analysis, and preregistered decisions therefore belong to the experiment design, and table 14.10 turns those constraints into a deployment decision:

Table 14.10: A/B Test Decision Matrix: Deployment decisions should consider both primary metrics and guardrails. Improvements that come at the cost of guardrail violations require careful trade-off analysis rather than automatic deployment.

Primary Metric	Guardrails	Decision
Significant improvement	All pass	Ship new model
Significant improvement	Some fail	Investigate trade-offs, may need model iteration
No significant change	All pass	Evidence inconclusive; retain current model unless a prespecified equivalence or noninferiority test supports the change
Significant degradation	N/A	Do not ship; investigate root cause

The decision matrix is reliable only when the evaluation methodology is preregistered before launch, establishing expected effect sizes, the randomization unit, attribution windows, guardrail thresholds, and minimum runtimes prior to observing production traffic. Variance-reduction techniques such as CUPED (Controlled-experiment Using Pre-Experiment Data) (Deng et al. 2013) subtract the part of each user's outcome that pre-experiment behavior already predicts, shortening experiments without sacrificing power, while automated analysis pipelines protect the decision boundary from manual calculation errors and archiving negative results discourages repeating unproductive architectures. An A/B deployment decision is actionable only when the release machinery can promote, hold, or roll back the exact artifact that was evaluated, which is the guarantee

the model registry of section 14.3.1.2 provides. The keyword spotter keeps these operational goals (controlled rollout and fast rollback) while changing the constraints under which they must be met, because its devices have limited power, memory, and connectivity.



14.4.4 Edge AI deployment

Consider the keyword spotter after its detection drop. When its model degrades, an engineer cannot SSH into the device, roll back to a previous version, and restart. The device sits in someone's home on intermittent Wi-Fi, and its 200 KB model shares 4 MB of flash with the firmware that runs it. Every operational assumption from cloud MLOps (instant rollback, centralized logging, real-time monitoring) must be reimagined.

Edge AI runs machine learning inference at or near the data source rather than in centralized cloud infrastructure (Reddi et al. 2019), and its operations inherit the memory and power envelopes that separate the deployment tiers (section 2.8). A model reaches an edge device already quantized, pruned, or distilled to fit those envelopes (Warden and Situnayake 2020; David et al. 2021), and on microcontrollers (TinyML) it runs on specialized engines such as TensorFlow Lite Micro and CMSIS-NN (Lai et al. 2018). Power budgets span about four orders of magnitude, from milliwatts for sensors to tens of watts in automotive systems, and deployments split work across three tiers: sensor-level microcontrollers at 1–100 mW filter and detect, gateways at 1–10 W run heavier inference, and the cloud distributes models and retrains. Latency-critical decisions stay local while expensive work moves upward. Every operational control must fit inside the tier that runs it. An update shares flash with the running model, telemetry competes with the radio's energy budget, and a failed release must recover without a technician. Safety-critical real-time targets also add worst-case execution time (WCET) analysis to the release gate, because thermal throttling and memory contention can push inference past a deadline that average latency never reveals.

↩ The quantization, pruning, and knowledge-distillation techniques that edge deployment relies on are established in chapter 10.

Over-the-air (OTA) model updates are how operations reaches physically inaccessible devices. OTA pipelines need secure model distribution, artifact verification, and rollback mechanisms; delta or differential updates can reduce transfer volume when devices need not receive a complete model artifact. The keyword spotter's fail-safe OTA design uses dual-bank flash memory, a pattern common on microcontroller and embedded targets. The device keeps running from Bank A while it writes the candidate model and runtime to Bank B. After switching to Bank B, a hardware watchdog timer and a post-update self-test supervise the first inferences; if the new model triggers memory faults, hangs, or violates latency budgets, the bootloader automatically reverts execution to Bank A, preventing physically inaccessible devices from being bricked. Update scheduling must account for device connectivity patterns, power availability, and operational criticality.

Power budgets across the three edge tiers span about four orders of magnitude.

Monitoring and tier coordination must fit inside the same power and bandwidth budgets. Because continuous streaming would drain the battery, lightweight telemetry reports compact operational counters (inference latency, power draw, and accuracy indicators) alongside device-level health signals (thermal status, battery levels, and connectivity quality) that predict maintenance needs before a node fails. When local load or link quality shifts, edge-cloud coordination can offload heavier inference to a gateway where feature caching avoids redundant computation, while federated learning lets edge devices contribute model updates rather than raw training records, paired with secure aggregation and differential privacy to limit what those updates reveal under an explicit threat model (section 15.5.2 develops both).

Graceful degradation is a core operational pattern for edge AI. When thermal limits or battery depletion constrain hardware capacity, edge runtimes must dynamically shed load (downsampling input sample rates, bypassing speculative execution branches, or falling back to shallow heuristic models) within a fallback policy validated for the application's safety and quality requirements. Each of these controls, on the device and in the cloud, reserves resources for a version that serves little or no traffic, and the size of that reservation depends on the workload's regime.

14.4.5 Memory and compute of release controls

Every control in this section keeps a second version of the model alive, and for a capacity-bound model that second version, not the extra arithmetic, is the dominant cost (table 14.11). A shadow deployment scores every request twice. A canary, an A/B test, and a blue-green switch divert traffic rather than adding work, yet each must hold the candidate's full embedding tables in accelerator

memory whatever share of traffic it serves, and a hot standby for immediate rollback holds the previous version for the same reason. The ranking service's 5 percent canary therefore doubles the accelerators that hold tables, from two to four, while it carries a twentieth of the requests. A compute-bound ResNet-50 service pays the opposite way. Its 51.2 MB of FP16 weights fit beside the serving copy on one accelerator, so its canary costs almost no memory and only its share of compute. The keyword spotter's dual-bank update costs flash instead of accelerator memory, a second 200 KB bank that brings the model's share of the device's 4 MB to 400 KB.

Table 14.11: Release Controls on a Capacity-Bound Model: Extra resident memory and inference work that each release control adds to the DLRM ranking service on H100 accelerators, and to the keyword spotter's flash. Every server-side control holds a second full copy of the embedding tables regardless of the traffic share it serves, so release safety for this model is paid in memory rather than arithmetic.

Release control	Extra resident memory	Extra inference work	What it buys
Shadow deployment	Second copy of the tables (100 GB); 2 → 4 H100s	Every request scored twice	Output and latency comparison with no user exposure
Canary (5% of traffic)	Second copy; 2 → 4 H100s	None; a share of requests is diverted	Live quality evidence on a bounded share of users
A/B test	Second copy; 2 → 4 H100s	None; traffic is split between variants	A statistically valid outcome comparison
Blue-green switch	Full second environment; 2 → 4 H100s	Duplicate provisioned capacity during the switch	Rollback by a single routing change
Hot standby	Previous version resident; 2 → 4 H100s	None until rollback	Immediate rollback without a cold start
KWS dual-bank update	Second flash bank (200 KB in 4 MB of flash)	None	Automatic revert after a failed update

Checkpoint 14.2: Evidence for a release

- ☐ **Promotion evidence**: A shadow model has acceptable latency and similar output distributions, but outcome labels have not arrived. What has been established, and what quality evidence is still missing?
- ☐ **Recovery state**: A canary changes an embedding dimension. Which artifacts and cached state must a tested rollback restore together?
- ☐ **Converted artifact**: Explain why passing aggregate accuracy before quantization does not replace numerical, slice-level, and runtime checks after conversion.

Getting a model into production, and back out again, is only half the operational challenge. A successfully released model can still degrade through distribution shift or corrupted upstream features without raising runtime errors, and none of the controls above will notice. Production monitoring supplies the evidence that tells the team a release, a rollback, or a retraining run is needed at all.

14.5 Production Monitoring

A newly promoted ranking model can pass its canary gate on Monday, only to lose five points of accuracy by Thursday when an upstream catalog migration or a competitor's promotion alters live user traffic while every HTTP and GPU gauge stays green. *A deployed model loses accuracy at a rate that must be measured rather than assumed.* Every decision left in the operations loop (retrain, roll back, or wait) rests on evidence that only production monitoring can supply, including the decay rate that the retraining economics of section 14.6 must fit. An ML service is correct only while its live inputs resemble the data it learned from, so as they change (the silent degradation of section 1.6), predictive quality may decline. Monitoring is where the third critical interface, production-monitoring, makes

that risk observable. Staged rollout paired with input and outcome monitoring lets teams investigate failing versions and limit their impact, within the time needed to collect evidence.

14.5.1 Infrastructure telemetry and hardware utilization

When an on-call engineer is paged for a p99 latency spike on the ranking service, a single GPU busy-time gauge cannot tell them whether the accelerator is saturated with math, stalled on embedding-table memory gathers, throttling its clocks from heat, or sitting idle while a host thread waits on the feature store. Confirming whether predictive quality has changed also requires ground-truth labels that often arrive with substantial delay, so monitoring cannot wait for outcomes alone. In production, serving failures span two different physical regimes: immediate hardware execution bottlenecks and gradual distributional drift. Disentangling them requires two distinct telemetry layers: infrastructure metrics that reveal whether the serving system itself is compute-, memory-, or I/O-bound, and distribution and outcome metrics that connect data movement to model performance.

The first layer is infrastructure-level monitoring, which tracks indicators such as CPU and GPU utilization, memory bandwidth, disk consumption, network latency, and service availability. Measuring GPU utilization alone is incomplete; an accelerator reporting high execution time may still be stalled waiting for DRAM or PCIe transfers, while low utilization often signals host-side preprocessing bottlenecks. Correlating kernel execution times with memory bandwidth utilization and input pipeline queue depths distinguishes compute-, memory-, and I/O-bound behavior.

Power-efficiency metrics (such as inferences per joule or FLOP/s/W, depending on workload) add a cost-normalized view that enables mixed-workload scheduling. Thermal monitoring similarly informs operational scheduling, particularly under sustained high load where thermal throttling forces hardware clocks down, introducing tail-latency spikes that violate SLOs. An MLOps telemetry pipeline incorporates thermal headroom metrics to steer traffic across available accelerators before throttling occurs. Time-series engines such as Prometheus[18] (Cloud Native Computing Foundation 2024b), Grafana (Labs 2024), and Elastic (Elastic NV 2024) collect and visualize these operational metrics across the serving fleet.

[18] **Prometheus**: Prometheus periodically scrapes targets and stores time series for aggregation. Scrape and rule-evaluation intervals jointly affect alert latency and may miss short excursions. Monitoring per-accelerator thermals allows precise workload routing at higher data cost, while server-level aggregates can mask component-level throttling.

Hardware counters locate a bottleneck inside the accelerator, but a latency regression often originates elsewhere on the request path. Request scheduling, batching, and runtime selection belong to the serving system, and section 13.3.1 shows that model inference is only one slice of end-to-end latency, and often not the largest (principle 12). Operations uses that decomposition as a diagnostic instrument. When p99 regresses, per-stage timings for network, feature retrieval, parsing, inference, and serialization tell the on-call engineer which stage moved, and therefore which fix and which team the incident needs. Without stage-level tracing, every latency regression looks like a model problem, and the reflexive responses of rolling back or quantizing further cannot recover time lost in a feature store or a network hop (principle 8).

The serving endpoint contributes two of those stages, parsing and serialization, and its capacity model adds a third when it scales to zero. Protocol and serialization costs are developed in section 13.2.2, and the cold start that scale-to-zero capacity pays after every idle period in section 13.8.1. Operations inherits both as stages to trace, so that a regression in either is not mistaken for a model problem.

Alerts convert these signals into intervention before silent degradation reaches downstream consumers. A sustained drop in model accuracy triggers drift investigation; infrastructure alerts signal memory saturation, thermal throttling, or degraded network throughput. The latency of these alerts governs the window of undetected failure. Alerts must record the model version, affected input subpopulation, and triggering aggregation window so responders can isolate and reproduce the failure state.

Example 14.2: Recommendation monitoring at scale

Scenario: Consider the ranking service at high throughput, its latency within the SLO while recommendation quality declined as user behavior changed.

Diagnosis: Traditional infrastructure metrics (CPU utilization, HTTP error rates) remained green while cohort-level CTR fell. The engagement decline motivates investigation of traffic, feature pipelines, and ranking behavior; it does not establish classification accuracy loss.

Systems lesson: Infrastructure telemetry alone cannot establish recommendation quality. Cohort-level outcome tracking exposes localized engagement changes, while matched comparisons and mature labels are needed to assess predictive-quality changes and their causes.

14.5.1.1 Hardware utilization patterns

Standard administrative GPU utilization metrics, such as the reading from `nvidia-smi`, report the fraction of time a kernel is executing rather than the fraction of peak arithmetic throughput achieved, the distinction between busy time and model FLOPs utilization (MFU) drawn in section 8.5. The ranking service's gathers of non-contiguous embedding vectors can therefore hold a high utilization reading while every resident warp stalls on memory, and a green gauge on the operations dashboard says nothing about compute efficiency.

Distinguishing compute execution from memory or pipeline stalls requires evaluating streaming multiprocessor (SM) execution efficiency alongside memory bandwidth and I/O saturation. Table 14.12 gives illustrative screening patterns. Here GPU utilization is kernel-active time; measured FLOP rate, execution traces, and relevant stall counters are needed to test the proposed bottleneck:

↩ The analytical model separating compute-bound execution from memory-bandwidth saturation across arithmetic intensities is established in section 11.6.

Table 14.12: GPU Utilization Patterns: Illustrative utilization signatures suggest hypotheses, not unique diagnoses. High kernel-active time does not establish compute saturation. Confirm candidates with achieved arithmetic throughput, memory traffic, stall counters, and an execution trace before choosing an optimization.

Pattern	GPU Util	Memory bandwidth util.	Optimization Strategy
Possible compute limit	>85%	<70%	Check achieved FLOP rate; evaluate faster kernels or compute capacity
Possible bandwidth limit	50–85%	>85%	Check traffic and stalls; evaluate quantization or memory access
Possible input limit	<50%	<50%	Trace input starvation before changing prefetch or storage
Batch-starved	Variable (spiky)	Variable	Dynamic batching, request queuing on single server

Each candidate maps to a term of the iron law of ML systems (principle 3). The compute-bound signature points to $O/(R_{\text{peak}} \cdot \eta_{\text{hw}})$, the memory-bound signature points to D_{vol}/BW, and low utilization of both points to the data pipeline, so the trace and counters guide which term to investigate when a latency SLO is violated.

Utilization targets differ by workload. Batch training and batch (static) inference, which tolerates queuing and offline scheduling, can run above 80 to 85 percent kernel-active time while the team measures useful throughput. Online inference instead targets 50–70 percent of measured sustainable capacity at median load, holding back headroom so that bursts do not cascade into p99 timeouts (section 13.4). These figures are diagnostic starting points rather than thresholds, because kernel-active time and demand relative to capacity have different denominators. For large language model (LLM) serving, KV-cache utilization on each node, the per-request store of past attention state, is an equally important capacity-planning signal, because near the limit the scheduler must queue or reject requests, shrink batches, or shorten the admissible context (section 13.9.5 sizes and schedules the cache).

Utilization and memory telemetry also feed the number the business sees. Cost per inference, the hourly accelerator bill divided by sustained throughput, is defined and worked out in section 13.10.1; operationally it belongs on the same dashboard as the utilization signatures in table 14.12, because a rising cost per thousand inferences at constant pricing is often the first visible symptom of efficiency erosion (smaller effective batches, a shift in traffic mix, or a regression that stays inside the latency SLO).

14.5.2 Statistical monitoring and drift detection

Even when GPU utilization, memory bandwidth, and stage-level latency sit comfortably inside their operating bands, a model can still return systematically wrong predictions if live user inputs drift away from the training distribution or if an immature evaluation window compares pending outcomes against completed ones. Infrastructure telemetry shows how the serving hardware behaves; statistical monitoring shows whether the model's predictions remain correct. Unit tests can verify deterministic components but cannot by themselves establish population-level predictive performance, which must be estimated statistically. Monitoring implements observable degradation (section 14.1.1), transforming this theoretical limitation into operational practice. Once monitoring surfaces a symptom (a latency SLO miss, throughput below target, or memory creep), section A.5.3 maps that symptom to its dominant D·A·M term and tells the operator which optimizations will move the binding constraint and which will be wasted on serving infrastructure. Without continuous monitoring and the deeper **observability** it enables (the ability to infer internal state from outputs), teams lack the evidence needed to distinguish a healthy model from an unobserved regression.

Effective monitoring spans both infrastructure health and statistical model behavior. On the infrastructure side, metrics track hardware saturation, memory allocation, and latency distributions. On the model side, teams track evaluation metrics such as accuracy, precision, recall, and confusion matrix shifts (scikit-learn developers 2024) across live prediction streams.

Those quality metrics require joining predictions to outcomes under a fixed evaluation horizon. Consider a conversion model whose prediction log records a request identifier, prediction time, score, and the immutable version actually served. The outcome log records the same identifier, event time, and observation time. For an older request served by the previous version, a purchase event within the horizon supplies a positive label once observed; a completed observation window with no purchase supplies a negative label, provided outcome collection is complete. A recent request served by the candidate with no recorded purchase remains pending until its horizon and the permitted reporting delay have elapsed. The absence of a purchase record while that window is open is unknown, not a negative outcome. Joining by identifier and retaining the served version attributes each completed outcome to the model that made the prediction rather than to whichever model is deployed when the label arrives.

A quality comparison groups predictions by serving period and version, then evaluates cohorts whose outcome windows have matured under the same horizon and reporting policy, with comparable traffic conditions. Each metric and slice must report label coverage, the fraction of eligible predictions with resolved outcomes. An apparent drop caused by comparing the candidate's pending outcomes with the previous version's completed outcomes does not justify retraining; it calls for completing the window or repairing outcome collection. Even a mature window can contain selective labels if outcomes are observed only for exposed recommendations or reviewed transactions. Coverage and collection-policy checks must accompany uncertainty estimates before a quality regression supports diagnosis and a retraining decision.

Statistical monitoring has to separate two axes of distribution shift,[19] because they differ in what a monitor can observe. The three kinds of shift defined for the data pipeline in section 4.12.1, where the keyword spotter's microphone change is the worked case, fall on those two axes. Covariate shift[20] changes the input distribution $p(x)$ while the relationship between inputs and labels, $p(y \mid x)$, stays stable; label shift changes how often each label occurs while the inputs typical of each label stay the same; and concept drift changes $p(y \mid x)$ itself. Covariate shift and label shift can usually be detected without labels, from input statistics or from the model's prediction distribution, and together make up data drift. Label shift does change $p(y \mid x)$, because the probability of each label given an input follows the changed label frequencies, but its signature appears in the prediction distribution before any outcome arrives. Concept drift, a change in $p(y \mid x)$ that changed label frequencies do not explain, forms the second axis, and detecting it requires labeled outcomes. The degradation equation compares P_0 and P_t, the training-time and serving-time measurements of the data distribution in which these shifts appear.

Operations adds one distinction that the definitions alone do not make. **Model decay** is the observed decline in prediction quality over time while the model code stays unchanged, and data drift is only one possible cause of it, alongside concept drift and changes in the surrounding pipeline. Monitoring model outputs alone can miss input drift or mistake a benign output change for quality

[19] **Label-free vs. label-dependent detection**: A change in $p(x)$, or in the model's prediction distribution, can be estimated from sufficient samples without labels, although detection is not immediate. Concept drift generally requires labeled outcomes, which in high-stakes domains (medical diagnosis, fraud detection, legal decisions) can take days, weeks, or months. Proxy metrics such as prediction-confidence distributions and output entropy can provide imperfect early warnings that trade false-alarm rate for detection speed.

[20] **Covariate shift**: Importance-weighting corrections for covariate shift assume that the support of the training distribution covers the deployment distribution: every deployment input could have appeared in training, just with different probability. When deployment contains genuinely out-of-distribution inputs (new product categories, new demographics, adversarial inputs), the correction can fail and the model can produce confidently wrong outputs with no warning signal, making support coverage the hidden assumption that determines whether drift correction or full retraining may be required.

loss, so operations also tracks the input feature statistics behind the divergence $\mathcal{D}(P_t \| P_0)$, using the distance measures of feature distribution monitoring (section 22). These statistics can warn earlier than labeled performance because ground-truth feedback is often delayed.

The signature of data drift in live telemetry is a feature distribution that moves in step with a quality metric, and three synchronized telemetry tiers aligned over time expose how covariate shift erodes model performance (figure 14.7). Across the top panel, discrete request samples transition from predominantly green (online sales) to orange (in-store sales); the figure's "online store" and "offline store" labels name sales channels, not the feature-store tiers of section 14.3.1.1. The middle panel charts this shift as an expanding offline area in the sales_channel feature distribution, directly matching the steep decline of the model accuracy curve in the bottom panel. This temporal alignment motivates comparing input feature distributions with outcome metrics; their co-movement supplies a diagnostic hypothesis rather than establishing the cause by itself.

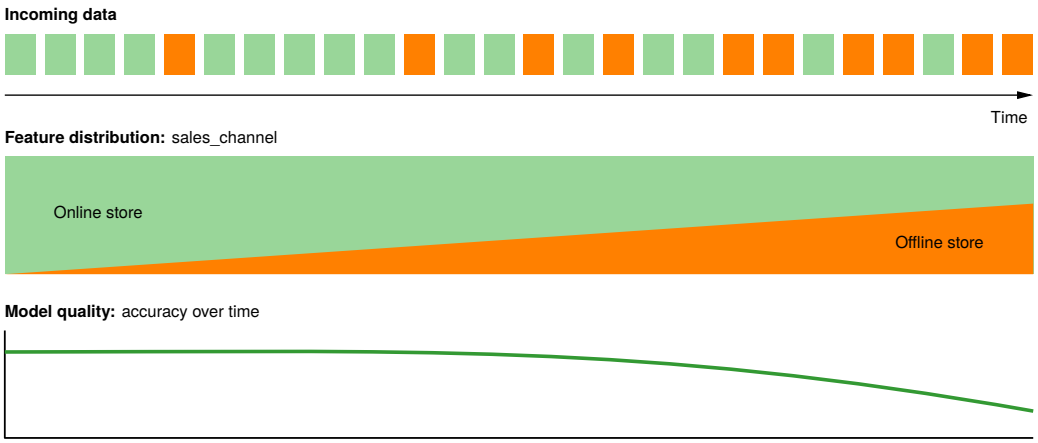


Figure 14.7: Data Drift Impact: In this illustrative scenario, incoming samples shift from predominantly online to increasingly offline sales while model accuracy declines over the same interval. Monitoring inputs and outcomes together helps determine whether the distribution shift is associated with the loss in accuracy.

The **drift detection delay**, how quickly a statistical test can confirm that predictive quality has degraded, limits statistical monitoring. The speed of confirmation is governed by sample arrival rates and statistical power requirements. Low-traffic services may wait days or weeks to accumulate enough labeled outcomes to distinguish genuine performance erosion from stochastic noise. No tooling removes this gap, because a change cannot be confirmed faster than labeled examples arrive. Monitoring architectures must therefore keep the two axes apart. Data drift can be estimated from sufficient unlabeled samples, while concept drift generally requires labeled outcomes. Neither statistical estimate is instantaneous.

Drift detection speed is bounded by the sample rate.

Napkin Math 14.2: The drift detection delay

Problem: A 95 percent-accurate model may fall by 5 percentage-point. The monitoring policy budgets 1,000 labeled examples. A power calculation of the same kind as equation 14.4 sets the minimum such a test needs; the budget is a policy choice above that floor, adding margin for label noise, dependence between outcomes, and per-slice checks. Calculate the collection duration required across high-rate and low-rate arrival scenarios.

Math:

1. **Evidence budget**: 1,000 labeled examples.
2. **High-rate case**: At 1 labeled outcome per second, collection takes 1,000 seconds ≈ 16.7 minutes.
3. **Low-rate case**: At 100 labeled outcomes per day, collection takes 10 days.

Systems insight: Detection is bounded by labeled-outcome arrival, which may lag far behind traffic. Low-volume or delayed-label domains may need days or weeks, so high-stakes systems supplement statistical monitoring with proactive model audits.

Detection delay has a direct cost. When a silent failure persists until the next review, every day of delay is lost revenue, which is the economic case for automated drift detection.

Napkin Math 14.3: The cost of silent failures

Problem: Is building an automated drift detection system worth the engineering effort?

Scenario: Consider a product recommendation engine generating $50M in annual revenue. **Failure mode**: A deployment bug causes training-serving skew, dropping recommendation quality by 5 percent. This degrades conversion rate proportionally.

Assumptions: The incident begins immediately after a scheduled check, remains detectable at the next check, and ends with an effective repair immediately after detection. The calculation therefore compares nearly full review-interval delays, rather than expected detection times for incidents arriving throughout an interval. It excludes label delay and diagnosis or recovery time.

Cost analysis:

1. **Manual ops (monthly review)**:
   - **Detection time**: ~4 weeks (28 days).
   - **Revenue loss**: $\$50\text{M} \times 0.05 \times 28 \text{ days}/365 \text{ days} \approx \$191{,}781$.
2. **Automated MLOps (daily checks)**:
   - **Detection time**: 1 day.
   - **Revenue loss**: $\$50\text{M} \times 0.05 \times 1 \text{ day}/365 \text{ days} \approx \$6{,}849$.

Systems insight: Under these timing and recovery assumptions, a single silent failure costs $184,932 more with monthly review. Across this scenario's 4 incidents/year, daily checks avoid nearly $739,726 in annual loss. An operational budget must instead use the measured time from incident onset to effective recovery, including evidence collection, diagnosis, and mitigation. An earlier alert saves money only when it enables an earlier reduction in harm.

14.5.2.1 Data quality monitoring

Waiting for labels is not the only option, because many silent failures begin as defects in the inputs themselves and can be caught at the input boundary before a prediction is served. Drift statistics reveal shifted inputs, while outcome metrics establish whether prediction quality has declined, yet by the time downstream business metrics degrade, upstream data corruption may have persisted for days or weeks. Data quality monitoring exposes these input defects before inference occurs, while output and outcome monitoring confirm whether distributional shifts impair prediction accuracy. The first input guardrail is executable validation: listing 14.3 illustrates schema expectations that reject malformed batches before inference, turning implicit data assumptions into enforceable checks.

Listing 14.3: Input Data Validation: Schema validation rules check column existence, data types, null values, and statistical bounds to catch data quality issues before they propagate to model inference.

```
schema.require_column("user_id")
schema.require_type("timestamp", "datetime")
schema.require_non_null("feature_a")

schema.require_range("age", min_value=0, max_value=120)
schema.require_mean_between(
    "purchase_amount", min_value=10, max_value=1000
)
```

Input data validation Schema validation[21] catches structural defects at ingest time. These checks enforce column existence, strict data typing, null-value limits, and numerical boundary invariants.

Feature distribution monitoring Schema validation catches structural corruption (missing columns, wrong types, null values) but cannot detect the subtler failure mode where data arrives in the correct format but from a shifted distribution. A feature representing user age can pass every schema check while its mean silently migrates from 32 to 45 over three months as marketing attracts an older demographic. This distributional shift can change model accuracy without producing a structural anomaly; labeled outcomes are needed to determine its effect.

Gradual long-term degradation evades coarse detection thresholds. Small day-to-day changes in a quality metric compound into material degradation over a year without tripping monthly alerts. Seasonal patterns compound this complexity; a model trained in summer may perform well through autumn but fail in winter conditions it never observed. Detecting such gradual degradation requires multi-timescale monitoring: performance baselines across multiple time horizons (daily, weekly, quarterly), sliding window comparisons that detect slow trends, and seasonal profiles that account for cyclical variation.

Statistical distance measures quantify this divergence by comparing serving distributions against training baselines, and four are common. The population stability index (PSI)[22] suits categorical and binned features, and the Kolmogorov-Smirnov (KS) statistic of the CI/CD distribution screen suits continuous ones. Jensen-Shannon divergence gives a symmetric, bounded comparison of probability distributions, and the Wasserstein distance, also called earth mover's distance, measures the probability mass that must move, and how far, to turn one distribution into the other. Each needs an alert threshold, and sample size makes that choice harder than it looks.

Feature-by-feature comparisons can miss changes in how inputs occur together. Consider two binary sensor flags. In the training population, equal groups have both flags off or both on; in the serving population, equal groups have one flag on and the other off. Each flag is still equally often on and off, so its individual histogram is unchanged, but the relationship between flags has reversed. Even perfect training-serving feature parity would not detect this population change. Monitoring selected feature combinations, relevant cohorts, or a joint-distribution statistic complements marginal screens; labeled outcomes are still needed to determine whether the change harms predictions.

In high-throughput production monitoring, statistical significance alone is an inadequate alert policy. With large samples, tests such as the two-sample KS test or the chi-square test (the standard test for differences in categorical frequencies) can detect small genuine differences that have little operational significance. The mechanism is the sample-size term in the test's critical value. The KS critical value c_{crit} used in the data pipeline's drift test (section 4.5.3) scales with $\sqrt{(n_0+n_t)/(n_0 n_t)}$, so it shrinks roughly as $1/\sqrt{n}$, and a monitor that compares millions of serving requests against a large training sample rejects equality for shifts far smaller than the 0.1 gate of listing 14.2. These detections are not necessarily statistical false positives, but paging on each one creates unnecessary alerts. Conversely, small-sample edge telemetry may lack power to detect a meaningful change. Monitoring must consider effect size, sampling uncertainty, and the cost of missed change together.

Production monitoring therefore combines distribution-distance measures with uncertainty and operational thresholds. The population stability index that section 4.12.1 defined for the data pipeline, the binned relative entropy between expected (training) and actual (serving) proportions over n_{bins} fixed bins, is a common choice. KL divergence, defined there alongside it, is its asymmetric relative, and PSI equals the sum of the two directed KL divergences, which is why a shift in either

[21] **Schema validation**: The rules in listing 14.3 prevent silent data contract violations, such as a feature column changing from an integer to a float. Without this input-level guardrail, downstream model monitoring cannot distinguish a data quality error from a true performance regression, masking the root cause. A schema mismatch in a critical feature can invalidate an otherwise well-formed prediction batch.

[22] **PSI**: PSI is widely used in credit-risk scorecard monitoring to compare expected and observed binned populations; Yurdakul and Naranjo analyze its statistical properties (Yurdakul and Naranjo 2020). The common 0.1 and 0.25 bands are useful operational conventions, not universal statistical laws. ML operations adopted PSI because it works on binned categorical or continuous features and provides an interpretable drift score that non-specialists can review.

direction raises it. Operations adds what the definition leaves open, the response, by turning the conventional scorecard bands into an escalation policy. An illustrative policy has three bands:

- PSI < 0.1: Below this policy's warning threshold; continue monitoring outcomes and critical slices.
- $0.1 \leq$ PSI < 0.25: Warning range; investigate population changes and upstream pipeline behavior.
- PSI ≥ 0.25: Escalation range; notify the owning team under the service's calibrated severity policy. Diagnosis determines whether intervention is needed.

Production monitors require a documented zero-bin policy, such as Laplace smoothing, because any empty bin in the denominator yields an undefined logarithm, and they must preserve fixed bin boundaries across comparison periods. PSI is a drift signal, not an automatic retraining trigger, because divergence alone does not establish that accuracy has changed (principle 10). Every threshold, whether a PSI band or a KS or Jensen-Shannon cutoff, must be calibrated per feature against sample size and the cost of missed drift, because a shift that is plainly visible on a histogram can still produce a small aggregate score.

The ranking service monitors user age as an input feature, and a shift toward older cohorts produces the bin-by-bin PSI decomposition shown in table 14.13:

Table 14.13: PSI Worked Example: User age distribution drift from training to serving, decomposed across six age bins. The total PSI is 0.029, well below the 0.1 warning threshold, even though several bins shifted by 3 percentage points. Aggregate PSI summarizes movement across bins; action depends on a calibrated threshold, sample size, and business cost.

Age Bin	Training	Serving	Difference	ln(Serving/Training)	Contribution
18–25	15%	12%	-0.03	-0.223	0.0067
26–35	25%	22%	-0.03	-0.128	0.0038
36–45	20%	18%	-0.02	-0.105	0.0021
46–55	18%	20%	+0.02	+0.105	0.0021
56–65	12%	15%	+0.03	+0.223	0.0067
66+	10%	13%	+0.03	+0.262	0.0079

Summing the six bin contributions yields a total PSI of 0.029. The difference column is in proportion units, so a 3 percentage-point shift appears as ± 0.03. Even with such shifts in several bins, the aggregate drift is well below the 0.1 warning threshold. Operational action depends on a calibrated threshold, sample size, and business cost.

↪ KL divergence, its asymmetry, and a worked drift example that computes both KL divergence and PSI are collected for reference in section B.2.3.

Data freshness monitoring Feature stores and data pipelines can become stale without triggering obvious errors. Data freshness monitoring catches that failure mode, and listing 14.4 shows a configuration that monitors feature freshness and triggers fallback behavior when data becomes stale.

Listing 14.4: Data Freshness Alert Configuration: This configuration monitors the `user_purchase_history` feature for staleness, alerting operations teams via PagerDuty and Slack and falling back to default values when the feature exceeds the maximum allowed age.

```yaml
# Example freshness alert configuration
feature: user_purchase_history
max_staleness: 6h
alert_channels: [pagerduty, slack]
on_stale:
  action: fallback_to_default
  default_value: []
```

A freshness policy turns staleness from a silent data defect into an explicit fallback, and the same pairing of a detector with a response must cover every layer of the monitoring stack, including the upstream dependencies feeding the ML system: database replication lag, feature-store ingestion watermarks, and pipeline completion status. In one representative incident, a recommendation

service detected a material shift in its `user_lifetime_value` feature within two days, tracing the anomaly to a database migration that silently altered an aggregation window. Without input-layer distribution monitoring, such upstream corruption degrades model predictions for weeks before ground-truth outcome metrics expose the failure.

14.5.3 Monitoring cost model

Every layer of that stack costs money to run, and the first cost is the telemetry itself. Collecting these signals at production scale introduces severe network and storage constraints, because capturing uncompressed telemetry for every request can saturate the very networking fabric that serves the model. These overheads force a deliberate trade-off between monitoring granularity and infrastructure operating expense.

Napkin Math 14.4: The economics of observability

Trade-off: "Measure everything" is economically infeasible at scale. Let N_{series} be the expanded series count, f_{sample} the sampling frequency per series, s_{sample} the bytes per sample, and $T_{\text{retention}}$ the retention duration; $C_{\text{ingest/sample}}$ and $C_{\text{storage/byte-time}}$ are provider-specific ingestion and storage prices. Equation 14.5 combines these terms into an operating cost rate:

$$\text{Cost rate} \approx N_{\text{series}} f_{\text{sample}} \left(C_{\text{ingest/sample}} + s_{\text{sample}} T_{\text{retention}} C_{\text{storage/byte-time}} \right) \tag{14.5}$$

The product is an operating cost rate, not a one-time setup cost.

Both data volumes follow from the same two-step arithmetic. At full fidelity, every request's telemetry enters the stream: 1M req/s × 1 KB per request = 1 GB/s. Retaining one in 60 request traces reduces average ingest to 16.7 MB/s; batching sampled traces every 60 s changes delivery timing, not the average byte rate. Table 14.14 places the two regimes side by side with their cost impact.

Table 14.14: Trace Sampling vs. Observability Cost: Retaining one in 60 request traces yields a 60× data-volume difference at 1M req/s, assuming 1 KB per request. Batch intervals do not cause the reduction.

Sampling	Granularity	Data Volume (1M req/s)	Cost Impact
All traces	Micro-bursts	~1 GB/s	High (Requires dedicated cluster)
1-in-60 traces	Trends	~16.7 MB/s	Lower (Policy-dependent)

Systems insight: Sample by outcome rather than uniformly. The worked case keeps one trace in 60 regardless of outcome; a production policy keeps 100 percent of errors and only 1 percent of successful requests, because errors are rare and carry most of the diagnostic signal. Monitor aggregate counters every 1 s and high-cardinality sketches every 60 s. The cost components below turn these choices into a monthly budget for one node.

Sampling policy alone moves telemetry volume by 60× (notebook 14.4). A complete budget must also price storage, dashboard queries, and alert evaluation, and then weigh the total against the incidents that monitoring prevents.

Cost components

Monitoring costs break down into four categories, as equation 14.6 decomposes:

$$\text{Monitoring Cost} = C_{\text{ingest}} + C_{\text{storage}} + C_{\text{compute}} + C_{\text{alert}} \tag{14.6}$$

The four C_* terms are cost components over the same accounting window: data ingestion, retained storage, query or dashboard compute, and alert-rule evaluation. Separating them matters because each scales with a different control knob. Table 14.15 provides representative unit-cost assumptions for each component, and translating these unit costs into a concrete budget estimate clarifies the real expense of monitoring even a single production model:

Table 14.15: Monitoring Cost Components: Illustrative scenario unit costs used for the worked example. Costs scale differently across components: metric ingestion scales with cardinality (number of unique metric series), storage scales with retention, and query costs scale with dashboard usage patterns.

Component	Illustrative Unit Cost	Scaling Factor
Metric Ingestion	\$0.10–0.50 per million data points	Number of metrics × sample rate
Log Storage	\$0.50–2.00 per GB/month	Log verbosity × retention period
Query Compute	\$0.01–0.05 per query	Dashboard refresh rate × users
Alert Evaluation	\$0.001–0.01 per evaluation	Number of alert rules × check frequency

Napkin Math 14.5: Single-model monitoring budget

Problem: Calculate the monthly metric ingestion, time-series storage, and query compute cost required to monitor a single ML serving node under production assumptions.

Variables:

- one model with 3 deployment variants (production, canary, staging), each emitting 50 metrics
- Metrics sampled every 15 seconds
- Retention requirement: 30 days
- 2 dashboards (model health, infrastructure), 3 team members, five-minute refresh

Metric ingestion:

- Data points per month: $3 \times 50 \times (4 \text{ samples/min} \times 60 \times 24 \times 30 \text{ days}) = 25.9\text{M}$
- Cost at \$0.30/million: \$7.8/month

Storage:

- At 8 bytes/point compressed: 25.9M × 8 bytes = 0.2 GB
- Cost at \$1/GB: \$0.21/month

Query compute:

- Queries per month: 2 dashboards × 3 users × (12 queries/hour × 8 hours/day × 22 days) = 12,672 queries/month
- Cost at \$0.02/query: \$253.4/month

Total: ~\$261.4/month for a single ML node. Alert evaluation and platform overhead are excluded.

Systems insight: Under these assumptions, cost scales linearly with identical nodes; at platform scale, query-cost optimization becomes increasingly important.

Cost optimization strategies

Each cost component in equation 14.6 maps to a distinct engineering fix. The primary driver of C_{ingest} and C_{storage} is metric cardinality. High-cardinality labels such as `user_id` or `request_id` multiply the number of series in time-series indexes, and that growth outweighs raw compute costs. Dropping unnecessary labels or aggregating them into a bounded set of buckets reduces cardinality. Hashing each identifier to another distinct identifier alone does not reduce the number of series. The second driver of storage cost is temporal resolution. Retaining raw 15-second metrics across 30 days is rarely justified. A tiered retention policy (high-resolution telemetry for recent incident debugging, downsampled rollups for historical trend analysis) preserves diagnostic fidelity while reducing retained volume. For C_{compute}, dashboard query overhead accumulates through auto-refresh loops across dozens of unattended user sessions; setting conservative refresh intervals and auto-pausing inactive sessions bounds query load. Finally, C_{alert} scales with evaluation frequency. Consolidating

overlapping threshold checks into composite multi-condition rules can reduce redundant evaluation and notifications; thresholds, ownership, and actionability still determine alert fatigue.

Cost-benefit framework

Justify monitoring investments against incident costs using the monitoring benefit-cost ratio in equation 14.7:

$$\text{Monitoring Benefit/Cost} = \frac{\text{Incidents Prevented} \times \text{Avg Incident Cost}}{\text{Annual Monitoring Cost}} \tag{14.7}$$

Suppose an average incident costs $50,000 (downtime, engineering time, and reputation) and monitoring prevents 5 incidents annually at $50,000 in monitoring cost:

$$\text{Benefit/Cost} = \frac{5 \times \$50K}{\$50K} = 5\times$$

This framework helps justify monitoring investments and prioritize which metrics deserve fine-grained observation vs. coarse sampling. The monitoring systems themselves require resilience planning to prevent operational blind spots. When primary monitoring infrastructure fails (Prometheus experiencing downtime or Grafana becoming unavailable), teams risk operating blind during critical periods. Production-grade MLOps implementations therefore maintain redundant monitoring pathways: secondary metric collectors that activate during primary system failures, local logging that persists when centralized systems fail, and heartbeat checks that detect monitoring system outages.

Robust deployments also monitor the monitor. An external watchdog checks the telemetry pipelines themselves, so a heartbeat check from an independent system catches a dead pipeline and alerts through an alternative notification path. This reduces the risk of undetected simultaneous model and telemetry failures, provided the alternative paths do not share the failed dependency.

Checkpoint 14.3: The monitoring stack

ML monitoring has several layers. The prompts in this checklist test whether each symptom can be traced to the responsible layer.

- ☐ **Infrastructure utilization**: Explain why a GPU reporting high kernel-active time can still be memory-bound, and which measurements (achieved FLOP rate, memory traffic, stall counters) would confirm it before choosing a remedy.
- ☐ **Telemetry sampling**: Explain what retaining one request trace in 60 preserves for trend monitoring, and what short-lived anomalies it can miss.
- ☐ **Data freshness**: Detect stale feature ingestion pipelines before plausible predictions mask obsolete real-world states.
- ☐ **Data drift**: Evaluate PSI or KL divergence metrics to detect when serving inputs diverge from the training baseline.
- ☐ **Model accuracy**: Account for delayed ground-truth labels when interpreting real-time task performance alerts.
- ☐ **Cohort bias**: Apply stratified cohort analysis to detect subgroup degradation hidden by aggregate top-level accuracy.

Layered monitoring converts silent degradation into signals. Infrastructure telemetry shows whether the serving path is compute-, memory-, or I/O-bound, drift statistics show that inputs have moved, and delayed outcome metrics confirm whether the movement cost accuracy. A signal is not yet a response, however. The first decision a quality signal forces is whether to retrain, a choice that weighs the value the drift is costing against the cost of a run. Alerts that point to a fault rather than to drift go to incident response, which follows that decision.

14.6 Retraining Decisions

A team that retrains the ranking model on every minor PSI spike burns thousands of dollars in accelerator time and risks training on corrupted upstream logs, while a team that waits blindly for a quarterly calendar tick lets accuracy slide six points before anyone acts. Retraining is the most expensive response the operations loop can choose, and the easiest to automate badly. Monitoring supplies two kinds of evidence, a divergence that a label-free monitor measures continuously and outcome metrics that arrive later, and the retraining decision turns them into one of three actions: retrain, roll back, or wait. The decision has three parts, taken in turn below: the candidate strategies and a gate that tests whether a run is worth its cost now, a cadence that sets how often runs should happen, and a policy comparison between a fixed schedule and an evidence trigger. On the ranking service every run is also paid in accelerator-hours on hardware that serves live traffic.

The degradation equation of equation 1.1 turns divergence into a forecast of accuracy when outcome evidence supports one:

$$\text{Accuracy}(t) \approx \text{Accuracy}_0 - \lambda \cdot \mathcal{D}(P_t \| P_0)$$

where λ is fitted per deployment from historical degradation data, as the statistical drift diagnostic (principle 10) requires. While not a universal law, tracking distributional divergence $\mathcal{D}(P_t \| P_0)$ can provide an earlier warning than delayed outcomes; it does not establish the direction or size of a quality change.

14.6.1 Retraining decision framework

Because distributional divergence warns early without proving how much accuracy was lost, an automated training pipeline still leaves one operational decision open: when to run. Deciding when to retrain a model means balancing accuracy degradation against compute and validation expense across three candidate policies. Table 14.16 provides illustrative schedules across domains, from daily retraining for rapidly shifting ad click prediction to quarterly updates for stable medical imaging applications:

Table 14.16: Illustrative Retraining Schedules by Domain: These represent starting points; actual cadences depend on observed drift rates and business impact, and organizations typically calibrate them through operational experience.

Domain	Illustrative Schedule	Rationale
Ad click prediction	Daily	User interests shift rapidly
Fraud detection	Weekly	Attack patterns evolve continuously
Demand forecasting	Monthly	Seasonal patterns change slowly
Medical imaging	Quarterly	Disease presentations are stable

The ranking service sits between the table's first two rows. Its users' interests shift daily, yet the economics below put its optimum at a few days. Those schedules are starting points, not invariant rules. In a *scheduled retraining* policy, pipeline execution runs on a fixed calendar cadence (daily, weekly, or monthly) regardless of incoming performance telemetry. This strategy is simple to automate and guarantees that freshly accumulated training data is integrated periodically. However, it burns accelerator hours during quiet periods and reacts slowly when distribution shifts strike between scheduled intervals.

A *triggered retraining* policy initiates pipeline execution when monitoring systems detect statistical drift or performance degradation exceeding predefined thresholds. This approach can conserve compute by responding to evidence rather than a fixed schedule, but it relies heavily on low-latency label streams or accurate proxy metrics to prevent delayed responses or false-alarm retraining runs.

A *continuous retraining* policy updates model weights incrementally as labeled records arrive, using streaming micro-batches or online learning algorithms. While this strategy minimizes staleness lag, it amplifies validation risk, because corrupted, unrepresentative, or adversarial data can poison model parameters before automated anomaly detectors or engineering teams can intervene.

The operating choice among these strategies depends on four physical and operational constraints: retraining compute cost, validation pipeline latency, automated rollback capability, and label arrival

delay. Re-optimizing a model on multi-accelerator nodes incurs tangible energy and cluster costs; triggered policies require statistically reliable proxy signals when true labels arrive with long delays; and every continuous deployment pipeline demands robust canary and rollback mechanisms. The policy should follow from these costs and the label delay, not from habit.

The economic and validation constraints become executable in listing 14.5. The decision function schedules a run only when the estimated recovered value exceeds the total cost of a run (compute, validation, deployment, and the expected cost of a bad rollout, the four terms that equation 14.10 formalizes below), and only when fresh validation data are available.

Listing 14.5: Triggered Retraining Decision: The decision combines quality loss, feature drift, prediction shift, and the cost of a run so automatic retraining fires only when the expected benefit exceeds that total cost.

```
quality_loss = baseline_accuracy - current_accuracy
feature_drift = max(population_stability_index(features))
prediction_shift = distribution_distance(
    baseline_predictions, live_predictions
)

benefit = estimate_value_recovered(
    quality_loss=quality_loss,
    feature_drift=feature_drift,
    prediction_shift=prediction_shift,
)
total_cost = (
    compute_cost + validation_cost + deployment_cost + rollout_risk
)

if benefit > total_cost and validation_data_is_fresh():
    schedule_retraining_run()
```

The gate separates detecting drift from authorizing retraining. Drift contributes to estimated benefit, while fresh validation data and positive net value determine whether automation acts. Turning that gate into a cadence requires measuring how fast an unretrained model loses value.

14.6.2 Quantitative retraining economics

To turn the trigger gate of listing 14.5 into a concrete schedule, a team must measure how fast an unretrained model loses value and weigh that loss rate against the fixed cost of a run. When outcome data support a locally exponential fit, the fitted decay rate gives a measurable timescale.[23] Its **half-life**,[24] the time for fitted accuracy to fall to half its initial value, states that timescale in intuitive units, although no production model is left to lose half its accuracy before retraining. The economically optimal interval is set by the cost of staleness and the cost of a run, and in the scenario worked below it is far shorter than the half-life. The derivation takes three steps: a staleness cost, a retraining cost, and the interval that minimizes their sum per unit time.

The staleness cost function

Model accuracy can degrade over time, creating a staleness cost. For economic planning, a team may fit the observable impact over a stable local regime as an exponential decay process. Here γ is a temporal decay rate under the assumption that measured degradation accumulates steadily; it is not determined by distribution divergence alone. The exponential model is a simplification that enables closed-form economic analysis. Let $\text{Accuracy}(t)$ represent accuracy at time t since last training, and Accuracy_0 represent initial accuracy. Equation 14.8 captures this fitted scenario, where the rate γ depends on domain volatility and observed outcomes:

$$\text{Accuracy}(t) = \text{Accuracy}_0 \cdot e^{-\gamma t} \tag{14.8}$$

This temporal model is a time-domain summary of the degradation equation (equation 1.1), which predicts accuracy from divergence, $\text{Accuracy}(t) \approx \text{Accuracy}_0 - \lambda \cdot \mathcal{D}(P_t \| P_0)$. If divergence grows at a roughly steady rate over an interval, that equation makes accuracy fall linearly in time at rate λ

[23] **System entropy**: The fitted decay rate γ measures system entropy, the silent degradation of section 1.6, in which quality decays while code and weights stay unchanged. It can differ substantially across deployments and must be estimated from outcome data. A shorter decay timescale demands more responsive monitoring, but it does not by itself require continuous training; label delay, validation risk, retraining cost, and rollback capacity determine the operational cadence.

[24] **Half-life** (from nuclear physics, where it measures the time for half of a radioactive sample to decay): In ML operations, the metaphor is a convenient approximation, not a universal law. For the exponential fit in equation 14.8, derived below, the half-life is $\ln(2)/\gamma$. Retraining cadence also depends on traffic, value, retraining cost, and risk; seasonal, abrupt, or adversarial change requires a richer drift process.

times the growth rate of $\mathcal{D}(P_t \| P_0)$, while the exponential of equation 14.8 falls at rate $\text{Accuracy}_0 \gamma$ while γt is small. Matching the two slopes shows that γ is an empirical stand-in for how fast the input distribution moves, scaled by the fitted sensitivity λ and divided by Accuracy_0. The retraining interval derived here uses the time-domain γ, because a schedule is set in days; the drift statistics of section 14.5.2 (the population stability index, the KS statistic, and KL divergence) estimate the divergence itself and alert on it directly. Steady divergence growth is an assumption rather than a law, so both forms must be checked against observed outcomes.

A longer-horizon fit would decay toward a floor, such as chance-level accuracy, rather than toward zero. The unshifted form in equation 14.8 suffices for the intervals that retraining exists to enforce, the early, small-loss regime ($\gamma t \ll 1$) on which the square-root approximation below also depends.

The cost of staleness accumulates based on the daily query volume Q_{day} and the value impact V of a unit change in accuracy fraction. Integrating the instantaneous accuracy loss $(\text{Accuracy}_0 - \text{Accuracy}(t))$ over the retraining interval T yields equation 14.9:

$$\begin{aligned} \text{Staleness Cost}(T) = \int_0^T Q_{\text{day}} \cdot V \cdot (\text{Accuracy}_0 - \text{Accuracy}(t))\, dt = \\ Q_{\text{day}} \cdot V \cdot \text{Accuracy}_0 \cdot \left(T - \frac{1 - e^{-\gamma T}}{\gamma} \right) \end{aligned} \tag{14.9}$$

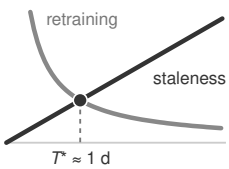
The integral accumulates cost over time t from 0 to T, and the closed form follows from substituting equation 14.8 for $\text{Accuracy}(t)$.

The retraining cost function

Each retraining incurs fixed costs including compute, validation, and deployment overhead. Equation 14.10 decomposes these:

$$\text{Retraining Cost} = C_{\text{compute}} + C_{\text{validation}} + C_{\text{deployment}} + C_{\text{risk}} \tag{14.10}$$

where C_{compute} is the cost of the training run itself, $C_{\text{validation}}$ is the cost of evaluating the new model before release, $C_{\text{deployment}}$ is the cost of rolling it into production, and C_{risk} is the expected cost of potential regression from the new model. These are the four terms that `total_cost` sums in listing 14.5.



Optimal retraining interval

The optimal retraining interval T^* minimizes total cost per unit time, as equation 14.11 shows:

$$T^* = \arg\min_T \frac{\text{Staleness Cost}(T) + \text{Retraining Cost}}{T} \tag{14.11}$$

Under the assumption $\gamma T \ll 1$, a Taylor expansion of the exponential yields a closed-form approximation. Specifically, the second-order Taylor approximation $e^{-\gamma T} \approx 1 - \gamma T + \frac{1}{2}(\gamma T)^2$ reduces the bracketed staleness term $\left(T - \frac{1-e^{-\gamma T}}{\gamma}\right)$ to $\frac{1}{2}\gamma T^2$. Dividing total costs by T yields an average cost rate of $\frac{1}{2} Q_{\text{day}} V \text{Accuracy}_0 \gamma T + \frac{C}{T}$, where C is the Retraining Cost of equation 14.10. Differentiating with respect to T and setting the derivative to zero balances marginal staleness loss against amortized setup expense and yields the square-root economic interval of equation 14.12:

$$T^* \approx \sqrt{\frac{2 \cdot C}{Q_{\text{day}} \cdot V \cdot \text{Accuracy}_0 \cdot \gamma}} \tag{14.12}$$

The best interval sits where amortized retraining meets accrued staleness.

An exact optimum requires minimizing equation 14.11 without the expansion. The interval grows with the cost of a run and shrinks with traffic, value, and decay rate, each under a square root.

Napkin Math 14.6: The optimal retraining interval

Problem: How often should the team retrain the model to maximize profit?

Physics: In this fitted scenario, model accuracy $\text{Accuracy}(t)$ decays exponentially at rate γ. Each successful update is assumed to restore initial accuracy with negligible training and rollout delay; traffic and value remain constant.

- Q_{day}: Daily Query Volume (Traffic).
- V: Financial value per query for a unit change in accuracy fraction. With this convention, $V = \$0.50$ means 1 percentage point of accuracy is worth $\$0.005$ per query. The Value per Point of equation 14.3 is the same quantity accumulated over a decision horizon, $V/100$ per query multiplied by the number of queries in that horizon.
- C: Fixed cost of a retraining run, including compute and operational overhead.

Formula: Equation 14.12 gives the interval T^* that minimizes the sum of staleness losses and training costs per unit time.

Math: Consider the ranking service in an illustrative scenario ($\text{Accuracy}_0 = 0.94$):

- **Traffic** (Q_{day}): 1,000,000 ranking requests/day.
- **Utility** (V): \$0.50/query for a unit accuracy change.
- **Retraining Cost** (C): \$5,000.
- **Drift Rate** (γ): 0.24 percent per day.

$$T^* \approx \sqrt{\frac{2 \times 5{,}000}{1{,}000{,}000 \times 0.50 \times 0.94 \times 0.0024}} \approx \textbf{3 days}$$

Systems insight: High traffic and valuable accuracy shorten T^*, so label availability, validation requirements, and achievable update delay become the binding limits. If T^* is less than the team's manual deployment time, the proposed cadence exceeds its operational capacity, and the team must shorten the update path or reconsider the policy and its assumptions.

With the parameters collected in table 14.17, the approximation places the economic optimum near 3 days. The ranking service's drift, a 0.24 percent daily decay fitted to its observed four-week slide, is slow enough that a daily run would not yet pay for itself at this run cost. Four times the traffic would bring the optimum to about 1.5 days, the daily cadence that table 14.16 lists for ad click prediction, while a slower-moving domain or a costlier run would push the same formula toward the table's weekly or monthly rows.

Table 14.17: Retraining Decision Parameters: Example values for the ranking service processing 1,000,000 requests daily.

Parameter	Value	Description
Q_{day}	1,000,000	Ranking requests per day
V	\$0.50/query	Value per query for a unit accuracy change
Accuracy_0	0.94	Initial accuracy
γ	0.0024	Daily decay rate (0.24% per day)
C	\$5,000	Total retraining expense

Sensitivity analysis

Under the square-root approximation, T^* scales with the square root of these parameters. Table 14.18 shows that a fourfold change in retraining cost, query volume, or decay rate moves the approximated interval twofold.

Table 14.18: Retraining Interval Sensitivity: Under the square-root approximation a fourfold change in an input moves the interval only twofold, and the directions differ. More expensive retraining lengthens the interval, while higher query volume or a faster decay rate shortens it.

Change	Effect on T^*
4× retraining cost	2× longer interval
4× query volume	2× shorter interval
4× decay rate	2× shorter interval

Accelerator-hours and contention

The run cost C bundles the four terms of equation 14.10, and on the ranking service the accelerator term is the smallest of them. In an illustrative scenario, a run that retrains on the logs gathered since the previous run occupies four H100s for six hours. Those twenty-four accelerator-hours cost $96 at the registry's training rate, about 1.9 percent of the $5,000 run. Validation, deployment, and rollout risk make up the rest, which is why automating the validation path (section 14.3.2.3) shortens the economic interval more than faster training would. The accelerator-hours matter instead as contention. The serving copy of the tables already holds two accelerators, so on an eight-accelerator node a run that holds its own copy and training state on four more leaves room for exactly one further copy of the tables while it executes (figure 14.8). That copy can be a canary, a shadow, or the hot standby of table 14.11, but not more than one of them, so a team that releases and retrains on the same node must schedule the two so that a retraining run never evicts the copy that makes rollback immediate.

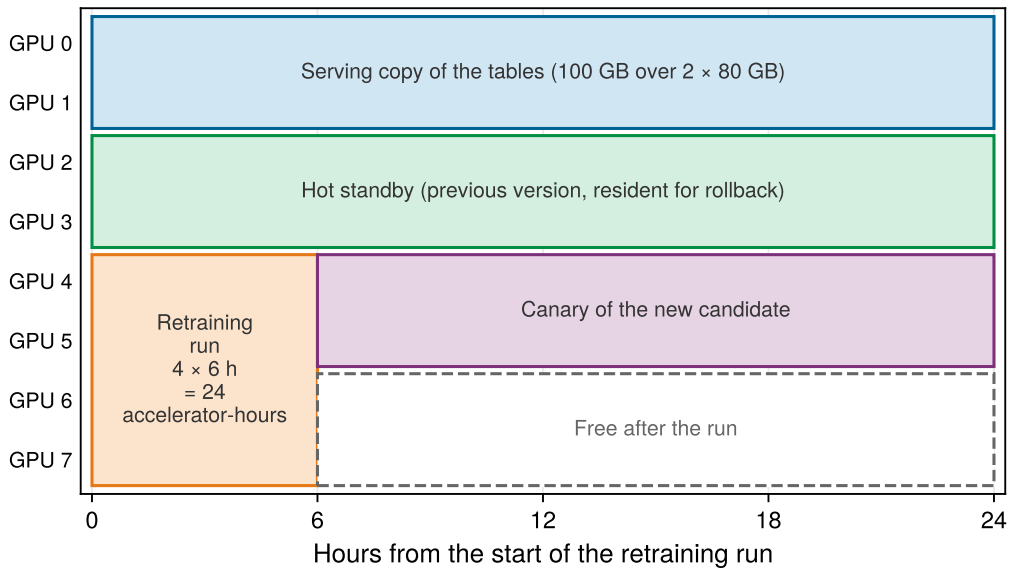


Figure 14.8: One Ranking Node's Day: Accelerator occupancy on an eight-accelerator H100 node over the day of a retraining run, under one schedule that keeps rollback immediate. The serving copy of the 100 GB tables holds 2 accelerators and the hot standby holds 2 more. The retraining run holds 4 accelerators for 6 h, so while it runs the standby is the only further copy of the tables that fits. After the run, the candidate it produces can go out as a canary on 2 of the freed accelerators. The schedule is illustrative and built from the chapter's worked numbers.

Model limitations

This closed-form framework provides a first-order approximation for operational planning, but its utility depends on several simplifying assumptions. First, the exponential decay formulation presumes gradual drift at a steady rate γ; sudden covariate shifts or acute data outages require immediate statistical change-point detection rather than smooth decay models. Second, the formulation assumes a constant marginal value V per accuracy point, whereas real-world utility often has

nonlinear thresholds or asymmetric penalties. Third, the model treats retraining events as independent resets to initial accuracy with negligible delay, setting aside update failures, time spent training and validating, and transfer learning across cycles. Finally, infrastructure costs are modeled as fixed sums, whereas cloud spot pricing, queue contention, and elastic compute availability introduce dynamic variations. Parameters improve through empirical calibration against historical telemetry as operational experience accumulates, and the framework implements cost-aware automation (section 14.1.1) with thresholds grounded in measurable business impact.

14.6.3 Scheduled versus triggered retraining

The interval derived in equation 14.12 fixes a calendar schedule from average drift, whereas the decision gate of section 14.6.1 lets observed evidence decide when to run. Over a 365-day deployment on the ranking service, the two policies trace different sawtooths against a drift threshold of 0.88 accuracy (figure 14.9). Under a scheduled policy (orange sawtooth), the model retrains at rigid 90-day intervals, repeatedly dipping below the quality floor before each reset. In contrast, a triggered policy (green sawtooth) initiates retraining the moment monitored accuracy touches the threshold, illustrating an idealized instantaneous reset; in practice the trigger is often a divergence or proxy signal calibrated against accuracy. Both curves are drawn from the temporal decay model of equation 14.8. In deployment, sample collection, label arrival, training, validation, and rollout delays can carry accuracy below the trigger before recovery; the policy does not guarantee a performance floor.

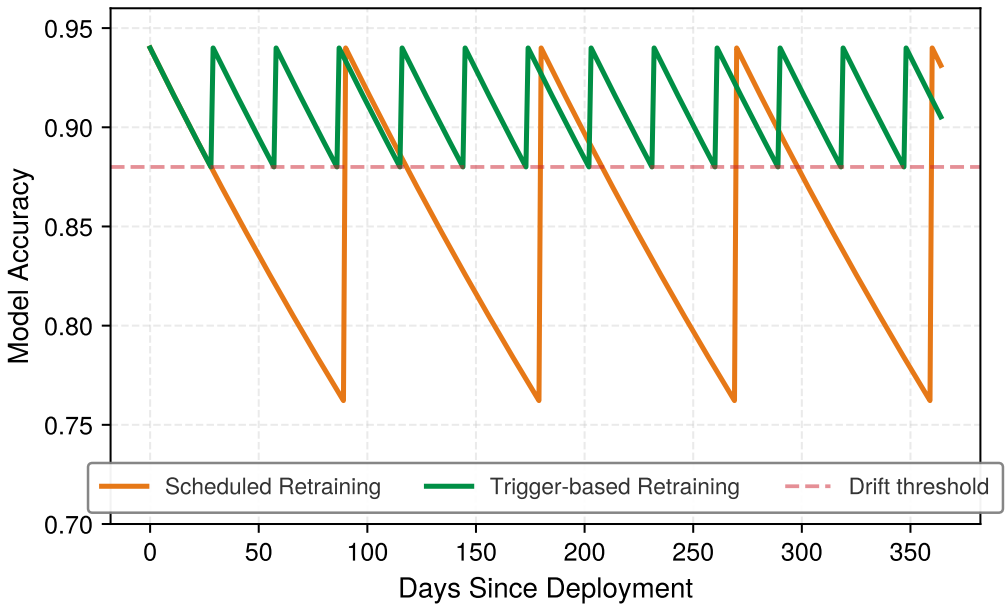

Figure 14.9: The Rotting Asset Curve: An illustrative exponential accuracy decay under two maintenance policies, both drawn as sawtooths. The scheduled policy resets every 90 days regardless of accuracy and dips below the drift threshold before each reset, while the triggered policy resets on crossing that threshold and holds a higher floor in this zero-delay model. Real response delays and update quality must be measured; neither cadence is universal.

In this zero-delay model the scheduled policy dips below the floor each cycle and the triggered one does not: scheduled retraining is easy to plan but can retrain too early or too late, whereas trigger-based retraining requires stronger telemetry but aligns intervention with observed degradation. Whichever policy fires, a retrained replacement or a rollback depends on the registry lineage of section 14.3.1.2, which links each version to the code, data, hyperparameters, and weights that produced it and so lets a responder return to a known-good checkpoint, even though lineage still cannot guarantee bitwise replay if driver versions, CUDA libraries, or nondeterministic reduction kernels vary across the fleet. Retraining answers gradual drift, whereas a sudden drop with a

cause inside the system, such as a broken feature transform, a bad release, or a corrupted upstream table, calls for a different response, because the failing layer must be found and contained, often by rollback, long before a retraining run could finish, and that is the work of incident response.

14.7 Incident Response and Governance

The ranking service from the opening of this chapter drew attention only in week eight, and a product manager noticed before any system did. Drift monitoring could have raised the alarm by week four, when accuracy had already fallen to 88 percent, but an alert only relocates the problem. Someone must then decide quickly whether the signal is real, which system caused it, and whether to roll back, and the organization must already have decided which models were allowed to ship and who owns them. Incident response supplies the first set of decisions, governance supplies the second, and the ML Test Score, taken up with operational maturity (section 14.8.1), audits whether both are in place before a failure tests them.

14.7.1 Incident response and operational practices

An unowned drift alert that fires on a Friday night without a severity policy, a diagnostic checklist, or rollback authority sits in a Slack channel until Monday while live traffic absorbs the damage. Incident response, debugging, and on-call rotation form the human half of the monitoring loop, turning a statistical signal into an engineering action within a bounded time.

14.7.1.1 Incident response for ML systems

At 2:00 AM, an on-call engineer receives an alert: the ranking service's click-through rate has dropped 12 percent over the past hour. There is no stack trace, no error log, no crashed process, just a statistical signal that something has changed. The responder must distinguish among four candidate root causes: an upstream data-pipeline failure, model drift, a seasonal traffic pattern, or statistical noise. This ambiguity is common in ML incidents, whose symptoms may appear as degradation in outcome or predictive-quality metrics rather than explicit errors, so incident response must account for statistical uncertainty.

Severity classification provides the foundation for prioritizing response in this ambiguous landscape. Table 14.19 gives one recommendation service's illustrative policy, with response deadlines from 15 minutes to 24 hours. Priority depends on affected traffic, consequences, and the need for containment. Click-through rate measures engagement rather than classification accuracy, and a population stability index value alone establishes neither quality loss nor incident severity.

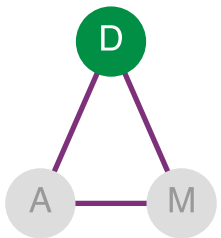
Table 14.19: Incident Severity Classification for ML Systems: Illustrative response deadlines belong to this service's policy. Impact, evidence, and containment needs determine priority; drift magnitude alone does not.

Level	Criteria	Response Time	Example
P0	Service unavailable across live traffic	15 minutes	Null predictions prevent recommendation delivery
P1	Broad harmful impact needing containment	1 hour	CTR falls across major cohorts; replay confirms a broken feature contract, while longer-term outcomes remain pending
P2	Bounded impact with a validated fallback	4 hours	A localized feature defect is contained; the owner investigates remaining exposure and pending outcomes
P3	No observed impact or immediate exposure	24 hours	Training is delayed while the current release remains within its measured operating limits

Once an incident is classified, responders execute a structured response workflow where urgent containment can proceed alongside evidence collection:

1. Detection identifies which monitoring signal, affected metric, and threshold triggered the alert.
2. Impact assessment quantifies the fraction of serving traffic, user cohorts, or downstream services exposed.

3. Change correlation audits recent deployments across model weights, serving runtimes, feature transforms, and upstream data pipelines.
4. Mitigation evaluates and executes containment options, including traffic shifting, fallback enablement, or rollback to a known-good checkpoint.
5. Root cause analysis isolates whether the defect originates in data pipelines, model representations, or serving infrastructure.



For P0 and P1 incidents, postmortem documentation is required. These postmortems analyze timelines, root causes, user impact, and preventive measures, specifically identifying which monitoring gap allowed the issue to reach production and what automated validation would have caught it earlier.

14.7.1.2 Model debugging: From detection to diagnosis

Incident response triages and mitigates; model debugging identifies root causes. Monitoring detects that something is wrong; debugging determines *why*. ML debugging must account for probabilistic and data-dependent failures in addition to conventional software defects. An incorrect prediction does not throw an exception or generate a stack trace, making systematic debugging essential for resolving ML incidents efficiently.

The debugging decision tree When model performance degrades, the following five stages provide a starting workflow; recent changes and incident severity can alter their priority. Section A.5.2 supplies a systematic diagnostic matrix that maps symptoms to D·A·M (Data · Algorithm · Machine) axes.

1. **Data pipeline integrity**: Inspect upstream data pipelines for schema changes, missing values, serialization errors, or input distribution shifts. Data integrity is an effective starting boundary because altered inputs, corrupted labels, and upstream feature changes can affect every downstream prediction.
2. **Training-serving skew**: Replay matched requests through the versioned offline and serving transformations and compare feature values, missingness, units, and time cutoffs. KS or PSI separately screen for population divergence; neither verifies that the two paths compute the same value for a given request.
3. **Subpopulation slicing**: Disaggregate performance across operational dimensions (such as geography, client hardware, or user cohorts). Localized degradation isolates data coverage gaps and slice-specific label noise that aggregate metrics conceal.
4. **Temporal degradation dynamics**: Evaluate performance trends across time. Abrupt drops prioritize recent release artifacts and upstream infrastructure outages, whereas gradual degradation motivates checking seasonality and changing predictive relationships.
5. **Model and representation attribution**: After verifying data pipeline integrity and ruling out serving skew, evaluate model-level failure modes through prediction confidence distributions, calibration curves, and feature attribution.

Production debugging starts on the data axis of D·A·M.

Slice analysis Slice analysis can guide pipeline and serving-skew investigations by testing whether the apparent system-wide problem is concentrated in a subpopulation. Performance metrics aggregated across all traffic can mask significant problems in subpopulations. **Slice analysis** exposes that masking by computing the same metric separately for each segment, and table 14.20 shows how a healthy overall accuracy can hide severe degradation in one of them.

Table 14.20: Slice Analysis Example: Overall accuracy of 91 percent appears acceptable, but tablet users (5 percent of traffic) experience 62 percent accuracy, a severe degradation masked by aggregation. Effective debugging requires systematic slice analysis across key dimensions.

User Segment	Traffic %	Accuracy	Impact
Desktop users	45%	94%	Nominal
Mobile (iOS)	30%	92%	Nominal
Mobile (Android)	20%	88%	Minor degradation

User Segment	Traffic %	Accuracy	Impact
Tablet users	5%	62%	Severe, investigate
Overall	**100%**	**91%**	**Masks tablet problem**

↪ Post-hoc feature attribution methods, Shapley value computational costs, and model interpretability boundaries are developed in section 15.3.3.1.

Feature attribution for debugging When slice analysis identifies a problematic segment, feature attribution techniques help identify which features the model relies on within its incorrect predictions. The common choice is SHAP values, feature-attribution scores that estimate how much each input feature contributed to an individual prediction, computed over the mispredicted examples of the failing slice and summarized across them. Their cost and their limits as explanations belong to responsible engineering; for debugging, one caveat governs their use. An attribution summary identifies features the model relied on within the failing slice; it does not establish whether those features caused the errors, so diagnosing stale features, missing coverage, or semantic shift requires checking feature lineage and production distributions. Attribution can also expose a zombie feature (perspective 14.1), an input the model should no longer depend on because nobody maintains it, whereas counterfactual analysis asks the complementary question about one decision at a time.

Counterfactual analysis For individual mispredictions, counterfactual analysis identifies the minimal change that would flip the prediction. If a churn prediction would flip to "engaged" when `user_session_length` rose from 12 minutes to 45, that sensitivity suggests checking for the definition mismatch illustrated in the skew case study (section 7). Matched-input comparisons and feature lineage must establish whether the churn system has the same pipeline defect before the counterfactual can guide a repair. Counterfactuals reveal which feature boundaries drive decisions and whether those boundaries make semantic sense, and counterfactuals that require implausible changes ("user age would need to be -5 years") often indicate feature engineering problems. Together, the debugging decision tree, slice analysis, feature attribution, and counterfactuals form a unified debugging toolkit that teams codify into a repeatable checklist.

Debugging checklist The diagnostic lenses identify places to investigate; a six-phase checklist organizes how to test a suspected cause. The ordering is deliberate because each phase narrows the search space for the next:

1. **Reproduce**: An ML failure that cannot be reproduced on held-out data is often data-dependent, an insight that redirects investigation toward the D·A·M taxonomy's data layer.
2. **Isolate**: Once reproduced, identifying the minimal input set that triggers the failure transforms a diffuse "the model is wrong" complaint into a specific, testable condition.
3. **Bisect**: If the failure correlates with a recent deployment, controlled comparisons of versioned model, feature-transform, and runtime artifacts help isolate which change introduced the regression.
4. **Attribute**: Feature attribution applies interpretability techniques to identify which input factors drive the erroneous behavior.
5. **Validate**: Confirming that the hypothesized root cause, when corrected, actually resolves the failure distinguishes genuine fixes from coincidental improvements.
6. **Prevent**: Converting each resolved incident into a monitoring rule or validation check systematically closes the gap between detection and recurrence. This cumulative hardening can reduce repeated failure modes over time because each incident strengthens the observability infrastructure.

The session-duration defect illustrates how these phases lead to a specific response. Suppose the CTR alert coincides with a serving-transform release on one of the ranking service's hosts. The model weights, runtime, and offline feature definition are unchanged. Request logs place the new transform on the affected sessions, and replaying those exact inputs reproduces the wall-clock versus foreground-active mismatch. Representative traces show unchanged feature-retrieval and model-execution durations, weakening a latency-regression explanation without ruling out every infrastructure fault. Mature recommendation outcomes for the new release are still pending, so the responder has established a feature-contract violation, not its eventual effect on accuracy or revenue.

The owning engineer restores the prior serving transform and its compatible feature-cache namespace, first checking the rollback on replayed requests and then exposing it through a bounded canary. Matched values agree again, and the same-input scores return to the prior artifact's outputs within the declared tolerance. Those observations demonstrate recovery of the feature contract; later comparable, mature outcome cohorts must establish whether user outcomes recover. A weights-only rollback leaves the changed feature computation in place, and immediate retraining would teach against the defect rather than repair the contract. The prevention step adds the affected idle-session inputs to parity validation and records the transform, cutoff, and cache versions needed for future replay.

14.7.1.3 On-call practices for ML systems

The debugging techniques in section 14.7.1.2 assume an engineer investigating during business hours. Production systems fail at 3:00 AM on weekends, and the person responding may not be the one who built the model. On-call practices keep someone with the right expertise available and equipped, and ML adds two difficulties to an ordinary on-call rotation. Its incidents are ambiguous. An engineer facing a 3 percent accuracy drop must decide whether it is statistical noise, a changed predictive relationship, or a failure that needs mitigation, which demands statistical context rather than log analysis. Its impact is also delayed. A ranking model that began serving slightly worse recommendations on Monday may not move revenue until Friday, by which time the window for easy diagnosis has closed, and the cause often lies in an upstream data system owned by another team.

These challenges motivate tiered escalation structures that match expertise to incident complexity. Table 14.21 illustrates one possible structure, where primary responders handle routine issues using standardized runbooks while escalation paths connect to specialists capable of deeper investigation. A parallel data on-call role can reduce time to resolution when the root cause lies in an upstream data system.

Table 14.21: ML On-Call Structure: Tiered escalation with parallel data on-call enables efficient incident response. Tier 1 handles routine issues using runbooks; Tier 2 addresses complex debugging; Tier 3 manages critical incidents requiring architectural decisions.

Tier	Responder	Responsibility
Tier 1 (Primary)	ML Engineer	Initial triage, standard runbooks, escalation decisions
Tier 2 (Escalation)	Senior ML Engineer/Data Scientist	Complex debugging, cross-system investigation, model-specific issues
Tier 3 (Critical)	ML Platform Lead	Architecture decisions, major incidents, vendor escalation
Data On-Call (Parallel)	Data Engineer	Data pipeline issues, feature store problems, upstream dependencies

Effective on-call depends on runbooks and on alert discipline. Each production model's runbook records its purpose, owner, and criticality; the latency, throughput, and accuracy ranges that define healthy behavior; past incidents and their resolutions; the diagnostic queries for recent predictions, feature distributions, and confidence scores; and the escalation and rollback criteria, including when to roll back without approval. Alert fatigue, the tendency to dismiss alerts after too many false positives, erodes all of it, so teams consolidate related alerts into one notification, use thresholds that follow weekly and seasonal patterns, retire alerts that are rarely actionable, and require a follow-up ticket before any alert is silenced. Structured shift handoffs carry active incidents, recent deployments, scheduled changes, and suppressed alerts across rotations, while limits on consecutive on-call days, compensatory time off after severe incidents, and automation that removes toil keep the rotation sustainable over years of operation. Even so, dashboards fail if no one is responsible for acting on alerts and runbooks languish if team structures do not support their use, which is why production ML operations need organizational infrastructure alongside the technical: clear governance, defined roles, and communication patterns that enable cross-functional coordination.

14.7.2 Governance and team coordination

On-call runbooks address real-time operational failures after a model is already serving traffic, whereas proactive governance sets the behavioral, legal, and ownership rules a candidate must satisfy before a data scientist hands a checkpoint to an infrastructure team for release. Without those pre-release checks, a model can ship into production with no signed feature contract, no subgroup fairness check, and no named owner, producing biased predictions or opaque decisions that neither team has the context to catch. Within an operational pipeline, governance enforces three concrete objectives: transparency through auditable training data lineage and verifiable model weights, fairness through evaluation against the application's selected and justified criteria, and compliance through adherence to privacy, retention, and auditability rules. While chapter 15 details the statistical metrics and interpretability algorithms required for these properties, MLOps provides infrastructure to collect evidence and enforce specified checks across the deployment lifecycle, alongside accountable policy and domain review.

ML governance spans the full lifecycle of the artifact, from automated pipelines that record feature schemas, training data provenance, and hyperparameter configurations during development, through prerelease validation gates that evaluate out-of-distribution robustness and selected fairness criteria, to production monitors that track changes in subgroup metrics alongside aggregate accuracy. Encoding testable governance policies in CI/CD pipelines makes release checks repeatable, while choices about acceptable risk, fairness criteria, and applicable obligations still require accountable review.

Concretely, a model registry promotion gate requires a signed feature contract, a recorded training-data lineage hash, subgroup metrics above policy thresholds, a canary SLO with automated rollback criteria, and a designated artifact owner before a model transitions from staging to production. That gate turns documented release requirements into assertions enforced by the deployment machinery. Passing those assertions establishes that the specified checks passed, not that every governance obligation has been satisfied.

Governance policies define the release criteria, but operational reliability depends on execution across organizational boundaries. Because machine learning systems span data engineering, statistical modeling, and distributed serving infrastructure, role handoffs represent the most failure-prone interfaces in the operational lifecycle. Versioned experiment stores and centralized model registries provide the shared substrate required for reproducible transitions between research and production engineering. At the data interface, formal schema specifications and lineage DAGs ensure that data scientists and platform engineers share identical assumptions regarding feature semantics, default null handling, and label arrival latency.

Titles and boundaries vary across organizations, but one common decomposition uses the five roles in table 14.22. The table maps each role to a primary responsibility without implying that every organization needs five separate positions:

Table 14.22: ML Team Roles Matrix: Clear role boundaries prevent gaps and overlaps. Data Scientists focus on model quality while ML Engineers handle productionization. Data Engineers own data pipelines while Platform Engineers own MLOps tooling. SREs ensure overall system reliability.

Role	Primary Focus	Key Deliverables	Collaboration Points
Data Scientist	Model development, experimentation, algorithm selection	Trained models, experiment results, performance benchmarks	Hands off to ML Engineer for productionization
ML Engineer	Production ML systems, training pipelines, serving infrastructure	Deployed models, training pipelines, serving systems	Receives from Data Scientist; works with Platform Engineer on infrastructure
Data Engineer	Data pipelines, feature engineering, data quality	Feature pipelines, data quality systems, feature stores	Provides data to Data Scientist; maintains feature store for ML Engineer
Platform Engineer	MLOps infrastructure, tooling, automation	CI/CD pipelines, monitoring systems, compute infrastructure	Enables ML Engineer; maintains shared infrastructure
DevOps/SRE	Reliability, incident response, system health	SLOs/SLAs, on-call procedures, runbooks	Supports all roles; owns production health

Clear role definitions matter most at handoff points, where artifacts transition between specialists. The most failure-prone transition occurs between Data Scientists and ML Engineers. An exploratory notebook script frequently fails in production environments due to undocumented data preprocessing steps, hardcoded local file paths, hidden state execution orders, or unpinned library dependencies. Similarly, the handoff from ML Engineers to SREs (Beyer et al. 2016) requires verified monitoring dashboards, active alerting rules, documented runbooks, and tested rollback procedures. Data Engineers interface with model builders through feature contracts, formal specifications of data schema, freshness SLOs, and distribution invariants that prevent upstream pipeline modifications from surfacing as silent downstream prediction failures weeks later. Teams eliminate these interface risks by requiring standardized container images, hermetic build manifests, and automated reproducibility assertions before any artifact advances to the next stage.

14.7.2.1 Stakeholder communication

While cross-functional handoffs govern internal engineering execution, stakeholder communication sets the shared expectations between technical teams and organizational decision-makers. Learned behavior adds dependence on the data and population, alongside latency-accuracy trade-offs and possible distribution drift. When stakeholders consider only service availability, misalignment can arise regarding expected predictive quality, latency budgets, and maintenance costs.

A frequent communication failure is the unconstrained request to "make the model more accurate." Model accuracy cannot be scaled independently of system costs. Boosting validation accuracy by two percentage points often requires moving to a significantly larger model architecture, incurring higher FLOP counts per sample, increasing memory bandwidth demands, and violating strict inference latency SLOs. Grounding improvement discussions in the Pareto frontier (principle 5) forces explicit decisions among model accuracy, inference latency budgets, training compute costs, and dataset acquisition expenses.

Translating statistical metrics into operational impact requires mapping errors to their consequences, which are rarely symmetric. Accuracy, ROC-AUC, and F1 treat errors symmetrically. The ranking service's errors differ in cost only mildly, so a separate illustrative case with a sharper asymmetry carries the argument. In an automated fraud detection pipeline, a false positive creates friction at checkout while a false negative allows unrecoverable theft. With missed fraud ($500 per incident) five times as costly as a blocked legitimate user ($100), the total cost across classification thresholds reaches its minimum near 0.34, well left of the symmetric 0.50 baseline (figure 14.10).

When monitoring detects distribution drift or an inference regression triggers an automated rollback, the status report must state the evidence directly: the statistical divergence metric, the demographic or tenant cohort affected, the canary rollback target, and the estimated recovery timeline. Dismissing an anomalous output distribution as noise without a hypothesis test lets a silent failure reach production decisions.

In the same fraud detection case, consider a team evaluating a proposed model upgrade. When stakeholders request improved capture rates, the engineering team frames the initiative as a concrete systems trade-off: increasing the fraction of fraud dollars captured from 92 percent to 94 percent requires integrating external feature pipelines, extending training duration by two weeks, and accepting 30 percent higher infrastructure costs. In return, the upgrade prevents an estimated $2 million in annual fraud losses while a separate assumption of a 20 percent cut in false-positive alerts removes 50,000 of them per month. Framing model improvements around financial impact, latency budgets, and compute expenditure keeps governance decisions tied to verifiable engineering trade-offs.

Checkpoint 14.4: From alert to accountable action

- ☐ **Diagnosis**: A cohort's accuracy drops while its feature distribution shifts. What additional evidence would distinguish a feature-pipeline defect from a changed predictive relationship?
- ☐ **Release authority**: Name an automated promotion check and a policy decision that its passing result cannot make on the team's behalf.

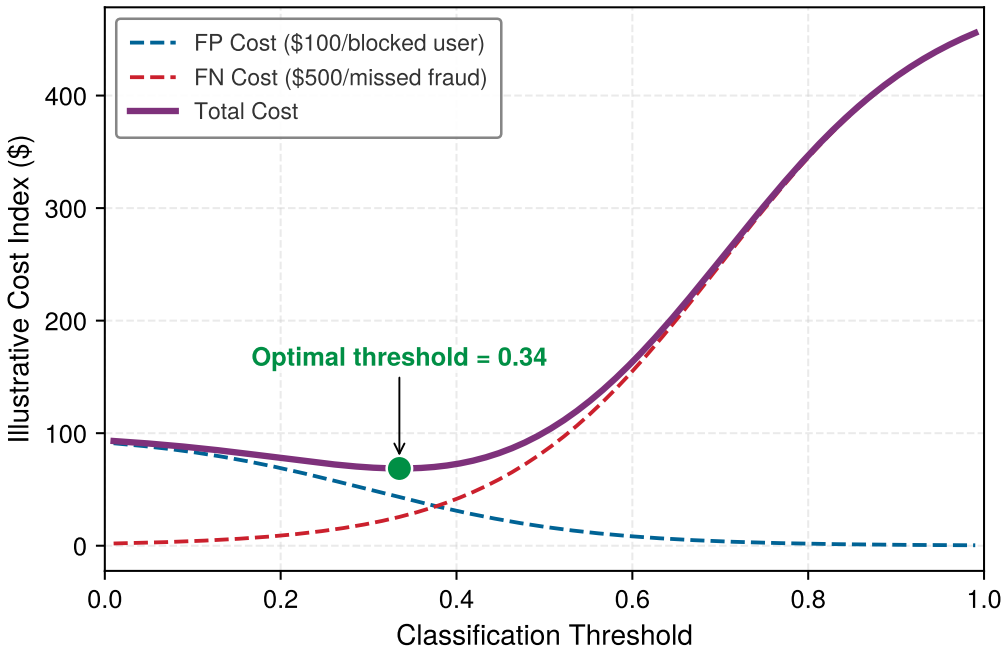


Figure 14.10: The Business Cost Curve: An equal-class-weighted illustrative cost index vs. classification threshold. Technical metrics like ROC curves hide the economic reality: errors have different costs. Here, a false negative (missed fraud) costs $500, while a false positive (blocked user) costs $100. The system flags a transaction as fraud when its score exceeds the threshold, so a lower threshold flags more transactions. Because missing fraud is $5\times$ more costly, the optimal threshold shifts left of center, making the system more aggressive at flagging suspicious transactions and accepting more false positives to minimize expensive misses. With equal costs the optimum would sit at threshold = 0.50; the asymmetry pulls it toward threshold ≈ 0.34. A population expected cost would also weight each term by class prevalence. MLOps tunes thresholds as costs and prevalence change.

14.8 Operational Maturity

An organization deploying its initial ML model might rely on a hand-run Jupyter notebook, a scheduled cron job, and minimal monitoring. A mature enterprise runs thousands of models through automated pipelines with drift detection, canary deployments, and continuous validation. Both are doing "MLOps," yet they differ greatly in reliability, cost efficiency, and deployment velocity. Empirical surveys of production deployments reveal that systems failures cluster around data dependencies, pipeline boundaries, and monitoring blind spots rather than core model architectures (Paleyes et al. 2022). Operational maturity provides the systems framework for evaluating this progression. Organizations evolve from ad hoc experimentation toward fully automated operations, and locating a system on this continuum guides resource allocation better than adopting tooling indiscriminately. Placing a system on the continuum starts with an audit of its current practices and then raises three questions in turn: what architecture the next level requires, which organizational and failure-containment patterns keep that architecture working, and how much the move is worth.

14.8.1 ML test score

A team can spend months perfecting offline hyperparameter sweeps and unit tests for its model code while leaving production monitoring and schema checks completely unbuilt, only to suffer a multi-week silent outage on the first upstream database change. Auditing the debt patterns of table 14.6 and the controls built to pay them down requires a formal technical debt assessment rubric that turns subjective readiness debates into measurable engineering gates. The ML Test Score (Breck et al. 2017) structures this evaluation across four operational categories: data tests, model tests, infrastructure tests, and monitoring tests. The rubric specifies 28 tests, seven per category. A documented manual test whose results are distributed receives 0.5 points; an automated test run

repeatedly receives 1 point, and an unperformed test receives 0. The composite score is the weakest category score, not an average:

$$\text{ML Test Score} = \min(\text{Score}_{\text{data}}, \text{Score}_{\text{model}}, \text{Score}_{\text{infra}}, \text{Score}_{\text{mon}})$$

where each category score $\text{Score}_{\text{cat}} \in [0, 7]$. A deployment with exhaustive offline model validation ($\text{Score}_{\text{model}} = 7$) but absent production telemetry ($\text{Score}_{\text{mon}} = 0$) receives an overall score of 0. The min operator is deliberate, because an unmonitored serving path can deliver corrupted predictions despite strong offline benchmark accuracy.

Three of the four suites partition production risk along the D·A·M axes, and the fourth watches all three. The data suite (D) verifies that feature distributions conform to declared schemas, privacy boundaries remain unviolated, and each feature justifies its inference latency and memory footprint. The model suite (A) confirms that architectures and hyperparameter configurations are version-controlled, staleness bounds are enforced, and offline benchmark improvements translate into live metric gains. The infrastructure suite (M) tests training reproducibility under documented execution conditions, serving-path parity between training and inference pipelines, and automated rollback mechanisms. The monitoring suite is the feedback layer across all three axes; it verifies that schema changes, invariant violations, training-serving skew, and stale weights generate actionable alerts that help limit downstream impact. Table 14.23 summarizes representative tests across each category:

Table 14.23: ML Test Score Checklist: Representative production-readiness tests from the ML Test Score rubric. The original rubric contains 28 tests grouped into four sections of seven tests each; section scores expose whether production risk comes from data validation, model validation, infrastructure, or monitoring rather than hiding the weakness in a single total. Based on Breck et al. (2017).

Category	Test	Implementation Example
Data Tests	Feature expectations are captured in schema	Great Expectations, TFX Data Validation
	All features are beneficial (no unused features)	Feature importance analysis, ablation studies
	No feature's cost exceeds its benefit	Latency/accuracy trade-off analysis
	Data pipeline has appropriate privacy controls	PII detection, access logging
Model Tests	Model spec is reviewed and checked into version control	Git-tracked model configs
	Offline and online metrics are correlated	A/B test validation of offline improvements
	All hyperparameters are tuned	Automated HPO with tracked results
	Model staleness is measured and bounded	Performance decay monitoring
Infrastructure Tests	Training is reproducible	Fixed seeds, versioned data, locked dependencies
	Model can be rolled back to previous version	Model registry with versioning
	Training and serving code paths are tested for consistency	Feature store integration tests
	Model quality is validated before serving	Automated validation gates in CI/CD
Monitoring Tests	Dependency changes result in alerts	Data schema monitoring
	Data invariants hold in training and serving	Distribution comparison tests
	Training and serving features are not skewed	Training-serving skew detection
	Model staleness is monitored	Alerts and evidence-based retraining review

Because the composite score is bounded by the minimum category, reliability audits must prioritize the bottleneck subsystem limiting the system score. Expanding a model test suite from 5 to 6 points while monitoring remains at 1 leaves the composite score unchanged, but can still improve actual coverage. The score highlights the weakest category without quantifying every reliability gain. Regular audits against this rubric reveal whether reliability risks stem from unvalidated input pipelines, offline-online distribution divergence, or uninstrumented serving paths, and so direct refactoring effort toward the debt that most threatens production. Each low category score also names the infrastructure that pays the debt down. A weak data score calls for schema contracts and shared feature definitions, a weak infrastructure score for versioned and reproducible pipelines, and a weak monitoring score for production telemetry.

14.8.2 Maturity levels

While the ML Test Score audits individual verification gates, **operational maturity** measures how cleanly those practices fit together across data pipelines, model training, and serving hardware

(Zaharia et al. 2018). Adopting an experiment tracker such as MLflow while leaving feature extraction in ad hoc notebooks and model rollout to manual file copies raises isolated test counts without reducing production outages. Although operational maturity exists on a continuum, grouping systems into three distinct maturity levels clarifies how workflows evolve from exploratory prototypes into reliable production infrastructure.

At the lowest level, workflows are ad hoc: training runs manually on local workstations, feature extraction is embedded in ephemeral scripts, and deployment relies on manual file transfers. As maturity increases, workflows become repeatable: teams introduce version-controlled pipelines, centralized artifact registries, and scheduled batch jobs. At the highest level, systems become scalable: declarative infrastructure-as-code, continuous validation pipelines, and real-time observability decouple model iteration from production serving.

Table 14.24 summarizes this architectural progression from disconnected execution toward unified lifecycle management.

Table 14.24: Maturity Progression: Machine learning operational practices evolve from manual, fragile workflows toward fully integrated, automated systems, impacting reproducibility and scalability. Key characteristics and outcomes at each maturity level emphasize architectural cohesion and lifecycle integration for building maintainable learning systems.

Maturity Level	System Characteristics	Typical Outcomes
Ad Hoc	Manual data processing, local training, no version control, unclear ownership	Fragile workflows, difficult to reproduce or debug
Repeatable	Automated training pipelines, basic CI/CD, centralized model storage, some monitoring	Improved reproducibility, limited scalability
Scalable	Fully automated workflows, integrated observability, infrastructure-as-code, governance	High reliability, rapid iteration, production-grade ML

Consider how the ranking service evolves across these maturity levels:

- **Ad hoc**: A data scientist trains a model in a Jupyter notebook, exports it as a pickle file, and hands it to an engineer who deploys it to a single server. When accuracy drops, the data scientist retrains manually by running the notebook again with fresh data. Debugging requires the original data scientist because no one else understands the preprocessing steps.
- **Repeatable**: The training script is version-controlled, with a scheduled Jenkins job that retrains monthly. Features are computed in a SQL script that engineering maintains separately. The model is deployed via container, with basic accuracy monitoring. When the feature SQL changes, the data scientist must manually verify the model still works.
- **Scalable**: Training and serving use the same feature store, reducing skew. A CI/CD pipeline investigates drift when PSI exceeds 0.25, retrains when evidence supports it, validates the new model against the baseline, and deploys via canary release. Monitoring tracks per-cohort click-through rate, triggering investigation when specific segments degrade. The entire lineage from raw data to production prediction is auditable.

Moving between maturity levels takes substantial engineering investment, and its return is a lower mean time to recovery (MTTR) and fewer silent failures, which matters most for mission-critical services. Evaluating an organization against this spectrum isolates specific architectural bottlenecks (such as manual data transfers or unversioned preprocessing logic) before they compound into production outages.

14.8.3 System design implications

The repeatable ranking service above already automates training and deployment, yet a change to its separately maintained feature SQL still requires manual validation. More frequent retraining would increase the manual validation burden without removing the mismatch risk. A versioned feature contract and matched-request parity tests address the failure boundary first; a shared feature store becomes useful when maintaining that contract across pipelines warrants the additional infrastructure. Maturity assessment therefore selects the next missing control for each system.

Figure 14.11 provides a coverage map for that assessment. Service uptime is visible at the tip, while data- and model-health failures can remain hidden below the waterline. For each failure mode, the assessment must identify the evidence that exposes it and the action that contains it.

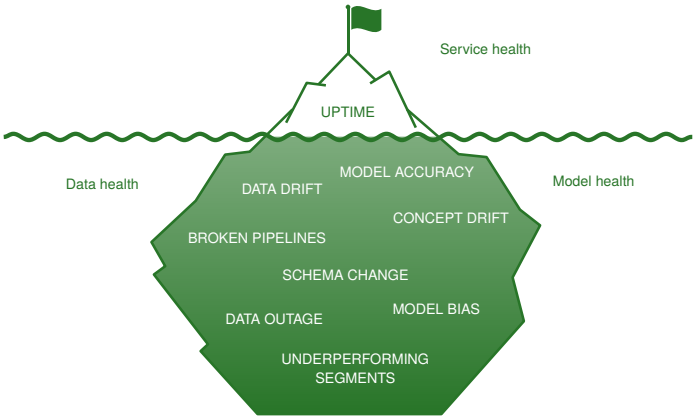

Figure 14.11: Uptime Dependency Stack: The waterline separates visible service uptime from data- and model-health failures that can remain hidden while the service stays available; the surrounding labels organize the monitoring surface into data, model, and service health.

A system that logs all three health domains can still lack a response path. If stale features are detected but no validated fallback exists, containment is the next investment. If quality outcomes are recorded without the served model version, attribution must be repaired before automatic promotion can rely on them. If a canary can exhaust the production worker's memory, resource isolation takes priority over another dashboard. Each finding identifies a specific capability to add and a failure against which to test it.

14.8.4 Design patterns and anti-patterns

Buying a commercial feature store or drift dashboard before deciding who is allowed to trip a fallback or isolate a misbehaving canary leaves the on-call team watching a failure they have no mechanism or authority to contain. Once the maturity assessment names a missing control, containment depends on an owner with the authority to change the affected system. A centralized MLOps team can maintain shared controls across models, while a federated model places engineers within product teams under shared architectural standards. Either arrangement must resolve the same handoff: who validates a fallback, who can activate it, and who confirms recovery. Buying a feature store or alerting platform before settling that handoff is the tool-first anti-pattern.

Once ownership is explicit, the residual failure determines the technical protection. Broken inputs require a way to stop harmful predictions; competing model versions require resource isolation. The cost of these controls is justified by the exposure they contain, and their effectiveness must be tested against that specific failure.

A circuit breaker automatically routes traffic away from a failing service when its error rate exceeds a threshold, and in ML serving it needs ML-specific trip conditions. Conventional circuit breakers trip when RPC timeouts or HTTP 5xx error rates exceed a set threshold. In an ML serving context, circuit breakers must also monitor invariants whose violation signals broken inputs rather than gradual drift: sudden shifts in feature bounds, missing-feature rates, or output distribution collapse. Gradual drift scores such as PSI open a diagnosis instead of tripping the breaker. When triggered, the circuit breaker bypasses the model to serve predictions from a deterministic heuristic fallback, a cached lookup table, or a simpler baseline model, preventing corrupted inferences from cascading into downstream transactional systems.

Similarly, bulkhead patterns[25] isolate candidate or canary models from primary serving paths. For the ranking service, the bulkhead must reserve a canary's full copy of the tables, 100 GB across two accelerators (table 14.11), rather than a slice proportional to its traffic share. On multi-tenant accelerator hardware, an unconstrained experimental model suffering an out-of-memory abort,

[25] **Bulkhead pattern**: This pattern partitions system resources to contain failures within isolated zones. In ML serving, a bulkhead allocates fixed accelerator memory, host RAM, and worker thread pools to experimental model versions, so a canary's resource exhaustion is less likely to terminate the primary serving path; the protection depends on the process and hardware isolation actually enforced.

memory leak, or thread-pool exhaustion can crash the shared serving runtime or stall the PCIe bus. Containerized memory limits, isolated worker queues, and supported hardware partitions can contain specific resource failures. Shared memory bandwidth, interconnects, and device-level faults still require explicit isolation analysis and testing.

Redundancy has a hard limit in ML serving. Replicating a model across workers or voting across ensemble members protects against crash faults, and agreement protocols can keep replicas consistent with one another, but agreement is not correctness. When every replica shares the same inductive biases or training-distribution blind spots, the replicas fail together and silently, and no amount of voting reveals the error before delayed ground truth arrives. Circuit breakers, bulkheads, and replication therefore strengthen an MLOps implementation only when each is applied to the failure class it can actually detect.

These patterns, like every operational practice in this chapter, must also adapt to physical, regulatory, and organizational constraints. A standard CI/CD pipeline may be infeasible without direct host access, monitoring may require indirect signals or on-device anomaly detection, and privacy regulations may limit data collection; these adaptations apply the same principles under constraint. Organizations operating many ML nodes consolidate into platform architectures with shared infrastructure and centralized governance, which raises challenges beyond single-node operations (cross-model resource allocation, system-level observability, and fault tolerance across interdependent pipelines). Sound single-model practices remain prerequisites, because gaps in monitoring, testing, or deployment multiply across the model portfolio.

14.8.5 MLOps investment economics

Spending $100K a year on an enterprise feature store and automated retraining pipeline for an internal analytics model that drives $20K in decisions is an engineering failure of its own, just as starving a $50M ranking engine of basic drift checks invites a six-figure outage. MLOps pays off when the investment matches the model's production value. This chapter has already put a number on each control separately. Training-serving skew cost a fixed fraction of daily queries (equation 14.2); automation paid back once manual hours overtook its build cost (notebook 14.1); retraining was worth a run only when recovered accuracy outweighed run cost and rollout risk (equation 14.3), with equation 14.12 setting its cadence; detection delay measured the cost of the gap between monthly and daily review (notebook 14.3); and monitoring earned its keep through the incidents it prevented (equation 14.7). An investment decision combines these separate estimates within a single accounting boundary rather than naively summing them. Because an unmitigated skew event manifests simultaneously as lost prediction value, an extended silent failure, and a production incident, adding those estimates directly would count the same underlying damage multiple times. Rigorous accounting establishes a common baseline and evaluation horizon, counts each prevented loss exactly once within a primary category, and separates routine deployment labor savings from emergency response hours already captured in incident costs. For a single ML node, the resulting accounting determines whether deployment speed, incident reduction, and monitoring coverage justify the operational spend; for a portfolio, the same discipline scales to justify platform investment.

14.8.5.1 Single-model MLOps investment

For a single production ML system, the first threshold is the annual cost of making the node observable, deployable, and recoverable. Table 14.25 summarizes the main cost categories:

Table 14.25: Single-Model MLOps Investment: Illustrative planning inputs for putting one production ML system under operational control. Open-source tooling (MLflow, Feast) can reduce software costs; cloud-managed services trade higher unit costs for reduced engineering overhead.

Component	Illustrative Assumption	Justification
CI/CD pipeline setup	$10–30K one-time	Reduces deployment time from days to hours
Monitoring and alerting	$2–10K/year	Shortens detection and response delays
Feature store (basic)	$5–20K/year	Reduces one source of training-serving skew
Model registry	$0–5K/year	Enables rollback, audit trails

Component	Illustrative Assumption	Justification
Engineering time	1–2 FTE-months setup	Initial automation and integration

14.8.5.2 Single-model ROI calculation

The return threshold then depends on model criticality. A revenue-facing model can justify more operational spend because avoided incidents and deployment-time savings have measurable value. Equation 14.13 formalizes that single-node calculation by extending the monitoring benefit-cost ratio of equation 14.7 with a second benefit term, the engineering labor that automation recovers:

$$\text{Annual Benefit/Cost} = \frac{\text{Incidents Avoided} \times \text{Avg Incident Cost} + \text{Time Savings} \times \text{Hourly Cost}}{\text{Annual MLOps Investment}} \tag{14.13}$$

where Incidents Avoided is the count of production failures the tooling prevents per year and Avg Incident Cost is the total loss per failure, so their product is the value of avoided incidents; Time Savings is the engineer-hours that automation reclaims per year from routine release and maintenance tasks (strictly distinct from emergency triage labor already subsumed under Avg Incident Cost), and Hourly Cost is the loaded labor rate, so their product is the value of recovered deployment labor; the denominator is the annualized investment, including recurring tooling and engineering costs plus setup costs amortized over the chosen planning horizon. The worked investment below applies this non-overlapping accounting boundary. The ratio expresses benefit per dollar invested, not net profit per dollar.

Consider a revenue-facing model with the following annual figures:

- 4 incidents/year avoided (at \$25K each) = \$100K saved
- 20 hours/month deployment time saved (at \$150/hr) = \$36K saved
- MLOps investment of \$30K/year

$$\text{Benefit/Cost} = \frac{\$100K + \$36K}{\$30K} = 4.53\times$$

14.8.5.3 When to invest more

The 4.53× benefit-cost ratio holds because the model is expensive enough that preventing incidents and shortening deployments outweigh the annual platform spend. The returns from single-model MLOps practices compound when teams add additional models. The transition from operating several independent ML nodes to building a centralized platform involves different economics entirely, including shared infrastructure amortization, platform team overhead, and cross-model coordination costs.

For single-model operations, invest in MLOps in proportion to model criticality. A model driving \$10M in annual revenue justifies more operational rigor than an internal analytics model. Monitoring, lineage, and repeatable deployment are often the first investments. Add a feature store when shared feature definitions and online-offline parity become material problems, and automate retraining only when evidence supports the trigger and the validation loop can contain a bad update.

The choice of operational controls also depends on what a deployment can measure and change. The case studies in section 14.9 follow the keyword spotter's edge deployment and a proposed clinical framework. Battery limits and clinical authority reshape how each system preserves evidence, validates updates, and responds to failure.

Checkpoint 14.5: Choosing the next investment

- ☐ **Accounting boundary**: Identify the setup, recurring tooling, and engineering costs needed to interpret an annual benefit-cost ratio.
- ☐ **Readiness score**: Explain how adding a useful model test can improve coverage while leaving the minimum-category ML Test Score unchanged.

- ☐ **Priority**: For a single model with unowned alerts and a tested deployment pipeline, justify the next operational investment before selecting additional tools.

14.9 Case Studies

A cloud MLOps playbook fails immediately if applied unmodified to a battery-powered voice trigger that cannot stream audio off the device, or to a clinical decision-support loop where an unreviewed weight update can harm a patient. Operational constraints in machine learning systems are governed by the physical envelope of the serving hardware and the failure consequences of the application. The chapter's keyword spotter operates under a milliwatt-scale power budget, kilobytes of on-device memory, and telemetry that must leave the device as aggregates rather than audio. In contrast, regulated AI-enabled medical devices require evidence and change controls appropriate to their intended use. FDA guidance for predetermined change control plans describes planned modifications, validation methods, and impact assessment (U.S. Food and Drug Administration 2025). These contrasting environments dictate how engineering teams manage data pipelines, model artifacts, and hardware execution across the lifecycle. Edge architectures devote most engineering effort to bridging the hardware gap between high-throughput cloud training clusters and microcontrollers, whereas clinical systems devote it to provenance tracking, cohort monitoring, and human-in-the-loop validation gates.

The edge case in section 14.9.1 follows the keyword spotter from its detection drop through deployment and monitoring, reusing the three-tier partition that a published wearable design makes concrete. The clinical case, ClinAIOps, places clinicians inside the operations loop. Despite their contrasting operating regimes, both deployments must satisfy the same core MLOps disciplines. Table 14.26 maps these foundational principles across the two environments, demonstrating how physical hardware limits and regulatory mandates alter implementation mechanisms without altering the underlying operational requirements.

Table 14.26: MLOps Principles by Case Study: Side-by-side mapping of the five foundational MLOps principles to the keyword-spotting edge design and the ClinAIOps framework, showing how domain constraints reshape implementation without changing which principles apply.

Principle	Keyword-spotting edge design	ClinAIOps
Reproducibility	Versioned audio datasets, DSP front end, and firmware alongside model weights	Audit trails, decision provenance
Separation of concerns	Independent data, training, and serving layers with an edge-specific OTA pipeline	Distinct clinical validation and deployment stages with regulatory compliance isolation
Consistency	One feature-extraction kernel shared by training and on-device inference	Standardized clinical data pipelines ensuring training-serving parity
Observable degradation	Aggregate on-device proxies (wake rate, false-wake reports, duty cycle)	Cohort-specific monitoring, outcome tracking
Cost-aware automation	Updates gated on accuracy gain against radio energy, flash wear, and rollout risk	Automated model updates with human-in-the-loop gates balancing update cost and patient risk

14.9.1 Keyword spotting at the edge

Six months after launch, the keyword spotter's detection rate had fallen four percentage points below target because of three silent changes in section 4.12: a new microphone revision with a different frequency response, evaluation labels revised under new guidelines, and an unannounced change to the device metadata schema. Operations inherits that failure on the chapter's power-bound case. The fix must reach devices that no one can touch, the evidence must be gathered without uploading audio, and a bad update must be reversible without disabling the device.

14.9.1.1 Context and motivation

Keyword spotting partitions its computation across three tiers. The microcontroller runs the audio front end and the 200 KB INT8 DS-CNN continuously in its always-on island, a companion device or hub runs a heavier verification model when the detector fires, and the cloud aggregates fleet

statistics and retrains. The partition is not peculiar to keyword spotting. A published sleep-staging wearable, the Oura Ring, uses the same three tiers, and its published evaluation makes the work of each tier concrete (Altini and Kinnunen 2021). The ring captures accelerometry, optical photoplethysmography (PPG)[26] for pulse rate and heart-rate variability, and skin temperature, and its 15–22 mAh battery rules out continuous Bluetooth Low Energy (BLE) streaming. Sensor preprocessing and lightweight activity classification run in the ring's microcontroller firmware, the heavier multi-sensor sleep-stage sequence model runs on the companion phone during periodic synchronization, and historical aggregation and retraining run in the cloud. The versioning, telemetry, over-the-air, and lifecycle controls described later are a design for the keyword spotter informed by that partition, not a reported account of any vendor's production system.

14.9.1.2 Model development and evaluation

The wearable study also shows how an edge model is evaluated against a reference standard, the step on which the keyword spotter's monitoring depends. The ring's reference labels come from polysomnography (PSG),[27] the laboratory-grade multichannel physiological recording used as the clinical reference for sleep staging. Accelerometer-only models achieved 57 percent four-stage sleep classification accuracy because movement alone cannot separate quiet wakefulness from light or REM sleep. Adding heart rate, heart-rate variability, and circadian temperature features lifted accuracy to 79 percent. The resulting 22 percentage-point gain closes roughly 84.6–88 percent of the gap between the baseline and human PSG scorers, who agree with each other at only about 82 percent to 83 percent. The evaluation paired the ring with simultaneous laboratory PSG for 106 participants and 440 nights of data (Altini and Kinnunen 2021); across 5-fold cross-validation, each added sensing modality raised four-stage accuracy, which is the evidence that justified the ring's heavier phone-tier model.

The keyword spotter faces the same evaluation problem with a weaker reference. Its labels come from reviewed recordings, and because the device uploads audio only when it wakes, a spoken wake word that the detector misses leaves no recording at all (section 4.12.1). Measuring the false rejections behind the four-point drop therefore takes a separate, consented collection, and the evaluation set must be versioned by microphone revision so that a hardware change appears as a slice rather than being averaged away. Deploying the retrained model across the tiers then adds requirements that no offline study covers: reproducible quantization, numerical validation of the converted model on the device, and a runtime energy budget.

14.9.1.3 Key operational insights

Following offline validation, the systems challenge shifts from statistical accuracy to deployment safety and runtime efficiency. The toolchain for the keyword spotter needs an automated quantization pipeline that converts FP32 weights to INT8 with calibrated scale factors, deterministic cross-compilation for the firmware that runs the model, cryptographically signed release packages for each hardware revision, and fault-tolerant OTA delivery through the dual-bank scheme of section 14.4.4, whose cost is a second 200 KB flash bank (table 14.11).

Edge MLOps operates under physical constraints distinct from server-side pipelines. Model accuracy must be co-designed with battery life, radio bandwidth, and on-device storage, and real-time ground-truth labels are nearly absent. In the power-bound row of table 14.5, health monitoring relies on operational proxies (wake rate, duty cycle, false-wake reports, and confidence distributions) rather than verified outcomes. Recovering the four-point detection drop in the field requires configuration management across every execution target (the microphone hardware revision, the DSP front end, the firmware, and the quantized model weights) so that each fielded device's combination can be traced and receive the right update.

These constraints map directly onto the five principles of table 14.26. Versioned audio datasets provide reproducibility by linking every deployed model to the recordings, labeling guidelines, and microphone revisions that trained it. Tiered software architecture enforces separation of concerns, isolating the device's audio drivers and feature extractor from the hub's verification model and the cloud's aggregation, so that firmware, model, and fallback behavior can be updated independently. A feature-extraction kernel shared between training and the device reduces implementation divergence, while parity tests verify numerical agreement between the Python pipeline and the device's DSP

[26] **Photoplethysmography (PPG)**: Optical technique that infers blood-volume changes from variations in detected light after illuminating tissue. For ML operations, PPG introduces a data quality challenge absent in controlled environments. Motion artifacts from wrist movement corrupt the signal, creating a data drift pattern where the same physiological state produces different input distributions depending on user activity. Models must either filter corrupted windows before inference or learn to be robust to motion noise, and monitoring must distinguish genuine physiological changes from artifact-induced distribution shift.

[27] **Polysomnography (PSG)**: A multi-parameter sleep study that provides the clinical ground truth data for this classification task. This "truth" is inherently noisy; expert human scorers interpreting the same PSG recordings agree with each other at about 82 percent–83 percent reliability (Altini and Kinnunen 2021). Inter-scorer agreement indicates label uncertainty but does not impose an accuracy ceiling against a fixed or adjudicated reference.

routine across firmware versions. Privacy-preserving telemetry keeps degradation observable by sending aggregate diagnostics (per-band energy histograms, wake counts, duty cycle, and battery drain) without streaming audio off the device. Finally, cost-aware automation applies to the over-the-air update, because every update must show that its accuracy gain outweighs the radio energy of reception, the flash rewrite cycles, and the risk of altering software on a device that is always listening. Where the keyword spotter shows how milliwatts, kilobytes, and radio bandwidth dictate MLOps design, moving machine learning from consumer devices into regulated healthcare shifts the primary constraint from hardware physics to patient safety, clinical validation, and algorithmic accountability, the operational domain of ClinAIOps.

14.9.2 ClinAIOps case study

On an always-listening consumer device, the engineering envelope is bounded by milliwatts, memory footprint, and radio bandwidth; in regulated medical care, the governing constraint shifts to patient safety and clinical liability, because an unreviewed model update or an uncalibrated sensor stream in a blood-pressure monitoring system can recommend an unsafe dose before a physician sees the chart. In continuous therapeutic monitoring (CTM),[28] wearable sensors stream physiological telemetry to guide personalized medical interventions. General-purpose MLOps frameworks provide lifecycle automation (orchestrating pipelines, tracking artifacts, and monitoring availability). Clinical use adds intended-use-specific evidence, oversight, and authorization requirements because predictions may influence treatment. General-purpose MLOps can incorporate human gates; the clinical framework makes their responsibilities explicit. The case is read here as an operations loop with clinicians inside it: who may change a model, on what evidence, and how a change is reversed. Whether the objectives such a system pursues, and their effects on patients, are the right ones is a question of responsibility that chapter 15 develops.

[28] **Continuous therapeutic monitoring (CTM)**: Healthcare approach using wearable sensors for real-time physiological data collection and personalized treatment adjustments. CTM forces MLOps to confront constraints absent in typical deployments: feedback loops require oversight appropriate to the intended use, training labels need clinical validation, and model changes must follow applicable authorization and change-control requirements. These constraints reshape every MLOps principle, making CTM a stress test for operational maturity.

The proposed ClinAIOps framework (Chen et al. 2023) adapts MLOps principles to these constraints by formalizing the boundaries between algorithmic inference and clinical authority. Rather than treating human oversight as an external obstacle, ClinAIOps builds multi-party feedback loops directly into the serving architecture. The framework partitions operational control across three actors (patients, clinicians, and machine learning engineers), each operating on distinct timescales with explicit safety gates.

14.9.2.1 Feedback loops

Three interlocking feedback loops organize the proposed integration of machine learning into clinical practice; their effectiveness and safety require validation in the intended setting. Figure 14.12 models these three interlocking feedback loops as a triangular protocol among the patient, clinician, and AI developer. Each pair of actors exchanges different information in both directions: the patient streams wearable sensor telemetry and receives clinician-approved therapy alerts; the AI developer provides longitudinal monitoring summaries while accepting physician-defined dosing bounds; and the clinician directly governs patient therapy regimens while establishing safety boundaries for algorithmic actuation. The outer cycle connecting all three nodes forms the overarching clinical governance framework.

Each feedback loop operates on a distinct timescale to balance responsiveness against clinical verification. The **patient treatment loop** executes continuously in real time, capturing sensor telemetry and delivering bounded adjustments for patient self-management. At an asynchronous supervisory cadence, the **clinician oversight loop** reviews aggregated trends, sets operational boundaries, and validates treatment recommendations before interventions occur. Finally, the **developer feedback loop** aggregates telemetry and clinician override patterns back to engineering teams, driving offline retraining and interface calibration.

Patient treatment loop The patient treatment loop executes localized inference over high-frequency physiological streams captured by wearable devices, such as continuous glucose monitors or optical pulse sensors, while the edge serving runtime evaluates these incoming feature vectors against recent patient history from electronic health records. In this proposed design, recommendations follow a tiered execution model as one safety control: minor adjustments that fall strictly within clinician-defined bounds are surfaced directly to the patient, whereas significant changes, and recommendations generated when model uncertainty exceeds an acceptable margin, are blocked

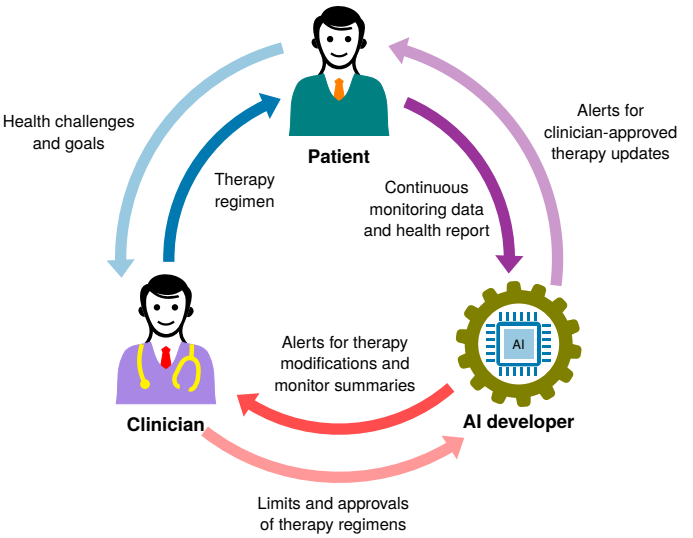

Figure 14.12: ClinAIOps Feedback Loops: The cyclical framework coordinates patients, clinicians, and AI developers to support continuous model improvement and safe clinical integration. Patients and clinicians use AI outputs in care workflows, while AI developers receive feedback from both groups to refine models and operations. Source: (Chen et al. 2023).

from automated delivery and escalated to the clinician. This structure enables rapid adaptation to dynamic physiological states within validated, authorized operating limits; those limits and the escalation mechanism must be tested.

Clinician oversight loop The clinician oversight loop provides supervisory control over automated inference. Rather than burdening medical staff with continuous raw sensor telemetry, batch aggregation pipelines distill time-series streams into longitudinal summaries, such as circadian variance, multi-day trends, and signal-quality metrics. When the system generates a therapy recommendation, such as adjusting an antihypertensive dosage for a patient with persistent hypotensive readings, the clinician evaluates the proposal alongside diagnostic factors unobserved by the wearable model and may approve, modify, or reject the recommendation. This decision is written to an audited event log, which enforces clinical accountability at the point of care and records expert feedback for later review, though approval or override is not by itself a verified patient outcome and using it as training supervision requires a defined label interpretation and validation. Clinicians also update the operational thresholds that govern the patient treatment loop, recalibrating the boundary between automated guidance and mandatory review.

Developer feedback and patient-clinician coordination Offloading continuous data logging and low-level trend detection to the AI pipeline changes the patient-clinician relationship itself. Consultations shift from routine measurement gathering to targeted clinical evaluation and goal setting, an outcome the patient and clinician loops produce together, while the third loop, developer feedback, links that clinical practice back to engineering infrastructure. Operational telemetry generated during these interactions provides engineering teams with direct visibility into production behavior: overrides, rejection frequencies, and reported adverse events motivate investigation of model behavior, workflow fit, patient mix, and sensor quality, even though they do not uniquely diagnose covariate shift. Engineers use the resulting evidence to evaluate targeted retraining, refine data validation schemas, and eliminate usability failure modes that induce alert fatigue in clinical staff.

14.9.2.2 Hypertension case example

Hypertension management illustrates how these three operational loops could coordinate care in the proposed framework. Blood pressure fluctuates continuously under exertion, stress, and circadian cycles, requiring individualized, long-term pharmacological adjustments that benefit from continuous therapeutic monitoring.

Data infrastructure Research systems estimate systolic blood pressure indirectly from electrocardiography (ECG), photoplethysmography (PPG), pulse-transit time, and heart-rate features (Q. Zhang et al. 2017). In the illustrative workflow, these signals are augmented by accelerometer streams to identify motion artifacts and self-reported medication logs. Clinical use requires rigorous calibration and prospective validation for the intended task, together with any applicable regulatory authorization; authorization alone does not establish accuracy for every cohort. When properly validated for the target cohort, this multimodal data stream is merged with electronic health records to supply feature context for inference.

Loop implementation The hypertension workflow labels each of its three panels by the two parties in the exchange (figure 14.13), so the panels do not line up one-to-one with the three loops of figure 14.12. The patient-AI panel is the patient treatment loop, the clinical-AI panel is the clinician oversight loop, and the patient-clinical panel is the coordination those two loops produce together; the developer feedback loop operates out of band, as described in section 14.9.2.1, and does not appear. Across the top of the figure, the two AI-assisted loops operate concurrently: the patient-AI panel (upper left) captures continuous blood-pressure telemetry and issues recommendations for bounded dose titrations, while the clinical-AI panel (upper right) alerts the physician to severe hypertensive excursions and accepts updated titration boundaries. Below them, the patient-clinical panel captures the resulting clinical relationship, where routine telemetry offloaded to the AI loop frees consultation appointments for longitudinal trend review, adverse-event evaluation, and shared lifestyle goal setting.

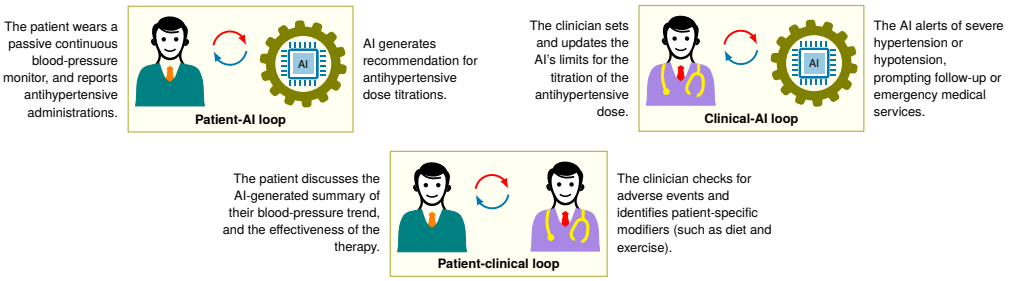

Figure 14.13: Hypertension Management Loops: The three panels, labeled patient-AI, clinical-AI, and patient-clinical, each carry a two-way exchange. In this proposed workflow, the AI issues bounded dose recommendations within validated, authorized clinician-set limits and escalates severe readings, which leaves the patient-clinical panel for trend review, adverse-event checks, and treatment decisions. The developer feedback loop of ClinAIOps is not among them and is discussed in the prose. Source: (Chen et al. 2023).

The three panels illustrate a proposed boundary for clinical automation, not an established treatment protocol: routine monitoring and bounded dose recommendations operate within validated, authorized clinician-defined thresholds, while acute escalations, adverse events, and regimen changes require explicit human authorization. That boundary is the point where ordinary MLOps practices require the additional clinical coordination summarized next.

14.9.2.3 MLOps vs. ClinAIOps comparison

The hypertension case illustrates the operational contrasts between standard software pipelines and healthcare deployments. General-purpose MLOps provides technical lifecycle controls such as automated testing, continuous integration, model registries, and drift monitoring. ClinAIOps extends this foundation into regulated clinical environments where outputs directly influence medical interventions. Table 14.27 compares the two approaches across eight operational dimensions.

Table 14.27: Clinical AI Operations: General-purpose MLOps supplies technical lifecycle controls; ClinAIOps extends them with clinical workflows, evidence, human oversight, and accountability.

	General-purpose MLOps emphasis	ClinAIOps extension
Focus	Technical model lifecycle	Human and AI decision-making

	General-purpose MLOps emphasis	ClinAIOps extension
Stakeholders	ML, data, platform, and operations teams	Adds patients, clinicians, and clinical governance
Feedback loops	Monitoring, retraining, and release	Adds treatment, clinician, and developer feedback
Objective	Reliable, governed ML operations	Safe, effective, and accountable care support
Processes	Automated pipelines and operational controls	Integrates clinical workflows and human gates
Data considerations	Lineage, quality, freshness, and access control	Adds consent, clinical provenance, and protected data
Model validation	Predictive, operational, and slice-level metrics	Adds clinical utility, safety, and cohort outcomes
Implementation	Technical integration and operational ownership	Adds clinical accountability and stakeholder incentives

The table's central distinction is that clinical deployment alters risk ownership. Statistical accuracy is a prerequisite, but it does not protect against liability when an erroneous prediction drives a medical intervention. The ClinAIOps framework therefore changes the governing constraint from device efficiency to clinical accountability. The model participates in care delivery, but it cannot own clinical decisions. Every recommendation and subsequent clinician action must be traceable to the underlying sensor inputs, model version, and inference metadata; otherwise the system cannot support regulatory audit or retrospective incident analysis. Separation of concerns shifts from an architectural preference to a safety invariant: sensor ingestion, inference scoring, clinical diagnosis, and parameter updates must be decoupled by explicit software interfaces and human approval gates.

The same accountability requirement transforms monitoring. Standardized clinical data pipelines support training-serving parity, but clinical validation requires evaluating model recommendations against standard-of-care outcomes and cohort-specific effects. Observable degradation extends beyond statistical loss and latency to clinical metrics: blood pressure control rates, adverse events, clinician overrides, and subgroup disparities. In this regime, multi-tier feedback loops are not unwanted operational latency; they are deliberate architectural controls that balance automated edge adaptation against legal and ethical accountability. Cost-aware automation operates strictly inside those gates. Model refreshes occur only when validated clinical benefits outweigh validation costs and patient risks, and low-confidence predictions trigger deterministic fallback to human clinical review.

14.9.3 Case study synthesis

The keyword spotter and ClinAIOps cases separate stable MLOps principles from the deployment constraints that reshape their implementation: copying an edge OTA pipeline into a hospital workflow or imposing clinician sign-off gates on every consumer wake-word update fails because it mistakes a domain-specific tool for the underlying principle. The keyword spotter is a resource-envelope case. Its operations must preserve reproducibility, consistency, and observable degradation while battery, telemetry, and weak ground truth limit what can be measured and updated on the device. ClinAIOps is an accountability-envelope case. The same principles apply, but validation, audit trails, and human gates dominate because the model influences clinical action.

The shared engineering lesson is that MLOps maturity is not tool accumulation. It is the ability to identify the governing constraint, choose the operational controls that match it, and preserve evidence when the model changes. Production ML systems fail when teams apply code-focused operational intuitions without accounting for statistical behavior and shifting distributions, exposing common fallacies and operational pitfalls.

Checkpoint 14.6: Transferring the operational principles

- ☐ **Evidence and design**: Separate the wearable study's reported offline accuracy from the keyword spotter's deployment and monitoring design, and name two proxy signals the spotter can report without uploading audio.

- ☐ **Feedback quality**: Explain why human scorer agreement is not a strict accuracy ceiling and why a clinician override is not automatically a verified patient outcome.
- ☐ **Shared principle**: Choose one MLOps principle and explain how battery limits and clinical accountability lead to different implementations of it.

14.10 Fallacies and Pitfalls

Operating production machine learning systems under conventional software assumptions creates distinct failure modes. The following fallacies and pitfalls highlight where standard software engineering intuitions break down against the statistical realities of deployed models.

Fallacy: *MLOps is just applying traditional DevOps practices to machine learning models.*

Engineers often assume that standard CI/CD pipelines transfer directly to machine learning. Traditional DevOps automates code builds, testing, and artifact deployment with controls for dependencies and execution environments. In an ML system, code represents only one axis of the D·A·M triad. Model execution depends jointly on code, large evolving datasets, and accelerator compute budgets. As detailed in section 14.3.2.1, ML pipelines introduce stateful retraining, multi-metric validation gates, and immutable artifact registration. Standard CI/CD engines cannot natively track data lineage, orchestrate feature stores, or detect distribution drift. When teams apply DevOps without ML-specific adaptations, they maximize the computational availability of their serving cluster while leaving statistical behavior unmonitored. The system achieves high uptime and low latency, yet silently serves degraded predictions due to unvalidated data shifts and training-serving skew. The cost is concrete. A 1 percent skew rate on 1,000,000 queries/day costs $365,000 a year (equation 14.2) while every DevOps health check stays green.

Pitfall: *Treating model deployment as a one-time event rather than an ongoing process.*

Treating deployment as a terminal milestone assumes that deployed weights remain permanently aligned with the production input distribution. Unlike compiled binaries whose execution semantics remain fixed, model quality can change as real-world distributions shift. Monitoring statistical indicators such as PSI (section 14.5.2.1) provides an early signal of feature drift, distinguishing benign variance from actionable distribution change. Crossing a warning threshold requires operational diagnosis rather than unvalidated retraining. As established in section 14.6.2, scheduling updates is an economic balancing problem. The optimal retraining interval $T^* \approx \sqrt{\frac{2C}{Q_{\text{day}} \cdot V \cdot \text{Accuracy}_0 \cdot \gamma}}$ weighs the fixed compute and engineering cost C against the business losses accumulated from daily query volume Q_{day}, unit accuracy value V, and staleness decay rate γ. For the ranking service, a 0.24 percent daily decay on 1,000,000 requests a day puts that optimum near 3 days (notebook 14.6), a cadence no one-time deployment can meet. Operating a production model demands treating deployment as a continuous control loop that balances monitoring signals against retraining economics.

Fallacy: *Automated retraining ensures optimal model performance without human oversight.*

Automating pipeline execution does not eliminate the need for operational governance. Closed-loop retraining pipelines operate without semantic awareness; if upstream data ingestion suffers schema anomalies, corrupted labels, or sudden sensor drift, automated retraining bakes those errors directly into updated model weights. Furthermore, automated validation gates typically evaluate aggregate loss across a held-out test split, which easily conceals severe performance regressions on critical slices or low-frequency edge cases. For instance, retraining a ranking model on weekend traffic can degrade performance across latency-sensitive weekday workloads where user query distributions diverge, and an aggregate gate would pass it, just as the 91 percent overall accuracy in table 14.20 conceals a tablet slice at 62 percent. Resilient MLOps architectures decouple automated pipeline execution from automated production promotion, enforcing canary deployments, slice-level regression gates, and human sign-off when validation metrics deviate from expected historical envelopes.

Pitfall: *Focusing on technical infrastructure while neglecting organizational and process alignment.*

Investing in MLOps tooling without defining organizational interfaces leads to fragmented operational ownership. Machine learning systems bridge two distinct engineering cultures: model

developers optimizing offline accuracy metrics and platform engineers managing host-level latency, memory capacity, and throughput budgets. When organizations treat deployment as a handoff between isolated teams, root-cause triage stalls during production incidents. Infrastructure engineers inspect container health and GPU utilization without insight into model prediction distributions, while model authors inspect offline training curves without understanding runtime serving constraints. The ML Test Score (section 14.8.1) makes the gap measurable, because a deployment with a perfect model suite and no production monitoring scores 0 under its minimum-category rule. Tools such as feature stores and registries provide technical scaffolding, but reliability requires institutional alignment: unified SLOs spanning statistical accuracy and serving latency, joint on-call runbooks, and shared accountability for production regressions.

Fallacy: *Training and serving environments automatically remain consistent once pipelines are established.*

Establishing an initial end-to-end pipeline does not guarantee permanent parity between training and serving. Training-serving skew arises from fundamental architectural divergences between offline and online execution paths. Training typically runs as an offline batch workflow (such as distributed SQL queries or Spark pipelines) optimized for high-throughput scans over historical logs, whereas online serving runs in low-latency microservices under millisecond latency constraints. Maintaining dual implementations of feature transformations across these environments risks numerical disparities, differing missing-value semantics, or lookahead bias in historical joins. On the ranking service, the two paths computed `user_session_length` with means of 45 and 12 minutes and cost 8 percent of accuracy with no change to model code (section 7). As demonstrated in section 14.3.1.1, feature stores alleviate this divergence by unifying transformation logic and synchronizing batch and point-lookup stores. However, software pipelines alone cannot guarantee consistency; operational verification requires request-keyed value comparisons and schema assertions between offline replays and online inference inputs, alongside separate distribution monitoring to catch divergence before it degrades downstream decisions.

Pitfall: *Assuming comprehensive monitoring prevents all production incidents.*

Dashboards and alert thresholds cannot prevent production outages caused by silent data failures. Monitoring supplies evidence; reducing harm also requires a response. Input-boundary checks can catch some defects before inference, while statistical quality estimates may arrive after affected predictions have been served. Furthermore, tracking output metrics alone leaves critical blind spots along the data pipeline. As shown in section 14.5.2.1, measuring service latency and prediction distributions fails to detect input anomalies such as feature staleness. An inference service can maintain nominal p99 response times and normal prediction ranges while consuming stale user embeddings caused by upstream database replication lag or cache eviction failures. By the time downstream business metrics degrade, corrupted predictions have already impacted users; an input-boundary check acts on the first malformed request, without waiting for labeled outcomes to accumulate. Production reliability requires defensive boundary controls alongside passive observability: strict input schema enforcement, feature freshness assertions, and circuit breakers that fall back to deterministic heuristics when input quality slips below operational tolerances.

Fallacy: *Accuracy is the first production signal to monitor, so leading indicators can wait on a dashboard.*

Teams often configure accuracy dashboards as their primary operational tripwire, assuming degradation will register there first. When outcome labels arrive late, ground-truth accuracy is a lagging indicator. In production environments such as fraud detection, ad conversion, or credit underwriting, ground-truth labels arrive with substantial latency, often requiring weeks or months to accumulate through chargebacks or repayment histories. Relying solely on accuracy dashboards leaves the system operating blind throughout this label-delay window. Furthermore, aggregate accuracy can remain deceptively stable even as input distributions diverge across critical sub-populations. As detailed in section 14.5.2.1, monitoring input feature distributions with metrics like PSI or Kullback-Leibler (KL) divergence supplies indicators that can be estimated from sufficient input samples without labels. These statistical signals detect distribution shifts without waiting for labels, often enabling investigation before delayed outcome metrics are available, without guaranteeing that prediction errors have not already occurred. The delay is large. The same evidence budget that one labeled outcome per second fills in about 16.7 minutes takes 10 days at 100 outcomes a day, and in

the silent-failure scenario each incident detected at monthly rather than daily review costs $184,932 more (notebook 14.3). A leading indicator recovers that time only when it is routed to an owner with a response deadline, an escalation rule, and a diagnostic runbook; drift and freshness warnings parked on an informational dashboard accumulate unnoticed until an emergency forces a response.

Observability in production machine learning extends far beyond passive dashboard telemetry. It requires closed operational loops across the entire D·A·M architecture: enforcing input data integrity and feature stability, bounding model behavior through automated validation gates, and routing leading indicators directly to engineers empowered with diagnostic runbooks to investigate changes and limit harm.

14.11 Summary

MLOps extends software reliability with controls for learned behavior, data dependencies, and statistical uncertainty. A crashed server or network timeout turns availability dashboards red immediately, alerting operators to take corrective action. A degraded model introduces a silent statistical failure mode. The serving infrastructure returns 200 OK responses within latency deadlines, yet prediction quality can deteriorate undetected. Machine learning operations keeps that decay observable by treating model quality as a dynamic runtime variable rather than a static deployment artifact.

The five principles of table 14.2 provide an evaluation framework that applies regardless of scale or domain, and each now has a home in the operations loop. Reproducibility lives in versioned artifacts and the model registry, separation of concerns in the boundaries that releases and incidents respect, consistency in shared feature definitions checked by request-keyed parity tests, observable degradation in layered monitoring, and cost-aware automation in the retraining gate and the interval it implies.

Infrastructure components implement these principles across three critical operational boundaries: feature stores and data versioning govern the data-model interface by reducing training-serving inconsistency, CI/CD pipelines and model registries govern the model-infrastructure interface by enforcing reproducibility and enabling rollback, and monitoring systems, incident response frameworks, and on-call practices govern the production-monitoring interface by making degradation observable and actionable while the retraining decision framework connects measured degradation to economic thresholds. Domain constraints reshape *how* these principles are implemented without changing *which* principles matter. The capacity-bound ranking service pays for safe releases in memory, a second resident copy of its embedding tables for every shadow, canary, or standby, and pays for retraining in accelerator-hours that contend with those copies. The power-bound keyword spotter pays in flash, radio energy, and evidence it cannot upload. Similarly, ClinAIOps demonstrates why high-stakes clinical deployments require graceful-degradation and human-oversight controls, with three feedback loops functioning as architectural patterns rather than operational overhead.

The chapter's operating rules fit on one page (table 14.28). Together they let an engineer estimate, before an incident forces the question, what a control costs and when it pays for itself.

Table 14.28: Key Equations: The chapter's operating rules in the notation of the sections that derive them, in chapter order. The skew cost and retraining gate are stated with the principles, the sample size with A/B testing, the delay, PSI, and cost rules with monitoring, and the decay and interval with the retraining decision; the interval is the square-root approximation valid while decay over one interval is small.

Quantity	Formula	Where derived
Skew cost	$\text{Skew Cost} = \text{Rate}_{\text{skew}} \times Q_{\text{day}} \times C_{\text{error}}$	equation 14.2
Retraining gate	Retrain if: $\Delta\text{Accuracy} \times \text{Value per Point} > \text{Training Cost} + \text{Deployment Risk}$	equation 14.3
A/B sample size	$n = \frac{2(z_{\alpha/2}+z_{\beta})^2\sigma^2}{\delta^2_{\text{MDE}}}$	equation 14.4
Detection delay	Evidence budget in labeled examples divided by the labeled-outcome arrival rate	Notebook 14.2
Population stability index	$\text{PSI} = \sum_{i=1}^{n_{\text{bins}}} (\text{actual}_i - \text{expected}_i) \times \ln\left(\frac{\text{actual}_i}{\text{expected}_i}\right)$	section 4.12.1
Telemetry cost rate	$\text{Cost rate} \approx N_{\text{series}} f_{\text{sample}} \left(C_{\text{ingest/sample}} + s_{\text{sample}} T_{\text{retention}} C_{\text{storage/byte-time}}\right)$	equation 14.5

Quantity	Formula	Where derived
Monitoring benefit and cost	$\text{Monitoring Benefit/Cost} = \frac{\text{Incidents Prevented} \times \text{Avg Incident Cost}}{\text{Annual Monitoring Cost}}$	equation 14.7
Accuracy decay	$\text{Accuracy}(t) = \text{Accuracy}_0 \cdot e^{-\gamma t}$	equation 14.8
Optimal retraining interval	$T^* \approx \sqrt{\frac{2 \cdot C}{Q_{\text{day}} \cdot V \cdot \text{Accuracy}_0 \cdot \gamma}}$	equation 14.12

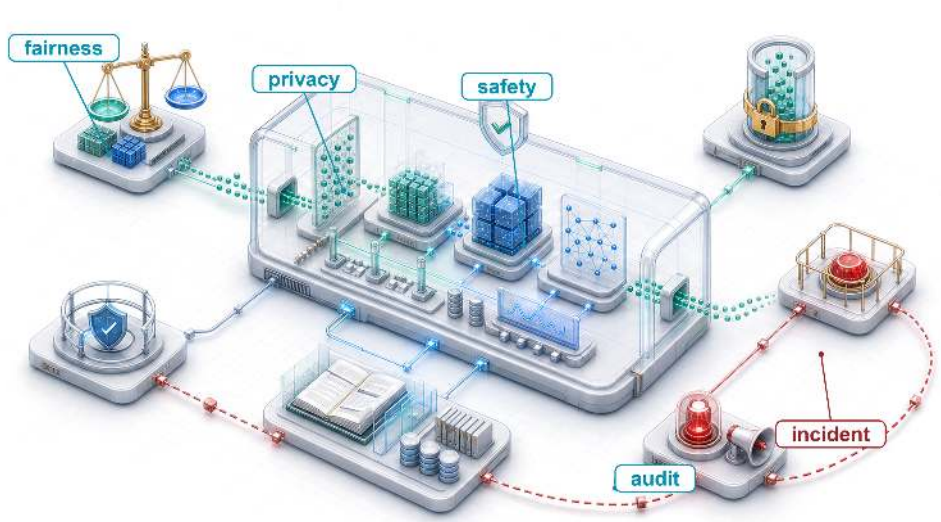
Key Takeaways: Perfectly available, perfectly wrong

- **ML systems fail silently without outcome monitoring**: Model quality may degrade as distributional divergence $\mathcal{D}(P_t \| P_0)$ grows, although divergence alone does not determine accuracy loss. Because a serving node can maintain perfect uptime while predictions fail, tracking ground-truth outcomes is essential rather than relying on server health checks alone.
- **Training-serving skew corrupts inference without crashing**: Feature stores mitigate skew by unifying feature definitions and transformations across environments, but maintaining parity still requires continuous validation across online and offline data pipelines.
- **Deploy through graduated rollout with pretested rollback**: Canary, blue-green, and shadow deployments partition release risk across production traffic, backed by tiered rollback procedures that must be verified through regular operational drills. For a capacity-bound model, each of these controls holds a full second copy of the model in memory, whatever share of traffic it serves.
- **Retraining is an engineering optimization, not a guess**: The fitted staleness cost model ($T^* \approx \sqrt{2C/(Q_{\text{day}} \cdot V \cdot \text{Accuracy}_0 \cdot \gamma)}$) balances retraining compute against prediction quality decay, connecting update cadence to quantitative economics under its stated assumptions.
- **Stage infrastructure investments by system risk**: Instrumentation and continuous deployment form the initial operational baseline. High-consequence systems justify greater operational rigor; feature stores and automated retraining should be added as skew and scale demand.
- **The five principles transfer across domains**: Reproducibility, separation of concerns, consistency, observable degradation, and cost-aware automation remain invariants across applications; domain constraints reshape only their concrete mechanisms and tool implementations.
- **Operational maturity is organizational as well as architectural**: Managing a single model differs qualitatively from governing a production fleet. While the core principles scale, operational complexity grows with fleet size, making unified incentives and shared on-call rotations as essential as tooling.

This operational discipline distinguishes production ML engineering from development experimentation. When a deployed model degrades, systematic instrumentation enables practitioners to isolate the failure mode: identifying data drift through distribution divergence checked against labeled outcomes (principle 10), training-serving skew through preprocessing parity audits (principle 11), configuration debt through artifact provenance, and feedback loops through temporal output tracking. Treating production ML as a "deploy and forget" exercise ignores these distinct dynamics.

This operational reality roots ML engineering in the D·A·M taxonomy. In an ML system, code, weights, and accelerator hardware can remain unchanged while the data axis moves beneath them, changing the predictive behavior that the system must validate. That exposure is the other side of the bitter lesson. Behavior learned from data rather than written by hand is what lets these systems outperform hand-built rules, and it is also what lets their behavior change whenever the data does, with no line of code recording the change. The match between model and world is not

an engineering state reached once at deployment, but an ongoing cost paid continuously through telemetry, validation gates, and cost-calibrated retraining. System reliability must therefore measure prediction outcomes rather than server uptime alone, because the most dangerous failure mode in production is a green dashboard masking a drifting model. That machinery keeps a model faithful to its objective; whether the objective itself was right, and for whom, is the next question.



What's Next: From reliability to responsibility

What if the model never drifts and still does harm? Operations keeps a model faithful to its objective as the world shifts, but it cannot tell whether that objective was the right one. A system that tracks its training target perfectly can still reproduce historical bias, misallocate errors across groups, or mishandle personal data, while every reliability check and aggregate accuracy metric stays green. Chapter 15 takes up that specification gap, extending the monitoring discipline of this chapter from predictive quality to the outcomes a system produces for the people it affects.

Purpose

Why can a system that does exactly what it was told to do still cause harm?

Latency, availability, and accuracy targets do not say whether they describe the right behavior, whom the system serves, or which costs its specification leaves unmeasured. An ML system can satisfy latency, throughput, and aggregate accuracy requirements while reproducing historical discrimination, rewarding harmful engagement, consuming unjustified energy, or using data without adequate privacy and accountability controls. Such a system has not malfunctioned; it is efficiently optimizing an incomplete specification. The omitted constraints appear as uneven outcomes across populations, lifetime cost and emissions, decisions people cannot understand or contest, and evidence that cannot be reconstructed after harm occurs. If those consequences are not defined as requirements before deployment and monitored afterward, conventional health checks can remain green while harm accumulates. A credit model that treats groups unevenly can repeat that decision millions of times before anyone aggregates the outcomes, while its dashboards report healthy latency and accuracy throughout. Responsible engineering treats such outcomes as system failures to be diagnosed, measured, and mitigated with the same rigor as latency or accuracy regressions. That work requires translating broad obligations into testable bounds, documented assumptions, traceable data, and response paths that remain enforceable in production, so that a harm found after launch can be traced and corrected. In D·A·M terms, responsibility broadens the definition of correctness: data must be examined for encoded harms and lawful use, algorithms must be bounded by defensible outcome and efficiency requirements, and machine infrastructure must monitor, document, and enforce those boundaries throughout the system lifecycle.

Learning Objectives

- Explain how a model that meets its training objective can still cause harm when that objective is a proxy that drifts from the goal
- Apply data-algorithm-machine diagnosis to localize responsibility failures in data, algorithm objectives, or monitoring infrastructure
- Calculate fairness metrics from confusion matrices and compare trade-offs on the fairness-accuracy Pareto frontier
- Design disaggregated release gates and per-group monitoring, fitting the bias feedback model to project when a passed gate will fail
- Analyze total cost, inference dominance, and carbon impact as measurable responsibility constraints
- Construct model cards, datasheets, lineage records, and audit trails for accountability
- Evaluate privacy, access-control, and compliance designs against regulatory and human-review requirements

15.1 Responsibility as Systems Engineering

A credit model decides whose loan applications are approved, a ranking model decides which items millions of people see, and a voice assistant decides when audio from a private room leaves the device. None of these outcomes appears in a loss curve or a latency dashboard, yet every deployed model settles them, and a system can meet every latency, uptime, and aggregate accuracy target while rejecting qualified minority applicants, amplifying clickbait, or leaking private audio. **Responsible engineering** is systems engineering applied to the consequences that a model's objective leaves unstated: whose errors the system makes, how much energy and money each decision draws, and whether a harmful decision can later be explained, traced, and corrected. Each of those outcomes is fixed by concrete engineering choices about data, objectives, and infrastructure.

Chapter 14 built the machinery that keeps a deployed model faithful to its objective as data and traffic change, and that machinery assumes the objective was the right one. If MLOps is the control loop for *reliability*, then responsible engineering is the control loop for *safety*. Where MLOps monitors runtime health and predictive quality to guide operational response, responsible engineering monitors outcome distributions to guide intervention when systems generate harm. In systems engineering terms, a model can pass *verification* (conforming exactly to its specified training objective) while failing *validation* (failing to satisfy operational, safety, or legal requirements) (National Aeronautics and Space Administration 2016). The verification gap (principle 9) concerns the first of these activities. It bounds how much any finite test can establish about conformance to a specification, whereas validation asks whether the specification was the right one. The failure stems from an incomplete specification rather than a fault in compiler execution or numerical optimization.

↩ Continuous telemetry and automated retraining control loops for operational reliability are established in section 14.1.1.

Traditional software engineering isolates defects within modules, though shared dependencies can still propagate faults. Machine learning systems introduce data-dependent coupling: data flows through shared representations, so corrupted or biased inputs alter the dense parameter matrices that serve every subsequent inference. A biased training dataset does not trigger a compile-time assertion or runtime crash; it silently shifts decision boundaries across the entire system. Read for responsibility rather than performance, the D·A·M taxonomy isolates where such failures originate: unrepresentative or biased inputs (Data), misaligned loss formulations (Algorithm), or telemetry blind spots and unjustified resource footprints in the serving infrastructure (Machine). Responsibility therefore has to be designed in rather than patched on after deployment.

↩ The D·A·M taxonomy, which classifies a system bottleneck along its data, algorithm, and machine axes, is established in section 1.5.

Responsible engineering expands the definition of correctness for machine learning systems. Traditional correctness (numerical stability, bounded latency, and high service availability) remains necessary, but insufficient. A production system must satisfy broader operational bounds: bounded error disparities across demographic slices, defensible energy expenditure, and verifiable data lineage. This expanded correctness applies engineering discipline to failure modes that aggregate performance metrics ignore. A p99 latency spike triggers automated alerts on an operational dashboard; a demographic fairness regression remains invisible to aggregate loss metrics until real-

world harm occurs, and when the model's decisions shape its own future training data, the hidden disparity can grow with every retraining cycle (principle 13). Both demand rigorous telemetry and automated regression testing. The optimizations of the preceding chapters inherit the same blind spot, because each was judged by the cost terms its benchmark measured.

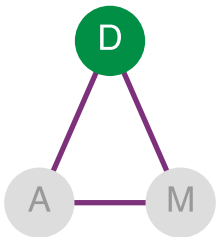
> **Systems Perspective 15.1: The full cost of the iron law**
>
> The iron law of ML systems (principle 3) decomposes execution time into data movement, computation, and fixed overhead. Compressing models, accelerating hardware, and automating operations each optimize these terms. Yet an optimization can create or shift costs that its benchmark omits.
>
> A model quantized for edge deployment can consume less energy, but its accuracy loss need not fall evenly across demographic groups, so the compressed model must be revalidated on the same subgroup slices as the original. A ranking model such as the DLRM service, optimized for engagement, maximizes a business metric but may amplify harmful content. Responsible engineering extends this accounting to include broader impacts: the carbon cost of computation, the fairness cost of optimization choices, and the societal cost of deployment at scale. The iron law accounts for how fast a system runs and says nothing about whom it serves well.

Three running cases carry the chapter, each chosen because it exposes a different kind of responsibility failure. The first is a credit service, a labeled composite rather than a documented deployment: a classifier that approves or rejects loan applications, constructed so that every fairness criterion in the chapter can be computed from its confusion matrices. Fairness criteria need labeled decisions about people, which none of the lighthouse models makes, so the composite carries the stages that specify, measure, explain, and monitor such decisions. The second is the DLRM ranking service, the capacity-bound lighthouse, whose model alone occupies 100 GB in its registry entry, more than the 80 GB of memory on one H100. Its rankings decide what people see, so the clicks it trains on are shaped by its own earlier outputs, and its request volume makes it the chapter's case for feedback, exposure, cost, and carbon. The third is the keyword spotting (KWS) system, the power-bound lighthouse, an always-listening microphone in private homes whose design must decide what audio may leave the device, which makes it the case for privacy, lineage, and audit.

The chapter follows those cases through the lifecycle stages at which each failure is still cheap to prevent (table 15.1). Section 15.2 explains why optimization can succeed while the system fails, through proxy targets, feedback loops, and distribution shift that leave every health check green. Section 15.3 then works through four chained stages on the credit service: specifying requirements before training, measuring fairness criteria as release gates, explaining decisions and documenting models, and operating the deployed model so that its disparity stays bounded under feedback. Section 15.4 measures the energy, carbon, and money that every stage consumes on the DLRM service. Section 15.5 builds, on the KWS system, the governance infrastructure (access control, privacy, regulatory capabilities, lineage, and audit) that makes each earlier guarantee provable to someone outside the team.

Table 15.1: Chapter Map: Each section addresses one class of responsibility failure at the lifecycle stage where it is still cheap to prevent, and names the machine resources that the remedy consumes.

Section or Stage	Failure It Addresses	What It Costs the Machine	Running Case
Engineering Responsibility Gap	Proxy targets, feedback loops, and shift that leave health checks green	Nothing yet; the diagnosis locates the failure on the data, algorithm, or machine axis	Credit service, DLRM
Lifecycle: Specify	Requirements nobody wrote down: target, populations, human oversight	Labeled evaluation data for every named subgroup; reviewer hours per escalated decision	Credit service
Lifecycle: Measure	Disparities hidden by aggregate accuracy	Per-slice evaluation; mitigation training with a second network head and a larger search	Credit service



Section or Stage	Failure It Addresses	What It Costs the Machine	Running Case
Lifecycle: Explain and document	Decisions no one can contest; models reused outside their envelope	Explanation compute on the serving path, exponential in feature count for exact attribution	Credit service, MobileNetV2
Lifecycle: Operate	Disparity that grows through retraining feedback	Per-group telemetry; randomized exploration traffic served at lower expected value	Credit service, DLRM
Environmental and Cost Awareness	Energy, emissions, and cost the task does not justify	Accelerator-hours, kilowatt-hours, and kilograms of CO_2 over the service lifetime	DLRM
Data Governance and Compliance	Evidence that cannot be reconstructed after harm	Audit-log bytes, lineage storage, privacy noise and its memory cost, retraining for erasure	KWS

15.2 Engineering Responsibility Gap

The credit service can approve 90 percent of qualified majority-group applicants but only 60 percent of equally qualified minority-group applicants and still report high aggregate accuracy, because the minority group contributes only a small share of the evaluated applicants. The worked example in section 15.3.2.1 computes exactly this outcome from its confusion matrices. The **responsibility gap** between this *technical correctness* and *responsible outcomes* is the distance that conventional testing does not measure. The gap manifests through concrete mechanisms: proxy variables, feedback loops, and distribution shift, each producing harm through a distinct pathway that conventional monitoring leaves invisible.

15.2.1 When optimization succeeds but systems fail

Amazon's experimental recruiting tool (a war story in section 3.5.1), which learned to downgrade resumes that mentioned women's organizations or women's colleges, places this gap on the data axis of the D·A·M taxonomy, because its failure stemmed from historical training signal rather than an algorithmic or software defect. A model trained on a decade of historical hiring data optimized faithfully for the objective it was given, but those historical patterns encoded gender bias that the system reproduced in candidate ratings (Dastin 2018).

The Amazon failure turns on the data axis, not the algorithm.

Under empirical risk minimization, the model reduced classification loss by finding word-level correlations across the resume corpus. Because past technical hires were mostly men, words tied to women's colleges, organizations, or activities correlated negatively with positive hiring labels. The optimizer faithfully extracted the empirical distribution of the training data, but that distribution reflected past hiring practices rather than candidate competence. High-dimensional text representations pick up and amplify these statistical patterns, baking social biases directly into the vectors that downstream models consume (Bolukbasi et al. 2016).

Amazon tried to fix the model by stripping explicit gender indicators and gendered words from the training pipeline. That change failed to produce unbiased recommendations because high-dimensional feature spaces contain **proxy variables** that retain demographic signal.[1] Scrubbing isolated attributes leaves correlated features intact: ZIP codes correlate with race through residential segregation, applicant names correlate with ethnicity, and healthcare spending correlates with socioeconomic conditions. In Amazon's resume pipeline, even after explicit gender terms were removed, remaining vocabulary (attendance at specific colleges or participation in particular student organizations) continued to encode sex-correlated patterns (Dastin 2018). Removing protected attributes from training data is therefore not enough to guarantee fairness.

Closing that gap takes changes across the full system lifecycle rather than a surface-level data filter. Before deployment, evaluating each demographic subgroup separately measures how scores differ across groups, and when those slices expose a disparity, training-time mitigations such as adversarial debiasing (developed with the credit-service worked example in section 15.3.2.1) can suppress protected-attribute signal in learned representations, though they still require continuous subgroup validation. Once the model is live, human review for borderline scores provides an operational safeguard only when reviewers are trained, empowered, and audited rather than used to rubber-stamp model outputs, while downstream monitoring tracks hiring outcomes over time

[1] **Proxy variable**: Removing one proxy may have little effect when other correlated features retain similar signal. Conversely, correlation alone does not prove discrimination or identify the appropriate intervention. Protected-attribute removal, subgroup evaluation, counterfactual tests, causal analysis, and review of the full decision process provide complementary evidence; no single diagnostic is a complete defense.

to catch disparate impact that offline loss metrics conceal. Because bolting these defenses onto an existing pipeline proved unworkable, Amazon scrapped the project (Dastin 2018).

The same outcome can originate on the algorithm axis instead, in the choice of target rather than in the data. When the target itself reflects historical inequities, the training objective encodes those disparities into the model's decision boundaries, and the harm lands on the subgroup the target mismeasures. Curating the data would not repair such a failure, because the data faithfully record the wrong quantity. That algorithm-axis version appeared with life-threatening consequences in clinical care management.

War Story 15.1: The proxy variable trap (2019)

Context: In 2019, Ziad Obermeyer and colleagues at UC Berkeley audited a commercial Optum algorithm used by health systems to enroll patients with complex needs into high-risk care management programs, examining roughly fifty thousand patients across one large academic hospital (Obermeyer et al. 2019).

Mechanism: The model predicted "future healthcare cost" as a proxy for "future health need." Because the US healthcare system spends less on Black patients than on White patients with the same illness level, the algorithm learned this pattern and assigned lower risk scores to Black patients.

Impact: At any given risk score, Black patients carried substantially more chronic conditions than White patients, reducing the share of Black patients enrolled in specialized care.

Response: The study showed that replacing cost with a direct measure of health need would raise the share of Black patients identified for additional care from 17.7 percent to 46.5 percent at the analyzed threshold.

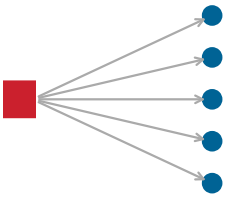
Systems lesson: Optimizing for a proxy inherits the biases of the system that generated the proxy. The proxy-target relationship must be audited across every demographic subgroup the system serves.

The recruiting tool and the care-management algorithm show that optimization success can coexist with system failure. Neither disparity requires a software bug or hardware malfunction to explain why a technically functioning model can fail its intended use. The architectural question is whether the problem specification captures acceptable outcomes. When the *technical objective* (such as minimizing empirical prediction error) diverges from the *system specification* (fair, defensible outcomes across user populations), improving the training objective can preserve or amplify harm.

Standard production telemetry cannot detect specification failures. Monitoring pipelines track inference latency, memory use, throughput, and aggregate validation loss, all of which remain green while a model systematically misallocates errors across subgroups. Preventing silent specification failures requires making responsibility metrics part of the primary test harness: verifying whether the loss function acts as a defensible proxy for the true system goal, and enforcing the justified, application-specific fairness criterion before deployment.

Checkpoint 15.1: Responsible design

Responsibility is a system property, not a model property.



Failure modes

- ☐ **Alignment**: test whether the loss function is a defensible proxy for the system's true goal.
- ☐ **Disparate impact**: compare error rates across subgroups rather than relying on aggregate accuracy.

Check

- ☐ **Pre-mortem**: before deploying, ask: "If this system causes a scandal in six months, what likely went wrong?"

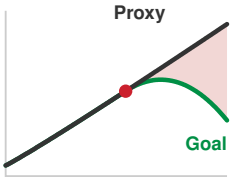
15.2.2 Silent failure modes

One upstream change; many silently affected.

↩ Drift monitors that quantify distributional divergence between serving and training data are established in section 14.5.2.

Consider the credit service after a change to its online application form alters how self-employed applicants' income is recorded. The model begins declining applicants it would have approved a week earlier, and a single upstream modification propagates across the system's blast radius (the set of downstream decisions, and the applicants behind them, that one upstream change reaches) without raising an alert. The model's confidence scores remain high, its inference latency stays within its service level agreement, and all system health checks pass green. The failure is silent. The input data distribution has shifted, but the service's pipeline monitors only service health and carries no drift monitors.

Availability-focused monitoring cannot detect this class of failure. It is the silent degradation of section 1.6, in which statistical failure modes produce degraded outputs indistinguishable from valid predictions while every kernel completes within its latency budget. The responsibility question is whom the degraded outputs reach.



Distribution shift, a deployment input distribution that differs from the one used to develop and evaluate the model, represents the first major mechanism behind this silent degradation. Its covariate, label, and concept forms, and the divergence statistics that detect them, are developed with data engineering (see the margin). The failure is environmental. The physical distribution of inputs changed after training, yet the model has no internal telemetry to detect the discrepancy. Through the responsibility lens the pitfall sharpens, because shift often lands on one subgroup first, where a population-wide divergence statistic barely moves, and concept drift on that slice stays invisible until its outcomes are labeled. A monitor that is adequate for the population can therefore be blind to the people the shift reaches first.

↩ Covariate, label, and concept drift, with the divergence statistics that detect them, are established in section 4.12.1.

Retraining on fresh data can partially restore accuracy under distribution shift. However, retraining cannot resolve a second, more fundamental mechanism of silent failure that persists even when the data distribution is perfectly stationary: metric misalignment.

Metric misalignment occurs when the objective function optimizes an observable proxy metric that diverges from the unobserved outcome the system is intended to deliver. Goodhart's Law, the benchmark trap in which a measure optimized as a target stops measuring the goal, applies with more force here than in benchmarking, because the training objective is the target and gradient descent searches it far more exhaustively than a team tuning against a benchmark. Up to a point the proxy and the goal improve together; past that point further optimization buys proxy gains at the goal's expense.

↩ Goodhart's law, under which a benchmark metric optimized as a target ceases to measure the goal, is established in section 12.1.

Past the knee, the proxy decouples from the goal.

> Systems Perspective 15.2: The alignment gap
>
> The DLRM ranking service optimizes a proxy metric (Clicks) because the true metric (User Satisfaction) is unobservable, and the two can diverge sharply. In an illustrative version of the service, Correlation(Clicks, Satisfaction) might begin at 0.8; once ranking maximizes clicks, it may find clickbait with high clicks but low satisfaction, and the correlation could fall to 0.2.
>
> The falling correlation is the symptom. The quantity that matters is how far the proxy's movement overstates the goal's, which equation 15.1 captures for metrics normalized to a common scale:
>
> $$\text{Gap} = \mathbb{E}[\text{Proxy}] - \mathbb{E}[\text{True}] \tag{15.1}$$
>
> Suppose both metrics start at the same normalized value v, so the gap is zero. A ranking change that raises Clicks by 20 percent and lowers Satisfaction by 5 percent moves them to $1.20v$ and $0.95v$, opening a gap of $0.25v$. Every dashboard that reports Clicks shows a 20 percent win, while the goal the system exists to serve has moved the other way.
>
> **Systems insight**: Engineers cannot directly optimize an unobserved goal. They need defensible proxy validation. A randomized holdout, a small random slice of users served without the new ranking, can estimate the ranking's causal effect on the gap, but only when the holdout's measured outcome reflects the goal or a justified surrogate for it.

The alignment gap illustrates a failure originating on the algorithm axis, where the loss function optimizes a misspecified objective, so even a model that generalizes with zero test error drives

outcomes that conflict with organizational or societal goals. Distribution shift, by contrast, originates on the data axis. The model logic remains intact, but the input distribution departs from the training distribution. Both failures can be silent, but they suggest different first interventions: objective redesign for a misspecified target, or pipeline investigation and possible adaptation for shifted inputs. These remedies can be complementary when both mechanisms are present. Isolating the root cause is the job the D·A·M taxonomy already performs for performance bottlenecks, and perspective 15.3 reads the same three axes for responsibility failures.

↪ The performance-bottleneck form of the D·A·M diagnosis, from profiler symptom to binding axis, is collected for reference in Appendix A.

> **Systems Perspective 15.3: Diagnosing responsibility failures with D·A·M**
>
> When a system causes harm, use the D·A·M taxonomy to identify the root cause. Responsibility failures are rarely "algorithm bugs"; they are structural flaws along one of the three axes:
>
> - **Data (information)**: The training corpus reflects historical bias or unrepresentative sampling (such as Amazon's recruiting tool learning from biased historical applicant data).
> - **Algorithm (logic)**: The objective function optimizes an unconstrained proxy metric that amplifies harm (such as engagement optimization driving polarization).
> - **Machine (physics)**: The serving and governance infrastructure cannot see or bound the harm, through telemetry that never slices outcomes by subgroup, missing lineage and audit records, or an energy and carbon footprint that exceeds the societal benefit of deployment (such as an overparameterized foundation model serving a low-complexity task).
>
> Locating the dominant failure in the taxonomy identifies the first remediation to test: better curation (Data), safer objectives (Algorithm), or better instrumented and more efficient infrastructure (Machine). Real failures can span axes, so the intervention must still be evaluated end to end.

The D·A·M taxonomy isolates *where* failures originate; production telemetry must also catch *when* they manifest, and statistical failures (data-quality defects, distribution shift, and fairness violations) can persist for days or months behind green health checks (section 14.5). A fairness violation is the slowest of these to surface, because it is visible only on a subpopulation and only once outcomes are labeled.

A third mechanism is the feedback loop, in which model predictions actively reshape the user behavior that generates future training data. The YouTube recommendation feedback loop illustrates this dynamic at scale (M. H. Ribeiro et al. 2020).[2] M. H. Ribeiro et al. (2020) audited radicalization pathways on YouTube, finding migration from milder to more extreme channel categories and recommendation reachability between those categories. The broader systems lesson is that feedback loops can work exactly as designed while producing outcomes that conflict with societal values. Recommendation objectives must therefore be tested against downstream harms, not only against engagement proxies.

Facebook's 2018 change to News Feed ranking shows the converse decision. The team moved the ranking objective from short-term engagement proxies (clicks, watch time) toward meaningful social interactions between people, accepting lower short-term engagement to arrest the proxy's decoupling from user welfare (Mosseri 2018). The DLRM ranking service faces the same choice whenever its objective is set, because the clicks it can observe are a proxy for the value it is meant to deliver.

Silent failure modes change what verification can establish. Traditional software verification relies on deterministic assertions. A unit test asserts that an output matches an exact value, memory bounds checkers assert that buffer allocations do not overflow, and watchdog timers ensure RPC latencies do not breach service level agreements. In an ML system, correctness cannot be verified by deterministic invariants alone, because, as the credit service's form change showed, every such invariant can hold while the model serves biased, uncalibrated, or harmful predictions. What can be verified is the statistical bound of the verification gap (principle 9), which holds only over a named deployment population, task distance, and tolerance. A bound stated over the aggregate population

[2] **Goodhart's law in feedback loops**: Recommendation feedback loops are the canonical ML manifestation of Goodhart's law. Gradient descent optimizes watch-time proxies at a speed no human curator can match, and the system's own outputs reshape the training distribution. Users who consume extreme content generate data that can reinforce extremity and can decouple the proxy from user welfare faster than manual editorial processes would.

↩ The YouTube feedback loop as a production technical-debt pattern is established in section 14.2.6.1.

says nothing about a subgroup that the aggregate averages away, so a responsible specification names each consequential subgroup as a population in its own right. Turning responsibility goals into routine engineering practice means running statistical checks continuously: watching for covariate shift within each demographic slice, auditing how well proxies track the real goal, and bounding closed-loop feedback before silent errors spread through production.

15.2.3 The testing challenge

Suppose two engineers test the same credit model and agree that it should treat demographic groups fairly. One checks whether qualified applicants in both groups are approved at the same rate; the other checks whether a given risk score means the same repayment probability in both groups. When the two groups have different base repayment rates and prediction is imperfect, passing the first test forces the model to fail the second (Chouldechova 2017; Kleinberg et al. 2017). Traditional software testing never faces that bind because it checks behavior against unambiguous specifications: an arithmetic function must return the exact sum of its operands, and a relational database must preserve foreign-key integrity. Those deterministic properties map directly to executable assertions.

Responsible ML properties resist that kind of single assertion. **Fairness** has multiple mathematical definitions that can conflict under conditions such as unequal base rates and imperfect prediction (Chouldechova 2017; Kleinberg et al. 2017). What counts as fair depends on context, values, and trade-offs that technical systems cannot resolve alone. Individual fairness requires that similar individuals receive similar treatment, while group fairness requires equitable outcomes across demographic categories. These criteria can conflict, and choosing between them requires value judgments beyond the scope of optimization.

Fairness constraints and predictive performance can also trade off, by an amount that depends on the application. The Pareto frontier (principle 5) carries over unchanged, and section 15.3.2.2 measures one such trade-off once the criteria have been defined. Choosing criteria is only half of the testing problem. Aggregate metrics cannot show which groups a model fails, so testing also requires deciding which slices to evaluate, which invariances to demand, and which stresses to apply, choices that section 15.3.2 turns into release gates.

These testing choices complement traditional software testing rather than replacing it, and no single group can make them alone. Legal specialists cannot specify which demographic slices matter for a healthcare algorithm, and product managers cannot determine appropriate invariance tests for a loan model. Domain experts, affected stakeholders, policy specialists, and engineers must define the relevant harms together; engineers then encode those requirements as measurable tests and production controls. Responsibility therefore needs clear ownership within engineering as well as independent oversight outside it.

15.2.4 When responsible engineering succeeds

When the 2018 Gender Shades audit exposed error rates on darker-skinned women more than thirty times higher than on lighter-skinned men in commercial gender classifiers (Buolamwini and Gebru 2018), "be fairer" was not an instruction an engineering team could execute. Where teams have closed that gap, each documented success did the same thing: it turned a vague responsibility goal into an engineering constraint that can be specified, tested, communicated, and, when necessary, used to stop deployment. Following Gender Shades, Microsoft invested in improving gender-classification performance across demographic groups. Targeted data collection, model changes, and systematic disaggregated evaluation gave the team an explicit error-rate target, bringing audited error rates for darker-skinned subjects below 2 percent (Raji and Buolamwini 2019). Publishing these disaggregated benchmarks established a verifiable baseline and turned external audit findings into an operational release gate.

↩ Gender Shades, and the way aggregate benchmark metrics conceal subgroup disparities, are established in section 12.9.1.1.

Twitter's automatic image cropping system shows the same discipline under a different constraint. In 2020, users raised concerns about racial and gender bias in preview thumbnails. Twitter audited the system, reported measured disparities and limitations, and shifted toward uncropped previews that gave users more control (Yee et al. 2021). In that case, responsible engineering changed the product design rather than relying on an incremental adjustment to an automated ranking threshold.

Differential privacy applies the same move to privacy. It turns a privacy requirement into a mathematical bound on how much any one record can change a system's outputs, a bound that can

be budgeted and audited rather than asserted (Dwork 2008). Its mechanism and systems cost are developed with the privacy protections in section 15.5.2.

In each case the constraint sat on a D·A·M axis, whether in curated training data, a bounded loss function, or a privacy budget tracked in the runtime. Enforcing such constraints requires the operational authority to halt deployment or retire components that violate specified bounds, and that authority has to sit with the people who can still change the design.

15.2.5 Engineering leadership on responsibility

That authority belongs in engineering because a prelaunch review two weeks before release arrives after the cheap fixes have already been closed off. When a late review flags a model that cannot explain why it rejected a loan applicant or a pipeline that never recorded the demographic attributes needed to audit disparity, tuning a threshold cannot repair the design: correcting a flawed target means changing what the model predicts, and adding slice evaluation means rebuilding the data pipeline. Responsible AI engineering cannot be delegated exclusively to ethics boards or legal departments. These groups provide essential oversight, but they lack the early technical access required to catch problems while the architecture is still fluid.

Legal or ethics review can identify a problem near deployment, but it cannot recover design options the system has already foreclosed. If the team trained the model without fairness constraints, chose an architecture that cannot support interpretability requirements, or built a data pipeline without the demographic attributes needed for monitoring, review can only accept, reject, or demand expensive redesign. Engineers therefore occupy a critical position in the ML development lifecycle because their choices define the solution space for all subsequent interventions: architecture determines which fairness constraints can apply, the optimization objective determines which patterns the system learns, and the data pipeline determines whether disaggregated evaluation is possible.

Definition 15.1: Responsible AI engineering

Responsible AI engineering is the engineering discipline of designing, deploying, and maintaining systems with probabilistic outputs by turning societal and regulatory requirements into testable constraints on the D·A·M axes: permissible data contents, provenance, and composition; allowable model behavior and robustness properties; and infrastructure bounds such as latency, energy, compute budget, carbon emissions, and audit-log retention.

1. **Significance**: Each D·A·M axis acquires concrete governance constraints: the data axis is bounded by privacy regulations such as the General Data Protection Regulation (GDPR), which limits which records, fields, and features can be collected; the algorithm axis is bounded by fairness and robustness metrics (for example, positive prediction rates that differ across protected groups by no more than 5 percentage points, or accuracy that degrades by less than 2 percent when an adversary may shift every normalized input feature by at most 0.01); and the machine axis is bounded by resource and infrastructure budgets such as latency, energy per inference, carbon emissions, and audit-log retention. Violating these bounds is a system failure, not a research shortcoming.
2. **Distinction**: Unlike AI ethics (which articulates aspirational values), responsible AI engineering translates those values into measurable, testable invariants that can be verified through automated testing and continuous monitoring, using the same lifecycle practices that enforce latency SLOs.
3. **Common pitfall**: Stating a bound the system cannot measure. A disparity limit is an intention when the pipeline never collected the demographic attribute needed to check it, and a retention rule is an intention when no storage was provisioned to hold the evidence. Late-stage remediation may remain possible, but it is often narrower, slower, and more expensive.

An engineering-centered approach does not diminish the importance of diverse perspectives in identifying potential harms. Product managers, user researchers, affected communities, and policy experts contribute essential knowledge about how systems fail socially despite technical success.

Engineers translate these concerns into measurable requirements and testable properties that can be verified throughout the development lifecycle.

Organizations also need a reason to fund that work, and three reasons recur. Systematic disaggregated evaluation, documentation, and monitoring reduce the legal and financial exposure that ML system failures create, and they preserve evidence of the engineering process if problems emerge. Regulation attaches risk-management, data-governance, transparency, and human-oversight duties to high-risk applications, and controls built in from the start are cheaper than evidence reconstructed after deployment (section 15.5.3). Demonstrated practice also differentiates: organizations that can show model cards, audit trails, and published disaggregated results may qualify for deployments that competitors cannot. Each reason pays off only through repeatable workflows (checklists, documentation standards, and testing protocols) that embed responsibility constraints in the engineering lifecycle itself.

15.3 Responsible Engineering Across the Lifecycle

The recruiting tool and the care-management algorithm were both found to fail after the design options that could have addressed them were closed, so the lesson concerns timing more than vigilance. Each responsibility failure in this chapter has a point in the ML lifecycle before which it is cheap to prevent and after which it becomes expensive or impossible to repair, so responsible engineering is organized around that lifecycle rather than around a list of concerns.

Six stages follow from that premise, and the first four form a chain in which each stage depends on the output of the one before it. *Specify* comes first because a system cannot be tested against a requirement nobody wrote down; the target, the populations that matter, the evaluation data those populations demand, and the boundary of human oversight must all be fixed before training forecloses the alternatives. *Measure* turns those written requirements into release gates, evaluating each named population separately and quantifying the trade-offs among fairness criteria. Evidence that lives only in an engineer's notebook cannot be contested, audited, or reused, so *Explain and document* makes individual decisions legible to the people they affect and whole models legible to the teams that inherit them. The documented operating envelope then tells *Operate* what to watch after launch, when feedback loops and distribution shift erode a model that passed every gate. The last two stages span the whole lifecycle rather than following it, so each receives its own section, while the four chained stages structure the subsections of this one, each worked on the credit service. *Resource* accounts for the energy, carbon, and money that every stage consumes (section 15.4), and *Govern* supplies the regulatory obligations and the data infrastructure of access control, privacy, lineage, and audit that make each earlier stage provable to someone outside the team that built it (section 15.5). The four chained stages and the two that span them form one loop (figure 15.1).

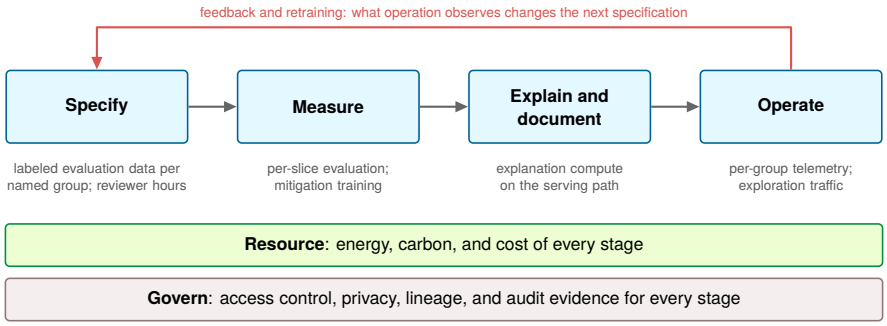


Figure 15.1: The Responsible Engineering Lifecycle: Four chained stages carry the credit service from requirement to production. Specify fixes the target, the named populations, and the oversight boundary; Measure turns them into release gates; Explain and document makes decisions and models legible; Operate watches the deployed model and feeds what it observes back into the next specification. Resource and Govern span every stage: each stage consumes accelerator-hours, energy, and money, and each must leave evidence that someone outside the team can audit. The machine cost under each stage names what the remedy consumes.

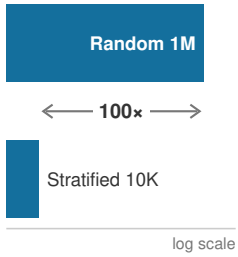


15.3.1 Specify: Requirements before training

The proxy variable trap (war story 15.1) was a specification failure. The care-management model predicted exactly what it was asked to predict, and the request was wrong. Specification is the stage with the most leverage and the least visibility, because its errors surface only after the model has learned them. Before the credit service reaches production, its team must therefore determine the provenance of the training data, identify who is represented and who is missing, anticipate failure modes, and define recourse for affected users. Table 15.2 organizes these questions by pipeline phase, distinguishing critical-path blockers from high-priority items that can proceed with documented risk acceptance. Its rows follow the pipeline rather than the six stages because specification must anticipate every phase in advance. The Evaluation row fixes what *Measure* will gate, and the Deployment and Monitoring rows fix what *Operate* will watch and how it will respond.

Table 15.2: Predeployment Assessment Framework: Critical Path items block deployment until addressed. High Priority refinements may follow launch under documented risk acceptance; a specified objective and tested monitoring and response paths remain prerequisites. Systematic coverage of responsibility concerns throughout the ML lifecycle reduces the chance that risks are overlooked.

Phase	Priority	Key Questions	Documentation Required
Data	Critical Path	Where did this data come from? Who is represented? Who is missing? What historical biases might be encoded?	Data provenance records, demographic composition analysis, collection methodology documentation
Training	High Priority	What is the system optimizing for? What does the loss implicitly penalize? How do architecture choices affect outcomes?	Objective function specification, regularization choices, hyperparameter selection rationale
Evaluation	Critical Path	Does performance hold across different user groups? What edge cases exist? How were test sets constructed?	Disaggregated metrics by demographic group, edge case testing results, test set composition analysis
Deployment	Critical Path	Who will this system affect? What happens when it fails? What recourse do affected users have?	Impact assessment, stakeholder identification, rollback procedures, user notification protocols
Monitoring	High Priority	How are anomalies detected? Who reviews system behavior? What triggers intervention?	Monitoring dashboard specifications, alert thresholds, review schedules, escalation procedures

The Training and Monitoring rows mix release prerequisites with later refinements: teams must specify the objective and test the minimum monitoring and response controls before launch, while the remaining refinements may proceed with documented risk acceptance and a remediation timeline. The Evaluation row in table 15.2 belongs to specification rather than to testing because naming the groups that matter also fixes a data budget. Showing that performance holds for each group requires a statistically valid test set per group, and the cost of that set grows with the group's rarity.

Random sampling needs 100× more images to reach a 1 percent subgroup.

Napkin Math 15.1: The statistics of representation

Problem: An engineering team needs to verify that a Face ID model works for a minority group representing 1 percent of the user base. The group's error rate must be known to within 1 percentage point at 95 percent confidence. The binomial standard error behind the statistical confidence trap of section 12.8.1 is largest at an error rate of 0.5, so the worst-case margin of error on n images is $1.96\sqrt{0.25/n}$, which falls to one percentage point near n = 10,000 images for this group.

Random sampling: To get 10,000 images of a 1 percent group in expectation via independent random sampling, the team must collect and label: $D_{\text{eval,total}}$ = 10,000 images / 0.01 = 1,000,000 images

Stratified sampling: Recruiting a representative, independently sampled evaluation set within this group requires 10,000 images.

Systems insight: Under these assumptions, natural-population sampling requires 100× as much total collection as direct subgroup recruitment, in expectation rather than as a guaranteed

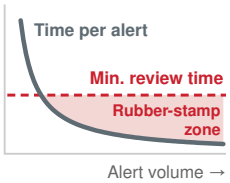
quota. Targeted recruitment must still represent the deployment subgroup; active selection of difficult cases cannot be treated as an unbiased evaluation sample without accounting for its sampling design. Fairness requires intentional data engineering rather than uncurated volume.

The representation cost derived in napkin math 15.1 settles what the evaluation must contain, but even a representative evaluation cannot prevent harm at deployment when human oversight is inadequate. The Deployment row of table 15.2 forces a second decision that cannot be deferred to launch: where people sit in the decision loop once the model is live, and what that arrangement must be designed to withstand.

War Story 15.2: The automation paradox (2018)

Context: Uber's Advanced Technologies Group (ATG) was testing self-driving cars in Arizona, relying on a human safety driver to intervene if the autonomous perception system failed (National Transportation Safety Board 2019).

Mechanism: The perception system detected a pedestrian crossing the road but repeatedly toggled its classification between vehicle, bicycle, and unknown, resetting its trajectory prediction while automatic emergency braking was intentionally disabled.



Impact: The safety driver was visually distracted by a personal phone and failed to take control, resulting in a fatal collision.

Fix: Uber retrofitted the fleet with driver-monitoring cameras, re-enabled automatic emergency braking, and established dual-operator staffing during autonomous road testing.

Systems lesson: Adding a human backup creates a new system with its own failure modes. High automation reliability can encourage complacency and reduce vigilance, so an effective fallback requires workload design, attention monitoring, and a safety case for the combined human-machine system.

For high-stakes applications, the specification should state where human oversight is required. Human-in-the-loop (HITL) systems route uncertain, high-consequence, or flagged decisions to human reviewers rather than acting autonomously; the clinician approval gates of ClinAIOps (section 14.9.2) are one proposed design. Effective HITL design must specify four requirements: the review scope (which decisions require human review), the confidence thresholds that trigger escalation, the training reviewers receive, and the mechanisms for monitoring reviewer performance. HITL is not a catch-all solution. Human reviewers can rubber-stamp automated decisions, introduce their own biases, or become overwhelmed by alert volume, so the human-machine boundary must be calibrated to the application's risks and the reviewers' capabilities.

Like an aviation preflight checklist, the assessment standardizes the questions a team must answer under schedule pressure, but answering them does not show that the system is safe. That evidence comes from measuring the model against the populations the specification named, which turns each written requirement into a gate the release must pass.

If reviewer hours stay fixed, rising alert volume eventually leaves too little time per alert for real review.

↩ The ClinAIOps clinician oversight loop, in which a clinician approves, modifies, or rejects each therapy recommendation, is established in section 14.9.2.1.

15.3.2 Measure: Fairness criteria as release gates

Turning the populations that specification named into release gates is what catches disparities that an aggregate metric hides: a commercial face classifier can post 95 percent overall accuracy while misclassifying more than a third of darker-skinned women when that group is a small share of the test set. Measurement selects the slices, metrics, and thresholds that decide whether the credit service may deploy, and responsibility properties become testable once engineers and stakeholders define criteria appropriate to the application and measure performance per subgroup. The Gender Shades audit,[3] introduced in section 15.2.4, demonstrated how **disaggregated evaluation** across demographic categories reveals disparities invisible in aggregate metrics (Buolamwini and Gebru 2018), exposing the subgroup failures that responsibility monitoring must catch before deployment. Table 15.3 shows the error-rate differences that commercial gender-classification systems produced across demographic groups. Measuring such slices carries the representation cost that specification

[3] **Gender Shades**: A 2018 study by Joy Buolamwini (MIT Media Lab) and Timnit Gebru (Microsoft Research) that audited commercial gender-classification systems from Microsoft, IBM, and Face++ using the Fitzpatrick skin type scale, a dermatological classification developed in 1975 for UV sensitivity (Fitzpatrick 1988) and repurposed here as a demographic benchmark for algorithmic auditing.

budgeted (napkin math 15.1), because small subgroups contribute few samples to a randomly drawn test set.

Table 15.3: Gender Shades Face++ Error Rates: The dark-female error rate is 43.1× the light-male rate. Source: (Buolamwini and Gebru 2018).

Demographic Group	Error Rate (%)	Relative to Light-Skinned Males
Light-skinned males	0.8%	Baseline (1.0×)
Light-skinned females	9.8%	12.2×
Dark-skinned males	0.7%	0.9×
Dark-skinned females	34.5%	43.1×

As table 15.3 quantifies, disaggregated evaluation revealed what an aggregate score concealed. The audit measured Face++ error rates of 0.8 percent for light-skinned males and 34.5 percent for dark-skinned females (accuracies of 99.2 percent and 65.5 percent). The aggregate metric gave no indication that the dark-female error rate was 43.1× the light-male rate.

No universal threshold defines acceptable disparity, but teams should establish explicit, justified bounds before deployment. A team might adopt an error-rate ratio below 1.25× or a false-positive-rate difference under 5 percentage points as an application-specific release policy. In US employment law, the disparate impact doctrine[4] shapes regulatory oversight, while the four-fifths rule[5] provides a separate, non-dispositive selection-rate diagnostic. Criteria must fit the application and its governing law, and one domain's threshold should not be borrowed for another.

Systems Perspective 15.4: The flaw of averages

A bridge that is "safe on average" but collapses under a heavy truck illustrates the **flaw of averages** (Savage 2009). An ML system that is "accurate on average" but fails for a specific demographic cohort presents the same design mistake. As with tail latency (p99), a release gate must test the conditions its aggregate metric conceals; disaggregated evaluation makes cohort-specific failures visible.

Selecting those conditions requires application knowledge. A vision classifier fails differently from a recommendation engine or an audio wake-word detector, so fairness metrics and evaluation slices must reflect the application domain. In healthcare diagnostics, demographic cohorts such as age and biological sex govern slice definitions. In content moderation, dialect and linguistic context dominate. In financial underwriting, credit regulations mandate auditing legally protected categories.

Lighthouse 15.1: Fairness concerns by lighthouse

The lighthouse workloads of section 2.3.2 were defined by the resource that binds each one, but their fairness risks come from somewhere else, from the data each learns from and the context each serves. Table 15.4 maps each lighthouse's data source and deployment context to a primary risk and metric.

Architecture alone does not determine fairness; each row identifies a deployment-specific risk to test first, not a universal property of the model family or its bottleneck.

[4] **Disparate impact**: In *Griggs v. Duke Power Co.* (1971), the US Supreme Court held under Title VII that an employment practice may be unlawful because of its operation even without discriminatory intent (Supreme Court of the United States 1971). Disparate impact is a legal claim with statute- and context-specific elements, not a synonym for any statistical disparity. Model outcomes and proxies can supply relevant evidence, but metrics alone do not establish liability.

[5] **Four-fifths rule**: The 1978 Uniform Guidelines on Employee Selection Procedures use the four-fifths rule as a practical employment-selection diagnostic (Equal Employment Opportunity Commission et al. 1978). A selection rate below 80 percent of the rate for the group with the highest rate is generally regarded as evidence of adverse impact, but the Guidelines also recognize that smaller differences may matter and that the ratio is not dispositive.

Table 15.4: Fairness Risk by Lighthouse: Fairness risks follow each lighthouse's data source and deployment context, not the resource that binds it.

Lighthouse (Home Regime)	Primary Fairness Risk	Key Evaluation Metric	Real-World Example
ResNet-50 (compute-bound)	Training data bias (underrepresentation of deployment-relevant groups)	Disaggregated accuracy by demographic group	Commercial face classifiers erred most on darker-skinned women (Gender Shades audited those systems, not ResNet-50)
GPT-2 (bandwidth-bound)	Corpus bias (overrepresentation of majority viewpoints in web text)	Toxicity rate by demographic prompt context; stereotype score	LLMs produce more toxic completions for prompts mentioning minority groups
DLRM (capacity-bound)	Feedback-loop amplification (popular items get more data)	Share of recommendation impressions by item category and supplier or creator group	Filter bubbles: the system recommends similar content to similar users, reducing discovery of niche creators
KWS DS-CNN (power-bound)	Deployment-context mismatch (trained on clean audio, deployed in noisy real-world environments)	False positive rate by acoustic environment and speaker accent	Voice assistants perform worse on accented speech; wake-word triggers on TV audio in some languages

Systems insight: Fairness evaluation must match each lighthouse's failure mode. Vision models require stratified demographic accuracy; large language models (LLMs) need toxicity and stereotype probes; recommenders need exposure audits; TinyML needs acoustic-environment tests. The KWS lighthouse faces exactly this challenge for its depthwise-separable convolutional neural network (DS-CNN). Trained on clean studio audio, it must perform equitably across accents, background noise levels, and speaker demographics in production homes, so its release gate needs accent and acoustic-environment slices, each reported with its own confidence interval.

Once the application has fixed the slices, three verification regimes expose latent responsibility failures that a uniform validation set hides. Slice-based evaluation partitions evaluation data into demographic and operational cohorts, computing metrics independently for each slice. A model may achieve 95 percent accuracy overall while dropping to 78 percent on low-income applicants or rural cohorts, a disparity that aggregate reporting never shows.

Invariance testing checks that model decisions stay unchanged when you swap features that should not matter. Swapping candidate names such as "John" and "Jamal" in a loan application must not alter approval probabilities when demographic features are legally and technically irrelevant to creditworthiness. Behavioral testing frameworks such as CheckList put this principle to work by organizing validation suites around behavioral capabilities and input swaps rather than a single static validation loss (M. T. Ribeiro et al. 2020).

Boundary and stress testing probe input regimes where empirical validation data is sparse or unrepresentative. Boundary evaluation maps behavior at the edges of the data distribution (extreme ages, rare transaction amounts, or sparse geographic categories), where prediction variance climbs sharply. Stress testing extends these margins into adversarial conditions: corrupted feature pipelines, sudden covariate shift, and synthetic edge cases designed to test safety margins under degradation. Stakeholder red-teaming complements automated suites by introducing adversarial domain probes from affected communities, surfacing failure modes that statistical benchmarks overlook.

Running these evaluations requires four linked capabilities in the testing infrastructure. It begins with stratified evaluation, which computes performance metrics separately for each cohort to expose error-rate disparities across populations, and extends to intersectional analysis across combinations of attributes so that compounding failure modes invisible in single-factor slices are caught as well. Because partitioning the test set into finer intersections leaves each slice with fewer examples, the harness must attach confidence intervals to every point estimate; the binomial resolution limit

that the statistical confidence trap of section 12.8.1 exposed for an aggregate test set binds hardest here, where each slice holds only a fraction of the evaluation data. Once the model ships, temporal monitoring carries the same cohort checks into production, catching distribution drift that degrades minority slices before it registers on aggregate health checks.

Open-source evaluation suites such as Fairlearn (Bird et al. 2020), AI Fairness 360 (Bellamy et al. 2019), and the What-If Tool (Wexler et al. 2020) compute stratified and intersectional metrics once the team has specified the metrics, slices, and alert thresholds. They compute whichever metric an engineer queries; they cannot decide which demographic boundaries matter, calibrate paging thresholds for on-call engineers, or select the legally appropriate fairness constraint.

An operational release gate must distinguish absence of evidence from evidence of parity. If a slice lacks sufficient labeled validation data to bound the error rate with statistical confidence, the CI/CD gate must report insufficient data rather than a false pass, which triggers targeted data acquisition or restricts deployment scope. Every population test therefore returns one of three results (pass, fail, or insufficient evidence), and only a pass permits release.

15.3.2.1 Worked example: Fairness analysis of the credit service

The credit service, the chapter's labeled composite, reports 85 percent accuracy on the majority group and 82.5 percent overall accuracy across the evaluated applicants, numbers that may satisfy a coarse aggregate dashboard. Evaluating the model separately across demographic cohorts exposes how aggregate metrics conceal severe disparities. This constructed evaluation assumes observed repayment outcomes for every applicant, independent of the model's approval predictions; those predictions are not the lending actions that produced the labels. The two cohorts' outcomes appear side by side, the majority cohort (Group A) in table 15.5 and the minority cohort (Group B) in table 15.6.

Table 15.5: Confusion Matrix for Group A (Majority): In this constructed scenario, loan approval outcomes for 10,000 applicants from the majority demographic group. The 90 percent true positive rate (4,500 approved of 5,000 qualified) and 20 percent false positive rate establish the baseline for fairness comparison.

	Approved (pred)	**Rejected (pred)**
Repaid (actual)	4,500 (TP)	500 (FN)
Defaulted (actual)	1,000 (FP)	4,000 (TN)

Table 15.6: Confusion Matrix for Group B (Minority): In the same constructed scenario, loan approval outcomes for 2,000 applicants from the minority demographic group. The 60 percent true positive rate (600 approved of 1,000 qualified) reveals a 30 percentage-point disparity compared with Group A; the confusion matrices alone do not identify its cause.

	Approved (pred)	**Rejected (pred)**
Repaid (actual)	600 (TP)	400 (FN)
Defaulted (actual)	200 (FP)	800 (TN)

Every rate in the calculations that follow can be reconstructed from the approved/rejected and repaid/defaulted cells of these two matrices. Three standard criteria for equitable treatment capture distinct operational objectives, and the credit service's two matrices violate all three.

Demographic parity (Dwork et al. 2012) requires equal positive selection rates across groups regardless of underlying qualification ($\Pr(\hat{Y}=1 \mid G=\text{A}) = \Pr(\hat{Y}=1 \mid G=\text{B})$). Group A receives approval at $(4{,}500+1{,}000)/10{,}000 = 55\%$, whereas Group B receives approval at $(600+200)/2{,}000 = 40\%$. The resulting 15 percentage-point disparity indicates unequal selection outcomes between cohorts.

Equal opportunity requires equal true positive rates among qualified applicants ($\Pr(\hat{Y}=1 \mid Y=1, G=\text{A}) = \Pr(\hat{Y}=1 \mid Y=1, G=\text{B})$). Group A achieves a TPR of $4{,}500/(4{,}500+500) = 90\%$, meaning 90 percent of creditworthy applicants secure loans. Group B achieves only $600/(600+400) = 60\%$. This 30 percentage-point disparity reveals that qualified applicants in Group B suffer disproportionate rejection relative to equally qualified peers in Group A.

Equalized odds tightens the constraint, demanding parity in both true positive and false positive rates ($\Pr(\hat{Y}=1 \mid Y=v, G=\text{A}) = \Pr(\hat{Y}=1 \mid Y=v, G=\text{B})$ for $v \in \{0,1\}$).[6] Neither group may then bear a disproportionate share of unjustified rejections (false negatives) or unjustified approvals (false positives). Group A yields an FPR of $1{,}000/(1{,}000+4{,}000) = 20\%$, matching Group B at $200/(200+800) = 20\%$. Although false positive rates align, the substantial true positive rate deficit violates equalized odds.

Both groups in this scenario have the same base rate (5,000 of 10,000 and 1,000 of 2,000 applicants repaid), so the impossibility results for unequal base rates do not bind here. Remediation remains possible in principle, but these matrices do not identify the cause of the disparity or which intervention would close it. Those results involve a fourth criterion, calibration within groups, which applies the probability calibration that evaluation already checks to each group separately: among applicants in group g who receive score s, the fraction who repay should be s, that is, $\Pr(Y=1 \mid \text{score}=s, G=g) = s$ for every group. Real populations often have unequal base rates, and with unequal base rates and imperfect prediction, calibration-style criteria and error-rate balance can conflict (Chouldechova 2017; Kleinberg et al. 2017). A score calibrated within each group then generally assigns the groups different false positive or false negative rates, so the operational guarantee must be selected and defended for the application rather than deduced from aggregate accuracy or calibration.

These metrics disagree because they encode different policy choices about which error rates matter most. In this scenario, the model rejects qualified applicants from Group B at a much higher rate (40 percent false negative rate vs. 10 percent) while maintaining similar false positive rates. These confusion matrices establish an operational disparity, not whether it arose from classification thresholds, labeling bias, omitted features, sampling skew, or historical discrimination. The COMPAS risk assessment system[7] shows the same disagreement in a deployed system whose groups had unequal base rates.

6 **Equalized odds**: Formalized by Hardt et al. (2016), requiring that both TPR and FPR be equal across protected groups; the weaker "equal opportunity" relaxes this to TPR alone. Equalized-odds postprocessing may require randomized, group-dependent decisions rather than deterministic thresholds alone. It also requires protected-group information at decision time and must be evaluated under applicable law; for example, US credit regulation generally restricts using protected bases to assess creditworthiness.

7 **COMPAS**: Correctional Offender Management Profiling for Alternative Sanctions.

War Story 15.3: The COMPAS recidivism algorithm audit (2016)

Context: COMPAS is a risk assessment tool used in US courtrooms to predict re-offending for bail and sentencing decisions (Angwin et al. 2016).

Mechanism: The audited scores combined approximate calibration across racial groups (a given score corresponded to about the same observed re-offense rate in every group) with unequal error rates. These observations expose a policy choice about acceptable errors; they do not establish which objective the original optimizer used.

Impact: Black defendants who did not re-offend were incorrectly flagged as high-risk at nearly twice the rate of White defendants (44.9 percent vs. 23.5 percent), while White recidivists were far more often mislabeled low-risk.

Response: The audit exposed why calibration alone could not settle whether the error distribution was acceptable. Any jurisdiction using such scores needs an explicit policy for which fairness criteria matter, independent validation across groups, and review of how the score enters the decision workflow.

Systems lesson: The scores were approximately calibrated by race but violated equalized odds, the criterion that requires equal true positive and false positive rates across groups. The credit service's confusion matrices show the error-rate side of the conflict, and COMPAS adds the calibration side, which is why the team must explicitly choose which fairness constraint governs.

Where collection and use of protected attributes are lawful and justified, production systems can automate these calculations and trigger review when disparities exceed predefined thresholds. Listing 15.1 handles the failure case explicitly, reporting undefined group rates as insufficient data rather than comparing them against a threshold. These denominator checks establish arithmetic validity only. A production release gate also needs minimum labeled sample counts and uncertainty checks for each relevant slice; a defined rate from one observation is not sufficient evidence.

Listing 15.1: Automated Fairness Monitoring: The core pattern computes per-group metrics from confusion matrices and alerts when disparities exceed application-specific thresholds. Production use requires sufficient data and lawful, justified handling of group attributes.

```
def compute_fairness_metrics(confusion_matrix):
    tp, fp, tn, fn = (
        confusion_matrix[k] for k in ["TP", "FP", "TN", "FN"]
    )
    total = tp + fp + tn + fn
    return {
        # Demographic parity
        "approval_rate": (tp + fp) / total if total else None,
        # Equal opportunity
        "tpr": tp / (tp + fn) if (tp + fn) else None,
        # Equalized odds (with TPR)
        "fpr": fp / (fp + tn) if (fp + tn) else None,
    }

# Compare groups and flag disparities exceeding threshold
for metric in ["approval_rate", "tpr", "fpr"]:
    if metrics_a[metric] is None or metrics_b[metric] is None:
        report_insufficient_data(metric)
        continue
    disparity = abs(metrics_a[metric] - metrics_b[metric])
    # e.g., 0.05 for high-stakes applications
    if disparity > FAIRNESS_THRESHOLD:
        trigger_alert(metric, disparity)
```

Automated monitoring tracks fairness metrics repeatedly at a scale manual auditing cannot reach and alerts when sufficient labeled evidence reveals a disparity. Label availability and the time needed to accumulate observations bound detection speed. The 30 percentage-point TPR disparity far exceeds this scenario's 5-percentage-point release threshold, indicating the model requires fairness intervention before deployment. Table 15.7 summarizes the computed metrics and resulting disparities across both cohorts.

Table 15.7: Fairness Metrics Summary: In the constructed credit-service scenario, approval rate and true positive rate differ across groups, while false positive rates match; the table establishes disparity but not its cause.

Metric	Group A	Group B	Disparity
Approval Rate	55%	40%	15 pp
True Positive Rate	90%	60%	30 pp
False Positive Rate	20%	20%	0 pp

Shared classification thresholds applied to differing score distributions illustrate how aggregate performance masks severe subgroup divergence (Barocas and Selbst 2016). Shifting between the two candidate decision boundaries (figure 15.2) lifts overall accuracy from 75 percent to 81.25 percent by achieving perfect separation in Subgroup A, yet simultaneously triples the misclassifications in Subgroup B. Because the two subgroups' scores are distributed differently, one shared boundary cannot sit at the best point for both, and the move that raises the global metric does so by trading away Subgroup B's outcomes. Aggregate accuracy alone cannot determine whether those outcomes are equitable for either cohort.

Mitigating these disparities means intervening before, during, or after training, and each stage imposes its own systems trade-offs. Preprocessing via sample reweighting fixes a weight for every training instance before training begins; the training loss then scales each Group B instance's penalty by its weight, amplifying gradient signal for underrepresented cohorts without discarding data.[8] The trade-off appears across the broader loss surface, where reweighting can degrade accuracy on majority slices.

[8] **Reweighting**: The technique descends from importance sampling in statistics, which corrects an estimate drawn from one distribution by weighting each sample toward a target distribution. Kamiran and Calders (2012) showed that appropriately chosen weights can reduce disparate impact from training data.

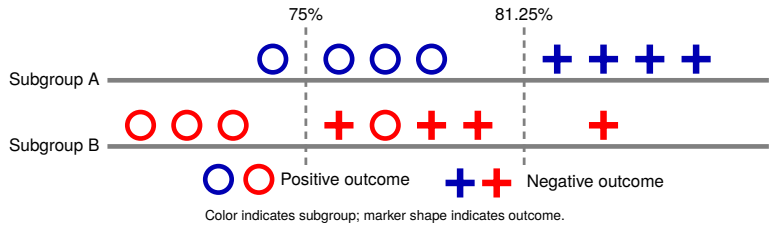


Figure 15.2: Threshold Effects on Subgroup Outcomes: Two candidate classification thresholds intersect different score distributions for Subgroups A and B. Circles mark positive outcomes (loan repayment), plus markers mark negative outcomes (default), and color distinguishes subgroup; each boundary approves the markers to its left. Each dashed line carries the overall accuracy that boundary achieves, not a score cutoff. Moving to the higher-accuracy boundary lifts overall accuracy from 75 percent to 81.25 percent, but the whole gain falls in Subgroup A, which becomes perfectly separated, while Subgroup B goes from one misclassification to three.

In-processing via adversarial debiasing turns the training loop into a minimax game between two neural networks. A primary model (encoder and predictor) transforms input features $\mathbf{x}$ (such as qualifications or income) into an intermediate latent representation $\mathbf{z}$, which a task head uses to predict the target label $\hat{y}$ under a loss $\mathcal{L}_{\text{task}}(\hat{y}, y)$ rewarding high predictive accuracy. Concurrently, an adversary head taps directly into the latent vector $\mathbf{z}$ and attempts to predict the protected attribute a (such as demographic group) by minimizing an adversarial loss $\mathcal{L}_{\text{adv}}(\hat{a}, a)$. During backpropagation, the adversary's gradient is negated as it flows into the shared feature encoder:

$$\mathcal{L}_{\text{total}} = \mathcal{L}_{\text{task}} - \lambda_{\text{adv}} \mathcal{L}_{\text{adv}}$$

Here λ_{adv} weights the adversarial penalty against the task loss. The adversary head minimizes $\mathcal{L}_{\text{adv}}$ alone, trying to recover a from $\mathbf{z}$, while the encoder and task head minimize $\mathcal{L}_{\text{total}}$, so the encoder lowers its objective only by making the adversary's task harder. It is therefore forced to purge latent features that correlate with the protected attribute, producing representations that remain informative for the task while suppressing, not eliminating, protected-attribute signal under the evaluated distribution.[9] The systems cost is real: a second (adversary) head to train, adversarial gradients that destabilize convergence, and a larger hyperparameter search.

Postprocessing via threshold adjustment decouples the decision boundary across groups, lowering the approval cutoff for Group B to equalize TPR. The operational trade-off is an increase in false positives within that cohort, admitting applicants who may subsequently default. The lever is also legally constrained. In the US, group-specific cutoffs are prohibited in employment selection and restricted in credit, so this intervention often exists only in principle, and teams move instead to reweighting, feature and label repair, or objective changes.

Selecting among these interventions requires stakeholder alignment on acceptable trade-offs for the specific deployment domain. Whichever intervention is chosen, its trade-off should be stated as a number that stakeholders can argue about.

> **Checkpoint 15.2: Fairness criteria**
>
> Fairness is not a single metric; it is a constrained design choice.
>
> - ☐ **Metric definitions**: can you distinguish demographic parity, equal opportunity, equalized odds, and calibration in terms of which rates must match across groups?
> - ☐ **Impossibility trade-off**: can you explain (at a high level) why base-rate differences make it impossible to satisfy all fairness criteria simultaneously?
> - ☐ **Systems interpretation**: given the confusion matrices in table 15.5 and table 15.6, can you identify which disparity matters operationally (TPR vs. FPR vs. approval rate) and what kind of harm it represents?
> - ☐ **Engineering decision**: for a concrete high-stakes domain (credit, hiring, criminal justice), can you justify which fairness constraint you would prioritize and why?

[9] **Adversarial debiasing**: The key differentiating property is representation pressure: the adversary discourages the primary model from encoding protected-attribute information, which can reduce protected-attribute leakage and help satisfy selected fairness criteria under the evaluated distribution (B. H. Zhang et al. 2018). It does not provide a general fairness guarantee under arbitrary deployment shift, because any guarantee depends on assumptions about invariance, labels, causal structure, and the type of shift. Post-processing methods such as threshold adjustment may also be appropriate under different assumptions but must be revalidated when deployment demographics or label processes change. The cost is additional training, hyperparameter tuning, and slice-level validation rather than a universal percentage overhead.

15.3.2.2 Quantifying the fairness-accuracy trade-off

The worked example showed that fairness criteria can conflict. A separate question is how a chosen engineering constraint changes predictive utility. The Pareto frontier (principle 5) collects the configurations for which one plotted objective cannot improve without degrading another. Figure 15.3 plots a hypothetical fairness-accuracy Pareto frontier against demographic disparity, measured as the difference between two groups' positive-prediction (approval) rates, the demographic parity gap defined in section 15.3.2.1. The disparity axis is inverted so that fairer configurations lie to the right. The figure contrasts an unconstrained maximum-accuracy operating point (A) against a balanced compromise (B) and a steep accuracy collapse under strict demographic equality (C). These annotated configurations illustrate candidate policy choices along the frontier; they do not imply that unconstrained training always maximizes accuracy at high disparity, that zero disparity must reduce accuracy, or that every application has a sweet spot.

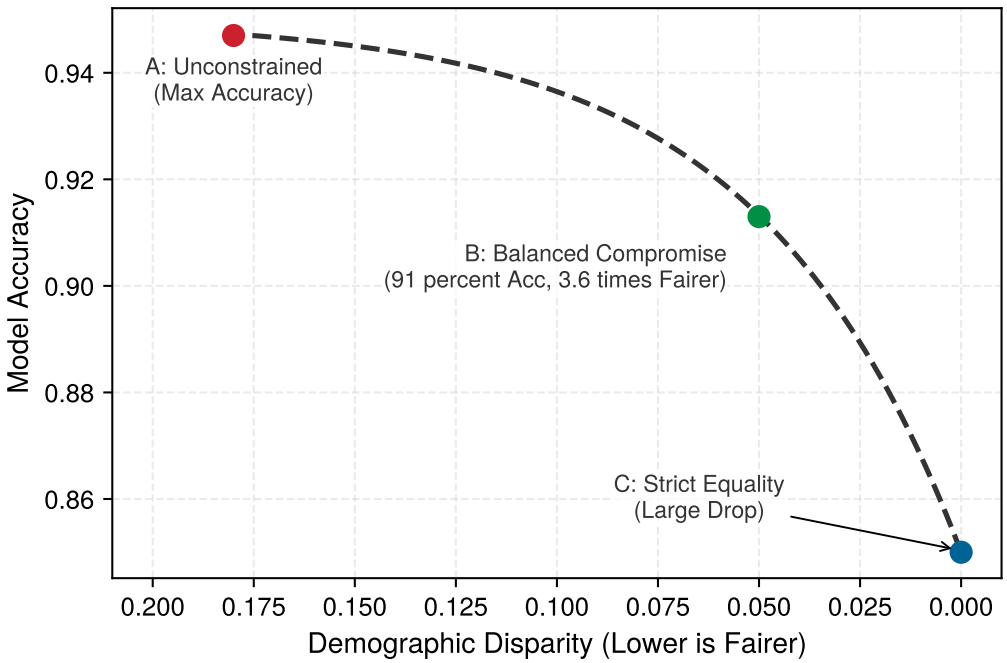

Figure 15.3: An Illustrative Fairness-Accuracy Pareto Frontier: A hypothetical relationship between model accuracy and demographic disparity. The x-axis is inverted so lower disparity lies to the right. Points A, B, and C illustrate three possible operating choices along this constructed frontier; B's label of 3.6 times fairer means its disparity (0.05) is 3.6 times smaller than A's (0.18). The curve is not an empirical or universal law.

The hypothetical frontier in figure 15.3 illustrates possible operating choices from A toward C; the deployment's measured candidate configurations, rather than that illustrative curve, determine its actual trade-offs. Quantifying this trade-off requires evaluating economic costs for the specific application. The credit service of section 15.3.2.1 makes the resulting penalty concrete because each lending outcome carries an explicit value, the margin on a repaid loan on one side and the loss on a default on the other.

Napkin Math 15.2: The price of fairness

Problem: Stakeholders demand elimination of the credit service's 30 percentage-point true positive rate (TPR) disparity. What is the "Price of Fairness" in lending outcomes?

Physics: TPRs can be equalized by adjusting the classification threshold (γ_{cls}) for the disadvantaged group.

- **Original state**: Group A (TPR = 90 percent), Group B (TPR = 60 percent, FPR = 20 percent).
- **Intervention**: Lower $\gamma_{\text{cls},g=\text{B}}$ until $\text{TPR}_{g=\text{B}} = 90$ percent. (US credit law restricts group-specific cutoffs, as the mitigation discussion noted, so the calculation quantifies the trade-off rather than a deployable intervention.)
- **The cost**: Lowering the threshold increases false positives (approving applicants who later default).

Math:

1. Under the scenario's assumed threshold response, closing the 30 percentage-point TPR gap produces a 20 percentage-point increase in false positives for the disadvantaged group.
2. If 50 percent of Group B applicants would repay, a repaid loan earns a margin of \$1,500, and a default loses \$3,000, both sides of the intervention must be counted:
   - Group B baseline utility evaluates the original expected payoff: $0.60 \times 0.50 \times \$1{,}500 - 0.20 \times 0.50 \times \$3{,}000 = \$150$ per applicant.
   - Evaluating the intervention requires counting both marginal terms: $\Delta\text{Utility} = \Delta\text{TPR} \times \text{Base Rate} \times \text{Loan Margin} - \Delta\text{FPR} \times (1 - \text{Base Rate}) \times \text{Default Loss}$.
   - The added true-positive value is \$225 per Group B applicant, while the added false-positive cost is \$300, producing a net loss of \$75.
   - Dividing this \$75 net loss by the \$150 baseline yields a 50 percent within-group utility loss. With Group B at 17 percent of applicants, the population-average loss is \$12.50 per applicant; calculating an aggregate percentage also requires the other group's baseline utility.

Systems insight: The "Price of Fairness", the fairness literature's name for the utility a system gives up to satisfy a fairness constraint, in this scenario is a 50 percent within-group utility loss, not a derivable aggregate percentage. The loss is not automatic: when a TPR gap reflects a miscalibrated threshold, closing it can raise net utility. It appears when the baseline threshold is near the utility optimum and the marginal approvals skew toward default. Engineering teams owe stakeholders both the Pareto frontier and the operational assumptions that produced it.

The calculation gives stakeholders a way to choose a point on the fairness-accuracy frontier, but it still does not explain any particular decision. When a credit-service applicant receives a rejection, stating that "the model's true positive rate for this demographic group is 60 percent compared to 90 percent for other groups" provides no actionable information. The applicant needs to know *why* the application was rejected and *what* could be changed. These questions require explainability, which is the ability to articulate which input features drove specific predictions.

15.3.3 Explain and document: Decisions and models made legible

When the credit service rejects a borrower with a bare probability score of 0.41, the applicant cannot tell whether the denial came from a high debt-to-income ratio or a corrupted credit-bureau field; six months later, when another team reuses that same classifier to screen rental tenants without knowing which populations it was tested on, the organization inherits a second failure at the model level. Explanation and documentation answer that single demand for legibility at two timescales. An explanation makes one decision understandable, at the moment it is made, to the person it affects. Documentation makes the model understandable across its lifetime to the engineers, auditors, and downstream teams who inherit it: what it was trained on, where it was validated, and what it must not be used for. Both exist for the same systems reason, since a guarantee that no one outside the team can inspect cannot be contested, audited, or safely reused.

15.3.3.1 Explainability requirements

An applicant whom the credit service denies may be entitled under applicable law to reasons or specific adverse-action factors, not merely aggregate statistics. **Explainability**[10] supports this

[10] **Explainability and interpretability**: *Interpretability* usually describes how readily a person can understand a model or its behavior, often through a constrained structure such as a short rule list or sparse linear model. *Explainability* is broader and includes post-hoc methods such as LIME and SHAP. Neither property is automatic: a linear model with opaque features can be difficult to interpret, and a feature attribution is not a causal account of a decision. The systems implication is that intrinsic constraints affect model selection, while post-hoc methods add a computation and validation path whose cost depends on the method, model, and serving workflow. GDPR access and automated-decision provisions use the phrase "meaningful information about the logic involved" for covered processing (European Parliament and Council of the European Union 2016), leaving the appropriate technical approach dependent on the decision and governing law.

capability. It enables human oversight of automated decisions, supports debugging when problems emerge, and can satisfy applicable requirements for decision transparency.

The level of explainability required varies by application context and regulatory environment, and the requirement constrains architecture rather than logging. When a rule requires specific reasons for an adverse action, a team can choose an inherently interpretable model, such as a sparse linear model, and accept whatever predictive capacity that structure gives up on the task. Alternatively, it can deploy a higher-capacity model with a post-hoc attribution method such as Shapley additive explanations (SHAP) or local interpretable model-agnostic explanations (LIME). The SHAP values that localized mispredictions during incident debugging now face an outside reader, which raises the bar. The explanation path adds serving latency, its fidelity to the model must be measured, and it yields a feature attribution rather than a causal account of the decision. Either way, the choice belongs in the design, because it determines which model family is trained and what the serving path must carry. Table 15.8 maps common deployment scenarios to their explainability needs.

↩ SHAP values, which estimate how much each input feature contributed to one prediction, are established as a debugging tool in section 14.7.1.2.

Table 15.8: Explainability Considerations by Domain: Requirements vary by decision, actor, jurisdiction, and governing rules. The engineering challenge is matching explanation mechanisms to applicable requirements while managing risks such as gaming.

Application Domain	Explainability Level	Typical Requirements
Credit decisions	Specific reasons for covered actions	Principal reasons may have to be disclosed to the applicant
Medical diagnosis	Decision support	Support clinical review and applicable documentation
Content moderation	Context-dependent	Support notices or appeals where required
Recommendation	Context-dependent	Provide transparency appropriate to the use and governing rules
Fraud detection	Controlled disclosure	Balance applicable notice duties with adversarial-gaming risk

Whatever the requirement, the candidate models lie along a gradient continuum from intrinsic interpretability to post-hoc explanation (figure 15.4). On the left, small trees and sparse linear or logistic models with meaningful features can expose decision logic to human inspection. Large trees or opaque engineered features can defeat that advantage. On the right, high-capacity representations, such as random forests, deep neural networks, and convolutional neural networks (CNNs) or transformers, often need supplementary explanation methods. LIME and SHAP require fidelity checks; attention maps alone do not establish faithful explanations. The spectrum organizes candidate approaches, not a categorical guarantee for any model family.

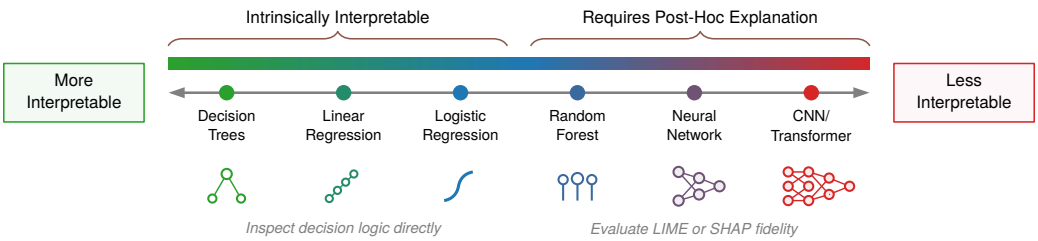

Figure 15.4: Model Interpretability Spectrum: A horizontal continuum groups decision trees, linear regression, and logistic regression as intrinsically interpretable, while random forests, neural networks, and CNNs/transformers require post-hoc explanation. The grouping is schematic: interpretability depends on model size and feature semantics, and any attribution method requires fidelity validation. It frames an auditability trade-off rather than a universal ranking of model quality.

Selecting an explainability strategy along this spectrum requires balancing explanation fidelity, serving latency, and architectural flexibility across three distinct design paradigms. Post-hoc explanation methods, including SHAP and LIME, generate feature importance scores for individual predictions without modifying model internals.[11] Model-agnostic explainers evaluate perturbed inputs or sampled feature subsets, introducing additional computation and approximation. Model-specific SHAP algorithms can exploit internal structure instead; the explanation method and where it runs determine latency and fidelity.

The explanation path has a measurable serving cost. For the credit service's 20 input features, exact Shapley attribution evaluates the model on every feature subset, 1,048,576 evaluations to explain a

11 **LIME (local interpretable model-agnostic explanations) and SHAP (SHapley additive explanations)**: LIME (Ribeiro et al. 2016) fits a local interpretable surrogate around each prediction; SHAP (Lundberg and Lee 2017) adapts Shapley values from cooperative game theory to compute feature contributions under a unified additive framework. Exact Shapley computation requires evaluating a feature's marginal contribution across all possible feature subsets, scaling exponentially with the feature count n_{feat} ($\mathcal{O}(2^{n_{\text{feat}}})$); practical production deployments therefore rely on polynomial-time model-specific algorithms (such as TreeSHAP for decision trees) or sampling approximations (such as KernelSHAP) to avoid unacceptable serving latency. The systems trade-off is that explanation fidelity, latency, and implementation complexity must be budgeted explicitly rather than treated as free.

decision that took one evaluation to make. Sampling explainers bound that work by evaluating a fixed number of subsets, but even 1,000 samples multiply the compute of every explained decision by the sample count, so the explanation path rather than the model can set the service's accelerator budget and its tail latency.

For the rejected credit application, a LIME explanation is dependable only if its local surrogate agrees with the model near the applicant and stays stable across resampling. The check fits the surrogate on perturbed applications drawn from a neighborhood of plausible applications (valid feature ranges, with dependencies such as income and debt-to-income ratio preserved). It then measures the surrogate's prediction error and approval agreement against the model on an independent set from the same neighborhood, and repeats the fit across sampling seeds and neighborhood widths to see whether the leading features and their signs persist. Acceptable error and stability must be specified before the check, and even a faithful surrogate describes model behavior without supplying a causal explanation or a legally sufficient reason.

Inherently interpretable models enforce transparency through structural constraints, using shallow decision trees, sparse linear models, or generalized additive models with inspectable feature effects. Interpretability still depends on model size and meaningful features; structural simplicity can limit expressive capacity on high-dimensional inputs, and internal representations such as attention weights do not constitute faithful post-hoc explanations of causal decision logic. Where inherently interpretable models constrain the architecture from the start, concept-based explanations probe what a trained network has already learned by projecting internal activations onto directions derived from labeled examples of a human concept, such as a "striped texture" direction in a vision model. The projection shows whether a representation encodes the concept; whether the prediction uses it requires a further test of how the output changes along that direction, and every concept needs its own annotated example set.

Example 15.1: The hospital shortcut

Scenario: Pneumonia detection vision models trained at Mount Sinai achieved high internal accuracy but failed on external hospital datasets (Zech et al. 2018).

Diagnosis: The neural network learned shortcut features (hospital-specific scanner artifacts and text tags) rather than true biological lung pathology.

Systems lesson: A model can learn whichever feature predicts the label most easily, including one unrelated to the disease. External validation is essential for detecting shortcut learning. Saliency maps, per-pixel heat maps of how strongly each input region influences the output, can provide supporting evidence but do not establish that the model learned the intended mechanism.

The hospital shortcut shows why interpretability is a systems requirement rather than presentation polish. Teams need sufficient transparency to detect and isolate spurious correlations before deployment. The choice among these paradigms depends on the application's accountability requirements. Credit law requires specific reasons for covered decisions but does not mandate a particular model architecture, and other applications face different transparency, safety, or contestability duties; section 15.5.3 maps those duties to the capabilities they demand. The spectrum does not imply "simple is always better," because a highly interpretable model that makes inaccurate predictions may also cause harm. An explanation, however, covers one decision at a time. The assumptions behind every decision the model makes need a durable record of their own, one that travels with the artifact.

15.3.3.2 Model documentation standards

When a team inherits a production model without that durable record, the artifact may post 94 percent accuracy on a designated test set while leaving the origin of the test set, the composition of the training data, and the evaluated demographic or environmental slices unrecorded, so updating or redeploying the model risks unmeasured regressions under distribution shift. **Model cards** provide standardized documentation for trained models[12] (Mitchell et al. 2019). Analogous to

[12] **Model cards**: The primary failure mode model cards address is scope creep, the gradual expansion from "it worked for case A" to "try it for case B" without revalidating intended use. In practice, cards are often written after deployment decisions are made, documenting observed behavior rather than constraining it. The companion "Datasheets for Datasets" (Gebru et al. 2021) applies the same principle to training data. Without both, the card becomes a historical record rather than an engineering guardrail.

component datasheets in computer engineering, model cards document operational boundaries, evaluation conditions, and intended operating regimes alongside the model artifact.

A complete model card covers seven core sections that together define the model's safe operating envelope. It begins with technical details (architecture, training procedures, and hyperparameters) that enable reproducibility and auditing. It specifies *intended use* alongside explicit out-of-scope applications, preventing scope creep where models trained for consumer photo indexing get repurposed for high-stakes surveillance. The card then documents which *factors* (demographic groups, environmental conditions, or sensor variations) affect performance, guiding both evaluation slicing and production monitoring.

The remaining sections quantify and bound empirical behavior. Performance metrics must report disaggregated results across the operational factors identified in section 15.3.2, because aggregate accuracy conceals systematic subpopulation disparities. Documenting the training and evaluation datasets isolates potential sampling biases and defines the distribution over which the reported metrics hold. Finally, ethical considerations, caveats, and recommendations make deployment trade-offs explicit by recording known failure modes, unmodeled edge cases, and operational mitigations.

Applying this schema to MobileNetV2 illustrates how these categories translate into concrete deployment constraints. Table 15.9 fills five of the seven sections for an edge classification service, and its accuracy entries reuse the illustrative FP32 and INT8 values of the compression validation in section 12.9.1.4.

Table 15.9: Illustrative Model Card: MobileNetV2 for Edge Deployment: Abstract model card categories translate to practical documentation that guides responsible deployment decisions. The numerical entries are scenario assumptions, not reported benchmark results.

Section	Content
Model Details	MobileNetV2 architecture with 3.5M parameters, trained on ImageNet using depthwise separable convolutions. INT8 quantized for edge deployment.
Intended Use	Real-time image classification on mobile devices with less than 50 ms latency requirement. Suitable for consumer applications including photo organization and accessibility features.
Factors	Performance varies with image quality (blur, lighting), object size in frame, and categories outside ImageNet distribution.
Metrics	70.9% top-1 accuracy on ImageNet validation after INT8 quantization (full precision: 71.8%). Accuracy varies by category: 85% on common objects, 45% on fine-grained distinctions.
Ethical Considerations	Training data reflects ImageNet biases in geographic and demographic representation. Not validated for high-stakes applications (medical diagnosis, security screening). Performance may degrade on images from underrepresented regions.

Datasheets for datasets provide the complementary record for the data tier (Gebru et al. 2021), capturing provenance, collection methodology, curation filters, and demographic composition. In D·A·M terms, a model card specifies the algorithmic and machine boundaries (including quantization precision and inference latency budgets), and a datasheet specifies the data that produced them. Together they state what the system is designed to tolerate and preserve the evidence that measurement produced, but both describe the system at the moment of release. Operation is the stage that keeps that description true once the model meets live traffic.

↩ Datasheets, as part of the governance pillar of a data pipeline, are established in section 4.2.2.

15.3.4 Operate: Fairness as loop stability

A credit model that passes its 5-percentage-point fairness gate at launch can breach that gate six quarters later without a single code change, simply because every quarterly retraining learns only from the applicants the previous model approved. A release gate measures a disparity at one instant, and the credit service then meets live traffic and closed-loop retraining that shift its behavior over time. Operating it responsibly requires the incident-response sequence that operations already runs (detection, assessment, mitigation, communication, and remediation) to treat a fairness violation or a slice-level regression as an incident in its own right, and to verify each control before launch: an alert threshold tested against historical replay, a rollback path exercised under load, and an on-call rotation with documented escalation. A requirement without a verified control is an intention rather than a safeguard, so monitoring and response must exist before the model takes production traffic, not after harm accumulates.

↩ The ML incident-response sequence of severity classification, detection, impact assessment, mitigation, and root-cause analysis is established in section 14.7.1.1.

Service-health monitoring catches crashes and timeouts, but the technical debt that ML systems accumulate surfaces as silent degradation (Sculley et al. 2015), and feedback loops can amplify small early errors across the user population. Incident response planning must therefore deploy telemetry for outcome disparities as well as input changes, with response plans that account for label delay and the evidence needed to detect harm.

Production monitoring infrastructure already tracks performance stability, input distributions, and delayed outcomes. The responsibility lens adds two requirements to that telemetry surface. Subgroup parity becomes a first-class monitor, with false-negative and false-positive rates tracked per cohort over time, because aggregate accuracy masks localized regressions. User complaints, contested decisions, and appeals feed the same surface, because statistical aggregation over millions of queries smooths away the rare harms that affected people report first. Parity monitoring matters most where the system's decisions shape its own future training data. In that regime the bias feedback model (principle 13) describes a disparity that evolves as $\Delta_g(k) \approx \Delta_g(0) \cdot \alpha_{\text{fb}}^k$ across feedback intervals rather than staying fixed. The credit service shows what that recurrence implies for a release gate.

↩ Production monitoring architectures for performance stability and distribution drift are established in section 14.5.

Napkin Math 15.3: Fairness as loop stability

Problem: After mitigation, the credit service from section 15.3.2.1 ships with a residual TPR gap of 3 percentage points, inside the scenario's 5 percentage-point release gate. Denied applicants generate no repayment labels in the routine training stream, so each quarterly retraining learns from a population the previous model selected. For this illustration, an independent audit sample provides observed repayment outcomes across both groups, including applicants not approved by the production policy. Without such outcome evidence or a justified missing-outcome correction, the all-qualified-applicant TPR gap would not be directly measurable. The next quarterly audit measures a gap of 3.3 percentage points. If the locally fitted growth factor persisted, when would the gap breach the release threshold?

Math:

1. **Fit the feedback factor**: $\alpha_{\text{fb}} = \Delta_g(1)/\Delta_g(0) = 1.10$ per quarter.
2. **Time to breach under the fitted model**: The projected gap exceeds the gate once $\Delta_g(0)\,\alpha_{\text{fb}}^k$ passes it, that is, for $k > \ln(\text{gate}/\Delta_g(0))/\ln\alpha_{\text{fb}}$. The model projects a breach after 6 quarterly retraining cycles, when the gap reaches 5.3 percentage points.
3. **Without mitigation**: The same factor would grow the original 30 percentage-point gap to 43.9 percentage points within 4 cycles, one year of retraining.
4. **Changing the loop**: If the team approves a small randomized sample of marginal applicants and observes their repayment, the loop again sees outcomes it previously censored. Suppose the refitted factor falls to 0.90; the same launch gap then decays to 1.6 percentage points over the same number of cycles.

Systems insight: A release gate passed at launch is a statement about $k = 0$. Under feedback, fairness is a stability property of the retraining loop. The projected breach time motivates a shorter audit interval, but two observations do not validate future dynamics. An intervention can change α_{fb} (through what data the loop collects) as well as $\Delta_g(0)$. The fitted factor is a local model; it must be refitted at every audit because intervention, saturation, or a shifting applicant pool changes the dynamics.

The DLRM ranking service runs the same loop with far more severe censoring. With 10 million daily users each shown 20 ranked items from a catalog of 1 million items, the service logs 200 million impressions a day, yet each user's feedback covers only 0.002 percent of the catalog, and the previous model chose every item in it. Items and creators the ranker stops showing generate no clicks and therefore no evidence that they deserved to be shown, which is the exposure form of the bias feedback model. The remedy mirrors the credit service's randomized approvals. Reserving 1 percent of slots for randomized exploration yields 2 million impressions a day that the previous model did not select, a sample from which each creator group's exposure share and engagement

can be estimated against an unbiased baseline. The cost is measurable like any other serving change, because that share of slots is served at lower expected engagement, and it is what keeping the feedback factor below one costs.

Telemetry infrastructure provides protection only when coupled with disciplined operational response. Automated dashboards require defined review cadences, clear on-call ownership, and explicit escalation procedures to ensure emerging anomalies trigger corrective engineering action rather than passive observation.

Checkpoint 15.3: Ethical deployment

Deployment is where safeguards must become operational.

Safety net

- ☐ **Rollback**: Verify that the previous model can be restored within the incident-response target.
- ☐ **Human-in-the-loop**: Verify that an operational routing path exists for human review of low-confidence predictions.

Monitoring plan

- ☐ **Silent failure**: Specify the subgroup metrics that will expose postdeployment bias.

Equitable performance across demographic cohorts addresses only one dimension of responsible engineering. The resource stage of the lifecycle addresses another, because every training run, inference request, and monitoring pipeline draws electrical power that converts to carbon emissions and operating expenditure. A pipeline can satisfy demographic parity while consuming orders of magnitude more compute than the task warrants, so responsible engineering must govern both whom the system serves and the physical resources consumed in serving them.

15.4 Environmental and Cost Awareness

In 2019, researchers estimated that development-scale training and architecture search for a large natural language processing (NLP) model could emit as much carbon as five cars over their entire lifetimes (Strubell et al. 2019). Later analysis showed that the most quoted architecture-search estimate was highly sensitive to proxy-task, hardware, data-center efficiency, and grid carbon-intensity assumptions (Patterson et al. 2021). The correction narrows the estimate without removing the point. Training runs consume megawatt-hours of electricity, inference at scale multiplies per-request inefficiencies into measurable environmental impact, and resource-intensive models exclude organizations that lack large compute budgets. The techniques that improve efficiency therefore also serve as instruments of responsible engineering, tying computational efficiency to environmental sustainability and economic accessibility. On the DLRM ranking service, request volume makes serving rather than training the term that dominates both the bill and the emissions.

15.4.1 Efficiency as responsibility

Training a single large language model consumes thousands of GPU hours and energy measured in megawatt-hours. The bitter lesson predicts that this footprint will keep growing, because the methods that win are the ones that convert additional compute into capability. Much of this expense, however, is not intrinsic to the learning task but represents *accidental complexity*: training from scratch when fine-tuning would suffice, deploying larger architectures than tasks require, and running hyperparameter searches that explore redundant configurations. Computational cost depends on engineering choices as well as model physics. Green AI treats that efficiency as a primary metric rather than an afterthought.[13]

The growth in training compute carries a price, and the price decides who can take part. Figure 15.5 plots the estimated compute cost of training notable models since 2016 in constant 2023 dollars. Across the models that Epoch AI flags as frontier at release, the cost of a training run rose about 2.9× per year, and the most expensive run in the data, Grok 4 in 2025, cost about $388M (Epoch AI 2026c). Cottier et al. (2024), using their own selection of frontier runs, estimate 2.4× per year. Either rate concentrates frontier training in the few organizations able to fund it, so efficiency is a question of access as well as of energy. For a frontier model the training run dominates the cost; for a high-traffic service such as DLRM, as section 15.4.2 shows, serving does.

At the hardware level, environmental impact scales with total electrical energy draw across the machine lifecycle, mediated by accelerator utilization, data-center cooling overhead (power usage effectiveness), and the **carbon intensity** of the local electrical grid, the mass of CO_2eq emitted per kilowatt-hour it delivers. Within the accelerator package, data movement can dominate energy dissipation. In the 45 nm reference behind the energy-movement principle (7), a single off-chip DRAM access costs two to three orders of magnitude more energy than a 32-bit floating-point operation, although total energy also depends on access width, event counts, reuse, and the device. Algorithmic and runtime optimizations reduce environmental burden only when they reduce measured watt-hours for a verified quality target under production load, curbing this physical dissipation at the silicon level.

Physical resource demands also dictate deployment accessibility. Oversized models that need multi-accelerator nodes linked by high-bandwidth interconnects (such as NVLink) just to hold their weights in memory confine deployment to centralized cloud facilities. Compressing models so their working sets fit within commodity DRAM or the unified memory of edge processors opens up who can run them. Running locally removes the need for a constant high-bandwidth network link and recurring cloud API bills, letting client devices run low-latency, private inference right where data is captured.

At production scale, where serving systems process millions of requests daily, per-query inefficiencies compound rapidly across accelerator fleets. Under the iron law of ML systems ($T = D_{\text{vol}}/\text{BW} + O/(R_{\text{peak}} \cdot \eta_{\text{hw}}) + L_{\text{lat}}$), per-query execution latency dictates the request throughput that an individual accelerator can sustain before violating service-level latency objectives. Reducing execution time allows a smaller provisioned cluster to support the same aggregate traffic, and capacity planning can turn that reduced service demand into lower provisioned-capacity costs. A fixed fleet may also save dynamic energy, although idle and baseline power remain. A valid comparison

[13] **Green AI**: Schwartz et al. (2020) contrasted "Red AI" (performance at any cost) with "Green AI" (efficiency as primary metric). The compute-growth anchor comes from AI and Compute's 2012–2018 trend analysis (the fit that gives a 3.4-month doubling time), which reported a 300,000× increase in compute used in the largest AI training runs over that six-year window (Amodei and Hernandez 2018b); comparisons that extend to later frontier models span a longer window and report larger factors. The Green AI proposal (reporting FLOPs alongside accuracy for every published result) reframes efficiency from an engineering preference into a scientific reporting obligation, making the resource cost of marginal accuracy gains visible and comparable across research groups.

↩ The bitter lesson, the historical pattern in which methods that scale with compute overtake hand-built knowledge, is established in section 1.4.

↩ The physical energy disparity between off-chip memory access and arithmetic execution is established in section 11.2.3.

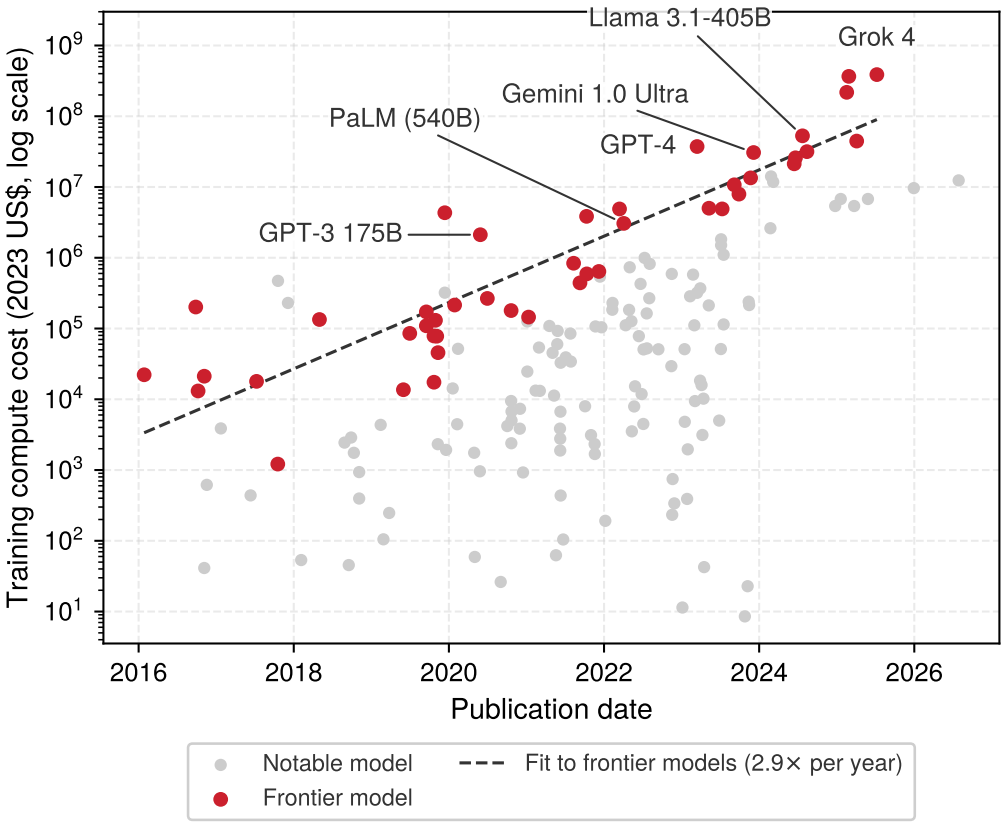

Figure 15.5: Cost of Training Notable Models: Estimated compute cost of the final training run of notable models since 2016, in constant 2023 U.S. dollars on a logarithmic axis. Red points are models flagged as frontier at release; the dashed line is a least-squares fit to them. Costs follow the amortized hardware and energy method of Cottier et al. (2024). Data from Epoch AI (2026c).

therefore measures total energy over the same traffic and quality target and distinguishes that result from savings on a capacity-based bill.

Each optimization developed earlier in this book attacks a specific term of these equations, and each reduces environmental burden only under the conditions its own chapter states. Quantization and pruning shrink the bytes moved D_{vol} and the operation count O when supported kernels retain the smaller representation, and knowledge distillation moves a large model's behavior into a smaller one (chapter 10). Selecting the data a model trains on removes training operations before they run (chapter 9), and specialized datapaths and fused kernels raise hardware efficiency η_{hw} (chapter 11).

Responsible engineering treats these optimizations as design constraints established before training and deployment, rather than post-hoc remedies applied to an oversized model. System requirements specify explicit upper bounds on latency, memory capacity, and energy consumption alongside target predictive quality, and the task is to find the most compact architecture and execution strategy that satisfies them. In practice this begins by establishing bounded machine envelopes (thermal design power, battery capacity, and peak latency) before choosing or training an architecture, and applies targeted optimizations such as quantization or kernel fusion only after the most compact adequate architecture has been selected.

Edge deployment makes these limits immediate, because passive thermal dissipation and battery capacity enforce power budgets that cannot be relaxed after the fact. A wearable with an illustrative 500 mW inference budget shows the consequence for model choice. Under the active-power profiles assumed here, the KWS lighthouse's DS-CNN (200K parameters at 50 mW) leaves a 10× power margin, while MobileNetV2 (3.5M parameters at 1.2 W) exceeds the same budget by 2.4× before

sustained thermals are considered. Fitting the envelope is necessary but not sufficient: a keyword detector does not substitute for a vision model merely because it fits, and per-inference energy compounds into aggregate emissions and operating cost once the model is deployed at scale. Techniques that lower measured energy per inference reduce lifecycle energy only when their savings outweigh any added training, preprocessing, or other workload costs, while cloud and cluster financial savings depend directly on provisioning and hardware utilization.

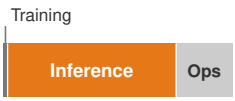
15.4.2 Total cost of ownership

On the DLRM ranking service, a training cycle that costs $3,200 is followed by roughly $500,000 per year in serving compute. That contrast shows how total cost of ownership,[14] the upfront and recurring expense of a system over its lifetime, can be dominated by recurring inference at high traffic. Where the cloud-versus-edge comparison used that total to choose a deployment, the lifecycle view splits one deployment's total into training cycles, recurring inference, and operations to find which term dominates. Other systems may be dominated by training, data, staffing, or idle capacity, so measurement determines where optimization should focus.

Consider the DLRM ranking service serving 10 million users daily. Training costs appear considerable: data preparation consumes 100 GPU-hours at approximately $4/hour ($400), hyperparameter search across multiple configurations requires 500 GPU-hours ($2,000), and the final training run uses 200 GPU-hours ($800). Total training cost reaches approximately $3,200.

Inference costs dominate in this scenario. With 10 million users each receiving 20 recommendations per day, the service runs 200 million inferences daily. Treating 10 milliseconds per inference as unbatched, non-overlapped dedicated GPU service demand yields approximately 23.1 GPUs running continuously. At $2.50/GPU-hour, the scenario's annual GPU cost reaches $506,944. That rate sits below the $4/hour the training runs pay because an always-on fleet is bought as continuously reserved capacity rather than on demand.

Over a three-year operational period, twelve total quarterly training cycles, including the initial cycle, produce training costs of approximately $38,400, while inference costs over the same period total $1.5M. The resulting 40:1 ratio is specific to these assumptions, but it dictates where optimization effort yields the highest return: inference latency and serving efficiency.



Per-query optimization becomes important when serving billions of requests. Shaving a fifth off the per-query accelerator service demand can reduce required hardware when other workload assumptions remain fixed. Hardware selection among CPUs, GPUs, and Tensor Processing Units changes costs and carbon footprint in workload- and deployment-dependent ways. Model compression through quantization and pruning can reduce high-volume inference costs when it lowers measured service demand without unacceptable quality loss.

The third term of the lifecycle total cost of ownership (TCO) is operations: monitoring, maintenance, retraining, and incident response, all of which scale with system complexity and with the rate of distribution shift in the application domain. Resources consumed by one ML system also cannot be used for other purposes, so wasteful consumption in one project constrains what other projects can attempt. Engineers should therefore evaluate return on investment (ROI), asking whether the value an ML system delivers justifies its resource consumption: a recommendation system that increases engagement by 1 percent might not justify millions of dollars in computational costs, while a medical diagnosis system that saves lives does. Deployment-to-training cost ratios vary with traffic, utilization, hardware, update cadence, staffing, and incident burden, so the right model choice depends on measured lifecycle cost and task value, not on a fixed ratio.

15.4.2.1 Accounting for cost and carbon

Converting the same scenario into carbon requires measured or estimated energy use, facility overhead, and applicable grid carbon intensity. The accounting keeps the walk-through's traffic, service demand, and training budget, adds the operations work that the walk-through left unquantified, and converts every accelerator-hour into emissions with one conversion factor. Training recurs with each retraining cycle, inference recurs with every request, and operations accumulate through telemetry, on-call engineering, and incident response, so each enters the three-year total on its own basis.

[14] **TCO (total cost of ownership).** The power, memory, and latency envelopes that separate cloud, edge, mobile, and tiny ML deployment are established in section 2.2. ML TCO also includes labeling, monitoring, retraining, remediation, energy, audits, and compliance costs that an estimate of compute alone omits. Utilization and update cadence determine how the balance between training and inference falls for a given service.

At production scale, recurring inference can dominate lifetime cost.

↩ Total cost of ownership as a comparison of cloud and edge deployments, weighing capital against operating expense, is established in section 2.5.2.

↩ Cost per inference, the serving cost that capacity planning divides among requests, is established in section 13.10.1.

Napkin Math 15.4: The carbon cost of compute

Problem: The cost accounting must convert GPU-only electrical energy into "kg CO_2eq." What carbon factor does one GPU-hour carry under the scenario baseline, excluding host, facility, and embodied impacts?

Variables:

- **Power**: 400 W per GPU (scenario baseline).
- **Intensity**: 0.4 kg/kWh CO_2eq (rounded grid baseline).

Math: Equation 15.2 captures the standard conversion:

$$\text{Carbon} = \text{Energy (kWh)} \times \text{Carbon Intensity (kg/kWh)} \tag{15.2}$$

Applying the baseline assumptions:

$$(0.4\ \text{kW} \times 1\ \text{hour}) \times 0.4\ \text{kg/kWh} = 0.16\ \text{kg}\ CO_2\text{eq per GPU-hour}$$

Systems insight: This GPU-only conversion factor lets the accounting track a modeled accelerator-carbon subtotal alongside dollar cost. Whole-system and facility emissions require incorporating the host, facility overhead, and embodied energy boundaries.

In table 15.10, inference accounts for 73.5 percent of the three-year cost, operations for 24.6 percent, and training for only 1.9 percent. Those proportions turn efficiency from a tuning preference into a responsibility check, because small serving-path reductions compound across every request the fleet handles.

Table 15.10: Three-Year Cost and Carbon of the DLRM Ranking Service: Training repeats data preparation, hyperparameter search, and final training at $4/hour for every cycle; inference converts daily requests into accelerator-hours under an unbatched, non-overlapped service model, which real batching and utilization change; operations cover monitoring, 0.5 FTE of on-call engineering, and incident response. The inference-to-training cost ratio is 40:1, and a 20 percent reduction in per-query accelerator demand saves about $304K and 19 t of modeled accelerator CO_2 under the same assumptions. The carbon column excludes operations, facility overhead, and embodied impacts.

Category	Basis	3-Year Cost	Share	Modeled Accelerator Carbon
Training	12 cycles × $3,200 per cycle	$38K	1.9%	1.5 t
Inference	556 GPU-hours/day × 365 × 3 years × $2.50/GPU-hour	$1.52M	73.5%	97.3 t
Operations	$170K/year × 3 years	$510K	24.6%	Not estimated
Total TCO		**$2.07M**	**100%**	**~98.9 t modeled subtotal**

Checkpoint 15.4: Efficiency as responsibility

Total cost of ownership reveals where responsible optimization has the most leverage.

- ☐ **Inference dominance**: under this scenario's assumptions, can you compare a 20 percent reduction in total inference cost with a 50 percent reduction in total training cost, and explain why reducing only final-run time does not establish the latter saving?
- ☐ **Carbon accounting**: can you convert GPU-hours into kg CO_2eq using power draw and carbon intensity, and explain how workload design, hardware, scheduling, and region affect the result?
- ☐ **Sufficiency test**: for a given ML system, can you justify that the model size is appropriate for the task, or identify where a simpler model would deliver comparable accuracy at a fraction of the cost?

15.4.3 Environmental impact

Two data centers can run the exact same DLRM serving fleet at the same dollar bill while one emits several times more carbon than the other because its local power grid burns coal instead of hydroelectricity, and a team that replaces working servers early to save 10 percent on electricity can raise net lifetime emissions once the carbon spent manufacturing the new silicon is counted (Gupta et al. 2022). The total-cost-of-ownership analysis in section 15.4.2 captures costs that someone pays directly, but computational resources also impose costs that no one is billed for. Operational emissions depend on measured energy, facility power usage effectiveness (PUE), and regional grid carbon intensity (gCO_2e/kWh); embodied manufacturing impacts require separate accounting. In power benchmarking, PUE separates server-plug energy from facility overhead; in carbon accounting, the same ratio, total facility energy divided by IT-equipment energy, becomes the multiplier that converts measured IT energy into the energy the facility actually draws. The same measurement boundary keeps server fans inside the IT term so that their energy is not counted twice.

A first-order operational emissions estimate is $\text{Energy}_{\text{hardware}} \times \text{PUE} \times \text{Carbon Intensity}$, where the hardware term covers the full IT-equipment boundary over the accounting window, not GPU-only energy. Operational carbon includes electricity consumed by both active work and idle provisioned equipment. In contrast, embodied carbon encompasses the greenhouse gases emitted across the hardware supply chain (silicon wafer fabrication, packaging, transport, and facility construction) before a chip executes its first cycle. Embodied carbon can account for a large share of lifetime emissions, and on low-carbon grids a majority (Gupta et al. 2022), so prematurely replacing older servers for slight operational efficiency gains can paradoxically increase net lifetime emissions. Per-request energy is measured in joules per inference, whereas joules per FLOP characterizes hardware work efficiency. An optimization that reduces TCO may not reduce energy or emissions if it changes utilization, hardware, or workload placement. Data-center electricity use makes workload design, hardware, cloud region, and timing part of responsible engineering (Henderson et al. 2020).

↩ The power measurement boundary that separates server-plug energy from facility overhead is established in section 12.7.1.

The DLRM accounting in table 15.10 shows how lopsided the carbon split can be. Under its service-demand assumptions, inference emits 63× as much modeled accelerator CO_2 as all 12 training cycles combined, so for a service of this kind the serving path, not the training run, is where carbon reductions have leverage. Efficiency optimization and environmental responsibility align when measured lifecycle energy and emissions fall for the required workload and quality target. More granular carbon accounting methodologies build on this foundation: lifecycle assessment tracks impacts across the system's full life, scope 1/2/3 emissions separate direct emissions, purchased electricity, and supply-chain or use-phase emissions, and carbon-aware scheduling shifts work toward lower-carbon times or regions.

The same physical quantities that govern performance also affect responsibility. Data movement and computation contribute to chip-level energy, while data-center emissions additionally depend on utilization, facility overhead, grid intensity, and embodied impacts. Pareto analysis applies to fairness, latency, and carbon alike, and the first question is always whether the current design lies on the frontier, because a dominated design can improve several objectives at once. *Responsible engineering extends the constrained optimization problem this book has been teaching to objectives that include societal impact alongside throughput and latency.* The magnitude of the carbon term becomes clearer in a scale calculation for training a large foundation model; under the grid assumption of napkin math 15.5, one such run exceeds a hundred passenger-car years of emissions (see the margin).

This training scenario exceeds 100 passenger-car years of emissions.

Napkin Math 15.5: The carbon cost of scale

Problem: A foundation model is being trained at the scale of GPT-3, consuming 1,287 MWh of electricity (Patterson et al. 2021). What is the operational carbon impact under the stated grid-intensity assumption?

Math:

1. **Energy consumption**: 1,287 MWh = 1,287,000 kWh.
2. **Carbon intensity**: This scenario uses ≈ 429 g/kWh CO_2 (0.429 kg/kWh) (Patterson et al. 2021), a US grid-average figure slightly above the rounded 0.4 kg/kWh baseline of

the cost accounting. Each calculation states its own grid assumption, and the difference changes the result by less than a tenth.

3. **Total emissions**: 1,287,000 kWh × 0.429 kg/kWh = 552,123 kg CO_2 (552 t).
4. **Comparison**: The scenario assumes 4.6 t CO_2 per passenger-car year. This per-year basis differs from the lifetime-car basis of the 2019 five-car estimate, so the two car comparisons are not directly comparable.

Systems insight: Under this training-energy scenario, the operational emissions equal the assumed annual emissions of 120 passenger cars. A 1 percent reduction in total training energy under the same grid mix would remove the equivalent of about 1.2 cars taken off the road for a year from the calculation.

Specification, measurement, documentation, and resource accounting define what a system must satisfy. The Govern stage of the lifecycle makes those guarantees provable to someone outside the team, which requires infrastructure that records validation results, preserves audit evidence, and enforces operational bounds in production.

15.5 Data Governance and Compliance

The keyword spotting system makes the governance problem physical. An always-listening voice assistant samples audio continuously in private homes, stores enrolled speaker profiles, and periodically syncs with cloud pipelines that retrain on population-wide audio, so every guarantee the earlier stages established now depends on what data the system may hold, who may touch it, and what evidence survives. **Data governance**, the engineering discipline that turns regulatory and ethical obligations into verifiable technical controls, is the enforcement layer that makes accountability operational. Fairness metrics, model cards, and impact assessments have practical force only if the system can prove what data it ingested, which principals accessed it, which legal basis authorized processing, and whether applicable deletion or contestability requests were executed. The legal-basis question alone can decide an enforcement outcome. In 2023, Ireland's Data Protection Commission found that Meta had relied on an invalid legal basis for personalized advertising and had violated transparency and fairness requirements, a governance failure that involved no security breach at all (Data Protection Commission 2023).

Storage architectures also serve as governance enforcement mechanisms that determine which principals access data, how queries are tracked, and whether pipelines satisfy legal requirements. Every architectural decision, from ingestion strategies through extract, transform, load (ETL) pipelines to persistent storage layout, carries governance implications that surface during regulatory audits, privacy investigations, or model recalls. Data governance translates abstract policy into concrete systems engineering through authenticated access controls on training partitions, immutable audit infrastructure that logs dataset access, privacy-preserving transformations during feature extraction, and deterministic lineage systems that trace training snapshots to deployed model checkpoints.

↩ The database, warehouse, and data-lake storage architectures, and the access patterns each one serves, are established in section 4.10.1.

Principle: Compliance as engineering constraint

Invariant: Data governance obligations are engineering requirements, not optional policy overlays.

Implication: Systems that process regulated data must map applicable duties to technical and organizational controls. Access control, erasure, contestability, audit, and lineage may be required or useful depending on the jurisdiction, data, actor, and use case. The General Data Protection Regulation (GDPR), California Consumer Privacy Act (CCPA), Brazil's General Data Protection Law (LGPD, *Lei Geral de Proteção de Dados*), and China's Personal Information Protection Law (PIPL) differ in scope and duties, so no single control checklist establishes compliance across them.

Data governance turns security, privacy, compliance, and lineage into mutually dependent engineering constraints, and the KWS system shows where each one binds. Continuous capture, enrolled

profiles, and fleet-wide retraining create obligations across consent management, data minimization, access auditing, and deletion rights, and the four domains map directly to hardware and pipeline enforcement points in this architecture. Security comes first by protecting raw features, training partitions, and model artifacts across the ingestion lifecycle through mutual authentication, role-based authorization, encryption at rest and in transit, and hardware-rooted key management: hardware keystores on edge microcontrollers protect stored speaker templates, mutual TLS authenticates telemetry in transit, and role-based access controls gate access to centralized training audio in cloud storage. Because access control alone does not limit what an authenticated consumer can learn from the records it reads, privacy regulates information exposure inside that boundary through differential privacy, k-anonymity, and automated feature redaction, keeping ambient KWS audio inside a circular SRAM buffer until an on-device trigger and bounding information leakage during fleet-wide acoustic model retraining.

Where privacy governs what leaves the device, compliance translates jurisdiction-specific statutes (such as GDPR, CCPA, and LGPD) into retention windows, consent verification, and cross-border replication rules once data arrives in the cloud, determining the legal basis for processing and the scope of any revocation or erasure workflow that removes in-scope voice profiles and acoustic data across primary stores and backups. Proving that those security, privacy, and retention rules were followed requires lineage and audit systems that render the entire data lifecycle inspectable. Retained lineage linking deployed weights through training snapshots to authorized source records supports verification of security claims and applicable obligations, and in the KWS pipeline it establishes provenance through content hashes and signed manifests that link each deployed DS-CNN binary back through specific training splits and acoustic augmentation seeds to the original raw recordings.

Governance works as an operating model rather than a single control. The framework in figure 15.6 arranges eight elements, from organizational oversight and compliance policies to data catalogs, sourcing, quality metrics, runtime operations, and security, around a central governance hub. Technical mechanisms and organizational processes must function as mutually reinforcing subsystems: encrypted storage without identity-mapped access controls still lets an insider copy data out, and compliant storage without verifiable audit trails cannot pass a regulatory inspection. Within the D·A·M taxonomy, data governance is the control plane of the Data axis. It enforces lawful sourcing, privacy bounds, and lifecycle integrity for the data that feeds the Algorithm, and it runs on Machine-axis infrastructure such as encrypted storage, access control, and audit logs.

Engineering teams do not operate in isolation. Team-level technical practices such as audit logging, bias testing, and explainable interfaces sit at the core of expanding organizational, industry, and regulatory structures, with requirements and legal mandates flowing inward across each boundary and the technical controls at the center supplying the evidence that external compliance rests on (figure 15.7). The rest of this section works at that innermost ring, starting with who may reach the data at all.

15.5.1 Security and access control architecture

When a data scientist queries the KWS feature store for training data, she can read aggregated voice features but cannot access the raw audio recordings from which they were derived, while the serving pipeline can read online features for inference without writing to the training dataset or modifying source data. That separation reflects a layered security architecture in which governance requirements translate into enforceable technical controls at each pipeline stage. Feature stores enforce role-based access control (RBAC) by mapping organizational policies to authenticated identities and database permissions. These controls operate across distinct storage tiers: object storage enforces bucket-level access policies, data warehouses implement column-level security and dynamic masking for sensitive fields, and feature stores maintain isolated read and write paths that separate low-latency online inference key-value lookups from high-throughput offline batch training extracts.

Access control mechanisms remain incomplete without encryption, which protects data at rest and in transit but does not prevent misuse after decryption or authorized access. Training corpora in data lakes use envelope encryption with keys held in a dedicated key management service, feature stores encrypt tables at rest and authenticate every service-to-service transfer, and KWS edge devices combine transport encryption for payload confidentiality with asymmetric code signing to verify

↩ The dual-storage architecture of offline columnar stores and online key-value caches is established in section 4.7.5.

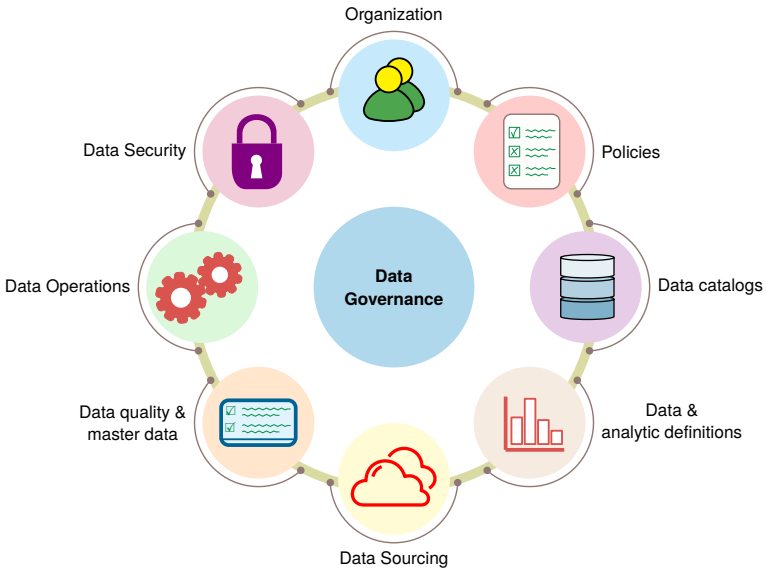


Figure 15.6: Data Governance Framework: Eight operating elements surround Data Governance as a central hub: policies, organization, security, operations, data quality and master data, sourcing, catalogs, and shared analytic definitions. The circular arrangement presents governance as a coordinated operating model rather than a single control, spanning organizational functions such as catalogs, sourcing, and analytic definitions alongside technical controls such as data security. Adapted from standard enterprise data governance frameworks.

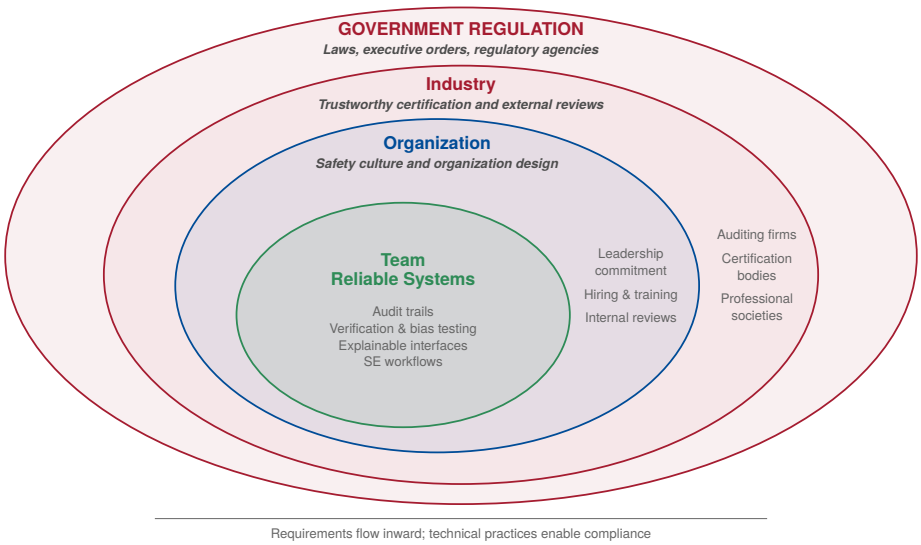

Figure 15.7: Responsible AI Governance Layers: Four nested ovals place team-level safeguards at the center, surrounded by organizational safety culture, industry certification and review, and government regulation. The nesting distinguishes implementation at the center from oversight outside it; the annotation states that requirements flow inward and technical practices enable compliance. Adapted from Shneiderman (2022).

model-update integrity. Each of these controls is only as strong as its key management and update authorization.

Protecting data while it is being computed on is a further layer, **confidential computing**. Hardware secure enclaves and trusted execution environments isolate protected memory and execution from host software outside their trust boundary, and attestation lets a client verify the approved configuration before releasing keys or data to it. The guarantee covers only the declared attacker

boundary and supported configuration, and it does not protect data from the application authorized to process it; the technique matters most when training and serving run on infrastructure that the data owner does not control.

Serialized weights and checkpoints require the same protection as training data. Deserializing an unverified checkpoint in a format that can embed executable objects (Python `pickle` archives are the common case) gives an attacker arbitrary code execution on training nodes and inference workers. Restricted serialization formats that store only tensors avoid that mechanism, and write-protected promotion gates with cryptographic signatures verify artifact integrity and authorized provenance before loading. These controls do not establish that a model is free of backdoors or that every parser and runtime is secure.

Authorized loading also leaves the model's behavior to be evaluated. Poisoned training samples can induce backdoors, perturbed inference inputs can induce misclassification (evasion attacks), and systematic queries can extract model functionality (Tramèr et al. 2016). Access control, cryptographic enclaves, and artifact verification therefore establish *who* can reach data and models and *how* they are protected across storage, transit, and execution, yet controlling access is only half the problem. Even authorized callers can compromise individual privacy if the data or model outputs themselves expose too much: prediction APIs or raw weights can reveal whether a particular record was present in training (Shokri et al. 2017), so artifact integrity and limits on information exposure require distinct controls.

15.5.2 Technical privacy protection methods

Even when role-based access control works as designed, a data scientist querying a training table does not need, and should not see, individual user records when aggregate statistics suffice, and a public prediction API can still leak whether a specific patient or customer was in the training set (Shokri et al. 2017). Privacy-preserving techniques[15] address this gap by determining what information systems expose even to authorized users, adding a second layer of protection beyond access control. Differential privacy bounds changes in an exported output distribution under a specified neighboring-dataset relation.[16] One training mechanism is Differentially Private Stochastic Gradient Descent (DP-SGD) (M. Abadi et al. 2016). It clips each sample gradient to an ℓ_2 norm threshold C, then adds calibrated Gaussian noise with distribution $\mathcal{N}(0, \sigma^2 C^2 \mathbf{I})$ to the sum of clipped gradients, where σ is the noise multiplier. A privacy accountant tracks the privacy loss composed across the sampled training steps and checks it against the chosen epsilon budget.

Clipping needs each sample's gradient norm, and the direct way to obtain it materializes one full gradient per sample, so gradient storage grows by the batch size. For the KWS acoustic model (200K parameters), one FP32 gradient occupies 800 KB and a batch of 256 per-sample gradients 204.8 MB; the same approach for the 1.5B-parameter GPT-2 would need 1.5 TB, far beyond the 80 GB of one H100. Specialized clipping implementations obtain the clipping factors without retaining every per-sample gradient, and small sequential microbatches trade the memory back for lost parallelism, so the cost of DP-SGD must be measured for the chosen implementation with its clipping, noise, sampling, and accounting assumptions intact.

Empirical attacks complement these formal checks. Membership inference attacks measure whether an observer can tell that a specific record was in the training set, and model inversion attacks use confidence outputs to reconstruct sensitive feature values or a training subject's likeness (Fredrikson et al. 2015). A successful attack reveals practical leakage, but no empirical attack can prove that an (ϵ, δ) bound holds.[17] Reducing confidence-score precision or restricting outputs to top-k classes reduces what some APIs expose, but neither is a complete defense; their value depends on the attacker's access and auxiliary information, while differential privacy provides a separate bound under its stated mechanism and accounting assumptions.

While differential privacy bounds information leakage from model outputs, collecting continuous raw sensor streams creates an immediate vulnerability if raw data leaves the capture device. Always-listening edge architectures, such as the lighthouse KWS system, operate under severe privacy constraints because continuous ambient microphone sampling must coexist with strict minimization and retention boundaries. To reduce routine transmission exposure, this design confines acoustic feature extraction and wake-word detection to local low-power microcontrollers or digital signal processors (DSPs). Incoming audio samples stream through a small volatile circular buffer in on-chip

[15] **Privacy-preserving techniques**: K-anonymity (Sweeney 2002) ensures each record is indistinguishable from at least $k_{\text{anon}} - 1$ others with respect to chosen quasi-identifiers, l-diversity adds attribute variety within equivalence classes (Machanavajjhala et al. 2007), and t-closeness bounds distribution distance (Li et al. 2007). These syntactic guarantees address different threats from differential privacy and do not by themselves protect against all ML-specific leakage: a model trained on de-identified data can still memorize examples or reveal membership signal under some conditions (Shokri et al. 2017). Differential privacy instead bounds the influence of one record under a specified mechanism and privacy budget, offering a semantic guarantee designed to remain meaningful in the presence of side information; the methods are therefore not a simple strength hierarchy, and the appropriate protection depends on the release, threat model, and utility requirements.

[16] **Differential privacy**: Introduced by Dwork et al. (2006), a randomized mechanism $\mathcal{M}$ satisfies (ϵ, δ)-differential privacy if for all neighboring datasets X, X' differing by one record and output sets $\mathcal{S}$, $\Pr(\mathcal{M}(X) \in \mathcal{S}) \leq e^{\epsilon} \cdot \Pr(\mathcal{M}(X') \in \mathcal{S}) + \delta$. Here ϵ controls the multiplicative bound and δ is additive slack in the inequality; their acceptable values depend on the neighboring-dataset relation, release, and policy. The systems trade-off is utility rather than mere implementation complexity: stronger privacy often requires more noise or tighter sampling, and privacy loss composes across repeated queries or training steps. Engineers must therefore track cumulative privacy loss with a valid accountant and report the assumptions behind the chosen budget.

SRAM, where older frames are continuously overwritten by newly sampled pulse-code modulation (PCM) data. The policy allows saving or sending audio only after an on-device wake-word trigger. Because detection can produce false wakes, validation must cover both the detector and the buffer and egress controls, including which pre-trigger audio becomes accessible after activation.

Confining raw audio to the device enforces data minimization but starves centralized training of the acoustic variety that improves accuracy. **Federated learning** recovers that variety by moving training to the data. Training-capable clients such as paired phones or home hubs train on authorized local examples and send model updates instead of raw audio, and a coordinator combines those updates into a shared model.[18] The constrained KWS microcontroller only runs the result. The approach exchanges centralization risk for physical bottlenecks: every round moves parameter updates over constrained wireless uplinks, battery-powered clients drop out mid-round, data that differ from home to home make local updates diverge, and raw updates can still leak training examples through reconstruction attacks (Zhu et al. 2019). Compression of those updates reduces communication but provides no privacy guarantee by itself.

Secure aggregation lets the coordinator learn only the aggregate of participating clients' updates, under the protocol's participation, dropout, and collusion assumptions (Bonawitz et al. 2017). What that aggregate and the final model reveal remains outside its protection; differential privacy bounds that release by limiting the effect of any one record or client, provided the training mechanism and privacy accountant support the chosen neighboring relation. A design that needs both must account separately for what a curious coordinator observes during training and what recipients can infer from released checkpoints.

When triggered audio recordings or aggregated model checkpoints must be retained on centralized infrastructure for verification or downstream training, privacy protection shifts to automated lifecycle management. Automated retention workflows apply time-to-live policies across primary stores, caches, training partitions, and backups. Cryptographic erasure destroys the keys needed to decrypt covered copies; physical overwrite is a distinct storage-sanitization mechanism. Neither removes every copy automatically. The workflow must inventory replicas, key copies, and backups, define applicable retention exceptions, and verify that in-scope data is no longer recoverable under the chosen threat model.

15.5.3 Regulation as architecture

Retention and erasure pipelines exist to satisfy legal obligations as much as engineering preferences. Regulation more broadly changes responsible engineering from a best-practice argument into architecture constraints. Suppose the credit service denies an applicant, and the applicant asks why, contests the decision, and later requests access to the data used about her. The system must do more than report an accuracy score. It must produce an explanation tied to the specific decision, preserve the model and data lineage that led to that output, route the dispute to a substantive human review path, retain audit logs, and support deletion or access workflows where data rights apply. Responsible engineering now operates within explicit regulatory frameworks that turn transparency, oversight, and accountability into technical requirements.

Regulation first enters the architecture through risk classification. The EU AI Act establishes a comprehensive framework, classifying AI systems by risk level and mandating requirements accordingly.[19] The Act entered into force on August 1, 2024 and applies in phases: prohibited-practice rules began applying in 2025, while high-risk and other operator obligations phase in by system category and implementation guidance (European Parliament and Council of the European Union 2024).

For systems engineers, compliance hinges on architectural capabilities rather than fine schedules. Covered high-risk systems[20] must implement risk management, data governance, technical documentation, transparency, human oversight, and accuracy, robustness, and security requirements. A covered credit-decision system therefore needs auditability from inception: model versions, training data provenance, validation evidence, human-oversight design, logging, and postdeployment monitoring must be part of the architecture rather than documents assembled after launch.

Contestability adds a second architectural requirement. GDPR moves the same applicant workflow into data-subject rights. Article 22 grants EU data subjects the right not to be subject to decisions based solely on automated processing that produce legal or similarly significant effects, subject

17 **Membership inference attack**: The attack uses model behavior to infer whether a record appeared in training; overfitting can increase the signal (Shokri et al. 2017). In practice, higher confidence on training samples can help distinguish members from nonmembers. Its measured success depends on model access, data distribution, and defense assumptions.

18 **Federated learning**: McMahan et al. (2017) introduced Federated Averaging (FedAvg), in which each client runs several local training steps before the coordinator averages the resulting models. Averaging after many local steps rather than after every gradient cuts the number of communication rounds, which is what makes training over constrained client uplinks practical.

19 **EU AI Act (Regulation 2024/1689)**: The first comprehensive AI legal framework, defining four risk tiers with penalties that vary by infringement category. The Act has extraterritorial reach: non-EU organizations may need to comply when they place systems on the EU market or when system outputs are used in the EU. Systems engineering implications are concrete: high-risk AI requires logging infrastructure for audit trails, human oversight mechanisms built into the architecture, and CE marking (the EU conformity mark), all capabilities that must be designed in from inception, not retrofitted after deployment.

20 **High-risk AI (EU AI Act Annex III)**: Annex III enumerates specified use cases in areas including biometrics, critical infrastructure, education, employment, essential services, law enforcement, migration, and justice. Classification depends on intended use and the Article 6 criteria, including exclusions for some systems that do not materially influence decisions or pose significant risk; profiling systems within Annex III remain high-risk. Model architecture alone does not determine classification.

to specified exceptions and safeguards.[21] Article 15(1)(h) separately gives data subjects access to meaningful information about the logic involved in automated decision-making referred to in Article 22. Engineering teams should determine which decisions are covered and design the required explanation and human-review capabilities accordingly. Where a substantive review path is required, it must be operationally staffed and supported by summaries, provenance, and audit tools. That staffing scales with decision volume. If 0.1 percent of 1M daily decisions are appealed or escalated, trained reviewers must work through 1,000 cases/day, a workload assumption rather than a model-error rate, and the review tooling must surface each case's explanation, lineage, and model version fast enough for that queue to clear.

US sectoral law reaches similar capabilities through domain-specific evidence requirements, less unified than the EU AI Act. In the credit example, the Equal Credit Opportunity Act (ECOA) and its implementing Regulation B require specific principal reasons for covered adverse actions, and those reasons must accurately describe the factors actually considered or scored (Consumer Financial Protection Bureau 2023). Healthcare regulation, including the Health Insurance Portability and Accountability Act (HIPAA)[22] and Food and Drug Administration (FDA) guidance, imposes the same pattern with different artifacts: protected-health-information controls, validation records, audit logs, and incident response. Across domains, the task is to translate each obligation into a concrete capability: explanation, human review, lineage, access control, deletion, monitoring, or incident response. Because the same safeguards recur across regimes, table 15.11 organizes them by capability rather than by jurisdiction.

Table 15.11: Regulatory Obligations as System Capabilities: Each obligation, named with an example source, maps to a capability the architecture must provide and to the resource that capability consumes. The mapping is illustrative rather than a legal checklist; applicability depends on jurisdiction, actor, data, and use.

Obligation (Example Source)	Capability the System Must Provide	Machine Cost
Risk management and record keeping for high-risk systems (EU AI Act)	Versioned models, data provenance, validation evidence, automatic event logs	Log storage and lineage-graph maintenance
Contestable automated decisions (GDPR Article 22)	Substantive human-review path with case summaries, explanations, and provenance	Reviewer hours that scale with decision volume
Reasons for a decision (GDPR Article 15; ECOA adverse-action notices)	Per-decision explanation or reason codes tied to the factors actually used	Explanation compute on the serving path
Data minimization and erasure (GDPR)	Retention limits, lineage-driven deletion, retraining or unlearning when weights are in scope	Retraining accelerator-hours; deletion workflows
Protected health information (HIPAA)	Access control, encryption, audit logs, retained documentation	Audit-log bytes over the retention window
Nondiscrimination (employment, credit, and housing law)	Disaggregated evaluation and monitoring against justified thresholds	Labeled per-group evaluation data; parity telemetry

Data-protection law reaches deeper into the pipeline than decision-level duties do, because its obligations attach to the data itself rather than to a decision. When a European user invokes an applicable right to erasure under GDPR, the voice assistant must determine which personal data and downstream artifacts are in scope and execute the appropriate workflow within the regulation's response deadlines (European Parliament and Council of the European Union 2016). These obligations become architecture constraints in pipeline design, storage choices, and operational procedures. GDPR's data minimization principle requires limiting collection and retention to what is necessary for stated purposes. Article 15 access rights cover personal data undergoing processing and specified information about that processing, not every artifact merely associated with a user.

Voice assistants operating globally face overlapping regulatory regimes because requirements vary by jurisdiction and apply differently based on user age and data sensitivity. GDPR cross-border-transfer rules permit transfers through adequacy decisions, appropriate safeguards, or limited derogations rather than imposing categorical data localization. These rules can still drive regional storage, replication, and processing choices. A structured data card turns these operational metadata requirements into reviewable fields. The card in figure 15.8, adapted from the Open Images Extended

[21] **GDPR (General Data Protection Regulation) articles 15 and 22**: Article 22 restricts certain solely automated decisions with legal or similarly significant effects and, for specified exceptions, requires safeguards including human intervention, the ability to express a point of view, and the ability to contest the decision; article 15(1)(h) contains the access right to meaningful information about the logic involved in such automated decision-making (European Parliament and Council of the European Union 2016). The European Data Protection Board's guidance emphasizes that required human oversight must be substantive and not merely a "rubber-stamping" exercise (European Data Protection Board 2018).

[22] **HIPAA (Health Insurance Portability and Accountability Act)**: Enacted in 1996, with Privacy Rule and Security Rule requirements establishing standards for protected health information (United States Congress 1996; U.S. Department of Health and Human Services 2003, 2005); PHI may be used for training under applicable authorization or another permitted pathway, such as an IRB or Privacy Board waiver; de-identified data and limited data sets with data-use agreements provide additional pathways. Model outputs may remain PHI when they identify or can reasonably identify individuals, and security-rule documentation retention must be reflected in audit and evidence design.

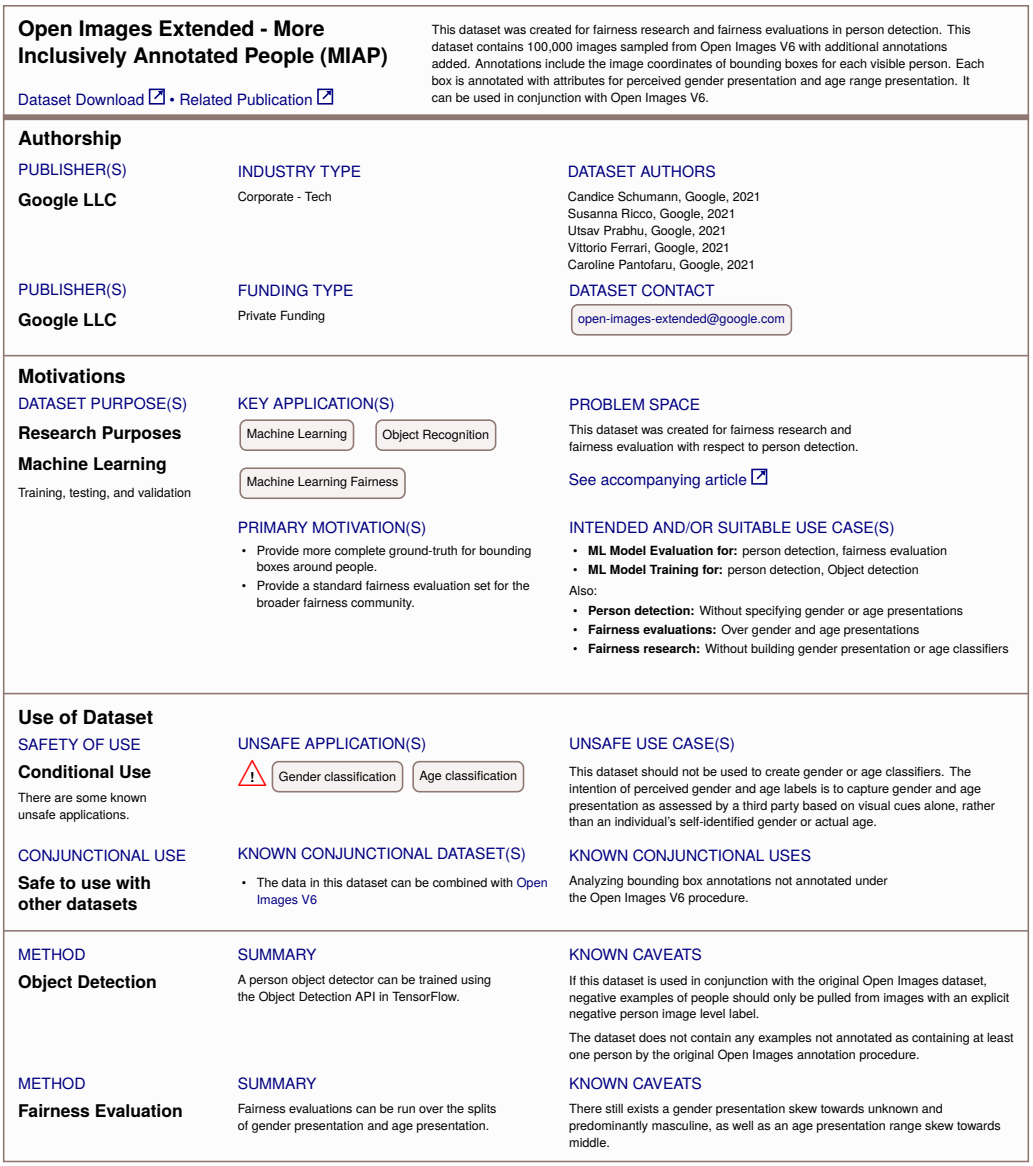

Figure 15.8: Data Governance Documentation: The populated Open Images Extended—More Inclusively Annotated People card organizes authorship, motivation, intended and unsafe uses, conjunctional use, and method caveats in one artifact. Recording permitted and prohibited uses makes the card reviewable governance evidence, though it does not establish compliance by itself. Adapted from the Open Images Extended—MIAP Data Card in Pushkarna et al. (2022).

(MIAP) specification (Pushkarna et al. 2022), partitions authorship, primary motivations, explicit safety prohibitions (such as forbidding age or gender classification), and methodological caveats. Although documenting these boundaries does not alone guarantee legal compliance, it provides the verifiable baseline necessary for pipeline ingestion checks.

The engineering response to these regulatory requirements is proactive architectural design. Teams that build documentation, monitoring, explainability, and human oversight into systems from inception demonstrate compliance efficiently. Teams that must retrofit these capabilities face expensive pipeline redesigns or deployment blocks. Nearly every regulatory obligation eventually asks the infrastructure the same two questions: which data produced this model, and who touched that data under what authority. Lineage and audit systems answer them.

15.5.4 Building data lineage infrastructure

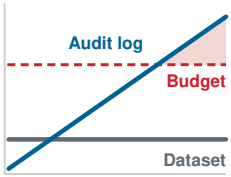
When a regulator audits which training data produced a deployed model, or a user invokes an applicable right to erasure, the organization must answer from infrastructure rather than manual investigation. The lineage graph built for reproducibility in section 4.8.1 and section 14.3.1.2, a directed acyclic graph (DAG) of artifact versions and transformation tasks, is the same structure an audit queries.[23] Governance adds obligations to that graph rather than a new system. Ingestion records must link each KWS recording to its acquisition method and consent basis, and the use boundaries declared on a data card (figure 15.8) decide which training jobs may consume which feature partitions.

The obligation that lineage serves most directly is lineage-driven deletion. When an erasure request arrives, traversing the graph from the source recording identifies candidate derived artifacts (cached spectrograms, feature embeddings, training snapshots, and checkpoint weights) for scope determination and possible invalidation, retraining, or legal review. Deployment edges extend the same traversal to the field. Because lineage records which model version each device downloaded, a quality or compliance defect later found in the training data can be traced to the devices running the affected models and recalled there. Lineage captures provenance, but accountable operation also requires access history: who touched the data, when, and under which authority.

15.5.5 Audit infrastructure and accountability

Recording that access history for HIPAA or Sarbanes-Oxley (SOX) audits creates a write-amplification bottleneck if a production feature store logs the full feature vector and intermediate activation tensor on every read, because the audit log can outgrow the training dataset itself and blow past its storage budget while the dataset stays flat. Accountability trails[24] record access events to meet legal obligations, and for a fixed event schema, retained volume depends on recorded events per unit time, bytes per event, and the retention window. More accesses or instrumented stages raise the event count, while logging full feature payloads and intermediate activation tensors greatly increases bytes per event. Separating compact audit metadata from raw payload data controls that multiplier.

Production keyword spotting architectures resolve this trade-off through a tiered audit topology that reconciles capture fidelity with storage overhead and edge bandwidth limits. At the edge tier, microcontrollers operating within strict SRAM budgets log local state transitions, wakeup timestamps, and power states to volatile circular ring buffers. To conserve radio energy and uplink bandwidth, devices batch telemetry over secure transport rather than streaming it continuously. Scheduled maintenance windows or charging cycles can provide upload opportunities only if the required evidence survives until then.



The retention requirement determines which events can use this volatile path. Dividing usable buffer capacity by the encoded telemetry byte rate gives the time to fill an empty buffer; the upload schedule must leave room for bursts and retries. Summaries may discard detail only when the retained fields still answer the specified audit questions. Events that must survive power loss require durable local storage until central storage acknowledges durable receipt, adding write energy and storage wear to the device budget. Sequence numbers and restart markers expose missing intervals after reconnection; an incomplete interval cannot establish that no incident occurred. If retention requirements exceed the available storage or uplink budget, the design must reduce optional telemetry or provision additional capacity before deployment.

Once telemetry reaches centralized infrastructure, auditing shifts from bandwidth-constrained edge devices to high-throughput feature stores. At this feature tier, offline and online feature stores emit append-only audit events for every read and write transaction. Rather than duplicating high-dimensional feature vectors, these events record requesting service identities, authorized subject pseudonyms, feature group hashes, and read timestamps. This metadata-only logging strategy enables fine-grained access verification while keeping log volume proportional to access transactions rather than payload sizes.

From feature stores, data flows into training pipelines running across accelerator clusters. At this training tier, cluster schedulers record deterministic manifests mapping training jobs directly to immutable data partition hashes, git commit SHAs, and hyperparameter configurations. While these manifests support checks of pipeline integrity and reproducibility, they reveal an inherent systems boundary: access logs confirm which records were processed, but they cannot demonstrate whether

23 **Data lineage systems**: Systems such as Apache Atlas and DataHub capture metadata about data flows from pipeline execution, creating graphs in which nodes are datasets and edges are transformations. GDPR Article 30 requires records of processing activities (European Parliament and Council of the European Union 2016), not automated model-level lineage specifically.

↩ Transformation lineage, which records the code version, parameters, and processing history behind each dataset, is established in section 4.8.1.

Audit volume can outgrow the storage budget while the dataset stays flat.

24 **Audit trail**: Audit integrity requires controls against unauthorized alteration, but retention and deletion duties vary by record type and law; append-only object storage with retention controls, or cryptographic hash chains, can provide tamper evidence without creating a universal rule that records are never deleted. A large platform may log billions of events daily; HIPAA's Security Rule also imposes multi-year documentation-retention obligations for required policies and procedures (U.S. Department of Health and Human Services 2005). Retention planning must distinguish records that must be preserved from personal data that must be minimized or deleted.

deleted user data persists within learned model weights. If the applicable erasure obligation covers a deployed model artifact, teams must evaluate retraining, validated **machine unlearning** (removing a training record's influence from learned weights without retraining from scratch (Cao and Yang 2015; Bourtoule et al. 2021)), or other legally appropriate controls; database access logs alone cannot establish removal of the training contribution.

Regulatory requirements extend audit responsibility from data access to prediction-time inference behavior. Reconstructing why the credit service denied a specific applicant in section 15.3.2.1, or why an edge voice assistant triggered a false wake-word activation, requires auditing the exact operational state at inference time. Without inference-time logging, an audit trail may confirm database access without capturing which model checkpoint, decision threshold, and runtime features produced a given decision. Saving raw input tensors for every inference request would overwhelm storage write bandwidth; production serving systems instead record compact, purpose-limited decision manifests. These manifests capture the active model version hash, runtime decision threshold, output confidence scores or reason codes, and cryptographic hashes of input features, supporting indexed retrieval of decision evidence. An input hash identifies content but cannot reconstruct it; replay also requires an appropriately retained source or an authorized recoverable representation, along with the relevant execution artifacts. Across these edge, feature, training, and serving tiers, governance uses Machine-axis logging and access control to prove Data-axis promises, yet comprehensive infrastructure still does not protect a team from its own intuitions, which the following fallacies and pitfalls collect.

15.6 Fallacies and Pitfalls

Teams can still fail after assembling assessment frameworks, fairness metrics, explainability mechanisms, efficiency analyses, and governance infrastructure. A team may retrofit fairness after benchmark success, trust aggregate accuracy, or treat compliance evidence as paperwork rather than system behavior, drawing on intuitions from traditional software engineering where bugs are local and testing is deterministic.

Fallacy: *Responsibility can be addressed after the system achieves technical objectives.*

Teams assume fairness constraints can be retrofitted once models demonstrate strong benchmark performance. In production, early architectural decisions constrain what interventions remain feasible. Amazon's recruiting tool, abandoned after remediation failed (section 15.2.1), is the case in point. Integrating fairness constraints early can be less costly than retrofitting them after data contracts, monitoring, and release gates are fixed.

Pitfall: *Relying on aggregate metrics to assess fairness.*

Engineers assume high overall accuracy indicates the system works well for all users. The flaw of averages (section 15.3.2) shows why this intuition fails, because aggregate metrics can conceal large subgroup disparities. The credit-service analysis in section 15.3.2.1 showed a 30 percentage-point TPR gap, with qualified minority applicants rejected at 4× the majority-group rate. These disparities can persist undetected when standard monitoring tracks only aggregates. Production systems require disaggregated evaluation with application-specific thresholds, such as the 5-percentage-point TPR threshold used for the credit service.

Fallacy: *Removing sensitive attributes from training data eliminates bias.*

Teams remove gender, race, and protected attributes expecting this ensures fairness. Other features can act as proxy variables when they correlate with sensitive characteristics. ZIP codes, purchase patterns, browsing history, college names, and language choices can carry indirect demographic signal. Amazon's recruiting tool kept encoding sex through college and organization names after explicit gender terms were removed (section 15.2.1), and the care-management algorithm (war story 15.1) reproduced racial disparity through its cost target, a proxy that no attribute filter would remove. Removing protected attributes does not by itself establish fairness.

Pitfall: *Treating documentation as sufficient accountability.*

Teams invest effort in model cards, then consider responsibility requirements satisfied. Documentation provides transparency (section 15.3.3.2) but not enforcement. A model card specifying "not

validated for high-stakes decisions" has no effect when the system is repurposed for loan approvals without technical restrictions. Accountability requires operational integration: monitoring dashboards, documented subgroup-disparity alert thresholds, incident response procedures, and access controls preventing deployment beyond validated use cases.

Fallacy: *Responsible AI is primarily a legal compliance issue.*

Teams treat responsibility as external oversight rather than engineering practice. Engineering decisions made months before legal review constrain the solution space more than any compliance assessment. Architecture selection determines what fairness interventions are feasible, while data pipeline design establishes whether disaggregated evaluation is even possible. As section 15.2.5 establishes, systems designed with responsibility as an engineering objective enable efficient validation; systems where responsibility is added at late-stage review face redesign or deployment with documented risks.

Pitfall: *Measuring the environmental impact of training but not inference.*

Public discourse focuses on training-run carbon, and engineers often follow this framing when assessing environmental responsibility. The illustrative TCO analysis in section 15.4.2 shows why this focus is incomplete: under its unbatched service-demand assumptions for the DLRM ranking service (table 15.10), the inference-to-training cost ratio is about 40:1, and inference emits about 63× as much CO_2 as training. A model trained periodically but served millions of times daily can have a lifecycle footprint dominated by inference rather than training. These values are scenario-dependent, but they show why lifecycle accounting must include both terms.

Fallacy: *Model weights are exempt from data governance and deletion requests.*

Teams often assume that once training data has been compiled into model weights, the data is gone and compliance obligations cannot reach the artifact. In reality, models can memorize training data, and membership inference attacks can reveal whether a sensitive record appeared in the training set (Shokri et al. 2017). Unlike a database delete, a neural network diffuses each training point's statistical influence across its parameters through gradient updates, so verifiably purging that influence forces systems trade-offs. Exact retraining from scratch on a cleaned dataset provides a reference for removing the excluded records' contribution, but it re-expends the training budget (potentially thousands of accelerator-hours) and its carbon emissions, and it does not erase other copies or facts inferable from retained data. Machine unlearning, introduced with audit infrastructure (section 15.5.5), aims to bound that cost, but verifying that an intervention removes statistical influence without degrading model utility remains an open systems challenge. Engineering teams must track data-to-model lineage and evaluate retraining, machine unlearning, or compensating controls with legal and privacy specialists whenever an erasure request affects deployed artifacts.

Across these failures, the recurring mistake is to treat responsibility as something added after the system is built rather than as a system property. Measurable constraints, continuous monitoring, and enforceable governance carry responsibility through the full lifecycle.

15.7 Summary

Responsible engineering is ML systems engineering done completely, not a separate discipline. The chapter traced a path from failure diagnosis through prevention to enforcement, beginning with the responsibility gap (the distance between technical performance and responsible outcomes) and demonstrating how proxy variables, feedback loops, and distribution shift can harm users while conventional metrics remain acceptable. The engineering response follows the model's lifecycle: specification that fixes targets, populations, and oversight before training forecloses them, fairness metrics that make disparities measurable, explanation and documentation selected for applicable stakeholder and regulatory requirements, and monitoring infrastructure that can surface silent failures and connect signals to response.

Translating responsibility concerns into measurable properties makes them tractable. A justified, application-specific bound on disparity is testable; "be fair" is not. This translation extends beyond fairness: in the chapter's illustrative TCO scenario, a 20 percent accelerator-service-demand reduction saves $304K and is modeled to avoid 19 t of CO_2 under the stated assumptions. Documentation becomes model cards with explicit intended use and known limitations. Governance becomes

access control, lineage tracking, and audit infrastructure that makes compliance evidence available rather than merely aspirational. Across these cases, abstract ethical obligations become concrete engineering requirements that can be specified, tested, monitored, and enforced.

Every row of the chapter map (table 15.1) now carries a measured machine cost: labeled evaluation data in proportion to how rare each named population is, a second network head for mitigation, explanation compute that grows exponentially with feature count for exact attribution, randomized exploration traffic to keep feedback in check, accelerator-hours and tonnes of CO_2 for the DLRM service, and log bytes, privacy noise, and retraining hours for governance. These practices share one principle: a responsibility property can be enforced only at a lifecycle stage that still has the freedom to change it. Measurement can gate only the populations that specification named, documentation can record only what measurement produced, and governance can prove only what the pipeline retained. A system that defers fairness, efficiency, transparency, or governance to a late review is therefore incomplete in the same sense as a system shipped without a latency budget; the requirement exists, but nothing in the architecture can meet it. The chapter's quantitative tools fit in one table (table 15.12), and each turns a responsibility requirement into a number a team can compute before launch and monitor after it.

Table 15.12: Key Equations: The chapter's responsibility quantities in the notation of the sections that derive them. Each converts a requirement (a fairness criterion, an evaluation budget, an explanation path, a feedback horizon, a carbon footprint, or an audit trail) into a value that can be computed before launch and monitored after it.

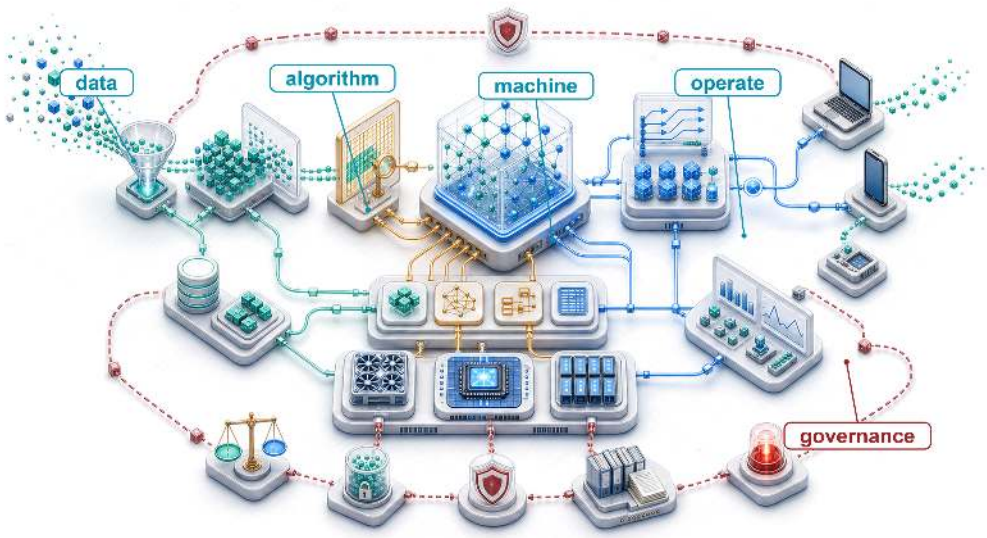
Quantity	Formula	Where Derived
Alignment gap	$\text{Gap} = \mathbb{E}[\text{Proxy}] - \mathbb{E}[\text{True}]$ for metrics on a common scale	equation 15.1
Demographic parity	$\Pr(\hat{Y} = 1 \mid G = \text{A}) = \Pr(\hat{Y} = 1 \mid G = \text{B})$, gated on the difference	section 15.3.2.1
Equal opportunity	$\Pr(\hat{Y} = 1 \mid Y = 1, G = \text{A}) = \Pr(\hat{Y} = 1 \mid Y = 1, G = \text{B})$	section 15.3.2.1
Equalized odds	Equal opportunity for both $v \in \{0, 1\}$, so true and false positive rates both match	section 15.3.2.1
Slice sample size	Worst-case margin $1.96\sqrt{0.25/n}$; random collection $D_{\text{eval,total}}$ = per-group target divided by the group's share	section 15.3.1
Exact attribution cost	$\mathcal{O}(2^{n_{\text{feat}}})$ model evaluations per explained decision	section 15.3.3.1
Bias feedback	$\Delta_g(k) \approx \Delta_g(0) \cdot \alpha_{\text{fb}}^k$	section 15.3.4
Operational carbon	$\text{Energy}_{\text{hardware}} \times \text{PUE} \times \text{Carbon Intensity}$	section 15.4.3
Audit log volume	Recorded events per unit time, times bytes per event, times the retention window	section 15.5.5

Key Takeaways: Reliable for whom?

- **Aggregate correctness hides harm**: A model can look accurate in aggregate while one subgroup's error rate is 43.1× another subgroup's rate, as in the Face++ Gender Shades audit. Responsible evaluation therefore starts with disaggregated and intersectional slices, not aggregate accuracy alone.
- **Responsibility becomes testable through thresholds**: "Be fair" is not testable, but bounded disparity, documented intended use, and explainability requirements are. Translating values into measurable constraints lets teams review trade-offs among fairness, accuracy, latency, and cost.
- **Efficiency is a social constraint**: An efficient model can reduce energy and cost and broaden who can deploy it. In the chapter's illustrative scenario, the inference-to-training cost ratio is 40:1, making per-query optimization responsible engineering.
- **Monitoring must watch outcomes**: Bias and privacy failures can continue with green uptime dashboards because harmful predictions look operationally normal. Production monitoring must track subgroup outcomes, data lineage, feedback loops, and incident paths with the same rigor as latency regressions.

- **Governance has to be built in**: Model cards, datasheets, access controls, erasure workflows, human-review paths, and audit trails are technical infrastructure, not optional policy overlays. Regulations such as GDPR require capabilities that should be designed into the pipeline; later remediation may remain possible but can be narrower and costlier once the system is serving decisions.

A system that does exactly what it was told is dangerous precisely because the telling is never complete. Every objective a model is given is a specification with gaps, and an optimizer is a machine for finding them. It can reproduce the bias latent in its data, chase the proxy instead of the goal, and call the result success because nothing in the objective said otherwise. Responsible engineering is the discipline of writing back in what the specification left out. Constraints and monitoring reduce the risk that optimization amplifies harms encoded in the data. The constraint is the same kind the rest of the book imposed in latency and memory, except that here it protects people the objective never named, and a model that is fast and accurate while wrong about whom it serves has not failed less than one that crashes, only more quietly.



What's Next: From local targets to the whole system

Responsibility was the last constraint this book added, and it behaves like the ones before it. A disparity bound, a carbon budget, or a lineage requirement can be met only if every upstream stage preserved the freedom to meet it, exactly as a latency budget can. Every constraint so far has been taught one layer at a time, yet the costliest failures arise where layers interact, when each component meets its own target and the system still misses its goal. Chapter 16 returns to the voice-assistant request that opened the book, follows it across every layer the chapters built, and gathers their quantitative principles, from the iron law (principle 3) onward, into one framework for reasoning across the whole stack.

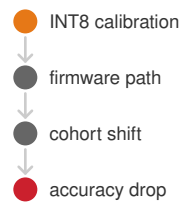
Purpose

What does mastering the full stack enable that expertise in any single layer cannot?

A single production decision travels through the entire stack. A data pipeline decides which events count as training signal. That signal shapes the architecture, which in turn fixes memory footprint and arithmetic intensity. Those properties constrain hardware choice, quantization strategy, serving latency, drift monitoring, and governance obligations. Mastered individually, each layer represents a valuable skill; mastered together, they confer the ability to reason across boundaries that no single specialty sees in full. An engineer who understands only compression can shrink a model, but cannot predict whether the accuracy loss matters for the deployment context. An engineer who understands only serving can optimize latency, but cannot trace a performance regression to a data pipeline change three stages upstream. Many of the costliest production failures arise at these boundaries, where every component passes its local tests yet the system as a whole misses its target. In D·A·M terms, what endures is the ability to analyze a system before it is built, reasoning about how data, algorithm, and machine constraints will interact, where bottlenecks will emerge, and which architectural commitments will prove irreversible. The constraints that govern these interactions outlive any specific framework, hardware generation, or model family, because the cost of moving data, the speed of light, and the gap between an assumed and a measured bottleneck do not turn over with them. Thinking in systems rather than components separates an engineer who can build a part from one who can build the whole.



Learning Objectives

- Trace how data, architecture, compression, hardware, serving, operations, and governance decisions propagate constraints across an ML system
- Apply lighthouse-model reasoning to diagnose bottlenecks across cloud, mobile, edge, recommendation, and TinyML deployments
- Synthesize core ML systems principles into a framework for reasoning across Data, Algorithm, and Machine constraints
- Evaluate deployment trade-offs using latency budgets, memory and energy movement, drift, and responsibility constraints
- Justify an engineering approach for emerging contexts such as embodied, composed, and multi-node systems, using cross-layer evidence to identify where single-node reasoning must widen its boundary

16.1 The System Is the Model

When a user asks a smartphone voice assistant a question, learned components convert speech to text, interpret intent, retrieve information, and generate a response within seconds (section 1.1), and a failure in any stage—a drifted feature, a miscalibrated quantization range, or a queueing spike—degrades the answer even when the model weights are untouched. **The system is the model**: the behavior a user receives from a machine learning service is produced by the data pipeline, the trained weights, the execution stack, the serving path, and the monitoring loop together, never by the weights alone. Every chapter since the introduction has given one stage of that request a mechanism and a cost. Chapter 15 added the last constraint the book imposes, the obligations a system owes the people it affects, and showed that it behaves like the latency and memory budgets before it, because it can be met only where every upstream stage preserved the freedom to meet it. Each constraint was taught one layer at a time. The costliest failures arise where the layers meet.

A composite scenario, extending the calibration pitfall analyzed in section 13.11 rather than reporting any one incident, shows such a failure. To deploy an image classification model across a fleet of mobile devices, the architecture team chooses depthwise separable convolutions to factorize spatial filtering from channel projection, the compression team quantizes the resulting weights and activations to INT8 so they fit within on-chip static RAM (SRAM), and the serving team brings end-to-end p99 latency inside a 50 ms target. Each team succeeded by its local metric, yet within weeks, accuracy dropped by four percentage points on specific firmware and device cohorts. INT8 quantization fixes its clipping ranges during quantization-range calibration, permanently encoding the statistical distribution of the calibration images. A firmware-specific preprocessing routine interpolated images differently and presented an altered input distribution to the quantized model on those cohorts. No component failed in isolation, and nothing crashed. Each team validated its component against standard inputs, and while latency was evaluated end to end along the deployed request path, accuracy was measured only as an aggregate scalar over an offline evaluation set, so users on the affected cohorts simply received worse predictions that the system's monitoring was never built to see. Heterogeneous edge environments require disaggregated cohort monitoring from day one.

A calibration choice surfaces as a cohort accuracy drop three stages downstream.

Most failures of this kind start at an interface between components, so the main task is to test the interfaces before they fail. Traditional software engineering treats functional correctness as decoupled from the underlying hardware; in machine learning systems, statistical behavior is physically inseparable from the pipelines, memory hierarchies, and accelerators that train, serve, and monitor the model.

The bitter lesson teaches that general methods scaling with computation outrun hand-encoded heuristics (section 1.4). Affording that scale is the job of the iron law of ML systems (principle 3), which sits at the center of this discipline. Its three terms (data movement, compute, and overhead) serve as the primary engineering levers for quantitative analysis. Building intelligence requires both statistical algorithms and adherence to the silicon contract (principle 4), the requirement that the

resource a model saturates first be the one the executing machine supplies in abundance. Arithmetic intensity and roofline modeling convert qualitative performance intuitions into quantitative upper bounds (Williams et al. 2009).

System capabilities emerge from co-design across the Data, Algorithm, and Machine (D·A·M) triad rather than from isolated algorithmic breakthroughs, and success and failure arise from the same mechanism, cross-layer coupling. The transformer architecture (Vaswani et al. 2017) scaled into models such as GPT-3 and Llama 2 (Brown et al. 2020; Touvron, Martin, et al. 2023) only because decisions in other layers made attention affordable: IO-aware attention kernels that keep intermediate scores in on-chip memory, low-precision tensor units that raise the peak arithmetic rate, and partitioning of tensor state across accelerators.

↩ IO-aware attention tiling, which keeps attention scores in on-chip memory, is established in section 8.6.4.

Integration has concrete consequences. Software engineering often treats the "model" as a weights checkpoint, a single file of floating-point numbers. In a production environment, however, the weights are only one component of the true model, and often not the most fragile. A model that produces high benchmark accuracy fails if it ingests corrupted features, and a model that converges cleanly during training fails if it cannot satisfy deployment latency constraints.

↩ The finding that model code is a small fraction of a production ML system, whose surrounding pipelines, serving, and monitoring are larger and more enduring, is established in section 1.2.

Checkpoint 16.1: Systems thinking

The system's dependencies, feedback loops, and request path make its boundaries testable.

The integration

- ☐ **Dependencies**: can you trace a data-pipeline change through training and serving to identify its latency effect?
- ☐ **Feedback loops**: have you mapped how the model's predictions influence its future training data?

The holism

- ☐ **End-to-end**: can you trace a user request from the user interface, through the network, preprocessing, model, postprocessing, and back to the user interface?

Tracing a request end to end exposes the coupling behind such failures. Every layer of the stack enforces physical and statistical constraints on the next. Data curation and selection bound what the learner sees; architectures, training systems, and frameworks lower the resulting computation onto hardware; compression, acceleration, and benchmarking move the physical boundaries; and serving, operations, and responsible engineering hold the result to tail-latency budgets, drift, and subgroup outcomes in production. Because these stages form a tightly coupled system rather than a sequence of isolated handoffs, engineering decisions never remain localized, and an engineer who optimizes a single layer in isolation cannot predict how the change will propagate.

The rest of the chapter makes that claim quantitative. The five lighthouse models come first, each traced from its home regime to the lever that paid off and the lever that was wasted. The thirteen quantitative principles follow, regrouped by the three questions the introduction asked of every ML system: what shapes its predictions, what limits its execution, and what evidence supports its deployment. The dual mandate is then measured on two lighthouses, DLRM for trustworthy behavior and the GPT-2 family for physical deliverability. The same principles then forecast where constraints bind next, from microcontrollers to composed services and fleets. The chapter closes on the responsibility that follows from building such systems, the cross-boundary forms of the book's recurring mistakes, and a final trace of the voice-assistant request through every layer.

16.2 Lighthouse Models: Constraint Propagation

Adding peak arithmetic throughput to a batch-one large language model (LLM) decoder leaves token latency untouched because every token waits on high-bandwidth memory (HBM) weight reads; adding memory bandwidth to a batched ResNet-50 convolution buys nothing once its arithmetic intensity sits right of the ridge point. The five lighthouse models each have a home regime, the binding resource that the workload exposes under its typical operating conditions: ResNet-50 is compute-bound, GPT-2 and Llama decode is bandwidth-bound, DLRM is capacity-bound, MobileNetV2 is compute-bound in its efficient regime, and keyword spotting (KWS) is power-bound. Across the book, each lighthouse rewarded the lever aimed at its binding term and wasted the effort aimed anywhere else (table 16.1).

↩ The five lighthouse models and their diagnostic execution regimes are established in section 1.7.1.

Table 16.1: Lighthouse Constraint Traces: Each lighthouse probes one home regime, and the lever that paid off was the one aimed at that regime's binding term. A regime describes a workload on a machine rather than a model name, so a lighthouse crosses regimes when batch size, phase, or precision changes.

Lighthouse	Home Regime	Binding Term	Lever That Paid	Lever Wasted
ResNet-50	Compute-bound	Compute, $O/(R_{\text{peak}} \cdot \eta_{\text{hw}})$	Batching that reuses filter weights across inputs; reduced-precision tensor arithmetic	More memory bandwidth once batched convolutions sit right of the ridge point
GPT-2/Llama decode	Bandwidth-bound	Data movement, D_{vol}/BW	Batching across requests; fewer bytes per weight; managing the per-request key-value cache	More peak arithmetic throughput, or compute-only kernel tuning at batch one
DLRM	Capacity-bound	Memory capacity, a precondition before any term applies	Placing and sharding embedding tables across memory tiers; caching frequently accessed rows	Faster dense arithmetic for the small fully connected layers
MobileNetV2	Compute-bound in its efficient regime	Compute within a phone's power envelope; depthwise layers cross to bandwidth-bound	Depthwise separable convolutions, then INT8 once depthwise layers became bandwidth-bound	Further operation cuts on layers already bound by bandwidth
Keyword spotting (KWS)	Power-bound	Energy per inference within a milliwatt budget	A sub-megabyte INT8 model with a tensor arena planned at build time	Streaming audio to the cloud, whose radio transmission costs more energy than local inference

The regime belongs to the workload on a machine, so the same model can change regime, and the regime has to be checked before an optimization is chosen. GPT-2 training is compute-bound even though its decode is bandwidth-bound, because a training step reuses each weight across every token in the batch. ResNet-50 became input-bound in chapter 8 when the data pipeline could not keep the accelerator fed, and INT8 arithmetic, which doubles the H100's peak rate without raising its memory bandwidth, doubles the ridge point, which leaves some ResNet-50 layers below it and bandwidth-bound. DLRM shows the same pattern at the large end of the deployment spectrum, where embedding capacity decides which term binds; MobileNetV2 and keyword spotting show it at the small end, where thermal and power envelopes do. A larger recommendation model, a larger decoder, or a faster vision network differs from its lighthouse in scale, not in which term binds, so the diagnosis carries forward to models that do not yet exist.

Applying each phase of the book to MobileNetV2 shows how cross-layer constraints converge on a single engineering artifact (table 16.2). Across nine phases, from the deployment tier's envelope through architecture, training, data selection, compression, acceleration, benchmarking, serving, and runtime operations, each engineering decision narrows the options available downstream.

Table 16.2: The Lighthouse Journey (MobileNetV2): Applying the book's nine phases to one model shows how decisions in one domain (for example, architecture) propagate constraints and opportunities into downstream domains (for example, hardware acceleration and monitoring).

Journey Phase	System Lens	MobileNetV2 Implementation
Foundations (chapter 2)	Deployment Tier Constraints	Mobile tier sets a watt-scale power, thermal, and battery envelope that every later phase must respect
Architecture (chapter 6)	Algorithmic Efficiency	Depthwise Separable Convolutions: 8.7× fewer FLOPs for a representative 3-by-3, 256-output-channel layer and 13.7× fewer operations than ResNet-50 at ImageNet scale
Training (chapter 8)	Throughput vs. Latency	Trained at high-throughput batch sizes for a model that will serve single requests at low latency
Data Selection (chapter 9)	Capacity-Matched Augmentation	Milder augmentation matched to a compact network's limited capacity, validated against deployment invariances such as device and lighting variation, at no inference cost
Compression (chapter 10)	Navigating the Pareto Frontier	INT8 Quantization: FP32 uses 4× and FP16 uses 2× the per-value storage of INT8, with accuracy revalidated per deployment
Acceleration (chapter 11)	Honoring the Silicon Contract	Mapping kernels to mobile neural processing units (NPUs) (for example, Apple Neural Engine) to maximize hardware execution efficiency
Benchmarking (chapter 12)	Component vs. End-to-End	Confirming that compression and accelerator gains survive the full pipeline by separating accelerator latency from preprocessing and transfer, and rechecking INT8 accuracy on edge cases such as unusual lighting
Serving (chapter 13)	Respecting the Latency Budget	p99 < 50 ms constraint; optimizing preprocessing (resize/normalize) to avoid CPU bottlenecks
Operations (chapter 14)	Managing System Entropy	Drift Monitoring: Detecting distribution shifts and tracking cohort-level accuracy across heterogeneous device populations and lighting conditions

Decisions in one row constrain options in the next. Depthwise separable convolutions cut the operation count, but depthwise filtering reduces cross-channel reuse and often leaves these layers bandwidth-bound on mobile hardware. When profiling confirms that regime, a further cut in operations buys little, and the compression row's reduction in bytes per value becomes the next lever. That lever pays only if the acceleration row confirms that the mobile NPU executes those INT8 operators, and only if the benchmarking row shows the gain surviving preprocessing and transfer. The same propagation runs through every lighthouse, and reasoning about it before profiling requires the quantitative principles the book accumulated part by part.

16.3 Thirteen Quantitative Principles

When an engineer alters an embedding table layout, doubles batch size, or quantizes an attention layer from FP16 to INT8, the performance outcome is not random; it is governed by physical bounds, empirical trade-offs, and operational feedback. Reasoning quantitatively about this behavior across the entire stack requires analytical tools with stated assumptions, and the book accumulated **thirteen quantitative principles** for that purpose across its four parts (table 16.3). They are not all the same kind of statement. Three are hard bounds (the Pareto frontier, the arithmetic intensity law, and Amdahl's Law), two are decompositions (the iron law and the energy-movement principle), two are fitted models (statistical drift and bias feedback), two are policies whose parameters a product decision sets (the verification gap and the latency budget), and four are heuristics (data-as-code, data gravity, the silicon contract, and training-serving skew). The heuristic label marks the silicon contract as a prediction about which resource an architecture saturates first, a prediction that the arithmetic intensity bound then tests. Each principle box on the part pages names its kind, and each principle is reliable only within its stated assumptions.

Table 16.3: Thirteen Quantitative Principles: Each tool appears in the part where its governing constraint or diagnostic use first becomes visible. The collection combines bounds, decompositions, fitted models, policy requirements, and heuristics. Each row holds under its stated assumptions; together they provide a shared analytical vocabulary for system design, optimization, and deployment.

#	Principle	Part	Core Equation/Statement	What It Predicts
1	Data-as-Code Principle	I: Foundations	Learned behavior ≈ Train(training data, training procedure)	Data changes behavior; other inputs also matter
2	Data-Gravity Principle	I: Foundations	Move compute toward data when repeated transfer costs exceed placement costs	Depends on volume, reuse, network, and compute mobility
3	Iron Law of ML Systems	II: Development	$T = D_{\text{vol}}/\text{BW} + O/(R_{\text{peak}} \cdot \eta_{\text{hw}}) + L_{\text{lat}}$; overlap ranges from max to sum	D·A·M factors multiply; stages add or overlap
4	Silicon Contract	II: Development	Each architecture saturates one resource (compute, bandwidth, or capacity) first	Design must target the resource saturated first
5	Pareto Frontier	III: Optimization	No feasible point is at least as good on every objective and strictly better on one	Along the frontier, improving one objective worsens another
6	Arithmetic Intensity Law	III: Optimization	$R_{\text{attain}} \leq \min(R_{\text{peak}},\ I \times \text{BW})$	More compute cannot raise a bandwidth ceiling
7	Energy-Movement Principle	III: Optimization	$E_{\text{total}} \approx D_{\text{vol}} \times E_{\text{move}} + O \times E_{\text{compute}}$; dynamic RAM (DRAM) to FLOP cost ratio: 173–582×	Total energy depends on bytes moved, operations, and per-event costs
8	Amdahl's Law	III: Optimization	$\text{Speedup} = \frac{1}{(1-f_{\text{parallel}}) + \frac{f_{\text{parallel}}}{G}}$	For fixed work, the serial fraction caps parallelism gains
9	Verification Gap	IV: Deployment	Deployment-population success probability must meet the specified target at the stated task-error tolerance	Specify distance, tolerance, population, and required success probability
10	Statistical Drift Diagnostic	IV: Deployment	$\text{Accuracy}(t) \approx \text{Accuracy}_0 - \lambda \cdot \mathcal{D}(P_t \| P_0)$	A local fit; drift need not lower quality
11	Training-Serving Skew Diagnostic	IV: Deployment	$S_{\text{skew}} = \mathbb{E}[\lvert f_{\text{serve}}(x) - f_{\text{train}}(x)\rvert]$	Output mismatch signals risk, not accuracy loss
12	Latency Budget Principle	IV: Deployment	$\Pr[L_{\text{lat,total}} \leq T_{\text{deadline}}] \geq q$, where $L_{\text{lat,total}}$ sums the request-path delays	The product SLO selects q and the deadline T_{deadline}
13	Bias Feedback Model	IV: Deployment	$\Delta_g(k) \approx \Delta_g(0)\alpha_{\text{fb}}^k$ with fitted α_{fb}	Feedback may amplify harm; measure and intervene

Notation Guide for table 16.3: In deployment models, d_{task} is the task-specific distance metric, τ_{tol} is the acceptable error tolerance threshold, q is the target success probability for latency deadline T_{deadline}, and α_{fb} is the amplification factor compounding disparity Δ_g at step k. The drift row restates the degradation equation (equation 1.1), in which λ is the sensitivity fitted from labeled outcomes and $\mathcal{D}(P_t \| P_0)$ measures how far the current input distribution has moved from the training distribution. S_{skew} is the expected absolute difference between serving-path and training-path outputs on the same input. In efficiency bounds, G is the speedup factor applied to the parallelizable fraction f_{parallel}. Finite tests estimate the deployment success probability with uncertainty; an evaluation must separately state the statistical confidence level of its interval or bound.

The thirteen principles are not independent axioms. The conservation-of-complexity heuristic[1] introduced in Part I connects them into an integrated framework. In Part III, model compression demonstrated this trade-off at the scale of a single model: pruning sacrifices capacity, quantization sacrifices precision, and distillation expends training compute. At the scale of the entire system the discipline is the same. After any local simplification, trace where the displaced complexity has migrated. The heuristic serves as a diagnostic rather than a physical conservation law. While thoughtful design can eliminate accidental complexity outright, systemic complexity often shifts elsewhere, as when quantizing a model moves it into validation.

The part pages introduced the principles in the order the book needed them. Read together, they sort more usefully by the three questions the introduction asked of every ML system (section 1.12): what shapes its predictions, what limits its execution, and what evidence supports its deployment. The three groupings that follow keep each principle's number, so every principle can still be found on its part page.

1 | **Conservation-of-complexity heuristic**: Tesler's Law, a design aphorism, says that an application's irreducible complexity must be handled somewhere in the interaction among user, application, and platform (Tesler 1984). Extending it to all ML-system complexity is an analogy, which is why the heuristic directs a search for displaced costs rather than guaranteeing that an equal compensating cost exists.

What shapes predictions (principles 1 and 13)

The data-as-code principle (1) answers the first question directly. The training dataset dictates learned behavior, so a modification to data curation is a behavioral change requiring the same rigorous versioning, code review, and regression testing applied to source code. The bias feedback model (principle 13) extends that answer past launch, because a deployed model's predictions shape the data its successor trains on. It treats disparity as a quantity that compounds across retraining cycles at a fitted rate, which turns fairness into a stability question about the deployment loop. An automated credit model may satisfy throughput and convergence targets while systematically compounding disparities against underserved groups, so the feedback loop must be intercepted by disaggregated monitoring rather than discovered in aggregate accuracy.

↩ The bias feedback model, with the fitted factor that projects when a disparity that passed its release gate will breach it, is established in section 15.3.4.

What limits execution (principles 2–8)

The data-gravity principle (2) opens the second question, because data volume dictates where computation must execute. Moving a petabyte-scale dataset between cloud regions costs days of transfer time and substantial egress fees, which readily justifies moving compute to the data rather than the reverse.

The lighthouse models carry the same placement constraint into execution. In DLRM, embedding tables that outgrow a single accelerator's memory make memory capacity a binding design constraint, requiring the execution system to be engineered around where the parameters physically reside. Compute-to-data placement recurs across deployment environments precisely because moving large, low-reuse datasets saturates interconnects.

↩ The transfer time and egress cost that make a large dataset the gravitational center of an architecture are established in section 4.9.1.

The iron law (principle 3) and the silicon contract (principle 4) govern execution efficiency. The iron law's multiplicative D·A·M form connects data scale (Samples/Task), algorithmic work (FLOPs/Sample), and machine pace (Seconds/FLOP), while its three-term physical decomposition isolates data movement, computation, and overhead; the silicon contract reveals which term limits performance on a given architecture-hardware pair. Actual shapes, kernels, and runtime conditions determine which regime of table 16.1 applies. Diagnosing whether an execution path is compute-bound, bandwidth-bound, or capacity-bound determines which optimizations yield speedup and which waste engineering effort. Execution time drops most when engineers target the binding term directly rather than distributing effort uniformly.

The remaining four principles of the second question form a tightly coupled diagnostic chain. Where the Pareto frontier (principle 5) identifies the designs that no alternative beats on every objective at once—so that improving one objective along the frontier requires a trade-off against another within the same feasible design set—the arithmetic intensity law (principle 6) diagnoses whether compute or bandwidth sets the ideal ceiling at each point along it. Moving bytes across that boundary also carries a power cost, which the energy-movement principle (principle 7) captures by combining per-event costs with event counts: under the reference energy constants, one DRAM access costs about 173–582× as much as one arithmetic operation, with the DRAM-versus-FP32 ratio from hardware acceleration (chapter 11) at the lower end and the cheaper FP16 operation at the upper end, though which cost dominates a whole workload still depends on how many of each event occur. Even after memory traffic and kernel execution are tuned, Amdahl's Law (principle 8) sets the ceiling on any parallelism gain, explaining why data loading and preprocessing can become bottlenecks in highly optimized systems.

↪ The bottleneck diagnostic that pairs each binding iron-law term with the optimizations that work and those that are wasted is collected for reference in section A.5.3.

MobileNetV2 touches all four. Depthwise separable convolutions reshape the Pareto frontier (Sandler et al. 2018). INT8 quantization exploits the arithmetic intensity law by raising arithmetic intensity through reduced memory traffic (Jacob et al. 2018). Measured energy savings, where the reduced traffic and supported execution lower total consumption, align with the energy-movement principle, while Amdahl's Law bounds end-to-end speedup when host-side preprocessing remains unaccelerated. Microcontroller workloads such as KWS compress these trade-offs further, operating under sub-megabyte memories that leave little room for avoidable overhead.

↩ The compute-versus-bandwidth-boundary and hardware balance (I_{ridge}) are established in section 11.6.2.

What evidence supports deployment (principles 9–12)

The third question concerns failures that bench testing cannot rule out, because a system can work correctly on the bench yet fail silently in production. The verification gap (principle 9) specifies the required success probability over a stated deployment population and error tolerance; finite

↩ Compression moves a model along the accuracy-efficiency frontier, as established in section 10.5.1.

testing estimates whether the system meets that requirement at a stated statistical confidence level, but it cannot establish correctness for every future input. Once the model is serving live traffic, the statistical drift diagnostic (principle 10) detects when that deployment population has changed and labeled outcomes fit how much the shift costs in accuracy, whereas the training-serving skew diagnostic (principle 11) catches internal divergence when training and serving paths compute the same features differently, and the latency budget (principle 12) holds the entire request path to the tail quantile the product selects.

↩ Reusing training-time transformation parameters at serving time, the consistency imperative that prevents skew, is established in section 4.7.1.

Monitoring infrastructure, drift detection, feature stores, and disaggregated subgroup metrics exist to make these principles measurable and to trigger corrective action. A recommendation system that achieves high offline accuracy still requires parity checks when training-serving skew corrupts feature pipelines (principle 11) and outcome auditing when user behavior shifts seasonally (principle 10).

↩ The monitoring infrastructure and drift quantification that surface these silent failures are established in section 14.5.

The integrated framework

The thirteen principles are not a sequence to apply in order. They constrain one another, and a single decision activates several of them in turn.

Quantizing a model from FP16 to INT8 illustrates these mutual constraints in action. This single intervention navigates the Pareto frontier (principle 5), trading numerical precision for memory traffic, and its consequences spread across the stack. Quantization alters the model's silicon contract (principle 4), shifting its operating point on the arithmetic intensity curve (principle 6) and transforming its energy profile (principle 7). In deployment, the latency budget (principle 12) dictates whether the resulting speedup meets the service-level objective (SLO), while the verification gap (principle 9) demands verifying that the lowered serving graph preserves the empirical accuracy measured during compression testing. The opening fleet failure escaped at exactly this step. Compression testing accepted the quantized model on images from the evaluation pipeline, while the firmware path presented a different population. The training-serving skew diagnostic (principle 11), comparing model outputs from the two preprocessing paths on the same captured inputs, is the measurement that would have exposed the mismatch before the affected cohort did. In that comparison the evaluation pipeline, which produced the calibration images, plays the role the diagnostic assigns to the training path, and the firmware path plays the serving path. The verification gap names why the failure escaped; the skew diagnostic names how to catch it.

The trace touched seven of the thirteen principles, and which seven depended on the decision. Had the same model moved off the device to a cloud endpoint, data placement (principle 2) would have entered, because every input image would then cross the network. Had preprocessing stayed on the host CPU while the NPU ran the faster INT8 kernels, Amdahl's Law (principle 8) would have bounded how much of that speedup the request path could see. The principles activate in turn as a decision moves from model representation to hardware execution to production validation, so a deployment proposal can be checked against the same principles before anyone writes code.

Checkpoint 16.2: Applying the principles

A colleague proposes quantizing your model from FP16 to INT8 to reduce serving costs.

Trace the principles

- ☐ **Pareto frontier** (principle 5): What accuracy are you trading for the bandwidth gain?
- ☐ **Silicon contract** (principle 4): Does the target hardware efficiently accelerate the required INT8 operators?
- ☐ **Verification gap** (principle 9): Does the quantized serving artifact preserve the behavior accepted during compression testing?
- ☐ **Training-serving skew** (principle 11): Do the calibration images pass through the same preprocessing path that every serving device uses?
- ☐ **Latency budget** (principle 12): Does the speedup bring you within SLO, or create headroom for batching?

Regrouped by the four parts in which they were introduced, the principles form a cycle rather than a pipeline (figure 16.1). The deployment principles (9–13) turn runtime telemetry into evidence that sends work back to the data foundations, so each production lesson becomes the starting condition of the next design pass. The conservation-of-complexity heuristic sits at the center of that cycle because every pass around it asks where the complexity displaced by the previous decision has landed. Along that return path, principles 9 through 13 expose the signals that trigger targeted remediations such as canary rollbacks, fallback heuristics, dataset augmentation, model retraining, or kernel retuning, so that failures are caught before they compound.

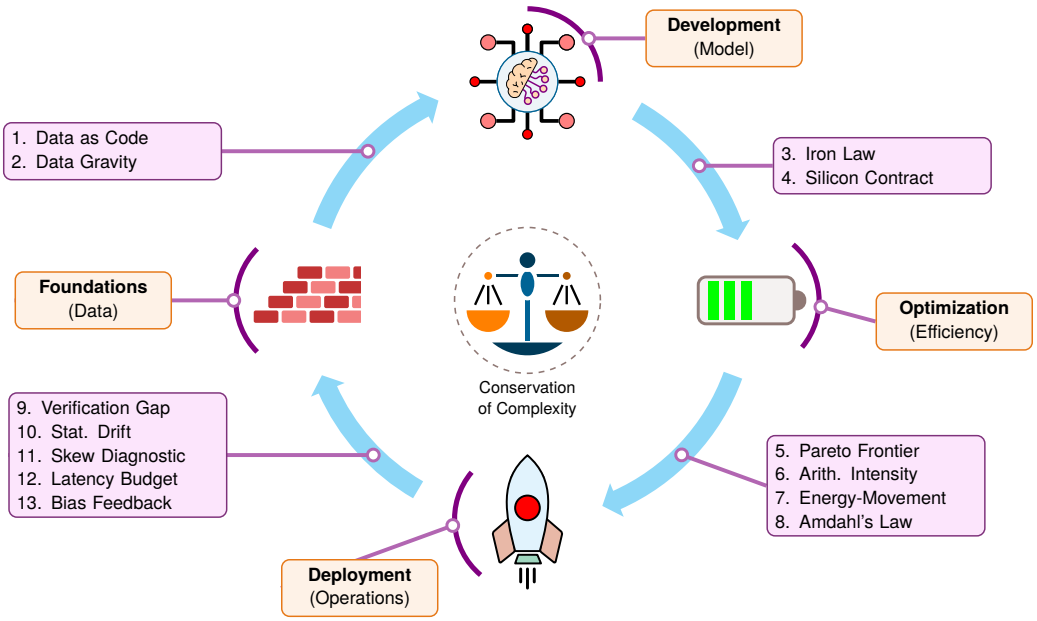


Figure 16.1: The Cycle of ML Systems (13 Principles): A four-phase systems engineering lifecycle organized around the conservation-of-complexity heuristic. The phases connect in a feedback cycle, and the thirteen principles sit along the transitions by the part that develops them, spanning bounds, decompositions, fitted models, policy requirements, and design heuristics whose assumptions must be checked. Icons mark the phases: bricks for the data foundations, a neural network for model development, a battery for the efficiency budget of optimization, and a rocket for launch into deployment.

The diagnostic framework is collected for reference in Appendix A, and the reference constants for back-of-the-envelope calculations appear in Appendix E. Tracing a quantization proposal through the principles it touches is one diagnostic pass, while the introduction posed a larger obligation that the same principles must serve, and two lighthouses can now measure it end to end.

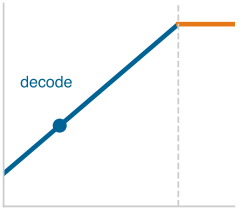
16.4 The Dual Mandate Revisited

A recommendation model that ranks well on launch day can, six months later, be serving a population that its own rankings shaped, on hardware whose cost per query decides whether the service survives. The introduction named this pair of demands the dual mandate: learned behavior must remain trustworthy, and the machine must deliver that behavior within physical and economic limits. The thirteen principles are the book's tools for both halves, and each half can be traced end to end on a single lighthouse.

Trustworthy learned behavior

↩ The dual mandate, trustworthy learned behavior delivered within the available time, memory, energy, and cost, is established in section 1.1.

DLRM carries the first half, because several mechanisms can erode trust in its learned behavior. The degradation equation (equation 1.1) introduced a local fit relating distribution shift to observed accuracy change; the statistical drift diagnostic (principle 10) turns that idea into production telemetry, with divergence over user and item features as the early signal and delayed click and conversion outcomes as the confirmation. Training-serving skew (principle 11) attacks the same model from



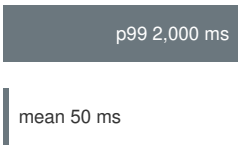
inside, when the online embedding lookup and the offline training pipeline compute a feature differently. The bias feedback model (principle 13) closes the loop, since items and creators that receive exposure generate the engagement data that earns them more exposure, and the resulting disparity can amplify or diminish across retraining cycles according to a fitted factor α_{fb}. The verification gap (principle 9) bounds what the launch evaluation actually established. Trust therefore has to be measured continuously, with alarms and a response plan, rather than certified once at launch.

Physical deliverability

GPT-2 carries the second half, and its family at scale shows the physics most sharply. Llama 2 70B is a decoder-only transformer of the same design with about 47× as many parameters as GPT-2's 1.5-billion-parameter release. The larger scale does not move batch-one decode off the bandwidth side of the ridge point, because every generated token still reads every weight once. Serving one Llama 2 70B token on two H100s makes that cost concrete.

↩ The intensity of batch-one decode, about 1 FLOP/byte in FP16 because each weight read feeds a single multiply-accumulate, is established in section 6.7.4.2.

Pricing that token repeats, at larger scale, the throughput ceiling computed for GPT-2 XL on one H100 in section 11.6.4 and the decode floor of equation 13.14. In FP16 the 70-billion-parameter model holds about 140 GB of weights, and each token costs about 140 GFLOP, two FLOPs per parameter. Sharded evenly across two NVIDIA H100s with an aggregate bandwidth of 6.70 TB/s and an aggregate FP16 peak of 1978 TFLOP/s (section E.2.2), the iron law (principle 3) gives a memory-transfer lower bound T_{memory} of about 20.9 ms against a peak-compute lower bound T_{compute} of about 0.07 ms, a ratio of 295.2×. The arithmetic intensity law (principle 6) accounts for that ratio. Intensity is still about 1 FLOP/byte, far left of the ridge in the margin roofline, so the time ratio is numerically the H100 ridge point itself. Sharding does not move the ridge, because it doubles peak rate and bandwidth together. The bound leaves out KV-cache traffic, activations, attention over the cache, interconnect communication, and dispatch overhead, so only profiling establishes the realized step time. Compute-only tuning can approach the 0.07 ms bound but cannot lower the 20.9 ms one; batching, which reuses each weight across requests, and quantization, which moves fewer bytes per weight, are the levers that can.



In this batch-one lower-bound model, decode sits left of the roofline ridge in the bandwidth-bound regime.

The estimate turns a physical bound into a diagnosis. The silicon contract (principle 4) exposes the architectural consequence. Accelerators are provisioned and purchased by peak arithmetic throughput, yet this workload saturates memory bandwidth first, so deliverable token generation speed is governed by bytes per second transferred from memory rather than by peak FLOP/s. The energy-movement principle (7) highlights the same weight traffic. A DRAM access costs far more energy than an arithmetic operation, by the ratio stated with that principle in section 16.3, and this workload performs only about one operation per byte fetched, so moving weights dominates the energy expenditure of each token. That ratio compares single access events with single operations, and because DRAM moves data in multi-byte bursts, an exact per-byte figure depends on transfer width and is settled by hardware telemetry.

↩ The energy ladder from registers to off-chip memory, which sets the per-access cost of moving a weight, is established in section 11.2.

Batching can amortize weight traffic across requests, and supported quantization can reduce bytes per weight. At the service level, the latency budget (principle 12) limits how far batching may go. The relevant delay now includes prompt processing and request waiting, not only token decoding. Consider an illustrative LLM chat endpoint whose mean time to first token is 50 ms but whose p99, driven by long prompts and by queueing behind long generations, reaches 2,000 ms, a tail 40× the mean (illustrated in the margin). Both values are scenario assumptions rather than outputs of a queueing model. The actual tail depends on the request mix and scheduling policy and must be measured; the general importance of tail latency is established in Dean and Barroso (2013). The product commits to the tail quantile, so the batching that improves throughput must stop where it pushes that quantile past its deadline.

Mean latency hides the tail; the selected tail quantile governs the SLO.

↩ The queueing model that relates utilization to tail latency, and the service-time assumptions under which its p99 estimate holds, is established in section 13.4.3.

The two traces use different principles, but they share one discipline: name the binding term, measure it, and budget for it. Scale keeps working only if the system can afford it and its results can still be trusted. The remaining question is where these constraints bind next, as ML systems spread across heterogeneous deployment targets, confront adversarial conditions, take on societal applications with public consequences, and grow into compositions of many components.

16.5 Future Directions

An autonomous vehicle navigating an unfamiliar intersection cannot wait for a cloud round-trip, and its sensor streams compete with the model for the same local bus; nor can a clinical assistant afford an uncalibrated diagnostic response under distribution shift. The framework is most useful when it forecasts where such physical and statistical constraints bind next. Three areas put the same physics under increasing pressure: deployment across diverse contexts, robustness under adversarial conditions (including deliberately crafted inputs (Goodfellow et al. 2015)), and societal applications whose failures carry public consequences. A fourth horizon, systems that compose multiple models, tools, and verifiers or grow beyond one machine, extends the same reasoning rather than replacing it.

Applying principles to emerging deployment contexts

Moving a workload from a data-center rack to a mobile phone or a battery-powered sensor strips away orders of magnitude in memory capacity and power budget while tightening latency deadlines. That span tests whether one quantitative framework can explain systems across contrasting resource regimes: the cloud offers abundant power and centralized hardware, edge and mobile devices operate under strict latency and battery budgets, and TinyML and embedded systems compress the same design problem into kilobytes and milliwatts.

In the cloud regime, the binding decision is how to turn abundant hardware into useful throughput, which for ResNet-50 means keeping batched kernels near the compute ceiling and for DLRM means placing embedding tables that exceed one accelerator's memory. Toward the small end of the spectrum, the MobileNetV2 and keyword-spotting lighthouses carry the forecast.

↩ The four deployment paradigms, and the physical constraints of power, latency, and memory that separate them, are established in section 2.1.

In contrast to the cloud, mobile and edge devices, the regime of the MobileNetV2 lighthouse, operate under strict power, thermal, and memory bounds that demand hardware-software co-design. Efficient network architectures combined with model compression enable deployment on platforms where a reference mobile device has about 10× smaller memory capacity and about 140× smaller power envelope than an H100-class accelerator. Edge deployment is mandatory when latency, privacy, intermittent connectivity, or egress bandwidth make centralized cloud inference infeasible. On these devices, efficiency decides whether a model runs at all.

↩ The per-device memory and power envelopes that separate the mobile tier from a data-center accelerator are established in section 2.4.2.

At the opposite extreme, TinyML and embedded systems, the domain of the keyword spotting lighthouse, operate within kilobyte SRAM budgets, milliwatt power envelopes, and multi-year operational lifecycles. At these extremes, profiling isolates memory traffic bottlenecks, custom operator lowering reduces particular dispatch and interpretation costs, and a fixed tensor arena, planned at build time from tensor lifetimes, replaces dynamic allocation so that peak memory is known before the device ships. Severe resource limitations historically catalyzed efficient architecture families such as MobileNets (Howard et al. 2017; Sandler et al. 2018) and EfficientNets (Tan and Le 2019), a direct case of machine constraints driving algorithmic innovation.

A related frontier is embodied AI and robotics, where models execute inside closed-loop sensorimotor control cycles. In this regime, the deadline T_{deadline} of the latency budget (principle 12) becomes a hard real-time safety constraint, because a tail-latency spike can cause mechanical instability or collision, and continuous high-bandwidth sensor streaming competes directly with model weight traffic across constrained on-device memory buses.

↩ The physical memory and latency envelopes that mandate compression for microcontroller and edge deployment are established in section 10.1.1.

Generative AI stresses all of these regimes at once. Autoregressive decode of the GPT-2/Llama family is bandwidth-bound at low batch, as the token estimate showed, and the serving responses to that bound each move the binding term in a different way. Batching raises weight reuse, and speculative decoding spends surplus compute on a small draft model to shorten the sequential path of the target model. Sufficiently long prompts shift the prefill phase toward the compute ceiling instead, so the same model crosses regimes within a single request.

The same physical bounds apply across these paradigms, while fitted statistical models and SLO policies remain deployment-specific. Success depends on checking those distinctions and applying the principles together rather than pursuing isolated optimizations. The more deployment contexts a system spans, the more failure surfaces it creates. Robustness, not coverage alone, therefore becomes a binding constraint at the next frontier.

↩ Continuous batching, key-value cache management, and speculative decoding for language model serving are established in section 13.9.

Building robust AI systems

Across those failure surfaces, a machine learning system can respond confidently and incorrectly while conventional infrastructure health checks remain green, allowing silent failures to persist undetected for weeks. Distribution shifts alter accuracy without code modifications, adversarial inputs (small, deliberately crafted perturbations that flip a prediction while leaving the input looking unchanged to a person) exploit vulnerabilities invisible to standard testing, and edge cases expose training-data boundaries that debugging alone cannot fix.

Finite testing estimates behavior on a defined population with uncertainty; it cannot prove correctness for every future input. Drift signals show when that population may have changed, while labeled outcomes determine whether quality changed. Together they motivate continuous monitoring as a design requirement, along with fallback policies and periodic revalidation, without claiming that every distribution shift causes degradation. The operational question is whether a failure will be detected and diagnosed before its impact spreads.

Robustness therefore demands designing for graceful degradation, not only prevention. At the single-system scale, that discipline appears as fallback paths, uncertainty thresholds, version-specific rollback policies, and monitoring hooks, with rollback reserved for a bad release rather than for external drift. At larger scale, the same logic extends to hardware redundancy and ensemble-style diversity. As AI systems assume increasingly autonomous roles in healthcare, transportation, and finance, the cost of an undetected failure grows.

↩ Incident response procedures, including the choice among rollback, fallback, and traffic reduction, are established in section 14.7.1.1.

AI for societal benefit

Robust systems are the prerequisite for deploying AI in domains where technical failures carry public consequences. The diabetic retinopathy screening case from chapter 3 shows why. A model that reaches expert-level performance on high-quality images from standardized research cameras can fail on blurry, poorly lit images from older clinic cameras, not because the algorithm is wrong but because the deployment population has moved outside the training envelope. In verification-gap terms (principle 9), the launch evaluation certified the model on the wrong population. Each societal domain stresses a different principle.

↩ The lab-to-field gap in the diabetic retinopathy screening case, where field images fall outside the training distribution, is established in section 3.6.1.

Scientific discovery workloads such as protein structure prediction, drug-interaction modeling, and materials screening can demand sustained training or inference throughput, so the iron law (principle 3) and the silicon contract (principle 4) decide how much of a search space a fixed compute budget can explore. Healthcare stresses the deployment principles instead. Calibrated uncertainty, external validation at each new site, clinical review, and continuous monitoring become safety requirements, because a diagnostic model trained on one hospital's population may degrade at another with different demographics, disease prevalence, or imaging equipment. Personalized education stresses data governance and the data-as-code principle (1), since the student-interaction records that drive personalization are both sensitive and, in effect, the program the model learns from; an interactive tutor must also meet its latency budget. A climate model that produces confident but uncalibrated projections carries the same verification problem into policy, where an overconfident forecast can steer decisions that are slow and costly to reverse.

In each of these domains the D·A·M taxonomy, the thirteen principles, and roofline analysis supply the systems questions, but the acceptable answers come from domain evidence such as clinical studies, educational outcome measurements, and physical validation, which no generic systems analysis provides. These applications also share a property that keeps their constraints tractable, because their task boundaries are fixed in advance. A diagnostic model classifies within a defined label set, and a structure predictor answers a defined kind of query. The next stress test removes that boundary.

System composition as a stress test

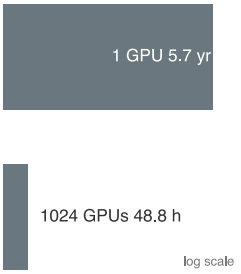
The most ambitious test of these principles is a system whose task boundaries are not fixed in advance. A task-general assistant or multi-component ML service may route one request through several components: retrieval, which fetches relevant documents from an index; a planner, a model that decides which steps to take; tool execution, which calls external programs such as a search engine or a calculator; generation of the answer; and a verifier, which checks the output against rules or with a second model. The governing challenge is systems engineering as much as algorithm design,

because the surrounding system must bound latency, reliability, cost, safety, and observability as work fans out across components.

System composition puts four of the principles under new load at once. As work fans out across retrieval, planning, tool execution, generation, and verification, the iron law must budget the computation and data movement of every stage, while the silicon contract fragments because each stage saturates a different resource: an index lookup leans on memory capacity and bandwidth, generation on the weight traffic of decode, and a tool call on network round trips, so no single accelerator suits the whole request. Balancing those heterogeneous stages expands the Pareto frontier from two or three metrics, such as accuracy, latency, and memory, to a larger surface that also includes safety, fairness, factuality, privacy, and cost, while statistical drift now threatens not only the final output but also retrieved documents, tool responses, and intermediate decisions.

The systems cost is visible in a single request. If an assistant fans out to retrieval, a planner, two tools, a generator, and a verifier, its realized latency follows the request's critical path. That path is the retrieval time, plus the planner's time, plus the slower of the two tool calls if they run in parallel, plus generation, verification, and the orchestration overhead between steps, and the latency budget (principle 12) must hold that sum at the selected quantile. Its reliability analysis must also account for each component, because every additional component creates another timeout, schema mismatch, stale index, or verifier false negative to monitor. Conventional microservices already face interface failures across process boundaries. Composed ML systems add probabilistic interfaces in which a large language model planner may invent a tool name that does not exist or produce JSON that deviates from the declared schema (the agreed format of each call), requiring defensive parsing, retry logic, and output validation at each interface boundary.

A composed system therefore cannot rely on a single model-quality claim; it needs interfaces whose behavior can be measured, because each interface is where one component's assumptions about another become testable (Lampson 1983). Composed systems trade monolithic simplicity for explicit coordination. Each step can be independently updated, monitored, and debugged, but each also adds an interface whose behavior must be specified and tested. The decomposition gives up latency and architectural simplicity in exchange for control and observability, a move along a Pareto frontier rather than a free gain. It also opens opportunities. Modular components can be compressed and accelerated on targeted back ends, each with its own silicon contract (principle 4) and arithmetic intensity profile, and the interfaces between them are natural observation points for drift, skew, and numerical degradation.



Systems Perspective 16.1: A new golden age

Hennessy and Patterson (2019) declared a "New Golden Age for Computer Architecture," driven by the end of Dennard scaling, the slowdown of Moore's Law, and new opportunities from domain-specific architectures, open instruction sets that any designer may implement without a license, and agile chip development with short, iterative hardware design cycles. Large-scale AI workloads are one domain where those pressures are visible. Building more capable AI services will not be a matter of writing a better loss function alone; it will be a systems engineering challenge involving energy efficiency, high-bandwidth interconnects, memory hierarchy design, and software stacks that keep heterogeneous hardware useful rather than idle. The thirteen principles provide a quantitative vocabulary for navigating that regime while preserving the distinction between physical bounds and deployment-specific assumptions.

A horizon note: From node to fleet

When workloads exceed a single node, the resource boundary moves outward, but bottleneck reasoning remains invariant. Local memory capacity constraints remain, while bisection bandwidth adds another limit; local exception handling expands into fleet-level fault tolerance, and training throughput becomes a distributed coordination problem. As the margin ladder illustrates, under a model in which every GPU fails independently at the same constant rate, regardless of its age, and any GPU failure halts the pool, a reference component mean time to failure (MTTF) of 5.7 years collapses into a cluster mean time between failures (MTBF) of about 48.8 hours across a 1,024-GPU pool, before accounting for correlated network or power outages. Under this model, a multi-week

Fleet scale turns rare component failures into routine system events.

training run is highly likely to encounter component failures. Such a run needs a fault-tolerance strategy, and checkpoint scheduling and recovery scope should follow the measured failure and recovery costs. At fleet scale, the analysis does not abandon single-node principles; it widens their boundary. The engineer still identifies the binding constraint, quantifies the governing cost terms in the iron law, and traces where displaced latency propagates.

This discipline rewards engineers who use bounds to guide benchmarks and measurements to test the assumptions behind those bounds. The same habit governs the last question this book raises, which is what the engineer owes the people a system affects.

16.6 The Engineering Responsibility

A model that requires an array of high-end data-center accelerators for inference excludes organizations unable to procure specialized capital;[2] upstream training data encodes historical sampling skews that distort downstream predictions; and sustained accelerator power draw directly drives facility thermal dissipation and regional grid carbon emissions. Ethical considerations cannot be separated from physical and algorithmic design, because the same decisions set both: choices from arithmetic precision to data curation distribute operational costs and societal consequences far beyond the engineering team.

Systems engineering extends beyond maximizing raw capability to operating deployments responsibly within societal and physical bounds. Production systems must achieve the arithmetic efficiency needed to run on accessible hardware, maintain fault tolerance against hardware anomalies, operate within strict thermal and power envelopes, and meet justified, application-specific fairness requirements across relevant demographic groups. Applications such as planetary climate monitoring and clinical diagnostic assistants make governance criteria first-class physical and operational constraints. Meeting them rests on three habits that outlast any model family or hardware generation: measuring hidden dependencies, bounding trade-offs against physical hardware limits, and holding production deployments to real operational constraints.

2 | **AI democratization**: Making AI accessible beyond a small number of well-resourced organizations through efficient systems engineering. Mobile-optimized models and cloud APIs can widen access, but doing so sustainably requires systematic optimization across hardware, algorithms, and infrastructure to maintain quality at scale.

The same responsibility demands continuous skepticism toward local wins. Optimizing a component in isolation is the most common way a system acquires failure modes that no team owns, and the benchmark win that does not survive production is its most familiar form. The recurring versions of that mistake are worth naming explicitly, because recognizing them early is far cheaper than a redeployment.

↩ The lifecycle that turns responsibility into written requirements, release gates, documentation, and operational monitoring is established in section 15.3.

16.7 Fallacies and Pitfalls

Fallacies and pitfalls in ML systems arise from one common source, which is treating the system as decomposable into independent parts. Each item below is the cross-boundary form of a mistake an earlier chapter met inside one layer, where optimizing one dimension, one metric, or one stage looks sufficient until that assumption meets production reality.

Fallacy: *Systems engineering complexity disappears with better tools and abstractions.*

Tools abstract complexity; they do not eliminate physical constraints. A high-level framework that hides memory management still consumes memory. An automated machine learning (AutoML) system that searches over hyperparameters still faces the Pareto frontier. Simplifying one interface may shift burden to another.

Pitfall: *Optimizing one metric without tracing displaced costs.*

When an optimization reduces latency by 50 percent, systems analysis demands asking what changed elsewhere. Quantization may add validation burden. Caching may trade memory capacity for serving speed. Some simplifications remove accidental complexity; others displace cost, and only profiling across the stack decides which occurred. Engineers who celebrate gains in one metric without tracing cross-stack effects build systems that fail in unexpected ways.

Fallacy: *Mastering individual components equals mastering the system.*

Component expertise is necessary but insufficient. An engineer who understands data pipelines, training, serving, and operations as isolated domains will still struggle with systems where a data schema change cascades through training, breaks quantization assumptions, and triggers silent

accuracy degradation in production. Integration can create more complexity than the components reveal in isolation because interfaces multiply failure modes.

Pitfall: *Scaling data collection without tracing its costs into the layers that absorb them.*

A data team that grows its collection judges the result by model quality, yet the costs land in other layers. Storage and preprocessing grow with every sample, each training epoch reads more bytes through the input pipeline, and repeatedly moving or scanning a larger dataset can exceed the cost of moving compute toward it, as the data-gravity principle (2) predicts. Within a fitted scaling regime, additional data can yield diminishing improvements (section 9.2.2) while those costs continue to grow, and coverage, data quality, model capacity, and distribution determine whether that fit remains useful for the next collection increment. If a team judges collection only by its own metric, it gathers data whose costs other teams absorb, so the marginal information value per sample has to be weighed against those downstream costs.

Fallacy: *A single accuracy metric captures model quality.*

A model evaluated solely on top-line accuracy ignores the boundaries it must cross. The composite fleet scenario that opened this chapter passed its aggregate offline evaluation while accuracy on specific firmware and device cohorts fell by four percentage points. The serving boundary imposes its own test. Under a 100 ms tail-latency SLO, a 95 percent-accurate model executing in 500 ms is infeasible, whereas a 93 percent-accurate model with a measured 50 ms tail meets that latency requirement. It is a feasible deployment only if its accuracy, subgroup behavior, resource costs, and other acceptance criteria also pass. Pareto analysis (principle 5) evaluates latency, throughput, memory footprint, energy, fairness, and serving cost together, and disaggregated evaluation exposes the subgroup disparities that an aggregate conceals.

↩ Disaggregated evaluation, which tests each relevant subgroup separately as a release gate, is established in section 15.3.2.

Pitfall: *Treating every drift alarm as an automated rollback trigger.*

The alarm fires in the monitoring layer, but its cause may sit in another layer entirely, and the response must follow the cause. Rollback is appropriate when a regression is traced to a flawed binary or pipeline release. External covariate drift, however, is not repaired by redeploying an older, equally stale checkpoint, and a shift introduced upstream, such as the firmware preprocessing path in the opening scenario, is repaired at the boundary where it entered. Safe operational responses include canary traffic shedding, fallback heuristics, prediction quarantine, or scheduled retraining once ground-truth labels confirm degradation.

Fallacy: *Optimizing the stage one team owns makes the system fast.*

Teams tend to profile the stage they own, and the model kernel is the one most visible, instrumented, and owned by the ML team, while the surrounding data path is split across storage, preprocessing, networking, and application code. Amdahl's Law (principle 8) shows what that division costs. Optimizing accelerator inference latency by 10× yields only 1.1× system speedup if CPU-bound preprocessing accounts for 90 percent of end-to-end latency. Serial fractions of that size can arise from host-side image augmentation, synchronous feature-store lookups, or tokenization that remains host bound in some implementations. End-to-end profiling across team boundaries keeps the target honest, because the stage to improve is the one that limits the system, not the one with the cleanest benchmark harness.

↩ Amdahl's law, which caps the gain from speeding up one stage by the share of request time that the other stages take, is established in section 11.1.

These fallacies and pitfalls share one root, local optimization that ignores the coupling of the system that executes it. Closing the chapter requires returning to the whole request path and measuring how those coupled stages behave together.

16.8 Summary

ML systems engineering differs from isolated component optimization by reasoning across boundaries. Because decisions couple across data, algorithm, and machine, the deployed system rather than the weights checkpoint is the model, and its costliest failures live at interfaces that no component test exercises. The thirteen principles, the conservation-of-complexity heuristic, and the lighthouse traces that carried them through the stack are the tools for reasoning about that system as a whole. Their stated assumptions distinguish exact bounds from fitted models, SLO policies, and design

↪ A diagnostic matrix that maps common production symptoms to candidate D·A·M axes and the measurements that confirm them is collected for reference in section A.5.2.

heuristics, allowing the tools to remain useful as frameworks, hardware generations, and model families change.

Key Takeaways: Reasoning across boundaries

- **Decisions couple across layers**: In the composite fleet scenario every team met its local metric while accuracy on specific device and firmware cohorts fell by four percentage points, because quantization calibration and a firmware preprocessing path met only in production. Isolated component tests miss such cross-layer interactions; cross-path parity checks, integration tests, and cohort-level outcome tracking test the governing assumptions at the interfaces.
- **Each lighthouse rewards the lever aimed at its binding term**: ResNet-50 is compute-bound, GPT-2 and Llama decode bandwidth-bound, DLRM capacity-bound, MobileNetV2 compute-bound in its efficient regime, and keyword spotting power-bound. The regime belongs to the workload on a machine, so batch size, phase, and precision can move a lighthouse across regimes, and the diagnosis carries forward to larger models of the same kind.
- **Assumptions matter across implementations**: The thirteen principles turn framework-specific craft into measurable reasoning by combining physical bounds, decompositions, fitted models, requirements, and heuristics. Apply each only within its stated scope.
- **Trace displaced costs without assuming conservation**: Compression, batching, monitoring, and governance can relocate burdens across data, algorithm, and machine. Measurement shows where each burden went.
- **Boundaries reveal the bottleneck**: In the idealized batch-one, two-H100 model, the memory-transfer lower bound for a Llama 2 70B token is about 295.2× the peak-compute lower bound, and in the illustrative LLM chat endpoint the p99 time to first token is 40× the mean. Systems thinking means measuring where physics, traffic, and users bind.
- **Both halves of the dual mandate are measurable**: Trustworthy behavior is tracked through drift, skew, and fitted feedback factors; physical deliverability through the iron law, the roofline, and energy per event. Neither is certified once at launch; both are budgets the system must keep meeting.

Hennessy and Patterson's *Computer Architecture: A Quantitative Approach* gave processor designers a shared analytical discipline by decomposing CPU time into instruction count, cycles per instruction (CPI), and clock period, so that any proposed improvement could be judged by which factor it changed (Hennessy and Patterson 2011; Hennessy and Patterson 2017). The iron law plays the same role for machine learning systems, and the thirteen principles around it extend that discipline from execution time to energy, trade-offs, and deployed behavior. Together they give a shared analytical baseline for evaluating trade-offs across data, algorithms, and machines.

The voice-assistant request that opened the introduction can now be traced through every layer, as a composite assembled from the book's lighthouses rather than from any one product's design. First, a keyword-spotting model of about 200 thousand parameters listens for the wake word on a microcontroller, its 200 KB of INT8 weights held in 1 MB of flash and its 20 MFLOP per inference repeated around the clock under a milliwatt power budget. Once the wake word triggers, an on-device speech front end, an efficient convolutional network sized like MobileNetV2, runs on the phone's neural processing unit, performing 600 MFLOP of work on 3.5 MB of INT8 weights within a 5 W envelope. When the transcribed query reaches the cloud, ranking the retrieved results falls to DLRM, whose 100 GB of embedding tables exceed one H100's 80 GB before any arithmetic begins. Finally, a GPT-2 decoder generates the response on an H100, where every token reads 3 GB of FP16 weights, a memory floor of about 0.9 ms per token that exceeds the compute floor by 295×, assuming graph capture hides dispatch overhead (section 7.3.6). Power, compute, capacity, and bandwidth bind in turn along one request, so an engineer who knows only one layer sees one of those four limits and misses the other three. The introduction's three questions take a different answer at each stage. Wake-word recordings and ranking logs shape the predictions, a different iron-law term

limits each stage's execution, and cohort-level monitoring across devices and users supplies the evidence that the whole request still deserves deployment.

What endures is the method: start from empirical evidence and physical bounds, quantify trade-offs, and treat system design as constrained optimization. This is the engineering corollary of the bitter lesson drawn from seven decades of AI research. Because general methods that scale with computation repeatedly outrun hand-crafted expertise, the durable advantage belongs to systems engineering that can absorb that computation, not to any single clever architecture (Sutton 2019). Frameworks, chips, and architectures will change; measuring against physical limits will not.

The world is rushing to build AI systems. Our task is to engineer them.

Prof. Vijay Janapa Reddi, Harvard University

BACK MATTER

A

The D·A·M Taxonomy

A system that runs slowly rarely announces why. An idle accelerator can stem from a starved input pipeline (Data), an algorithm with too little arithmetic intensity (Algorithm), or a saturated memory bus (Machine). This appendix maps profiler symptoms and measurements to the axis that binds execution, before optimization begins. Readers should arrive with the three axes from the opening chapters and the iron law that quantifies them.

How to Use This Appendix

Use the D·A·M taxonomy when a system misses a performance, cost, or quality target and the cause is not yet clear. Work through the framework in four passes:

1. **State the symptom and operating budget**: Record the missed end-to-end target, workload, and deployment context.
2. **Localize the candidate axis or boundary**: Use table A.2 for a first pass and table A.3 when the evidence crosses axes.
3. **Test the hypothesis**: Map the evidence to the iron law and arithmetic intensity, then gather confirming measurements with table A.5 and table A.6.
4. **Intervene and remeasure**: Choose a lever from table A.7, repeat the end-to-end measurement, and score the result with table A.8. If the target does not improve, revise the hypothesis.

Table A.1 maps each common need to the section that answers it. In every case the axis label is a hypothesis, not a verdict. The axes overlap, and a useful diagnosis may name both a dominant axis and a boundary effect.

Table A.1: Need-to-Section Lookup: Each row names a diagnostic need and the section of this appendix that answers it. Start from the need that matches the observed symptom.

Need	Section
Classify an optimization by the axis it acts on	section A.1
Reason about a technique that spans two or three axes	section A.2
Predict which iron-law term a change shortens	section A.3
Explain why overlapping two stages saved little time	section A.3.2
Decide whether a kernel is compute-bound or bandwidth-bound	section A.4
Narrow a symptom such as low accelerator utilization quickly	section A.5.1
Find the measurement and tool that confirm a hypothesis	section A.5.2
Choose the lever that moves the binding term	section A.5.3
Judge whether a measured system is efficient enough	section A.5.4
Avoid optimizing the wrong axis	section A.6
Follow a complete diagnosis on the reference accelerator	section A.7
Interpret a loss curve that stops improving as data grows	section A.8

A.1 The Three Axes

When a training step stalls or a serving call misses its latency budget, the cause can sit in JPEG decoding on the host, quadratic attention work in the model, or a saturated memory bus on the

accelerator. The taxonomy separates those causes along the three axes of the iron law of ML systems (section 1.7): Data is what the model learns from and what the pipeline must deliver, Algorithm is the computation the model performs, and Machine is the hardware that executes that computation. Table A.2 summarizes the role, primary physical constraint, and core optimization pathway for each axis.

Table A.2: D·A·M Axis Reference: Each axis maps to a constraint class and optimization strategy. Form a hypothesis, confirm it with measurements, then follow the chapter pointer.

Axis	Role	Physical Constraint	High-Leverage Optimization
Data (D)	What the model learns from	Volume, quality, arrival rate	Data Selection (chapter 9)
Algorithm (A)	The computation the model performs	Operations and dependencies	Model Compression (chapter 10)
Machine (M)	The hardware that executes it	Compute, memory, I/O	Hardware Acceleration (chapter 11)

This first-pass separation is useful, but production systems rarely suffer from a single axis-centered bottleneck. More often, the problem sits at the boundary between two axes, as when a data format choice determines whether the accelerator can be saturated or a pruning strategy changes the memory access pattern. Handling these cases requires mapping the intersections.

A.2 Axis Intersections

The conceptual Venn overlaps in figure 1.4 introduce the intersections of machine learning systems; the operational version is a diagnostic triad of Data, Algorithm, and Machine joined by bidirectional coupling (figure A.1). To diagnose a production bottleneck, an engineer first identifies which axis currently binds the workload, then uses the two incident edges to predict how an intervention will change memory, compute, or I/O pressure on the other two axes.

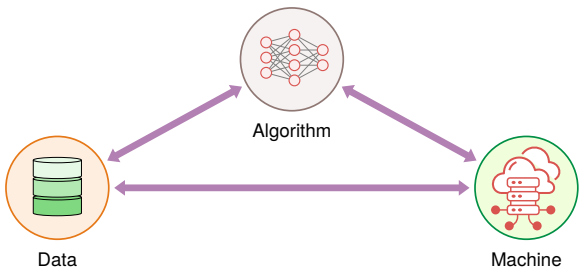


Figure A.1: The D·A·M Axis Triad: A compact diagnostic view of Data, Algorithm, and Machine as three interdependent axes. The bidirectional links emphasize that an intervention on one axis changes the constraints on the other two.

With the first-pass axis identified, the pairwise and three-way intersections expand into concrete engineering techniques and the chapters that teach them (table A.3). In the D·A·M acronym, Data, Algorithm, and Machine name the three diagnostic axes rather than single-letter algebraic variables; formal quantities follow the notation chapter, where D denotes logical dataset size (samples or tokens) and D_{vol} denotes physical data volume moved (bytes).

Table A.3: D·A·M Intersection Reference: Each zone maps specific techniques to the axes they span and the chapters that cover them. The pairwise intersections require reasoning about two domains simultaneously; the center requires all three.

Zone	Name	Key Techniques	Book Coverage
Data	Information	Storage formats, data quality, distributions	chapter 4
Algorithm	Logic	Loss functions, architectures, gradients	chapter 5, chapter 6
Data ∩ Algorithm	What to Learn From	Data selection, curriculum learning, compute-optimal scaling	chapter 9, chapter 8

Zone	Name	Key Techniques	Book Coverage
Data ∩ Machine	How to Move Information	I/O bandwidth, prefetching, data formats	chapter 4, chapter 11
Algorithm ∩ Machine	How to Execute Efficiently	Quantization, pruning, kernel fusion, mixed precision	chapter 7, chapter 10
Machine	Physics	Silicon, memory hierarchy, peak FLOP/s	chapter 11
Data ∩ Algorithm ∩ Machine	ML Systems Engineering	Iron law, Roofline, training loops, serving	chapter 8, chapter 13, chapter 12

In the D·A·M acronym, Data, Algorithm, and Machine name the three diagnostic axes rather than single-letter algebraic variables; formal quantities follow the notation chapter, where D denotes logical dataset size (samples or tokens) and D_{vol} denotes physical data volume moved (bytes). The axis-centered zones contain concepts that belong primarily to one axis: storage formats and distributions emphasize Data, loss functions and gradients emphasize Algorithm, and silicon physics and peak FLOP/s emphasize Machine. Single-domain expertise can introduce them, but deployed behavior may still depend on the other axes.

The pairwise intersections are where systems thinking begins. At Data ∩ Algorithm (*What to Learn From*), data selection, curriculum learning, active learning, and scaling laws (section A.8.1) couple information content to algorithmic capacity, because adding data that the model cannot absorb wastes compute while choosing architectures that outstrip available data wastes engineering time. Whereas that boundary governs statistical efficiency, Data ∩ Machine (*How to Move Information*) governs physical delivery through I/O bandwidth, prefetching strategies, data formats, and the energy-movement invariant, where data gravity manifests because the cost of moving bytes through the memory hierarchy decides whether the machine stays fed. Once data reaches the device, Algorithm ∩ Machine (*How to Execute Efficiently*) links mathematical structure to hardware execution across quantization, pruning, kernel fusion, mixed precision, and computational graph optimization, explaining why a pruning scheme that cuts FLOPs while fragmenting memory access can still run slower on silicon.

The center, Data ∩ Algorithm ∩ Machine, is where all three axes converge. The iron law, the roofline model, end-to-end training loops, serving pipelines, and holistic benchmarking all require simultaneous reasoning about data flow, algorithmic complexity, and hardware utilization. Whereas the intersections classify where a technique operates, isolating which axis actively throttles a workload requires translating these relationships into wall-clock execution time, which is the role of the iron law.

A.3 Iron Law Mapping

For any workload, the iron law connects the D·A·M axes to execution time T (seconds) in two steps. First, at the workload level (equation 1.2), time factors multiplicatively across the three axes:

$$T = \underbrace{\left(\frac{\text{Samples}}{\text{Task}}\right)}_{\text{Data}} \times \underbrace{\left(\frac{\text{FLOPs}}{\text{Sample}}\right)}_{\text{Algorithm}} \times \underbrace{\left(\frac{\text{Seconds}}{\text{FLOP}}\right)}_{\text{Machine}}$$

where the product of the Data and Algorithm factors sets the total arithmetic work $O = (\text{Samples/Task}) \times (\text{FLOPs/Sample})$ in FLOPs. Second, for serialized execution phases (equation 1.3), unpacking how the machine executes those operations maps work across the D·A·M interfaces into three physical time terms, where D_{vol} is bytes moved, BW is bytes per second, R_{peak} is peak throughput in FLOP/s, η_{hw} is dimensionless hardware efficiency, and L_{lat} is fixed overhead in seconds:

$$T = \underbrace{\frac{D_{\text{vol}}}{\text{BW}}}_{\text{Data/Machine}} + \underbrace{\frac{O}{R_{\text{peak}} \cdot \eta_{\text{hw}}}}_{\text{Algorithm/Machine}} + \underbrace{L_{\text{lat}}}_{\text{Cross-axis overhead}}$$

Dividing this serialized decomposition by O (and substituting arithmetic intensity $I = O/D_{\text{vol}}$) expresses the realized Machine factor (Seconds/FLOP) directly in terms of the three physical bottlenecks:

$$\frac{\text{Seconds}}{\text{FLOP}} = \frac{T}{O} = \underbrace{\frac{1}{I \cdot \text{BW}}}_{\text{Memory time per FLOP}} + \underbrace{\frac{1}{R_{\text{peak}} \cdot \eta_{\text{hw}}}}_{\text{Compute time per FLOP}} + \underbrace{\frac{L_{\text{lat}}}{O}}_{\text{Overhead per FLOP}}$$

Algorithm and Machine share the compute term, separated by which variable the engineer controls. Reducing the total operations (O) is a Data or Algorithm lever, while reducing the realized time per operation (Seconds/FLOP) by raising peak throughput (R_{peak}), utilization (η_{hw}), or bandwidth (BW) is a Machine lever. This per-FLOP expression also shows why training and inference occupy different regimes under the same law. In large-batch training, high arithmetic intensity (I) and large operation counts (O) shrink the first and third terms so Seconds/FLOP approaches the compute term (section 8.2); in small-batch or single-token inference, low I and small O per request inflate the memory and overhead terms (chapter 13).

The dominant measured cost appears in one of these terms. A slow system may move too much data (D_{vol}), lack bandwidth (BW), execute too many operations (O), fail to use the hardware's peak capability (η_{hw}), or pay cross-axis overhead (L_{lat}). A workload whose time is dominated by L_{lat} is overhead-bound: kernel launches, dispatch, and synchronization, not bytes or arithmetic, set its pace. The levers below map specific optimizations to the variables they improve.

A.3.1 Component levers

- **Data lever**: Reducing the samples processed per task (Samples/Task, which shrinks O) or the moved bytes (D_{vol}) through deduplication and selection, or increasing I/O bandwidth (BW).
- **Algorithm lever**: Reducing operations per sample (FLOPs/Sample, and thus O) through pruning, distillation, or architectural refinement, or reducing the bytes each weight and activation occupies through lower-precision representation. Quantization is an Algorithm choice that shrinks the Data/Machine term D_{vol} and may raise hardware throughput R_{peak}, lowering Seconds/FLOP without reducing operation count.
- **Machine lever**: Lowering Seconds/FLOP by increasing peak throughput (R_{peak}), memory bandwidth (BW), or the utilization factor (η_{hw}) via kernel fusion and scheduling.

A.3.2 From sum to max

The additive iron law represents sequential execution. Let $T_{\text{sequential}}$ denote time without overlap and $T_{\text{pipelined}}$ denote measured time with overlap. Overlap can move the sum toward a max, but dependencies, contention, and incomplete overlap keep the measured time above this ideal lower bound:

$$T_{\text{sequential}} = \frac{D_{\text{vol}}}{\text{BW}} + \frac{O}{R_{\text{peak}} \cdot \eta_{\text{hw}}} + L_{\text{lat}} \quad \xrightarrow{\text{overlap}} \quad T_{\text{pipelined}} \geq \max\left(\frac{D_{\text{vol}}}{\text{BW}}, \frac{O}{R_{\text{peak}} \cdot \eta_{\text{hw}}}\right) + L_{\text{lat}}$$

Compute should overlap with data movement wherever dependencies allow. Table A.4 summarizes key D·A·M coordination techniques that overlap work across axes.

Table A.4: D·A·M Overlap Techniques: Each technique overlaps work across axes, moving sequentially added Data/Machine and Algorithm/Machine time toward their ideal lower bound: the larger of the two terms. Dependencies and contention limit realized overlap.

Technique	D·A·M Axes Overlapped	Implementation
Prefetching	D overlaps M	DataLoader with `prefetch_factor`, `pin_memory=True`
CUDA Streams	D overlaps M	Separate streams for H2D transfer and compute
Async Gradient Sync	M (communication) overlaps A	Overlap bucketed AllReduce with remaining backward computation
Double Buffering	D overlaps M	Fill buffer N+1 while computing on buffer N

Overlaps provide the greatest relative speedup when the D·A·M time terms are reasonably balanced. If one term dominates (for example, a severely bandwidth-bound kernel), overlapping the smaller term with the larger yields negligible gain, because the max is still set by the same bottleneck. This balance occurs near $D_{\text{vol}}/\text{BW} \approx O/(R_{\text{peak}} \cdot \eta_{\text{hw}})$. The overhead term is treated separately below.

> **Systems Perspective A.1: The overhead that cannot hide**
>
> The unhidden latency term L_{lat} (kernel launch, synchronization barriers, Python dispatch) contains serialization points that cannot be fully overlapped. Kernel fusion can reduce this term by combining operations, but it does not eliminate all launch, scheduling, or synchronization overhead.

The iron law quantifies the time each term consumes. Whether data movement or arithmetic sets the ceiling for a given kernel depends on the ratio of the two, which is arithmetic intensity.

A.4 Arithmetic Intensity Boundary

Doubling an accelerator's peak FLOP/s leaves a kernel no faster if the arithmetic units spend most of each cycle waiting for bytes from memory. The boundary between the Data/Machine memory term and the Algorithm/Machine compute term is set by the arithmetic intensity[1] (I) of the workload. A kernel whose intensity falls below the hardware's ridge point $R_{\text{peak}}/\text{BW}$ is **bandwidth-bound**, the regime the roofline literature calls *memory-bound*; this book keeps the bandwidth name so the regime is not confused with running out of memory capacity. A kernel above the ridge point is compute-bound.

The reference accelerator places the boundary concretely. An H100's dense FP16 ridge point is about 295 FLOP/byte. GPT-2 XL decoding one token at batch one reads all 3 GB of its FP16 weights and reaches an arithmetic intensity of only about 1 FLOP/byte, more than two orders of magnitude below the ridge. With kernel launches captured into a replayable graph (section 7.3.6), the weight read takes about 0.9 ms while the arithmetic needs about 3 µs, so a faster arithmetic unit would leave the per-token time unchanged. Section 11.6 develops the ridge point, hardware balance, and the regimes on either side of it, section D.2.1 carries the worked roofline template, and section 13.9.2 turns the weight read into the decode floor a serving system plans around.

The roofline gives an upper performance bound when traffic and achieved rates are measured consistently. During a production incident, screening heuristics point to the measurements to collect first, which is where diagnosis begins.

[1] **Arithmetic intensity**: This book uses the term for floating-point operations per byte transferred. Williams et al. (2009) calls the measured DRAM quantity *operational intensity* in the Roofline Model. Comparing the workload ratio with the hardware ridge point ($R_{\text{peak}}/\text{BW}$) gives an upper-bound diagnosis of bandwidth- versus compute-bound execution.

A.5 Diagnosing a Bottleneck

When a benchmark or production service misses its target, diagnosis narrows the search in four passes. Fast screening heuristics come first, followed by confirming hardware counters and profiler traces, targeted interventions on the binding term, and a stopping scorecard that decides when to stop optimizing.

A.5.1 Screening rules of thumb

Under incident pressure there is rarely time to solve the full iron law. Quantitative heuristics narrow the search space quickly; the thresholds below are screening signals to check against profiler traces and hardware counters, not conclusions.

- **Low accelerator utilization (< 80 percent)**: Screen for data, CPU, or launch starvation. Confirm with input-pipeline wait, host CPU saturation, memory-bandwidth counters, and trace gaps.
- **High accelerator utilization (> 95 percent)**: Treat this as machine bound only if compute units are busy and memory bandwidth is not saturated. If memory bandwidth is saturated, the bottleneck is still on the Data/Machine boundary.
- **Batch size of one**: Treat this as a warning that launch or dispatch overhead may dominate; confirm with traces before labeling the algorithm itself the bottleneck.
- **Low arithmetic intensity (below ridge point)**: The workload is likely bandwidth-bound (Data/Machine boundary). The precise boundary is $R_{\text{peak}}/\text{BW}$ and depends on hardware and precision.
- **Development-production mismatch**: Treat data drift as one hypothesis alongside configuration, load, dependency, and runtime differences.

Common industry labels cross the axes. Bandwidth-bound execution sits on the Data/Machine boundary because both bytes moved and available bandwidth matter. Compute-bound execution couples Algorithm work with Machine throughput. Overhead-bound execution may reflect algorithmic serial depth, runtime dispatch, synchronization, or queueing. A screened candidate becomes a diagnosis only when a measurement confirms it.

A.5.2 Confirming the hypothesis

Once a screening heuristic flags a suspect axis, the next step is to collect the hardware counter or profiler trace that can confirm or falsify it. Table A.5 maps common production failure modes to candidate axes and the measurements that validate them.

Table A.5: D·A·M Diagnostic Matrix: First hypotheses and measurements for common failures. Confirm the binding component before intervening.

Symptom	Hypothesis	Confirm With	Act After Confirmation
Low Accelerator Utilization	Data/host starvation	Trace gaps; loader, CPU, storage, launch counters	Prefetch, parallelize, or cut launches.
High Latency (p99)	Algorithm/runtime/queue	Phase p99 and queue depth	Optimize the dominant phase.
High Training Cost	Low useful-work efficiency	MFU, communication, idle time	Reduce the largest loss or resize.
High Inter-GPU Overhead	Communication bound	Device trace; collective gaps	Bucket AllReduce; tune data-parallel overlap.
Out-of-Memory (OOM)	Algorithm/Machine fit	Peak weights, states, activations	Checkpoint, shard, quantize, or shrink batch.

Each measurement in the matrix comes from a concrete hardware or runtime counter. Table A.6 connects the D·A·M components to the profiling utilities that expose them (section 8.5 develops the top-down profiling method these tools serve), and once those measurements confirm which term binds, the remaining question is which optimization will move it.

Table A.6: D·A·M Tooling Map: Profiling utilities for diagnosing bottlenecks along each D·A·M axis. Start with the primary tool for quick triage; use secondary tools for deep-dive analysis when the primary tool's output is inconclusive.

Axis	Key Metric	Primary Tool	Secondary Tool
Data	Batch Load and Wait Time	Framework profiler trace	`iostat`, `pidstat` (I/O/CPU)
Algorithm	FLOPs, Model Depth	PyTorch Profiler	DeepSpeed Flops Profiler
Machine	Accelerator Utilization, SM Occupancy	Nsight Compute	`nvidia-smi`, Nsight Systems

A.5.3 Acting on the binding term

Optimizations must target the confirmed binding term. Table A.7 covers the four regimes the book's lighthouse workloads occupy, plus the overhead-bound regime that any of them enters when the fixed latency term dominates. The compute, bandwidth, and overhead rows are named by terms of the iron law. Capacity-bound and power-bound workloads are limited by preconditions the time equation assumes are already met, that the working set fits in memory and that the energy budget can pay for the run, so either can decide feasibility before any time term is evaluated (section 2.3.2). For each regime, the table contrasts the interventions that yield end-to-end gains against those that waste engineering effort.

Table A.7: What Works vs. What Is Wasted: Optimizing a nonbinding term yields little or no end-to-end improvement. A bandwidth-bound language model will not benefit from additional peak FLOP/s alone, though an accelerator with more memory bandwidth may help. Capacity and power limits act before time does, so they are checked first.

Regime	Binding Term	Lighthouse	Optimization That Works	Optimization That Is Wasted
Compute-bound	$O/(R_{\text{peak}} \cdot \eta_{\text{hw}})$	ResNet-50; MobileNetV2; GPT-2 XL training	Better kernels, Tensor Cores, faster accelerator, lower precision	More memory bandwidth (not the binding term)
Bandwidth-bound	D_{vol}/BW	GPT-2 and Llama decode	Quantization; structured pruning; batching for weight reuse; fusion that removes intermediate traffic	Faster accelerator (more FLOP/s will not help)
Overhead-bound	L_{lat}	Any workload served at batch one; small eager kernels	Batch within the latency budget; capture graphs; fuse or dispatch asynchronously; reduce serial depth	More compute or bandwidth unless the trace shows it binding
Capacity-bound	M_{total} vs. M_{device}	DLRM embedding tables	Shard or offload tables; quantize; checkpoint activations; shrink the batch	More FLOP/s or bandwidth before the working set fits
Power-bound	E_{total} per inference vs. budget	Keyword spotting	Integer arithmetic; fewer bytes moved per inference; duty cycling; smaller models	Higher peak FLOP/s that raises power without lowering energy per inference

The lighthouse column names each regime's home workload, and a workload can cross regimes. GPT-2's decode is bandwidth-bound, yet its training is compute-bound (section A.7.3), and ResNet-50, compute-bound in its kernels, becomes input-bound when the data pipeline cannot keep pace (section A.7.1). Section 7.3.4 develops the dispatch overhead behind the overhead-bound row, and section 11.10.3 develops the power envelope behind the last. A repaired system still needs a verdict on whether it is good enough, which is what the scorecard supplies.

A.5.4 Scoring the system

Raw profiler metrics (utilization percentages, FLOP counts, bandwidth measurements) mean little until compared with the workload's targets. The efficiency indicators of the D·A·M scorecard in table A.8 set those targets and show whether a repaired system can stop or must keep investigating. They are screening signals, not universal grades. Model FLOPs utilization (MFU)[2] is especially useful for large-model training.

Table A.8: D·A·M Screening Indicators: Context-dependent signals for investigation, not universal grades.

Axis	Metric	Definition	Investigate	Strong Signal
Data	I/O Overhead	$\frac{\text{Data Wait Time}}{\text{Total Step Time}}$	$> 10\%$ (screen)	$< 1\%$ (strong)
Algorithm	Avoidable Work	Profiler or ablation finds redundant operations	Redundant work found	End-to-end work falls
Machine	MFU	$\frac{\text{Achieved model FLOP/s}}{\text{Peak FLOP/s}}$	$< 30\%$ (large models)	$> 50\%$ (same regime)

The four steps work only when they are followed in order. In practice, teams under deadline pressure skip the confirming step and optimize the wrong axis with confidence, and these failure modes are common enough to deserve their own names.

[2] **MFU**: The ratio of achieved model FLOP/s to the hardware's theoretical peak FLOP/s, introduced in the PaLM paper (Chowdhery et al. 2022). Unlike raw accelerator utilization (which counts any work the accelerator performs), MFU measures model computation rate relative to peak hardware throughput, so non-model work and system overhead are not counted as achieved model FLOPs. Section 8.5 develops MFU as a training diagnostic.

A.6 Anti-Patterns

Before committing to complex kernel optimizations, watch for these common traps that waste engineering cycles. Each anti-pattern arises when a team applies an expensive engineering lever to an axis that does not bind end-to-end execution:

- **The hardware crutch**: Buying faster accelerators (*Machine*) to fix a slow Python data loader (*Data*). The new hardware will just idle faster.
- **The model twiddle**: Changing neural architectures (*Algorithm*) when the bottleneck is actually network bandwidth or disk I/O.
- **The premature optimizer**: Writing custom CUDA kernels (*Machine*) before verifying if the Algorithm is simply doing too many unnecessary operations.

Each anti-pattern follows the same root cause: acting before diagnosing. The case studies that follow show proper diagnosis on the reference accelerator, starting from a confusing symptom and narrowing to the binding term, and the first of them puts a number on the hardware crutch.

A.7 Case Studies on H100

The three cases below run the four-step workflow on an H100, the book's reference accelerator, each with a lighthouse workload in a regime the chapters develop: ResNet-50 starved by its input pipeline, DLRM paying launch overhead at batch one, and GPT-2 XL training against the compute term. In each scenario, an initial utilization reading could easily point to the wrong axis until a second measurement isolates the true bottleneck.

A.7.1 Case 1: The starving accelerator (Data)

A team moves ResNet-50 training from an A100 to an H100 and sees no change in epoch time. A well-tuned A100 sustains about 3,200 images/s, and at the same fraction of its higher peak the H100 would train about 10,100 images/s, yet `nvidia-smi` on the new machine shows utilization oscillating far below that. Screening flags low utilization, and the trace confirms the hypothesis, showing the accelerator idle in gaps while every loader process is saturated decoding JPEGs. With 9 workers each decoding and augmenting about 375 images/s, the pipeline delivers 3,375 images/s regardless of the accelerator, a rate that kept the A100 fully busy while leaving the H100 busy only about 33 percent of the time. Because the upgrade was the hardware crutch, the useful intervention lies upstream of the model: balancing the H100 requires about 28 workers' worth of decode throughput, supplied by adding loader parallelism where host cores allow and by moving decode onto the accelerator, as the supply-and-demand pipeline model in section 8.4.2 develops.

A.7.2 Case 2: The latency cliff (cross-axis)

A recommendation service on an H100 must rank 200 candidate items per request within a 10 ms p99 budget, and it misses badly while accelerator utilization stays low because the serving code scores each candidate with its own DLRM call at batch one. Screening flags the batch size, and a trace confirms an overhead-bound regime: each call issues about 40 kernels at about 15 µs of dispatch and launch apiece, costing 0.6 ms before any device work happens, whereas reading 51.2 KB of embeddings takes only about 15.3 ns at high-bandwidth memory (HBM) bandwidth and the multilayer perceptron (MLP) needs only about 2.1 ns of arithmetic. Because the L_{lat} term exceeds the other two by more than four orders of magnitude, scoring candidates one at a time multiplies that fixed tax to about 120 ms, and a faster accelerator or wider memory bus would shrink only the nanosecond terms. Instead, batching all candidates into one call pays the overhead once to bring the request to about 0.6 ms, while capturing the call as a graph shortens what remains. The cliff runs the other way too: with large tables the same model becomes capacity-bound, the embedding reads grow, and the measurements must be repeated. Section 13.5.1 develops why batching amortizes this fixed cost and where the latency budget stops it.

A.7.3 Case 3: The compute wall (Machine)

A team trains GPT-2 XL on one H100 in TF32. Accelerator utilization is pinned near its maximum, memory-bandwidth counters are unsaturated, and the profiler reports MFU near 50 percent, the

strong-signal end of the scorecard. Because the data path keeps the accelerator fed and the trace shows no dispatch gaps, the compute term binds: whereas GPT-2's home regime in serving is bandwidth-bound decode, training at batch reuses every weight across many tokens and crosses the ridge. The run needs about 1.5 ZFLOP of arithmetic, which at this efficiency takes about 70 days, so only levers on the compute term help while adding loader workers or memory bandwidth changes nothing. Lowering precision from TF32 to BF16 where numerically safe raises the H100's Tensor Core peak by about 2× (Choquette 2023), cutting the run to about 35 days, and data parallelism across the 8 accelerators of one node brings it to about 4 days before communication losses. Section 8.1.1 develops this workload as the training running example, including the memory limits that decide what batch fits.

Taken together, the three cases show why the same utilization number can imply different next steps. Low utilization meant a starved pipeline in the first case and dispatch overhead in the second, while high utilization in the third meant the run was already doing useful work and only the compute term could shrink. The same discipline applies when the question is not how fast the system runs but how much better the model can get.

A.8 Scaling Laws and the Roofline

When a training run's held-out loss flattens despite more GPUs and longer runs, the stall can reflect either a predictable power-law return or a data-quality floor that added compute cannot move. Empirical scaling laws characterize how loss decreases as compute, data, or parameters expand, while roofline bounds identify the physical ceilings imposed by memory bandwidth and arithmetic throughput.

A.8.1 Scaling laws

Scaling laws[3] are empirical power laws that predict how held-out loss changes as resources increase within the fitted regime. Two landmark results are Kaplan scaling (Kaplan et al. 2020), which studied loss against parameter count (P), data (D), and total operations (O), and Chinchilla scaling (Hoffmann et al. 2022), which estimated a compute-optimal balance for the dense autoregressive language-model regime studied, often summarized as roughly 20 training tokens per parameter ($D \approx 20P$). Section C.4.3 derives that balance from a parametric loss surface, so a reader can see where the tokens-per-parameter ratio comes from and which fitted exponents it depends on.

As planning tools, these fits estimate how held-out loss changes with compute inside the observed regime. They do not guarantee a task error-rate reduction or extrapolate unchanged across architectures and data distributions.

A.8.2 The information roofline

When held-out loss flattens below the fitted scaling trend while tokens, parameters, and compute keep growing, adding accelerators or parameters buys no further accuracy. The **information roofline** names this limit that data quality places on what a model can learn, the counterpart to the ceiling the roofline model places on how fast it computes. Because it is a diagnostic label rather than a quantitative law, that flattening pattern tells the team to examine the data before buying more hardware, using four checks to separate the causes: deduplicating the training set and remeasuring tests whether repeated examples inflated the apparent data volume, auditing a sample of labels estimates label noise, comparing per-slice validation loss exposes coverage gaps, and comparing the training and validation distributions detects shift. If loss resumes falling after cleaning or reweighting the data at fixed compute, data quality was binding; if it does not, the cause lies in optimization, model capacity, or evaluation noise, and the scaling-law fit itself should be rechecked.

For classification under a fixed data distribution and loss, the Bayes error rate[4] is an irreducible error floor, not a ceiling. Noise, label ambiguity, coverage gaps, and distribution shift can create data-quality limits above that floor, but they do not define one universal slope or breakpoint.

Adding accelerators or parameters is futile only after measurements establish that data quality is binding. Whether debugging a training step, evaluating hardware utilization, or planning a scaling campaign, measure which axis is binding before choosing a lever.

[3] **Scaling laws**: Empirical relationships, typically power laws with a fitted negative exponent, that predict model loss as a function of dataset size, parameter count, or compute budget. Kaplan et al. (2020) studied these relationships for neural language models at OpenAI; Hoffmann et al. (2022) later estimated the compute-optimal training trade-off for its studied dense language-model regime. Section 9.2.3 develops the compute-optimal frontier and its data-starvation diagnostic in detail.

[4] **Bayes error rate**: The lowest achievable error rate under 0–1 loss for any classifier on a given data distribution, determined by class priors and the overlap between class-conditional distributions (Goodfellow et al. 2016). No amount of data, parameters, or compute can reduce error below this theoretical floor.

Checkpoint A.1: D·A·M diagnosis check

1. A training job shows 95 percent accelerator utilization but loss has plateaued for two epochs. Which D·A·M axes could be responsible, and why is utilization alone insufficient to distinguish them?
2. Your colleague suggests adding more data loader workers to a job where `nvidia-smi` shows 98 percent GPU utilization. What trace evidence is needed before deciding whether this will help?
3. An inference server meets its latency SLO at batch size 1 but fails at batch size 16. Which iron-law terms and queueing effects may have changed, and which measurements identify the binding regime?

A.9 Summary

D·A·M localizes candidate causes across Data, Algorithm, and Machine. The iron law and arithmetic intensity translate those causes into time, operations, and bytes, and the four-step workflow screens, confirms, acts on, and scores them across the four lighthouse regimes, compute-bound, bandwidth-bound, capacity-bound, and power-bound, and the overhead-bound regime that a deployment choice such as batch-one serving can create. The anti-patterns and the H100 case studies show what skipping or following that workflow costs. Scaling laws and the information roofline then separate observed improvement trajectories from data-quality limits. Use the framework as a loop rather than as a label.

Key Takeaways: Where to look first

- Begin with cross-axis hypotheses; a symptom rarely identifies its cause.
- Translate each hypothesis into the relevant iron-law term, or the capacity or power precondition, and a measurement that could falsify it.
- Use arithmetic intensity and the scorecard to identify the binding constraint, not to assign universal grades.
- Apply the corresponding lever and remeasure end to end; a local gain that leaves the binding term unchanged is not a system improvement.

B

Data Foundations

DATA problems rarely present as data problems; they surface as a training run that will not speed up, an accelerator sitting idle, accuracy eroding while dashboards stay green, or an evaluation whose verdict does not survive a second test set. The chapters use the back-of-the-envelope calculations and statistical tools that trace such symptoms back to measurable quantities without deriving them, and this appendix supplies the derivations: transfer times, decode and storage-layout costs, tail probabilities, the sample sizes that make a measured rate trustworthy, and drift divergences. The tools lean on basic probability and on the data term of the iron law.

How to Use This Appendix

This appendix is a reference organized by symptom. Each section states its tool compactly and points to the chapter that teaches the concept and applies it to a lighthouse workload, and table B.1 maps each symptom to the section that carries the tool.

Table B.1: Symptom-to-Section Lookup: Each row pairs a symptom a chapter may name with the tool in this appendix that turns it into a measurement.

When the need is…	Tool	Section
Moving a dataset between sites or regions	Transfer time D_{vol}/BW	section B.1.1
An accelerator starving behind CPU decode	Decode throughput by format	section B.1.2
Reading a few features from wide records	Row versus columnar layout	section B.1.3
A feature pipeline whose cost explodes	Selection, projection, and join costs	section B.1.4
An average that looks fine while users complain	Session-level tail probability	section B.2.1
Deciding whether a measured rate or difference is real	Confidence interval, sample size, McNemar, A/B	section B.2.2
Accuracy drifting silently in production	KL divergence, PSI, KS statistic	section B.2.3
More data that no longer improves the model	Entropy and signal per byte	section B.2.4

The first half of the appendix, Moving and Storing Data, serves the data pipelines in section 4.5. The second half, Probability and Statistics, provides the tests that decide whether a measured number can be trusted for the evaluations in section 12.8.1 and the operational monitoring in section 14.5.2.

B.1 Moving and Storing Data

Before a model can learn from a record, the record must leave storage, cross a network, and be decoded into tensors, and each step costs time. This section collects the reference cost of each step. Chapter 4 develops each of them inside a working pipeline; the numbers here are templates for checking one by hand.

B.1.1 Data gravity

Copying a petabyte of training data across a 1 Gbps wide-area link takes months, whereas shipping the job to the cluster that already holds the data takes minutes. Data gravity[1] names this constraint, which transfer-time arithmetic makes precise, and section 4.9.1 applies it to petabyte-scale training

[1] **Data gravity**: Coined by Dave McCrory in 2010 to describe how large datasets attract services and applications toward them, much as massive bodies attract smaller ones in physics (McCrory 2010).

data. Network bandwidth is finite and does not grow with compute, so moving a large dataset can cost more time and energy than moving computation to where the data already lives.

The ideal line-rate transfer time is $T = D_{\text{vol}}/\text{BW}$ after converting data volume and bandwidth to compatible units (the calculations below convert decimal bytes and bits per second explicitly). For the large volumes here, latency is negligible; section D.3.2 gives the full equation with its latency term. Table B.2 gives lower bounds; protocol overhead and endpoint limits increase them.

Table B.2: The Cost of Inertia: These transfer times explain why we often "ship compute to data" rather than "ship data to compute." Network columns are lower bounds at sustained line rate. The truck entry is an illustrative elapsed-time model for 1 PB: 8 hours to load, 32 hours in transit, and 8 hours to unload, excluding scheduling and provisioning overhead.

Data Volume	1 Gbps (Standard WAN)	10 Gbps (High-End WAN)	100 Gbps (Direct Connect)	Truck (Illustrative)
1 TB	2.2 hours	13.3 minutes	80 seconds	N/A
100 TB	9 days	22.2 hours	2.2 hours	N/A
1 PB	3 months	9 days	22.2 hours	2 days

B.1.2 Serialization cost

[2] **Serialization**: From Latin *serialis* (forming a series). The process of converting in-memory data structures into a byte stream for storage or transmission, and the reverse (*deserialization*). In ML pipelines, the choice of serialization format can dominate end-to-end training time; section 4.10.4 covers pipeline design strategies that minimize this overhead.

Even after data arrives at the machine, it must be decoded before the accelerator can use it.[2] The CPU cost of that decoding can differ by an order of magnitude across formats (table B.3). Parsing text-based formats like JavaScript Object Notation (JSON) or CSV into floating-point numbers is CPU-bound and often leaves the accelerator idle.

Table B.3: Serialization Overhead: These illustrative values show why binary columnar formats can outperform row-based text, but they are not portable benchmarks. Arrow is an in-memory/IPC format; Parquet is a compressed storage format.

Format	Decoding Speed (MB/s)	Relative CPU Decode Cost	Suitability
CSV/JSON	~100 MB/s	High	Inspection/interchange
Protobuf	~300 MB/s	Medium	RPC/Messages
Parquet	~1,000 MB/s	Low	Columnar storage

B.1.3 Row and columnar formats

Decoding speed per byte is only half of the format cost, because the storage layout also decides how many bytes a query must read from disk in the first place. Row-oriented formats such as CSV and JSON store data record-by-record, so reading the `age` field still requires parsing every attribute in each row, a layout that suits append-only logs while penalizing feature filtering. In contrast, Parquet stores compressed column chunks on disk and Arrow provides a contiguous columnar representation in memory and across inter-process communication (IPC), allowing Parquet readers to use *projection pushdown* to fetch only the requested column chunks while both formats feed *vectorized processing*. Where the row layout forces a wide scan across all fields (`ID`, `Age`, `Loc`), the columnar layout isolates the target `Age` chunk and avoids moving irrelevant attributes (figure B.1). Section 4.10.5 develops format choice as a lever on the data term of the iron law.

> **Systems Perspective B.1: The accelerator starvation problem**
>
> The choice of file format often determines whether a training pipeline is I/O bound or compute bound. Row-oriented formats force full-record scans, so storage layout compounds the decode cost whenever models consume a subset of tabular features, and the data-movement term of the iron law can silently become the critical path. Section 4.9.3 develops that starvation condition and the stage that binds it.

B.1.4 The algebra of data

Layout fixes what a scan can skip; the operations a feature pipeline applies decide how much it must read. Feature engineering turns raw records into the columns a model can learn from. A

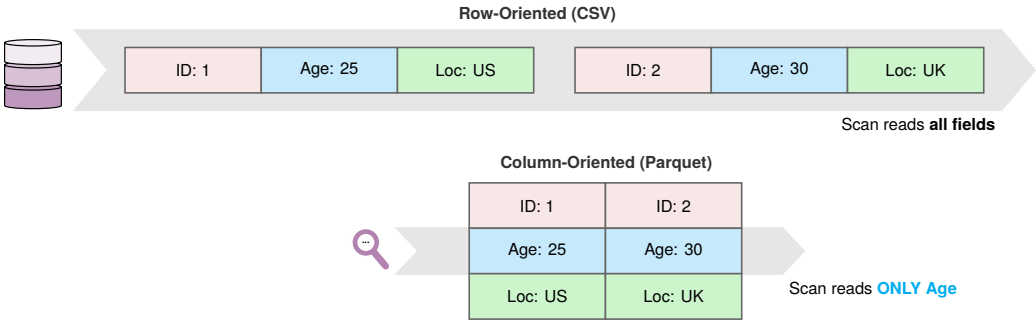

Figure B.1: Storage Layouts: Row-oriented formats group values by record, so the illustrated scan reads every field. Column-oriented formats group values by feature, so the illustrated scan reads only Age.

pipeline first narrows the population, then chooses the features, then attaches context from other tables. Those three moves correspond to three Structured Query Language (SQL) primitives, and their computational cost determines whether the feature job stays local, scans unnecessary bytes, or turns into a network shuffle.

1. **Selection (σ)**: Filtering rows (for example, `WHERE age > 30`).
   - **Cost**: For a table of N rows, $\mathcal{O}(\log N + K)$ if a B-tree index lookup returns K rows; $\mathcal{O}(N)$ for a full scan.
2. **Projection (π)**: Selecting columns (for example, `SELECT age`).
   - **Cost**: Selected chunks plus decoding and metadata in columnar formats. This row-format example reads 1 KB for a 4-byte integer, wasting 99.6 percent of the read.
3. **Join ($\bowtie$)**: Combining tables. Usually the most expensive operation.
   - **Shuffle Join**: Both tables are partitioned by key and exchanged over the network.
     - **Cost**: Reshuffling both 1 TB tables moves ~2 TB; partitioning and locality can reduce this.
   - **Broadcast Join**: One small table is sent to all workers.
     - **Cost**: $s_{\text{table}}(N_{\text{workers}} - 1)$ bytes; the s_{table}-byte table must fit on each of N_{workers} workers.

Section 4.7.4 shows when these costs push feature processing beyond one machine. Formats, serialization, and algebraic primitives determine how efficiently data moves. They say nothing about whether the numbers computed from that data can be trusted, or whether the data has changed character since training. Answering those questions requires probability and statistics.

B.2 Probability and Statistics

A 10 ms mean latency can hide a 63 percent session-level tail-spike rate, a 0.5-point accuracy change on a finite validation set can sit inside binomial noise, and a feature's mean can stay constant while its tails drift enough to degrade predictions. Four statistical tools separate those failures from noise: tail probabilities for multi-request sessions, confidence intervals and paired or online sample-size formulas for finite evaluations, divergence measures for distribution shift, and information-theoretic units for the signal a dataset carries.

B.2.1 Distributions and the long tail

In systems, the mean is often misleading. Latency distributions are often long-tailed, and user-visible services are commonly governed by high-percentile behavior rather than mean response time (Dean and Barroso 2013). A "p99" (99th percentile) latency of 500 ms means at most 1 percent of requests take longer than 500 ms; with many requests per session, the fraction of users who see at least one

slow request can be much higher. At scale (1M users), even a 1 percent affected-user rate would affect 10,000 users.

> **Napkin Math B.1: The median experience**
>
> For $N_{\text{session}} = 100$ independent requests, each with a 0.01 chance of being slow, the probability of at least one p99-tail event is $\Pr(\text{Slow}) = 1 - (0.99)^{100} \approx 1 - 0.366 = 63.4\%$.
>
> **Systems insight**: With independent requests, a 100-request session is more likely than not to include an event beyond p99. Correlated slowdowns can change this probability (Dean and Barroso 2013).

Section 13.4.3 develops tail latency for a serving system, where queuing produces the tail and request fan-out amplifies it. Tail probabilities describe one measured distribution; deciding whether a measured rate is itself trustworthy is a sampling question.

B.2.2 Sampling and estimation

Every accuracy, error rate, and conversion rate in this book is measured on a finite sample, so every one of them carries sampling error. The question that decides a release is whether a measured number, or a measured difference, is larger than that error. Four tools answer it: an interval for one rate, the sample size that makes the interval narrow enough, a paired test for two models scored on the same examples, and the traffic an online A/B test needs. Each reduces to a short formula for the number of labeled examples or user sessions an engineer must collect.

Confidence interval for a rate. A model that classifies a fraction $\hat{p}$ of N independent examples correctly has, by the normal approximation to the binomial, an interval of

$$\hat{p} \pm z_{\alpha/2} \sqrt{\frac{\hat{p}(1-\hat{p})}{N}} \tag{B.1}$$

at the confidence level $z_{\alpha/2}$ encodes (1.96 for 95 percent). ResNet-50 at 76 percent top-1 on the 50,000-image ImageNet validation set is therefore known only to within about 0.4 percentage points. Two models scored on independent samples of that size have a difference interval about $\sqrt{2}$ times wider, because the variances of the two estimates add, roughly 0.5 percentage points, so a smaller accuracy gap between them cannot be resolved that way. Section 12.8.1 applies the interval to benchmark reports and shows why a single accuracy number without one is not a result.

Sample size for a rate. Solving equation B.1 for N gives the number of examples a target half-width requires: the critical value squared, times $\hat{p}(1-\hat{p})$, divided by the square of the half-width. Because the half-width falls only as the square root of the count, halving it quadruples the labeling cost. A keyword spotter expected to detect 98 percent of wake words needs 3,012 labeled one-second clips to pin that rate within 0.5 percentage points (about 50 minutes of audio), and 12,047 clips (3.3 hours) to reach 0.25 percentage points. The count applies to every slice that must be certified separately. Section 15.3.1 multiplies it across demographic subgroups, where a rare group must be oversampled to reach the count at all, and section 9.2.3 needs it to confirm that a curated subset still reaches the target accuracy.

McNemar's test for two models on the same examples. When a baseline and a compressed model are scored on the same examples, the examples both get right or both get wrong say nothing about which is better. Only the discordant counts matter: n_{base} examples that only the baseline gets right and n_{comp} that only the compressed model gets right. The test statistic is

$$\chi^2 = \frac{(n_{\text{base}} - n_{\text{comp}})^2}{n_{\text{base}} + n_{\text{comp}}}, \tag{B.2}$$

and the difference is significant at 95 percent when it exceeds 3.84 (the square of 1.96). Suppose FP32 and INT8 ResNet-50 disagree on the ImageNet validation set as follows, an illustrative split: 300 images only the FP32 model gets right and 250 only the INT8 model gets right. The net loss is 50 images, 0.1 percentage points of accuracy, well inside the unpaired interval above, yet equation B.2 gives $\chi^2 = 4.55$, which exceeds the threshold. Pairing resolves a drop that independent samples

could not, which is why an evaluation harness must keep per-example outcomes rather than only the two accuracies. Section 12.8.1 works through the case in which the same marginal scores leave the verdict open, and chapter 10 produces the INT8 model whose accuracy loss the test checks.

A/B tests. An online comparison of two model versions assigns users at random to a control arm and a treatment arm and compares a rate, such as conversion, between them. With δ_{MDE} the smallest absolute difference worth detecting, σ^2 the per-user variance (the baseline rate times one minus it for a yes-or-no outcome), and z_β the critical value for the chosen power, the users needed per arm are

$$n = \frac{2(z_{\alpha/2} + z_\beta)^2 \sigma^2}{\delta_{\text{MDE}}^2}. \tag{B.3}$$

For a 2 percent relative lift on a 5 percent baseline at 95 percent confidence and 80 percent power, equation B.3 gives the release scenario of section 14.4.3.2 745,644 users per arm. A service that can route 100,000 users per day to each arm needs about 7.5 days to finish one test, and that duration, not compute, sets how often a recommendation model can be released on evidence.

Each of these tools assumes the examples come from one fixed population. When the population itself moves, the question changes from estimating a rate to detecting that the distribution has shifted.

B.2.3 Measuring drift

Comparing means is not enough to catch that shift because a distribution's tails or bin shares can move while its average stays fixed, so comparing the serving distribution (P_t) with the training distribution (P_0) requires a distance measure across the full distribution shape. Section 4.12.1 owns drift detection and its taxonomy, and section 14.5 decides what an alert should trigger; this section collects the three divergence measures they use, with one worked example.

For discrete outcomes x, equation B.4 expresses KL divergence[3] as the expected extra coding cost of approximating P_t with P_0 (Kullback and Leibler 1951; Cover and Thomas 2006). The displayed form is finite only when $P_0(x) > 0$ wherever $P_t(x) > 0$; production implementations therefore need explicit smoothing or zero handling.

$$\mathcal{D}_{\text{KL}}(P_t \| P_0) = \sum_x P_t(x) \log \frac{P_t(x)}{P_0(x)} \tag{B.4}$$

[3] **KL divergence**: Named after Solomon Kullback and Richard Leibler, who introduced it in 1951. Also called *relative entropy*, it quantifies the expected extra information needed to encode samples from one distribution using a code optimized for another; for drift monitoring in this book, the canonical direction is $\mathcal{D}_{\text{KL}}(P_t \| P_0)$. With natural logarithms, as in the example above, the unit is nats; with base-2 logarithms, the unit is bits.

Napkin Math B.2: Worked example: KL divergence for drift detection

Scenario: A keyword-spotting model was trained on audio windows binned by signal-to-noise ratio: 60 percent high, 30 percent medium, and 10 percent low. After the device maker changes the microphone in a new product generation, the windows arriving from the fleet shift to 45 percent high, 40 percent medium, and 15 percent low.

Math:

Training distribution P_0: [0.60, 0.30, 0.10]. Serving distribution P_t: [0.45, 0.40, 0.15].

$$\begin{aligned}\mathcal{D}_{\text{KL}}(P_t \| P_0) &= 0.45 \log \frac{0.45}{0.60} + 0.40 \log \frac{0.40}{0.30} + 0.15 \log \frac{0.15}{0.10} \\ &= 0.45 \times (-0.2877) + 0.40 \times (0.2877) + 0.15 \times (0.4055) \\ &= -0.1295 + 0.1151 + 0.0608 = 0.0464 \text{ nats}\end{aligned}$$

$$\begin{aligned}\mathcal{D}_{\text{KL}}(P_0 \| P_t) &= 0.60 \log \frac{0.60}{0.45} + 0.30 \log \frac{0.30}{0.40} + 0.10 \log \frac{0.10}{0.15} \\ &= 0.60 \times 0.2877 + 0.30 \times (-0.2877) + 0.10 \times (-0.4055) \\ &= 0.1726 + (-0.0863) + (-0.0405) = 0.0458 \text{ nats}\end{aligned}$$

The two directions give different values, $\mathcal{D}_{\text{KL}}(P_0 \| P_t) \neq \mathcal{D}_{\text{KL}}(P_t \| P_0)$. The population stability index (PSI) symmetrizes this by summing the two directions; the calculation below uses natural logarithms:

$$\text{PSI} = \sum (P_{0,i} - P_{t,i}) \log \frac{P_{0,i}}{P_{t,i}} = (0.15)(0.2877) + (-0.10)(-0.2877) + (-0.05)(-0.4055)$$
$$= 0.04315 + 0.02877 + 0.02027 = 0.0922$$

Systems insight: Since PSI = 0.0922 < 0.1, this drift sits just below the conventional warning threshold and well short of the critical threshold of 0.25 used in chapter 14. The right response is to keep the feature on the monitoring dashboard and look for corroborating drift signals rather than retraining from this statistic alone. The statistic is also cheap to collect on an always-on device, which can report three bin counters per interval instead of raw audio, so the check fits the power budget and raw recordings never need to leave the device.

Those PSI thresholds remain illustrative because their meaning depends on sample size, binning, smoothing, and zero handling, and because retraining requires model-quality evidence. Moreover, KL divergence and PSI compare binned or categorical distributions. For a continuous feature, such as the loudness of an audio window, the two-sample Kolmogorov-Smirnov statistic avoids binning altogether: it is the largest gap between the empirical cumulative distribution functions of a training sample and a serving sample,

$$\mathcal{D}_{\text{KS}} = \max_{x_{\text{feat}}} |F_{P_0}(x_{\text{feat}}) - F_{P_t}(x_{\text{feat}})|.$$

Its critical value shrinks with the square root of the sample sizes, so a large serving sample flags even a tiny shift as significant; whether that shift matters is a separate question. Section 4.5.3 works the test through with its critical value. All three measures rest on information theory, which supplies their units.

B.2.4 Information theory for systems

A training run can consume more examples, run longer, and still stop improving if the added data carries too little useful signal. At that point the limit is the information the data pipeline delivers to the learner, not compute or bandwidth. Section A.8.2 treats that data quality limit as a diagnostic constraint, and information theory provides the units for reasoning about it.

- **Entropy (H)**:[4] The average uncertainty in a distribution, defined as $H(X) = -\sum p(x) \log p(x)$. The log base sets the unit: natural logs give nats, while $\log_2$ gives bits. A uniform distribution has maximum entropy only over a fixed finite support. This connects directly to KL divergence above: $\mathcal{D}_{\text{KL}}$ measures the excess coding cost of using the wrong distribution.
- **Information density**: Used here as a book-level heuristic for useful learning signal per unit of storage, not as a standard information-theory quantity.
- **Signal-to-noise ratio (SNR)**: The ratio of signal power to noise power. In ML, the book uses low SNR qualitatively for data in which task-relevant structure is weak relative to noise; adding compute cannot compensate for missing task-relevant signal.

[4] **Entropy**: Shannon adopted the term in 1948 to quantify information content (Shannon 1948). In systems terms, Shannon entropy is a lower bound on average lossless code length. Practical prefix codes approach it, and block codes can approach it asymptotically. These bounds inform compression ratios and data-pipeline sizing.

B.3 Summary

When a data symptom appears, find its row in table B.1 and compute the number. Each section points back to the chapter that teaches the tool, where the lighthouse workloads show it deciding a design.

C

Algorithm Foundations

A profile showing low utilization is often misdiagnosed as a hardware limit when the cause is algorithmic: a matrix multiply shape that wastes Tensor Cores, a layout that breaks contiguity, or activation memory held for backpropagation. This appendix collects the computational complexity models, memory footprint derivations, numerical-stability rules, and proofs that the book's performance chapters lean on, enabling readers to evaluate algorithmic trade-offs before committing code to accelerators. It assumes familiarity with linear algebra and with the iron law introduced early in the book.

How to Use This Appendix

This appendix is designed as a reference. Reach for it when translating a profiler symptom ("slow matmul," "shape mismatch," "OOM during training") into a concrete computational or memory cause. Each symptom or need maps to one section (table C.1), and conventions throughout follow the book-wide notation (for example, B is reserved for batch size and BW denotes bandwidth). Every section names the chapter that teaches its concept in context; the chapter carries the argument, and this appendix carries the derivation or the reference formula.

Table C.1: Where to Look: Each row pairs a profiler symptom or a design question with the section that carries its derivation or reference formula.

Symptom or need	Section
A general matrix multiply (GEMM) runs far below peak throughput	section C.1.3
Sparsity is proposed to save memory or compute	section C.1.4

Neural networks turn linear algebra into learned behavior. Matrices transform activations, tensor layouts determine how data move through memory, and backpropagation carries error signals through the resulting computation. These foundations support the deep learning treatment in chapter 5, the framework internals in chapter 7, and the training strategies in chapter 8.

C.1 Linear Algebra

Shrinking a square matrix multiply from dimension 4,096 to 64 drops its arithmetic intensity more than tenfold below an H100's ridge point, turning a compute-bound layer into a bandwidth-bound

stall without changing a line of model logic. Most of the compute in a deep learning system is matrix multiplication, and although frameworks such as PyTorch hide the raw math, performance engineering still depends on the underlying linear algebra. Building on how numbers are stored in section D.4, this section focuses on how they are manipulated.

> **Systems Perspective C.1: Why this matters**
>
> Many dense neural networks, especially transformers and large convolutional neural networks, spend most of their compute in matrix multiplication or GEMM-like kernels: a self-attention block executes query, key, value, and output projection GEMMs alongside two attention-matrix products for scores and weighted values, and the layer's feed-forward block adds two or three more. Because those kernels dominate execution, GEMM performance characteristics explain why batch size governs throughput, why aligned layer dimensions run faster than unaligned ones, and whether a dense workload will be compute bound or bandwidth bound before any profiler trace runs.

C.1.1 Tensor operations and einsum notation

Tensor operations in deep learning contract across batch, head, sequence, and hidden dimensions at once, and Einstein summation[1] notation writes those contractions as a single index string rather than a chain of nested loops and transposes (implemented as `torch.einsum` in PyTorch and `np.einsum` in NumPy). Matrix multiplication $\mathbf{C} = \mathbf{AB}$ becomes:

$$C_{ij} = \sum_k A_{ik} B_{kj}$$

In einsum notation, this is `ik,kj->ij`. The same notation handles batched multi-head attention, `bhid,bhjd->bhij` (batch b, head h, query sequence i, key sequence j, and head dimension d). The head dimension d appears in both inputs but not in the output, so it is the index that is summed.

[1] **Einstein summation convention**: Repeated indices in a product are implicitly summed over, eliminating explicit summation signs. ML frameworks adopted the convention because it concisely expresses arbitrary tensor contractions in a single string.

C.1.2 The dot product as similarity

Comparing two token embeddings or feature vectors requires a scalar score that grows when the vectors point in the same direction and shrinks when they are orthogonal. The dot product $\mathbf{a} \cdot \mathbf{b} = \sum a_i v_i$ provides that score because it equals $\|\mathbf{a}\|\|\mathbf{b}\| \cos\phi$: for nonzero vectors, its sign distinguishes acute, right, and obtuse angles, while its magnitude also depends on both vector norms.

In attention mechanisms, query (**Q**) and key (**K**) vectors are dot-produced to compute a similarity score that determines how much each token attends to every other token. The resulting attention weights are then used to form a weighted combination of value (**V**) vectors, so every token can draw on every other token. Section 6.6 develops attention itself, including the cost of computing one score for every query-key pair.

C.1.3 General matrix multiply (GEMM)

Whether a dense layer saturates an accelerator's Tensor Cores or stalls on memory bandwidth depends on the three dimensions of its matrix multiply. Most training and inference FLOPs execute as general matrix multiplies (GEMMs):[2] for matrices of size $M \times K$ and $K \times N$, a GEMM performs $2MNK$ floating-point operations (counting multiply-accumulate as two operations).

The arithmetic intensity of GEMM scales linearly with matrix dimension. For square $N \times N$ matrices in FP16 (2 bytes/element), the ideal $\beta = 0$ bound reads **A** and **B** once and writes **C** once:

$$\text{Intensity} = \frac{O}{D_{\text{vol}}} = \frac{2N^3}{3N^2 \times 2} = \frac{N}{3} \text{ FLOP/byte}$$

Reading the old **C** when $\beta \neq 0$ changes the intensity to $N/4$ FLOP/byte. Three consequences follow for GEMM execution:

- **Larger batches can improve efficiency**: Batching increases effective matrix dimensions when it forms larger GEMMs or enables reuse; merely queuing independent small GEMMs does not raise intensity.

[2] **General matrix multiply (GEMM)**: The BLAS (Basic Linear Algebra Subprograms) family began with vector routines standardized in 1979 (Lawson et al. 1979); GEMM was standardized later as a Level 3 routine (Dongarra et al. 1988). The "GE" prefix stands for "general," as opposed to symmetric or triangular forms. GEMM computes $\mathbf{C} = \alpha\mathbf{AB} + \beta\mathbf{C}$ and is a performance-critical routine in deep learning. Section 8.3.1.1 explains how GEMM shapes determine training throughput.

- **Aligned dimensions help**: Hardware Tensor Cores are optimized for precision- and architecture-specific tile multiples. Dimensions that align with these multiples avoid padding overhead and improve kernel efficiency, but they do not need to be powers of two.
- **Small matrices are inefficient**: A square GEMM with $N = 64$ has intensity $64/3 \approx 21.3$ FLOP/byte, well below the ridge point of the book's reference accelerator, the H100 (295.2 FLOP/byte). Its roofline cap is ~7.2 percent of peak; launch and tiling overhead can lower realized throughput. Section 11.6 derives the ridge point and the compute-bound and bandwidth-bound regimes on either side of it, which is the comparison each of these consequences relies on.

C.1.4 Sparse matrix formats

When most elements in a matrix are zero, specialized storage formats avoid wasting memory on zeros and enable computations that skip them entirely. The **compressed sparse row (CSR)** format uses three arrays:

- `Values`: The nonzero elements, stored in row order
- `Col_Idx`: The column index of each nonzero element
- `Row_Ptr`: The starting position in `Values` for each row (length = num_rows + 1)

CSR is useful for sparse feature matrices in recommendation pipelines and for pruned model weights. For a matrix with n_{elem} elements, n_{rows} rows, and n_{nz} nonzeros, CSR uses $\mathcal{O}(n_{\text{nz}} + n_{\text{rows}})$ storage instead of $\mathcal{O}(n_{\text{elem}})$; when n_{nz} is large relative to n_{rows}, this is often summarized as $\mathcal{O}(n_{\text{nz}})$.

To see the trade-off concretely, consider a vocabulary embedding matrix with 100,000 rows and 10,000 columns (1B parameters):

- **Dense (FP32)**: 1B parameters $\times$ 4 bytes each = 4 GB.
- **Sparse** (1 percent density): CSR stores roughly 10M entries $\times$ (4-byte value + 4-byte column index), plus one row pointer per row and a final pointer, totaling $\approx$ 80.4 MB.
- **Result**: A 50$\times$ reduction in memory footprint, fitting a model that would otherwise trigger an out-of-memory (OOM) error.

The saving holds only at low density. Each stored nonzero carries its index, so at high density CSR occupies more memory than the dense tensor it replaces. Section 10.4.2.2 finds that break-even density for pruned weights, and section 11.4.5.3 shows the fixed pattern of two nonzeros in every four that an accelerator datapath decodes without a general index.

C.1.5 Operation cost reference

Each common layer type reduces to the GEMMs and elementwise operations above, so its parameter count and forward-pass FLOPs follow from its shapes (table C.2). Given layer dimensions and input shapes, the formulas give first-order estimates of model size and compute before hardware is provisioned. The attention row is the one to watch. Sequence length contributes an S^2 term, while hidden dimension contributes d^2 projection work, so long-context models can shift the dominant cost without changing the parameter count.

Table C.2: Deep Learning Tensor Primitives: Summary of shapes, parameters, and FLOP counts. Note: B is batch size, S is sequence length, and K is kernel size. The attention FLOPs include QKV projections and score interactions. The S^2 term applies to full-sequence training and prefill, while KV-cached generation is linear per token in cached context; d^2 projection work dominates at large hidden dimensions.

Layer type	Output shape	Parameters (P)	FLOPs (per forward pass)
Linear	(B, d_{out})	$d_{\text{in}} \times d_{\text{out}} + d_{\text{out}}$ if bias is enabled	$2 \times B \times d_{\text{in}} \times d_{\text{out}}$
Conv2D	$(B, d_{\text{out}}, H_{\text{out}}, W_{\text{out}})$	$K^2 \times d_{\text{in}} \times d_{\text{out}} + d_{\text{out}}$ if bias is enabled	$2 \times B \times H_{\text{out}} \times W_{\text{out}} \times K^2 \times d_{\text{in}} \times d_{\text{out}}$
Multi-head self-attention	(B, S, d)	$4 \times d^2$, plus $4 \times d$ if projection biases are enabled	$B \times (4S^2d + 8Sd^2)$
LayerNorm	(B, S, d)	$2 \times d$ if affine scale and bias are enabled	$\mathcal{O}(B \times S \times d)$

The formulas in table C.2 specify *what* each layer computes and how many operations it performs. Expressing those computations in code raises a second question: how frameworks represent multidimensional arrays in flat memory without copying data unnecessarily.

C.2 Tensor Programming Primitives

A shape mismatch crash, a silently wrong broadcast, and a kernel running at 5 percent of peak because of a noncontiguous tensor are common ML engineering failures, and all three trace back to the same layer of abstraction. *Tensor programming* translates the abstract math of linear algebra into concrete array manipulations that run on hardware.

C.2.1 Shapes, strides, and memory layout

Frameworks represent a tensor as a view over a flat storage buffer, described by shape, stride, dtype, and offset metadata rather than as a multidimensional array of pointers. Its shape specifies the logical dimensions of the tensor (for example, `(3, 4)`), while its stride defines how many elements to skip in storage to advance one step along each dimension, which means only contiguous tensors store their logical elements in a single adjacent block.

Operations like `transpose()` or `view()` often just change the strides, not the data in memory. This is fast ($\mathcal{O}(1)$) but can lead to noncontiguous tensors that fail in kernels requiring contiguous data. In such cases, calling `contiguous()` on a tensor of N elements forces an $\mathcal{O}(N)$ memory copy that can dominate runtime if triggered repeatedly inside a loop.

The order of the strides is the tensor's memory layout. Row-major and column-major layouts of the same matrix differ only in which dimension has stride 1, and that choice directly affects cache efficiency: iterating along the stride-1 dimension touches contiguous memory locations, which is dramatically faster than strided access.

A common optimization pattern is to materialize a transposed tensor once before repeated operations to ensure contiguous access in the hot loop. The one-time copy cost is amortized across many subsequent operations. Section 7.5.1.2 introduces strides and layouts in the framework that manages them, and section 11.7.6 shows how the layout choice (channels-last versus channels-first) changes accelerator throughput for convolutions.

C.2.2 Broadcasting

Zero-copy stride manipulation also powers **broadcasting**, the rule that lets arithmetic operators combine tensors of different shapes without materializing duplicate copies of the smaller input. Frameworks compare dimensions from right to left and treat two dimensions as compatible when they are equal or when one of them is 1; a singleton dimension is then stretched virtually by setting its stride to zero, though an unintended singleton alignment, such as adding a $(B, 1)$ column vector of predictions to a $(B,)$ row vector of targets, silently allocates a (B, B) output matrix that can exhaust memory or corrupt a loss calculation.

Adding a $(3, 1)$ column tensor (**A**) to a $(1, 4)$ row tensor (**B**) expands both virtually across their complementary singleton dimensions and generates a $(3, 4)$ matrix of pairwise sums $A_i + b_j$ (figure C.1). Dashed cell boundaries mark result elements whose operands are read through stride-0 views, so neither input is copied; only the $(3, 4)$ output is allocated, and hardware repeatedly accesses identical input buffer addresses.

Consider a concrete case: tensor A has shape `(32, 1, 64)` and tensor B has shape `(1, 128, 64)`. Comparing dimensions right to left, 64 matches 64, then 1 stretches to 128, then 1 stretches to 32, yielding result shape `(32, 128, 64)`. Writing out the expanded shape before running catches silent logic bugs that accidentally allocate a large tensor (for example, a `(Batch, Batch)` matrix instead of an element-wise `(Batch)` vector).

Shapes, strides, and broadcasting govern how tensors flow through a model's forward pass. Training adds a second requirement, computing how much each parameter contributed to the error. Backpropagation meets that requirement and imposes the memory costs quantified in the training-memory decomposition below.

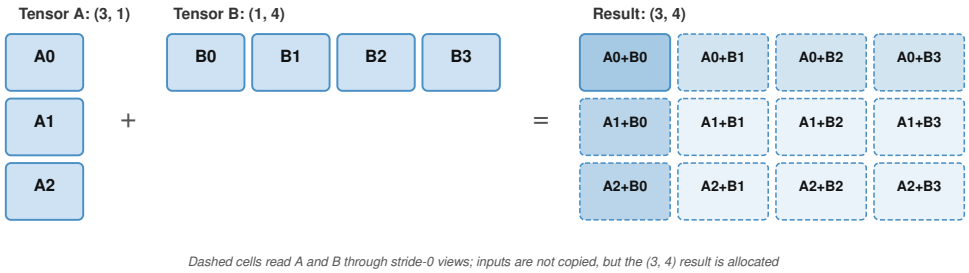

Figure C.1: Tensor Broadcasting Rules: A (3,1) column and a (1,4) row broadcast across complementary dimensions, producing the pairwise sums in a (3,4) result.

C.3 Mechanics of Learning

Training a neural network takes roughly three times the compute of a forward pass and holds gigabytes of intermediate activations in memory until the backward sweep consumes them. This section traces how the chain rule and reverse-mode automatic differentiation create that compute and memory footprint, how compilers fuse the resulting computational graph, and how the log-sum-exp shift prevents the softmax at the loss from overflowing in reduced precision.

> **Systems Perspective C.2: Why this matters**
>
> When training fails (loss goes to NaN, gradients explode, or memory runs out), understanding what backpropagation actually does is essential for diagnosing the problem. The backward graph supplies the mental model for reasoning about gradient flow and memory usage during training.

C.3.1 The chain rule and automatic differentiation

For a composed function $y = f(g(x))$, the derivative is $\frac{dy}{dx} = \frac{dy}{dg} \cdot \frac{dg}{dx}$. In a neural network, f and g are layers, and the composition can be many levels deep. For a three-layer network $y = f_3(f_2(f_1(x)))$, the chain rule extends to:

$$\frac{\partial y}{\partial x} = \frac{\partial f_3}{\partial f_2} \cdot \frac{\partial f_2}{\partial f_1} \cdot \frac{\partial f_1}{\partial x}$$

Each factor in this product is a local derivative, computed at one layer using only that layer's inputs and outputs. This locality keeps the bookkeeping cheap: the entire network never needs to be differentiated as a monolithic function. Instead, each layer computes its own local derivative during the backward pass and multiplies it by the gradient flowing in from the layer above.

Modern frameworks use reverse-mode automatic differentiation, which computes gradients for all P parameters in a single backward pass. Starting from the output and working backward (reverse mode) requires one pass regardless of the number of parameters, whereas starting from each input and working forward (forward mode) would require P passes, one per parameter. This is why a training step is a small constant multiple of inference, commonly about 2–3× a forward pass for dense networks, rather than P passes. Section 7.4.1 shows how frameworks implement both modes and why training uses reverse mode.

C.3.2 The backpropagation algorithm

Backpropagation[3] implements the chain rule efficiently through two passes: forward to compute outputs, backward to compute gradients. The gradient edges retrace forward dependencies, meaning each backward step requires intermediate activations retained from the corresponding forward operation. Figure C.2 traces these dual dataflow passes across a two-layer network: solid gray arrows stage forward activations ($\mathbf{x} \to \mathbf{h} \to \hat{\mathbf{y}}$) through weight parameters $\mathbf{W}_1$ and $\mathbf{W}_2$ to evaluate loss $\mathcal{L}$, while curved dashed red arrows propagate intermediate adjoints ($\frac{\partial \mathcal{L}}{\partial \hat{\mathbf{y}}}, \frac{\partial \mathcal{L}}{\partial \mathbf{h}}, \frac{\partial \mathcal{L}}{\partial \mathbf{x}}$) in reverse order.

[3] **Backpropagation**: Short for "backward propagation of errors." The algorithm was independently discovered multiple times, by Werbos (1974) and Linnainmaa (1970) for reverse-mode differentiation and by Rumelhart et al. (1986) for neural network training. Its key insight is that computing gradients for all parameters requires one backward pass through the graph rather than one pass per parameter. Section C.4.1 derives the constant-factor work bound and a representative dense-layer cost.

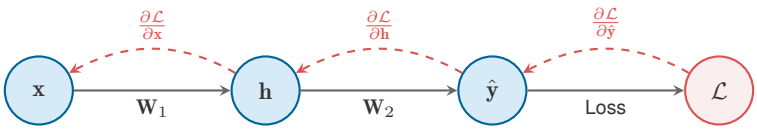

Figure C.2: Backpropagation Computational Graph: Solid gray arrows carry the forward computation from input $\mathbf{x}$ to loss $\mathcal{L}$, while dashed red arrows carry gradients backward along the same dependencies.

Forward pass

Using row-vector activations, omitting biases, and retaining intermediate activations for backward execution, computation begins at input $\mathbf{x}$. Multiplying $\mathbf{x}$ by weight matrix $\mathbf{W}_1$ yields hidden activation $\mathbf{h}$, which the execution runtime caches for backward differentiation. Multiplying $\mathbf{h}$ by $\mathbf{W}_2$ produces network output $\hat{\mathbf{y}}$, which is similarly cached. Finally, comparing $\hat{\mathbf{y}}$ to the target label produces scalar loss $\mathcal{L}$.

At this point, forward evaluation is complete, and memory holds input $\mathbf{x}$, cached activation $\mathbf{h}$, cached prediction $\hat{\mathbf{y}}$, and loss $\mathcal{L}$. For large models, these retained activation tensors frequently dominate overall memory consumption.

Backward pass

Gradient propagation begins backward from scalar loss $\mathcal{L}$. The loss function evaluates $\frac{\partial \mathcal{L}}{\partial \hat{\mathbf{y}}}$, the error gradient with respect to the network prediction, which starts the backward pass.

Because $\hat{\mathbf{y}} = \mathbf{h} \cdot \mathbf{W}_2$, the matrix chain rule yields two gradients at this layer:

$$\frac{\partial \mathcal{L}}{\partial \mathbf{W}_2} = \mathbf{h}^T \cdot \frac{\partial \mathcal{L}}{\partial \hat{\mathbf{y}}} \qquad \text{(weight gradient—used to update } \mathbf{W}_2\text{)}$$

$$\frac{\partial \mathcal{L}}{\partial \mathbf{h}} = \frac{\partial \mathcal{L}}{\partial \hat{\mathbf{y}}} \cdot \mathbf{W}_2^T \qquad \text{(input gradient—passed backward to the previous layer)}$$

Computing $\frac{\partial \mathcal{L}}{\partial \mathbf{W}_2}$ requires cached activation $\mathbf{h}$ from the forward pass. Activations must remain resident in memory because every layer's weight gradient depends directly on that layer's input.

Continuing backward to the first layer, the linear relationship $\mathbf{h} = \mathbf{x} \cdot \mathbf{W}_1$ produces:

$$\frac{\partial \mathcal{L}}{\partial \mathbf{W}_1} = \mathbf{x}^T \cdot \frac{\partial \mathcal{L}}{\partial \mathbf{h}}$$

Each backward step requires two operands: the gradient flowing in from downstream layers $\left(\frac{\partial \mathcal{L}}{\partial \mathbf{h}}\right)$ and that layer's cached input ($\mathbf{x}$). Consequently, the backward pass requires roughly $2\times$ the forward pass FLOPs: each layer executes two matrix multiplications (one for the parameter gradient, one for the upstream activation gradient) rather than one. Section 5.4.5 teaches the algorithm step by step on a running network. The cached inputs that every backward step needs are the reason training memory exceeds model size, which the next section quantifies.

C.3.3 Training memory

Because the backward pass holds those intermediate activations alongside weights, gradients, and optimizer buffers, training memory is the sum of four components rather than model size alone:

$$M_{\text{total}} = M_{\text{weights}} + M_{\text{gradients}} + M_{\text{optimizer}} + M_{\text{activations}}$$

For a standard Adaptive Moment Estimation (Adam) optimizer (Kingma and Ba 2015) in mixed precision (Micikevicius et al. 2018):

- **Weights**: 2 bytes (FP16/BF16) or 4 bytes (FP32).
- **Gradients**: Same size as weights.
- **Optimizer State**: Adam moments require 8 bytes per parameter; an FP32 master copy adds another 4 bytes, giving 8–12 bytes per parameter.

- **Activations**: Activations typically dominate the dynamic memory footprint during training. A recomputation- or tiled-attention-friendly estimate scales as $\mathcal{O}(B \times S \times N_L \times d)$; a full no-recompute attention implementation also materializes attention-score tensors that scale with S^2.

To see how these four components interact on a single accelerator, consider a concrete language model. Once the static model state is allocated, the remaining device capacity sets a hard ceiling on the batch size that can run without recomputation.

Napkin Math C.1: Worked example: GPT-2 (1.5B) training memory

The model: GPT-2 XL has $P = 1.5 \times 10^9$ parameters, 48 layers, hidden dimension $d = 1600$.
Model state (fixed per step):

- **Weights (BF16)**: $1.5 \times 10^9 \times 2$ bytes = 3 GB
- **Gradients (BF16)**: $1.5 \times 10^9 \times 2$ bytes = 3 GB
- **Optimizer (FP32 master + momentum + variance)**: $1.5 \times 10^9 \times 12$ bytes = 18 GB
- **Total model state**: 24 GB, which fits on an 80 GB-class H100 (85.9 GB in decimal units) but leaves only 61.9 GB for activations.

Activations (scale with batch):
Per-layer retained activations for this quick estimate are approximately $12 \times B \times S \times d$ BF16 elements, or $12 \times B \times S \times d \times 2$ bytes, where B is batch size and S is sequence length. The factor twelve accounts for the major intermediate tensors retained for backpropagation: input activations, QKV projections ($3d$), attention output, FFN intermediate ($4d$), and layer norm/dropout masks. This estimate assumes the implementation does not retain the full $B \times N_{\text{heads}} \times S^2$ attention-score tensor, as in recomputation- or tiled-attention-friendly accounting. With 48 layers, batch size 8, and sequence length 1024:

$$48 \times 12 \times 8 \times 1024 \times 1600 \times 2 \text{ bytes} \approx 15.1 \text{ GB}$$

Systems insight: Total memory reaches ~39.1 GB under this activation-accounting convention, which fits on one 85.9 GB accelerator. Each additional sample adds ~1.9 GB of activations, so under this quick estimate the remaining capacity fills near batch 32; at batch 64, activations grow to ~120.8 GB, well beyond it. The estimate omits smaller retained tensors such as dropout masks and softmax inputs. The full per-layer count of 34 bytes per token per hidden unit (Korthikanti et al. 2023) fills the same room near batch 23, the limit section 8.6.6 works from. That crossover is the threshold where gradient checkpointing or another memory-saving method becomes necessary; its savings and recomputation overhead depend on checkpoint placement and implementation.

C.3.3.1 Activation explosion

While weights are fixed ($\mathcal{O}(P)$), activations grow linearly with batch size and at least linearly with sequence length; implementations that materialize attention scores add an $\mathcal{O}(S^2)$ component. As the worked example above shows, activation memory can quickly exceed the room left after model state. Gradient checkpointing[4] reduces this pressure by storing only selected activations and recomputing the rest during backpropagation (T. Chen et al. 2016), and FlashAttention removes the quadratic term by tiling attention (Dao et al. 2022). The same decomposition provides a quick feasibility check: sum the per-parameter model state, add the activation term implied by batch size and sequence length, and compare the total against the accelerator's capacity. Section 8.3.2 applies the model-state terms to optimizer choice, and section 8.3.3 develops the activation term, with section 8.6.5.1 teaching the recomputation trade-off for the training loop.

[4] **Gradient checkpointing**: Trades compute for memory. Instead of storing all activations, only a subset (checkpoints) is kept, and the missing ones are recomputed during the backward pass. This reduces memory usage from storing every layer activation to roughly the square root of the layer count at the cost of ~33 percent more compute (T. Chen et al. 2016).

C.3.4 Computational graphs and optimization

The dependency structure exposed by backpropagation also gives compilers something to optimize. ML compilers represent models as directed acyclic graphs (DAGs), and that representation enables hardware-independent transformations.

C.3.4.1 Static single assignment

To transform a DAG safely, a compiler must know which write each read depends on. Static single-assignment (SSA) form makes those dependencies explicit by assigning each variable exactly once rather than overwriting tensor variables in place, enabling safe transformations such as operator fusion.

C.3.4.2 Operator fusion

Without fusion, each operation in a chain like `MatMul` → `Add (bias)` → `ReLU` produces an intermediate tensor that is written to high-bandwidth memory (HBM) and then read back for the next operation. For elementwise operations like `Add` and `ReLU`, the compute is trivial (one FLOP per element) but the memory traffic is not (read the tensor, write it back). The arithmetic intensity of unfused elementwise operations is therefore close to zero, which makes them strongly memory bound.

Fusion combines consecutive operations into a single kernel that reads the input once, applies all operations in registers or shared memory, and writes the final result once. For a sequence of n_{ops} elementwise operations on a tensor of N elements of s_{elem} bytes each, fusion reduces memory traffic from $2n_{\text{ops}}Ns_{\text{elem}}$ bytes (each operation reads and writes) to $2Ns_{\text{elem}}$ bytes (one read, one write), a $n_{\text{ops}}\times$ reduction. Section 7.3.2 develops fusion as a framework decision, and section 11.7.7 shows the accelerator-side limits on how much a single kernel can fuse.

FlashAttention is fusion applied to attention: it computes the score, softmax, and value-product stages in SRAM tiles without materializing the full attention matrix in HBM, reducing auxiliary attention memory from $\mathcal{O}(S^2)$ to $\mathcal{O}(S)$ for a fixed head dimension (Dao et al. 2022). Section C.4.2 derives the traffic bound step by step, and section 8.6.4 applies the algorithm to training.

Fused and tiled kernels keep results exact while moving fewer bytes. The softmax at the end of the forward pass raises a different question, whether its results stay finite at all.

C.3.5 Logits and numerical stability

A classifier's forward pass ends in a softmax over the final layer's outputs, and the cross-entropy loss is computed from that softmax. The softmax exponentiates those outputs, and the exponential of a large output exceeds the range of every reduced-precision format, so the softmax is a common overflow site in reduced-precision training.

Neural-network classifiers commonly output a vector of *logits*[5] $\mathbf{z}$ (unnormalized scores). For class index j, softmax normalizes z_j over all class indices k to produce a probability:

$$\text{Softmax}(z_j) = \frac{e^{z_j}}{\sum_k e^{z_k}}$$

The problem is that if z_j is large (for example, 100), the exponential e^{z_j} overflows common training and inference formats such as FP32, BF16, and FP16. FP64 can represent this specific value, but production ML kernels rarely use FP64 for softmax. The fix is to subtract the largest logit before exponentiating, the log-sum-exp trick. The shift leaves the result mathematically unchanged and keeps every exponent at or below zero, as the worked example below illustrates for realistic logit values.[6]

> Napkin Math C.2: Log-sum-exp in action
>
> **Setup**: A three-class classifier outputs logits $\mathbf{z} = [100, 101, 102]$.
> **Without the trick (naive softmax)**:
>
> $$\exp(100) \approx 2.7 \times 10^{43}, \exp(101) \approx 7.3 \times 10^{43}, \exp(102) \approx 2.0 \times 10^{44}$$

[5] **Logit**: Joseph Berkson coined the term in 1944 by analogy with *probit*. The logit function is the inverse of the logistic (sigmoid) function: $\text{logit}(p_{\text{sig}}) = \log(p_{\text{sig}}/(1 - p_{\text{sig}}))$. In deep learning, "logits" refers more loosely to the raw, unnormalized output of the final linear layer before any activation function is applied.

[6] **Log-sum-exp**: Implemented as `torch.logsumexp` in PyTorch and `scipy.special.logsumexp` in SciPy. It relies on the identity $\log(\sum e^{z_k}) = m + \log(\sum e^{z_k - m})$, where $m = \max(z_k)$. Shifted values $z_k - m$ are ≤ 0, ensuring exponentials never overflow.

These numbers are representable in FP64 but overflow FP32 (max $\approx 3.4 \times 10^{38}$). With FP16 (max $\approx 65{,}504$), even e^{12} overflows. Raw logits rarely reach magnitude 100, but large intermediate values do arise (for example, unscaled attention scores or overconfident outputs), and because FP16 and BF16 are the standard training precisions, a naive softmax risks overflow often enough that the stable form is used by default.

With the trick: Subtract $m = \max(\mathbf{z}) = 102$:

Shifted logits: $\mathbf{z} - m = [-2, -1, 0]$

Exponentials: $\exp(-2) \approx 0.135$, $\exp(-1) \approx 0.368$, $\exp(0) = 1.0$

Sum = 1.503. LogSumExp = $102 + \log(1.503) = 102.408$.

Softmax: $[0.135/1.503,\ 0.368/1.503,\ 1.0/1.503] = [0.090,\ 0.245,\ 0.665]$

Systems insight: The exponentiated shifted values and the resulting softmax probabilities are in $[0, 1]$, so nothing overflows, even in FP16.

Section 5.4.3.2 builds the cross-entropy loss on this stable softmax. The same maximum subtraction reappears, generalized to tiles of a long sequence, in the tiled-attention derivation of section C.4.2, one of the three proofs that close this appendix.

C.4 Derivations

Without a constant-factor bound on reverse-mode differentiation, training a 175-billion-parameter model would require 175 billion forward passes per step; without an online softmax recurrence, attention would have to materialize an $S \times S$ matrix in HBM; and without a constrained-optimum derivation, a fixed compute budget could be wasted on an oversized model starved of tokens. Each subsection below states one of these three results, proves it, and closes on the systems consequence that the chapters rely on.

C.4.1 Cost of reverse-mode differentiation

Evaluating the full gradient vector $\nabla f(\mathbf{x})$ of a scalar loss function $f : \mathbb{R}^N \to \mathbb{R}$ requires compute proportional to evaluating $f(\mathbf{x})$ itself, with a constant-factor bound independent of the input dimension N. Baur and Strassen proved this complexity result in 1983. Computing a function together with its full gradient takes at most four times the operations of the function alone when every operation counts, and at most three times when only multiplications and divisions count (Baur and Strassen 1983). The per-operation accounting below is simpler than their construction and proves the looser constant of five.

C.4.1.1 Statement

Let $f : \mathbb{R}^N \to \mathbb{R}$ be a multivariate scalar-valued function represented as a computational graph $G = (V, E)$ consisting of $W(f)$ elementary operations (additions, subtractions, multiplications, divisions, and unary functions such as $\exp, \ln, \sin, \sqrt{\cdot}$).

Theorem C.1: Cheap-gradient bound

If a scalar function $f : \mathbb{R}^N \to \mathbb{R}$ can be computed in $W(f)$ elementary operations, then the full gradient vector $\nabla f(\mathbf{x}) = \left(\frac{\partial f}{\partial x_1}, \frac{\partial f}{\partial x_2}, \ldots, \frac{\partial f}{\partial x_N}\right)^T \in \mathbb{R}^N$ can be evaluated in total work $\text{Work}_{\text{Reverse}}(f, \nabla f)$ satisfying:

$$\text{Work}_{\text{Reverse}}(f, \nabla f) \leq C \cdot W(f)$$

where $C \leq 5$ is a universal constant independent of the input dimension N. Furthermore, the backward pass alone requires work $\text{Work}_{\text{Backward}}(\nabla f) \leq 4 \cdot W(f)$.

C.4.1.2 Proof

Let the computational graph $G = (V, E)$ be topologically ordered with nodes $v_{1-N}, \ldots, v_0, v_1, v_2, \ldots, v_W$, where input variables are $x_m = v_{i-N}$ for $m \in \{1, \ldots, N\}$ and the final output is $f(\mathbf{x}) = v_W$. Each intermediate node v_j is evaluated via a primitive operation:

$$v_j = \phi_j(\{v_k \mid k \in \text{Parents}(j)\})$$

Define the *adjoint variable* $\bar{v}_i$ for every node v_i as the partial derivative of the scalar output v_W with respect to v_i:

$$\bar{v}_i \triangleq \frac{\partial f}{\partial v_i} = \frac{\partial v_W}{\partial v_i}$$

By the multivariate chain rule, the adjoint $\bar{v}_i$ is the sum of partial derivatives propagated from all successor nodes (children) that consume v_i:

$$\bar{v}_i = \sum_{j \in \text{Children}(i)} \bar{v}_j \cdot \frac{\partial v_j}{\partial v_i}$$

Reverse-mode automatic differentiation initializes $\bar{v}_W = 1$ and $\bar{v}_i = 0$ for all $i < W$, then traverses the nodes in reverse topological order from v_W down to v_1. For each primitive node v_j, its fully accumulated adjoint $\bar{v}_j$ propagates error signals to its parent nodes v_k ($k \in \text{Parents}(j)$) via:

$$\bar{v}_k \leftarrow \bar{v}_k + \bar{v}_j \cdot \frac{\partial v_j}{\partial v_k}$$

We bound the backward cost one operation type at a time:

1. **Addition/Subtraction ($v_j = v_i \pm v_k$)**:
   - Local derivatives: $\frac{\partial v_j}{\partial v_i} = 1$, $\frac{\partial v_j}{\partial v_k} = \pm 1$.
   - Backward updates: $\bar{v}_i \leftarrow \bar{v}_i + \bar{v}_j$ and $\bar{v}_k \leftarrow \bar{v}_k \pm \bar{v}_j$.
   - Cost: 2 additions in backward pass for 1 forward operation. Work ratio: $\text{Fwd}(1) + \text{Bwd}(2) = 3$ OPs $\leq 5 \cdot 1$.
2. **Multiplication ($v_j = v_i \cdot v_k$)**:
   - Local derivatives: $\frac{\partial v_j}{\partial v_i} = v_k$, $\frac{\partial v_j}{\partial v_k} = v_i$.
   - Backward updates: $\bar{v}_i \leftarrow \bar{v}_i + \bar{v}_j \cdot v_k$ and $\bar{v}_k \leftarrow \bar{v}_k + \bar{v}_j \cdot v_i$.
   - Cost: 2 multiplications + 2 additions = 4 operations in backward pass for 1 forward operation. Work ratio: $\text{Fwd}(1) + \text{Bwd}(4) = 5$ OPs $\leq 5 \cdot 1$.
3. **Division ($v_j = v_i / v_k$)**:
   - Local derivatives: $\frac{\partial v_j}{\partial v_i} = \frac{1}{v_k}$, $\frac{\partial v_j}{\partial v_k} = -\frac{v_i}{v_k^2} = -\frac{v_j}{v_k}$.
   - Backward updates: $\bar{v}_i \leftarrow \bar{v}_i + \frac{\bar{v}_j}{v_k}$ and $\bar{v}_k \leftarrow \bar{v}_k - \frac{\bar{v}_j \cdot v_j}{v_k}$.
   - Cost: Compute the quotient of the incoming adjoint and the denominator once, then reuse it in both updates: add it to the numerator adjoint, and multiply it by the cached forward output before subtracting from the denominator adjoint. This requires 2 multiplications/divisions + 2 additions = 4 operations in backward pass for 1 forward operation. Work ratio: $\text{Fwd}(1) + \text{Bwd}(4) = 5$ OPs $\leq 5 \cdot 1$.
4. **Unary transcendental operations ($v_j = \phi(v_i)$)**:
   - Local derivative: $\frac{\partial v_j}{\partial v_i} = \phi'(v_i)$.
   - Backward update: $\bar{v}_i \leftarrow \bar{v}_i + \bar{v}_j \cdot \phi'(v_i)$.
   - For $v_j = \exp(v_i)$, $\phi'(v_i) = v_j$, requiring 1 multiplication + 1 addition = 2 OPs.
   - For $v_j = \ln(v_i)$, $\phi'(v_i) = 1/v_i$, requiring 1 division + 1 addition = 2 OPs.

Summing across all primitive nodes in G, every forward operation generates at most 4 backward operations:

$$\text{Work}_{\text{Backward}}(\nabla f) \leq 4 \cdot W(f)$$

Adding the forward pass work $W(f)$ yields the total work bound:

$$\text{Work}_{\text{Reverse}}(f, \nabla f) = W(f) + \text{Work}_{\text{Backward}}(\nabla f) \leq 5 \cdot W(f) \qquad \blacksquare$$

> **Systems Perspective C.3: Why 175B-parameter large language models can be trained**
>
> The independence of $C \leq 5$ from input dimension N is the mathematical reason deep learning works. Consider training a transformer model with $P = 175 \times 10^9$ parameters:
>
> - **Forward pass**: Matrix multiplications $\mathbf{Y} = \mathbf{XW}$ require $2P$ FLOPs per token.
> - **Reverse-mode backward pass**: Computes both weight gradients $\frac{\partial \mathcal{L}}{\partial \mathbf{W}} = \mathbf{X}^T \frac{\partial \mathcal{L}}{\partial \mathbf{Y}}$ ($2P$ FLOPs) and input activation gradients $\frac{\partial \mathcal{L}}{\partial \mathbf{X}} = \frac{\partial \mathcal{L}}{\partial \mathbf{Y}} \mathbf{W}^T$ ($2P$ FLOPs), totaling $4P$ FLOPs per token.
> - **Total training work**: $2P(\text{fwd}) + 4P(\text{bwd}) = 6P$ FLOPs per token. The backward compute factor is exactly $\frac{4P}{2P} = 2$, so forward plus backward costs three times the forward pass, within both the bound of $C \leq 5$ proved here and Baur and Strassen's sharper constant of four.
>
> If we instead used forward-mode automatic differentiation (AD) or finite differences to compute $\nabla f \in \mathbb{R}^P$, evaluating each partial derivative separately would require P forward passes: $\text{Work}_{\text{ForwardMode}}(\nabla f) = \mathcal{O}(P \cdot W) = \mathcal{O}(P^2)$ FLOPs. For $P = 175 \times 10^9$, that method would require $2 \times (175 \times 10^9)^2 \approx 6.1 \times 10^{22}$ FLOPs per token, P times the forward-pass work and therefore prohibitive at this scale. Reverse-mode AD replaces this $\mathcal{O}(P)$ factor with a constant multiplier of 2 for the dense-layer accounting above.

Reverse mode achieves this constant factor by keeping the forward pass's intermediate values for the backward sweep, which is why the training-memory decomposition in section C.3.3 carries an activation term. Attention adds an intermediate whose size grows with the square of the sequence length, the subject of the next derivation.

C.4.2 Tiled attention and online softmax

Standard self-attention in transformers requires materializing an $S \times S$ attention score matrix in HBM, creating an $\mathcal{O}(S^2)$ memory bandwidth bottleneck. FlashAttention (Dao et al. 2022) reduces this bottleneck by tiling query, key, and value matrices and recomputing attention using an online softmax recurrence without materializing intermediate scores to HBM. Section 8.6.4 applies the algorithm to training; this subsection proves the online softmax recurrence it relies on and then its memory-traffic bound.

C.4.2.1 Memory traffic of standard attention

Given queries $\mathbf{Q} \in \mathbb{R}^{S \times d_{\text{head}}}$, keys $\mathbf{K} \in \mathbb{R}^{S \times d_{\text{head}}}$, and values $\mathbf{V} \in \mathbb{R}^{S \times d_{\text{head}}}$ for sequence length S and head dimension d_{head}, standard attention evaluates:

$$\mathbf{S} = \mathbf{QK}^T \in \mathbb{R}^{S \times S}, \qquad \mathbf{A} = \text{softmax}(\mathbf{S}) \in \mathbb{R}^{S \times S}, \qquad \mathbf{O} = \mathbf{AV} \in \mathbb{R}^{S \times d_{\text{head}}}$$

To prevent numerical overflow, row-wise softmax subtracts the row maximum (the log-sum-exp shift of section C.3.5) $m_i = \max_{1 \leq j \leq S} S_{ij}$:

$$A_{ij} = \frac{\exp(S_{ij} - m_i)}{\sum_{k=1}^{S} \exp(S_{ik} - m_i)}$$

Standard GPU implementations execute this in three discrete kernel launches:

1. Compute $\mathbf{S} = \mathbf{QK}^T$ in SRAM, then write $\mathbf{S} \in \mathbb{R}^{S \times S}$ to HBM ($\Theta(S^2)$ writes).

2. Read $\mathbf{S}$ from HBM, compute row max m and row sum z, compute $\mathbf{A} = \text{softmax}(\mathbf{S})$, write $\mathbf{A} \in \mathbb{R}^{S\times S}$ to HBM ($\Theta(S^2)$ reads + writes).
3. Read $\mathbf{A}$ and $\mathbf{V}$ from HBM, compute $\mathbf{O} = \mathbf{AV}$, write $\mathbf{O} \in \mathbb{R}^{S\times d_{\text{head}}}$ to HBM ($\Theta(S^2 + Sd_{\text{head}})$ reads + writes).

Total HBM memory traffic is $\Theta(S^2 + Sd_{\text{head}})$ elements. For $S = 8192$, $d_{\text{head}} = 128$ in FP16, $\mathbf{S}$ requires $8192^2 \times 2$ B $= 134$ MB per head per layer. Because modern GPUs feature massive compute throughput relative to HBM bandwidth, repeatedly reading and writing intermediate matrices $\mathbf{S}$ and $\mathbf{A}$ leaves GPU execution units memory-bound.

C.4.2.2 Online softmax recurrence

Tiling softmax is difficult because computing $z_i = \sum_{k=1}^{S} \exp(S_{ik} - m_i)$ requires the global maximum m_i across all S keys. The online softmax recurrence solves this by incrementally updating normalization statistics as sub-blocks arrive.

Theorem C.2: Online softmax recurrence theorem

Let a vector $\mathbf{x} \in \mathbb{R}^n$ be partitioned into two sub-vectors $\mathbf{x}^{(1)} \in \mathbb{R}^{n_1}$ and $\mathbf{x}^{(2)} \in \mathbb{R}^{n_2}$ with $n = n_1 + n_2$. Let the local statistics for block 1 be:

$$m^{(1)} = \max_{1\le j\le n_1} x_j^{(1)}, \qquad z^{(1)} = \sum_{j=1}^{n_1} \exp\left(x_j^{(1)} - m^{(1)}\right)$$

and for block 2 be:

$$m^{(2)} = \max_{1\le j\le n_2} x_j^{(2)}, \qquad z^{(2)} = \sum_{j=1}^{n_2} \exp\left(x_j^{(2)} - m^{(2)}\right)$$

Then the combined maximum m^{new}, normalization sum z^{new}, and accumulated output vector $\mathbf{O}^{\text{new}}$ satisfy the exact recurrence relations:

$$\begin{aligned} m^{\text{new}} &= \max\left(m^{(1)}, m^{(2)}\right), \\ z^{\text{new}} &= z^{(1)} e^{m^{(1)} - m^{\text{new}}} + z^{(2)} e^{m^{(2)} - m^{\text{new}}}, \\ \mathbf{O}^{\text{new}} &= \frac{z^{(1)} e^{m^{(1)} - m^{\text{new}}}}{z^{\text{new}}} \mathbf{O}^{(1)} + \frac{e^{m^{(2)} - m^{\text{new}}}}{z^{\text{new}}} \sum_{j=1}^{n_2} e^{x_j^{(2)} - m^{(2)}} \mathbf{V}_j^{(2)}, \end{aligned}$$

where $\mathbf{O}^{(1)} = \frac{1}{z^{(1)}} \sum_{j=1}^{n_1} e^{x_j^{(1)} - m^{(1)}} \mathbf{V}_j^{(1)}$ is the partial output accumulated from block 1.

Denominator recurrence Expanding the combined sum $z^{\text{new}} = \sum_{j=1}^{n} e^{x_j - m^{\text{new}}}$:

$$\begin{aligned} z^{\text{new}} &= \sum_{j=1}^{n_1} e^{x_j^{(1)} - m^{\text{new}}} + \sum_{j=1}^{n_2} e^{x_j^{(2)} - m^{\text{new}}} \\ &= \sum_{j=1}^{n_1} e^{\left(x_j^{(1)} - m^{(1)}\right) + \left(m^{(1)} - m^{\text{new}}\right)} + \sum_{j=1}^{n_2} e^{\left(x_j^{(2)} - m^{(2)}\right) + \left(m^{(2)} - m^{\text{new}}\right)} \\ &= e^{m^{(1)} - m^{\text{new}}} \underbrace{\sum_{j=1}^{n_1} e^{x_j^{(1)} - m^{(1)}}}_{z^{(1)}} + e^{m^{(2)} - m^{\text{new}}} \underbrace{\sum_{j=1}^{n_2} e^{x_j^{(2)} - m^{(2)}}}_{z^{(2)}} \\ &= z^{(1)} e^{m^{(1)} - m^{\text{new}}} + z^{(2)} e^{m^{(2)} - m^{\text{new}}}. \quad \blacksquare \end{aligned}$$

Output rescaling recurrence The true normalized output over the concatenated sequence is $\mathbf{O}^{\text{new}} = \frac{1}{z^{\text{new}}} \sum_{j=1}^{n} e^{x_j - m^{\text{new}}} \mathbf{V}_j$:

$$\begin{aligned}\mathbf{O}^{\text{new}} &= \frac{1}{z^{\text{new}}} \left[\sum_{j=1}^{n_1} e^{x_j^{(1)} - m^{\text{new}}} \mathbf{V}_j^{(1)} + \sum_{j=1}^{n_2} e^{x_j^{(2)} - m^{\text{new}}} \mathbf{V}_j^{(2)} \right] \\ &= \frac{1}{z^{\text{new}}} \left[e^{m^{(1)} - m^{\text{new}}} \sum_{j=1}^{n_1} e^{x_j^{(1)} - m^{(1)}} \mathbf{V}_j^{(1)} + e^{m^{(2)} - m^{\text{new}}} \sum_{j=1}^{n_2} e^{x_j^{(2)} - m^{(2)}} \mathbf{V}_j^{(2)} \right]\end{aligned}$$

Noting that $z^{(1)}\mathbf{O}^{(1)} = \sum_{j=1}^{n_1} e^{x_j^{(1)} - m^{(1)}} \mathbf{V}_j^{(1)}$, we substitute this directly:

$$\mathbf{O}^{\text{new}} = \frac{z^{(1)} e^{m^{(1)} - m^{\text{new}}}}{z^{\text{new}}} \mathbf{O}^{(1)} + \frac{e^{m^{(2)} - m^{\text{new}}}}{z^{\text{new}}} \sum_{j=1}^{n_2} e^{x_j^{(2)} - m^{(2)}} \mathbf{V}_j^{(2)}. \quad \blacksquare$$

C.4.2.3 Memory traffic of tiled attention

The recurrence lets each query tile be combined with one key-value tile at a time, so score tiles never need to leave SRAM. The remaining question is how many bytes then cross the HBM boundary.

Let M_{SRAM} be the fast SRAM capacity (in words). Following Algorithm 1 of Dao et al. (2022), FlashAttention sets $B_c = \lfloor M_{\text{SRAM}}/(4d_{\text{head}}) \rfloor$ and $B_r = \min(\lfloor M_{\text{SRAM}}/(4d_{\text{head}}) \rfloor, d_{\text{head}})$. The proof abstracts constant factors and buffer reuse, using $B_c = \Theta(M_{\text{SRAM}}/d_{\text{head}})$, $B_r = \Theta(\min(M_{\text{SRAM}}/d_{\text{head}}, d_{\text{head}}))$, and $B_r B_c = \mathcal{O}(M_{\text{SRAM}})$ for the on-chip working set.

The algorithm partitions $\mathbf{Q}$ into $T_r = \lceil S/B_r \rceil$ blocks of size $B_r \times d_{\text{head}}$, and partitions $\mathbf{K}, \mathbf{V}$ into $T_c = \lceil S/B_c \rceil$ blocks of size $B_c \times d_{\text{head}}$. It executes two nested loops:

- **Outer loop** over $j = 1, \ldots, T_c$: Load $\mathbf{K}_j$ and $\mathbf{V}_j$ into SRAM.
- **Inner loop** over $i = 1, \ldots, T_r$: Load $\mathbf{Q}_i$, $\mathbf{O}_i$, and its softmax statistics; compute $\mathbf{S}_{ij} = \mathbf{Q}_i \mathbf{K}_j^T$ in SRAM; then update and write $\mathbf{O}_i$ and the statistics without materializing $\mathbf{S}_{ij}$ in HBM.

This loop order is the source of the I/O reduction. A key-value tile remains resident while the algorithm visits every query tile, so each element of $\mathbf{K}$ and $\mathbf{V}$ crosses the HBM boundary once. The query and output tiles must be revisited for each key-value block, but the $B_r \times B_c$ score tile is consumed on chip and discarded. Standard attention instead writes and rereads the full $S \times S$ score and probability matrices.

Total memory access accounting Total HBM accesses comprise two components: key and value reads, where each element of $\mathbf{K}$ and $\mathbf{V}$ is loaded once (contributing $2Sd_{\text{head}}$ accesses); and query, output, and statistics passes, where each of the T_c column blocks reads all of $\mathbf{Q}$, reads and writes $\mathbf{O}$, and updates $\mathcal{O}(S)$ softmax statistics. The matrices dominate the statistics for head dimension $d_{\text{head}} \geq 1$, so each pass contributes $\Theta(Sd_{\text{head}})$ accesses and all passes contribute $\Theta(Sd_{\text{head}}T_c)$.

Because $T_c = \lceil S/B_c \rceil = \Theta(Sd_{\text{head}}/M_{\text{SRAM}})$, the total is

$$\text{HBM}_{\text{Flash}} = \Theta\left(Sd_{\text{head}} + Sd_{\text{head}}T_c\right) = \Theta\left(Sd_{\text{head}} + \frac{S^2 d_{\text{head}}^2}{M_{\text{SRAM}}}\right) = \Theta\left(\frac{S^2 d_{\text{head}}^2}{M_{\text{SRAM}}}\right),$$

where the final equality follows for $d_{\text{head}} \leq M_{\text{SRAM}} \leq Sd_{\text{head}}$.

The bound counts communication rather than arithmetic. FlashAttention still evaluates the same dense score blocks and may recompute intermediate quantities during backpropagation; its advantage comes from keeping those intermediates out of HBM.

I/O reduction ratio Comparing standard attention I/O to FlashAttention I/O:

$$\frac{\text{HBM}_{\text{Standard}}}{\text{HBM}_{\text{Flash}}} = \frac{\Theta(S^2 + Sd_{\text{head}})}{\Theta\left(Sd_{\text{head}} + \frac{S^2 d_{\text{head}}^2}{M_{\text{SRAM}}}\right)} = \Theta\left(\frac{M_{\text{SRAM}}}{d_{\text{head}}^2}\right) \quad \text{for } S \gg \max\left(d_{\text{head}}, \frac{M_{\text{SRAM}}}{d_{\text{head}}}\right)$$

Systems Perspective C.4: A100 I/O reduction

The asymptotic ratio $M_{\text{SRAM}}/d_{\text{head}}^2$ predicts how greater SRAM capacity can reduce HBM traffic, but hidden constants and kernel details prevent it from serving as an exact transfer count. In an NVIDIA A100 measurement, Dao et al. (2022) report the effect for a forward-and-backward attention workload with sequence length 1,024, head dimension 64, 16 heads, batch size 64, a key-padding mask, and no dropout:

- **Standard attention**: 35.3 GB of HBM reads and writes; 35.1 ms runtime.
- **FlashAttention**: 4.4 GB of HBM reads and writes; 11.7 ms runtime.

The measurements show the systems consequence of the I/O bound: substantially less HBM traffic coincides with lower runtime even though FlashAttention performs additional recomputation. They do not imply that every configuration becomes compute bound; tile size, sequence length, and kernel implementation determine the realized regime.

Tiling changes how many bytes cross the memory boundary for a fixed model. The last derivation applies the same accounting one level up and asks how large the model and its training set should be for a fixed compute budget.

C.4.3 Compute-optimal scaling laws

Determining the compute-optimal allocation between model parameters and training dataset tokens for a given floating-point budget O sets how large a language model and its training set should be. This subsection derives the compute-optimal allocation using Lagrange multipliers and contrasts the original findings of Kaplan et al. (2020) with the compute-optimal corrections of Hoffmann et al. (2022). Section 9.2.3 uses the result to test whether a training strategy is limited by data or by compute.

Notation note: This derivation writes model parameters as P, dataset size in tokens as D, and the training compute budget as O total FLOPs; Kaplan et al. (2020) and Hoffmann et al. (2022) write N for parameters and C for compute. The fitted constants E, A, B, α, and β and the Lagrange multiplier λ keep the papers' letters and are local to this section, so E is a loss rather than an energy and B is a fitted constant rather than batch size.

C.4.3.1 Parametric loss surface

The cross-entropy evaluation loss $\mathcal{L}(P, D)$ of an autoregressive transformer language model trained with P non-embedding parameters on D tokens is modeled by the power-law formulation:

$$\mathcal{L}(P, D) = E + \frac{A}{P^{\alpha}} + \frac{B}{D^{\beta}}$$

where:

- E: Irreducible loss representing the entropy of natural language data.
- $\frac{A}{P^{\alpha}}$: Capacity bottleneck loss resulting from finite model parameters P.
- $\frac{B}{D^{\beta}}$: Dataset size bottleneck loss resulting from finite training tokens D.
- $A, B > 0$: Empirical scaling constants.
- $\alpha, \beta > 0$: Power-law scaling exponents for model size and dataset size, respectively.

C.4.3.2 Constrained optimization

The total floating-point operations required to train a transformer with P non-embedding parameters for D tokens is given by

$$O = 6PD \text{ FLOPs},$$

where $2PD$ accounts for the forward pass and $4PD$ accounts for the backward pass.

Given a fixed training compute budget O_0, we formulate the constrained optimization problem to minimize the reducible loss $\hat{\mathcal{L}}(P,D) = \frac{A}{P^\alpha} + \frac{B}{D^\beta}$:

$$\min_{P,D} \left(\frac{A}{P^\alpha} + \frac{B}{D^\beta} \right) \quad \text{subject to} \quad g(P,D) = 6PD - O_0 = 0$$

We construct the Lagrangian function $\mathcal{L}_{\text{Lagrange}}(P,D,\lambda)$:

$$\mathcal{L}_{\text{Lagrange}}(P,D,\lambda) = \frac{A}{P^\alpha} + \frac{B}{D^\beta} + \lambda(6PD - O_0)$$

Taking partial derivatives with respect to P, D, and λ and setting them to zero yields:

$$\frac{\partial \mathcal{L}_{\text{Lagrange}}}{\partial P} = -\alpha A P^{-\alpha-1} + 6\lambda D = 0 \implies \alpha A P^{-\alpha-1} = 6\lambda D, \tag{1}$$

$$\frac{\partial \mathcal{L}_{\text{Lagrange}}}{\partial D} = -\beta B D^{-\beta-1} + 6\lambda P = 0 \implies \beta B D^{-\beta-1} = 6\lambda P, \tag{2}$$

$$\frac{\partial \mathcal{L}_{\text{Lagrange}}}{\partial \lambda} = 6PD - O_0 = 0. \tag{3}$$

Multiplying Equation (1) by P and Equation (2) by D gives:

$$\alpha A P^{-\alpha} = 6\lambda PD,$$

$$\beta B D^{-\beta} = 6\lambda PD.$$

Equating these expressions yields the power-law optimality condition:

$$\alpha A P^{-\alpha} = \beta B D^{-\beta}.$$

This condition states that at the compute-optimal allocation, the marginal loss reduction per fractional increase in parameter count must equal the marginal loss reduction per fractional increase in dataset tokens.

C.4.3.3 Compute-optimal exponents

From $\alpha A P^{-\alpha} = \beta B D^{-\beta}$, solving for D in terms of P yields:

$$D^\beta = \left(\frac{\beta B}{\alpha A} \right) P^\alpha \implies D = \left(\frac{\beta B}{\alpha A} \right)^{1/\beta} P^{\alpha/\beta}.$$

Substituting D into the compute constraint $O = 6PD$ gives:

$$O = 6P \left(\frac{\beta B}{\alpha A} \right)^{1/\beta} P^{\alpha/\beta} = 6 \left(\frac{\beta B}{\alpha A} \right)^{1/\beta} P^{\frac{\alpha+\beta}{\beta}}.$$

Solving explicitly for the compute-optimal parameter count $P^*(O)$:

$$P^*(O) = \left(\frac{\alpha A}{\beta B} \right)^{\frac{1}{\alpha+\beta}} \left(\frac{O}{6} \right)^{\frac{\beta}{\alpha+\beta}} \propto O^{\frac{\beta}{\alpha+\beta}}.$$

By symmetry, solving for the compute-optimal token count $D^*(O)$ yields:

$$D^*(O) = \left(\frac{\beta B}{\alpha A} \right)^{\frac{1}{\alpha+\beta}} \left(\frac{O}{6} \right)^{\frac{\alpha}{\alpha+\beta}} \propto O^{\frac{\alpha}{\alpha+\beta}}.$$

Empirical exponents and the $D/P \approx 20$ rule Fitting the parametric loss surface to over 400 experimental runs, Hoffmann et al. (2022) estimated $\alpha \approx 0.34$ and $\beta \approx 0.28$. Substituting these values gives exponents close to the paper's parametric-model result:

$$\frac{\beta}{\alpha+\beta} \approx 0.45, \qquad \frac{\alpha}{\alpha+\beta} \approx 0.55$$

Thus the parametric model predicts:

$$P^*(O) \propto O^{0.45}, \qquad D^*(O) \propto O^{0.55}$$

The paper's two direct empirical approaches report near-balanced exponents of $(0.50, 0.50)$ and $(0.49, 0.51)$, which motivate the common square-root shorthand. Under the parametric fit, however, D^*/P^* grows slowly with compute rather than remaining strictly constant. Across the regime studied, roughly 20 training tokens per parameter is a useful Chinchilla heuristic, not a universal invariant.

Systems Perspective C.5: Kaplan vs. Chinchilla scaling

The difference between Kaplan et al. (2020) and Hoffmann et al. (2022) shows how the training schedule used in empirical fits can alter system design conclusions:

- **Kaplan scaling model**: Kaplan et al. (2020) fit a different loss form with its own exponents and reported compute-optimal growth of $P \propto O^{0.73}$ and $D \propto O^{0.27}$; this split does not follow from substituting exponents into the two-term surface above. This led the field to scale model sizes aggressively while holding training dataset sizes relatively small (e.g., GPT-3 175B trained on 300B tokens, giving $D/P = 1.71$).
- **Methodological divergence**: Kaplan et al. (2020) used a fixed token budget and learning-rate schedule across models. Hoffmann et al. (2022) matched the schedule to each training horizon and found that the earlier setup understated the value of training smaller models on more data.
- **Chinchilla revision**: Hoffmann et al. (2022) found near-balanced parameter and token scaling: its three approaches report exponent pairs of $(0.50, 0.50)$, $(0.49, 0.51)$, and $(0.46, 0.54)$ rather than one exact universal ratio.
- **Practical impact**: Chinchilla (70B parameters trained on 1.4T tokens, $D/P = 20$) outperformed GPT-3 (175B parameters trained on 300B tokens) across downstream benchmarks while requiring $2.5\times$ less compute during inference (inference cost scales with parameter count) and $2.5\times$ lower weight memory at the same precision (Hoffmann et al. 2022).

Summary

An algorithm becomes a systems workload through its shapes, operation graph, data dependencies, and numerical representation. Linear-algebra primitives, memory layouts, broadcasting, and sparse formats determine work, traffic, locality, and usable parallelism. Automatic differentiation and backpropagation add saved activations and backward computation; computational graphs then expose opportunities for fusion and recomputation, and the log-sum-exp shift keeps the softmax at the loss finite in reduced precision. Among the derivations, the Baur–Strassen result bounds reverse-mode overhead, while FlashAttention shows how tiling and an online recurrence can reduce HBM traffic without changing attention semantics.

The same accounting connects kernels to scaling decisions. Compute-optimal scaling turns a fixed budget into a model-data allocation, but the fitted exponents remain empirical rather than universal. Before selecting an optimization, count the operations, the bytes moved, and the state saved for the backward pass.

D

Machine Foundations

A datasheet reports peak throughput; a workload almost never reaches it. Closing that gap requires knowing which physical limit binds execution first: memory bandwidth, arithmetic throughput, fixed overhead, or energy. This appendix collects the hardware models, ratios, and order-of-magnitude values used for single-node estimates in the book, so that chapter estimates can be checked against them. Architecture essentials support readers encountering memory hierarchies and hardware cost models for the first time; familiarity with undergraduate computer architecture is helpful but not required.

How to Use This Appendix

This appendix is designed as a reference. When diagnosing performance issues, use it to translate a vague symptom ("it is slow") into a specific constraint ("bandwidth bound at batch size one") and then choose the lever that addresses it. Each need in table D.1 leads to the section that carries the model or worked template and to the chapter that applies it to the book's workloads.

Table D.1: Where to Look: Each need maps to the section of this appendix that carries the model or worked template and to the chapter that applies it to the book's workloads.

Need	Reference Section	Applied In
Sanity-check feasibility with orders of magnitude	section D.1	section 2.4
Compare access times across memory, links, and storage	section D.1.1	section 11.5.3
Decide whether a kernel is compute or bandwidth bound	section D.2.1	section 11.6
Check that a performance equation is consistent	section D.2.2	section 1.7
Predict whether more accelerators shorten a run	section D.2.3	section 8.7.1
Estimate the wall-clock time of a training run	section D.2.4	section 8.2
Size request concurrency for a serving target	section D.2.5	section 13.4.1
Explain why data movement dominates energy	section D.3.1	section 11.5.3
Separate latency-dominated from bandwidth-dominated transfers	section D.3.2	section 11.5.4
Place a device class by compute, memory, and power	section D.3.3	section 11.11
Choose a numerical format	section D.4.1	section 10.3.1
Map floating-point values to integers	section D.4.2	section 10.3

Conventions used here follow the book-wide notation (for example, B is reserved for batch size and BW for bandwidth). The values in this appendix are ratios and orders of magnitude, which change slowly because they follow from physics and circuit design. The dated specifications of particular accelerators, links, and storage devices change with every product generation; Appendix E tabulates them so a reader can substitute current values without disturbing the relationships here.

D.1 Numbers to Know

Fetching a 32-bit weight from off-chip DRAM costs hundreds of times more energy and roughly a thousand times more latency than reading it from a register, a gap that no compiler flag can erase. Like Jeff Dean's "Latency Numbers Every Programmer Should Know,"[1] the reference numbers below give the order-of-magnitude intuition that ML systems design requires. Although absolute values and ratios vary by technology and workload, the hierarchy is more durable; memorize the relationships and use the specific values as sanity checks.

[1] **Jeff Dean**: A Google Senior Fellow and one of the architects of MapReduce, BigTable, and TensorFlow. His latency numbers, originally presented with Peter Norvig around 2010, became a canonical reference for systems engineers; Colin Scott's interactive visualization shows that the *hierarchy* of latencies has stayed stable across hardware generations (Scott 2012).

> **Systems Perspective D.1: Three numbers that matter most**
>
> - **Energy ratio**: In the cited 45 nm reference, a 32-bit DRAM read uses ~581× the energy of one FP16 multiply.
> - **Training-state footprint**: Model weights (2 bytes FP16) + gradients (2 bytes FP16) + master weights (4 bytes FP32) + optimizer states for Adaptive Moment Estimation (Adam) at 8 bytes. That totals 16 bytes per parameter, so Llama 3 8B (8.03B parameters) needs 128.5 GB just to start full training, more than one accelerator's memory.
> - **Fiber propagation limit**: Light travels about 200 km/ms in fiber, so propagation sets a floor on every round trip.

Reference relationships

The numbers above mix two kinds of quantities: invariant physical or arithmetic bounds, such as propagation delay in fiber and bytes per parameter, and technology-specific energy ratios that shift with each process node while preserving their ordering. The three tables below separate those reference anchors into propagation latency, memory-to-compute energy cost, and model-sizing arithmetic.

Speed of light

No network upgrade or routing optimization can deliver a cross-country round trip in 5 ms when light in fiber takes roughly 40 ms to make the journey. Each approximate round trip in table D.2 carries that irreducible propagation component.

Table D.2: Speed of Light Reference: Light in fiber travels ~200 km/ms. These approximate round trips include reducible overhead; only propagation is irreducible.

Distance	Round-Trip Latency	Implication
Same data center	~1 ms	Distributed training feasible
Cross-country (US)	~40 ms	Reduces the remaining request budget
Cross-Atlantic	~60 ms	Further reduces the request budget
Cross-Pacific	~100 ms	Data locality is critical

Energy hierarchy

Moving data across wires costs far more energy than computing on it once it arrives in an arithmetic unit. Raising reuse per byte therefore pays off across every hardware generation (table D.3).[2]

[2] **Energy hierarchy sources**: The DRAM and arithmetic values come from Horowitz (2014) (45 nm). The L1 SRAM/register ratio is an illustrative hierarchy anchor, not a Horowitz measurement. The headline ratio compares a 32-bit DRAM access with a 16-bit floating-point multiply. Both the absolute values and the ratio vary with process, circuit, memory technology, and operand width; wire distance helps explain why movement remains expensive.

Table D.3: Energy Reference Ratios: The first three ratios use Horowitz's 45 nm measurements; the L1/register ratio is an illustrative on-chip hierarchy anchor.

Relationship	Reference Ratio	Source and Interpretation
DRAM access vs. FP16 multiply	~581×	Horowitz 45 nm; wire capacitance scales with distance
FP32 vs. INT8 energy	~18×	Horowitz 45 nm; bit width determines switching energy
FP32 vs. FP16 energy	~3.4×	Horowitz 45 nm; narrower arithmetic reduces switching and datapath energy

Relationship	Reference Ratio	Source and Interpretation
L1 SRAM vs. register	~5×	Illustrative on-chip hierarchy anchor; distance to the arithmetic unit

Scaling rules

Memory and compute requirements for training and inference follow from a few arithmetic relationships (table D.4).[3] The examples use Llama 3 8B. Section 8.3.2.3 derives the 16 bytes per parameter of training state and why switching to 16-bit arithmetic does not shrink it.

[3] **Training memory (Adam)**: The 16 bytes/parameter rule assumes mixed-precision training with Adam. ZeRO optimization can reduce per-accelerator memory by sharding optimizer states across accelerators, but the total memory across all accelerators remains ~16× parameters.

Table D.4: Scaling Rules: These are arithmetic, not hardware-specific. Training memory includes FP16 weights (2 bytes), FP16 gradients (2 bytes), FP32 master weights (4 bytes), and Adam optimizer states (8 bytes for momentum + variance).

Rule	Formula	Example (Llama 3 8B)
Inference memory (FP16)	2 bytes× parameters	16.1 GB
Inference memory (INT8)	1 byte× parameters	8.0 GB
Training memory (Adam)	16 bytes× parameters	128.5 GB
Inference FLOPs (transformer)	~2× parameters per token	16.1 GFLOP per token
Training FLOPs	~6× parameters× tokens	4.8×10^{22} FLOPs on 1T tokens

D.1.1 The latency hierarchy

Distance costs time. Each step away from the arithmetic units, from registers through on-chip cache, off-chip memory, device and host links, the network, and storage, multiplies the wait for the first byte, and the largest jumps come from crossing a physical boundary (table D.5). If a register access took ten seconds, a read from accelerator memory would take hours and a read from local flash storage would take weeks.

Table D.5: The Latency Hierarchy: Access latency by tier, as the decade that contains it, as a multiple of a register access (rounded to one significant figure), and on a human time scale where one register access takes ten seconds. The largest gaps come from crossing physical boundaries: off-chip memory, device and host links, network fabric, and storage.

Tier	Latency (Decade)	Relative to a Register	If a Register Access Took 10 s
Register	0.1–1 ns	1×	10 seconds
L1 cache	1–10 ns	3×	33.3 seconds
L2 cache	1–10 ns	10×	2.2 minutes
Accelerator memory (HBM)	100–1,000 ns	1,000×	2.8 hours
Accelerator-to-accelerator link	100–1,000 ns	2,000×	4.6 hours
Host link (PCIe)	1–10 µs	3,000×	9.3 hours
Network fabric	1–10 µs	20,000×	1.9 days
Local flash storage (NVMe)	100–1,000 µs	300,000×	38.6 days

Bandwidth falls along the same path. On the reference accelerator, high-bandwidth memory delivers about 52× the bandwidth of the host link, and a network access costs about 16× the latency of an accelerator-memory access. Data that must cross the host link or the network should cross it once and be reused many times on the device.

Illustrative latency budgets

Latency budgets depend on application-specific safety requirements, user expectations, and service-level objectives. Table D.6 lists illustrative targets rather than universal limits; section 13.3.1 shows how a serving system divides such a budget among its stages.

Table D.6: Illustrative Latency Targets: Production requirements depend on the application and its service-level objectives.

Application	Budget	Constraint
Autonomous braking	<10 ms	At 100 km/h, 10 ms = 28 cm of travel
Voice assistant	<100 ms	Human perception of "instant"
Web search	<200 ms	User patience threshold
Video streaming	<1 s	Buffer tolerance
Batch training	hours–days	Throughput dominates latency

> **Systems Perspective D.2: A note on terminology: GPUs and accelerators**
>
> Throughout this book, "accelerator" is the general term for hardware acceleration. The principles of roofline analysis, memory hierarchies, numerical precision, and performance modeling apply to GPUs, Tensor Processing Units (TPUs), NPUs, application-specific integrated circuits, and other specialized AI accelerators. Vendor-specific features such as CUDA and NVLink are identified explicitly.

Appendix E tabulates the dated accelerator specifications, including the NVIDIA H100 that serves as the book's reference machine. Next, the roofline model shows which of those specifications limits a given workload by turning compute throughput and memory bandwidth into performance ceilings.

D.2 Physics of Computing

Raw hardware specifications (FLOP/s, bytes per second, watts) are necessary but insufficient for performance reasoning. Without compact analytical models, an engineer cannot distinguish a compute-bound workload from a bandwidth-bound one, or predict whether doubling the accelerator count will halve training time. The models in this section turn those distinctions into quantitative checks.

D.2.1 The Roofline model

A kernel that achieves 1 percent of an accelerator's peak FLOP/s may be poorly written, or it may already be saturating the memory bus at the physical limit of the chip. The Roofline Model (Williams et al. 2009) separates those two cases by bounding how fast a workload can run on a given hardware target according to whether it runs out of compute or memory bandwidth first.

Every operation has an **arithmetic intensity**: the ratio of computations performed to bytes moved from memory. Matrix multiplication achieves high arithmetic intensity because each loaded element is reused across multiple multiply-accumulate steps. In contrast, element-wise operations like rectified linear unit (ReLU) have low intensity because each element is fetched from memory, evaluated once, and written back. Plotting achievable performance against arithmetic intensity yields the roofline (figure D.1): a diagonal memory-bandwidth ceiling rises linearly from the origin until it meets the horizontal peak-compute ceiling at the ridge point. A workload's arithmetic intensity determines which ceiling governs execution, and therefore whether optimizations must target memory traffic or arithmetic throughput.

The **ridge point** determines the hardware's balance. Formally, when computation and data movement overlap completely (the overlapped form of the iron law), idealized wall-clock time is bounded below by the critical path:

$$T \geq \max\left(\frac{O}{R_{\text{peak}}}, \frac{D_{\text{vol}}}{\text{BW}}\right)$$

Attainable throughput $R_{\text{attain}} = O/T$ is therefore bounded by:

$$R_{\text{attain}} \leq \frac{O}{\max\left(\frac{O}{R_{\text{peak}}}, \frac{D_{\text{vol}}}{\text{BW}}\right)} = \min\left(R_{\text{peak}}, \frac{O}{D_{\text{vol}}} \times \text{BW}\right) = \min(R_{\text{peak}}, I \times \text{BW})$$

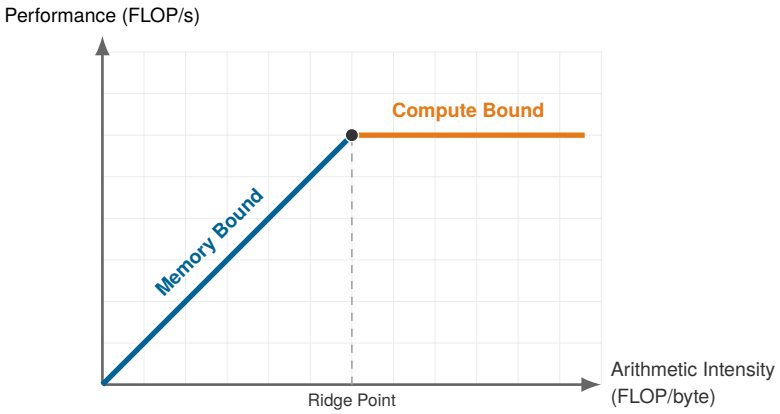

Figure D.1: The Roofline Model: The sloped memory-bandwidth ceiling and horizontal peak-compute ceiling meet at the ridge point. Plotting a workload by arithmetic intensity identifies which roofline ceiling applies.

where $I = O/D_{\text{vol}}$ is the arithmetic intensity measured at the DRAM interface. The ridge point I_{ridge} is the transition intensity where the compute and bandwidth ceilings meet:

$$R_{\text{peak}} = I_{\text{ridge}} \times \text{BW} \implies I_{\text{ridge}} = \frac{R_{\text{peak}}}{\text{BW}}$$

If a workload's arithmetic intensity falls below I_{ridge}, it is bandwidth-bound (the roofline literature says memory-bound); if above, it is compute bound. The memory-bound regime is the bandwidth-bound archetype of section 2.3.2, whose lighthouse is GPT-2 decode; the compute-bound regime is the compute-bound archetype, whose lighthouse is ResNet-50. Section 11.6 develops both regimes and the levers that move a workload between them.

> **Systems Perspective D.3: Batch size controls arithmetic intensity**
>
> For matrix multiplications, arithmetic intensity scales with the batch dimension. For $\mathbf{Y} = \mathbf{XW}$, where $\mathbf{X}$ is $(B \times d_{\text{in}})$ and $\mathbf{W}$ is $(d_{\text{in}} \times d_{\text{out}})$:
>
> - **FLOPs**: $2 \times B \times d_{\text{in}} \times d_{\text{out}}$ (multiply-adds).
> - **Bytes**: Moving $\mathbf{X}$, $\mathbf{W}$, and $\mathbf{Y}$ costs approximately $s_{\text{elem}}(Bd_{\text{in}} + d_{\text{in}}d_{\text{out}} + Bd_{\text{out}})$ bytes.
>
> Doubling B doubles FLOPs while weight traffic stays nearly constant when weights dominate, increasing arithmetic intensity. This is why batching often helps inference serving (section 13.5.1 develops the serving side, including the latency it adds), although activation traffic, cache behavior, shape, precision, and the ridge point determine whether it reaches the compute ceiling.

D.2.1.1 A concrete example: The H100 analysis

Consider an NVIDIA H100, the book's reference machine, with dense FP16 Tensor Core performance of 989 TFLOP/s and HBM3 bandwidth of 3.35 TB/s. The ridge point is 989 TFLOP/s/3.35 TB/s = 295.2 FLOP/byte (the Tera prefixes cancel, yielding FLOP/byte).

Two common operations fall on opposite sides of that ridge. General matrix multiply (GEMM) on two square matrices of size 4096 by 4096 has arithmetic intensity of approximately 1,365 FLOP/byte, so 1,365 FLOP/byte > 295.2 FLOP/byte and the operation is compute bound. An element-wise ReLU on an FP16 tensor performs 1 comparison while reading 2 bytes and writing 2 bytes (4 bytes total), yielding an arithmetic intensity of only $1/4 = 0.25$ FLOP/byte. Because 0.25 FLOP/byte $\ll$ 295.2 FLOP/byte, the operation is severely bandwidth-bound, achieving only about 0.08 percent of peak FLOP/s. This contrast is why frameworks fuse an element-wise operation into the preceding matrix multiply, so the intermediate result never makes a round trip through memory; section 7.3.2 develops fusion and the launch overhead it removes.

Precision moves the ridge. At INT8 the H100's peak rate doubles to 1,979 TOPS while its memory bandwidth stays fixed, so the ridge rises to about 591 operations per byte. A convolution layer that sits above the FP16 ridge can fall below the INT8 ridge, which is why quantized ResNet-50 inference can turn bandwidth bound on the same chip (section 11.6.2).

D.2.2 Dimensional analysis

The roofline model helps diagnose *where* a bottleneck lies. Before applying any performance equation, however, it must be verified as physically meaningful. Dimensional analysis provides this sanity check: any valid equation must be **dimensionally homogeneous**, meaning every term must resolve to the same units. If they do not, the equation contains an error.

Consider both levels of the iron law of ML systems (principle 3) introduced in section 1.7. First, in the multiplicative D·A·M form (equation 1.2), intermediate units cancel across the three factors to leave seconds per task:

$$T[\text{s}] = \frac{\text{Samples}}{\text{Task}} \times \frac{\text{FLOPs}}{\text{Sample}} \times \frac{\text{s}}{\text{FLOP}} = \frac{\text{s}}{\text{Task}}$$

Second, for serialized execution phases (equation 1.3), every additive term must resolve to time (seconds):

$$T[\text{s}] = \underbrace{\frac{D_{\text{vol}}[\text{bytes}]}{\text{BW}[\text{bytes/s}]}}_{\text{seconds}} + \underbrace{\frac{O[\text{FLOPs}]}{R_{\text{peak}}[\text{FLOP/s}] \cdot \eta_{\text{hw}}[1]}}_{\text{seconds}} + \underbrace{L_{\text{lat}}[\text{s}]}_{\text{seconds}}$$

- **Data term**: $\frac{\text{bytes}}{\text{bytes/s}} = \text{bytes} \times \frac{\text{s}}{\text{bytes}} = \text{s}$
- **Compute term**: $\frac{\text{FLOPs}}{\text{FLOP/s}} = \text{FLOPs} \times \frac{\text{s}}{\text{FLOP}} = \text{s}$
- **Latency term**: Already in seconds.

The equation is physically consistent. Apply this technique to any systems equation: if the dimensions do not match, the formula is wrong. "FLOPs" and "Bandwidth" cannot be traded directly because they have different units. Any such trade-off must convert through time, as the iron law does.

Once an equation is dimensionally sound, the next question is how its time terms scale across devices. Section D.2.3 answers that question with two complementary bounds.

D.2.3 Amdahl's law and Gustafson's law

Parallelization is the primary tool for scaling ML, but its limits depend on *how* the workload scales. The two laws differ in what they hold fixed. **Amdahl's law** governs how much faster a *fixed* task can run (optimizing latency). **Gustafson's law** governs how much *more* work can be done in the same time (optimizing throughput).

D.2.3.1 Strong scaling (Amdahl's Law)

Adding a thousand accelerators to a fixed training batch cannot shorten the step by more than 20× if 5 percent of each step is serial host dispatch or synchronization. **Strong scaling** measures how much faster a fixed-size problem runs as processors are added.

Amdahl's law (Amdahl 1967) states that speedup is limited by the serial fraction of the task.[4] Let $T(1) = 1$ be normalized single-processor execution time, composed of serial fraction $1 - f_{\text{parallel}}$ and parallelizable fraction f_{parallel}. If N_{workers} processors execute the parallel fraction with linear scaling and zero communication overhead, execution time on N_{workers} processors is:

$$T(N_{\text{workers}}) = (1 - f_{\text{parallel}}) + \frac{f_{\text{parallel}}}{N_{\text{workers}}}$$

The resulting theoretical speedup is:

$$\text{Speedup}(N_{\text{workers}}) = \frac{T(1)}{T(N_{\text{workers}})} = \frac{1}{(1 - f_{\text{parallel}}) + \frac{f_{\text{parallel}}}{N_{\text{workers}}}}$$

[4] **Gene Amdahl (1922–2015)**: A legendary computer architect at IBM, where he was the chief architect of the System/360. He later founded Amdahl Corporation to compete with IBM in the mainframe market.

As $N_{\text{workers}} \to \infty$, the term $\frac{f_{\text{parallel}}}{N_{\text{workers}}} \to 0$, and the speedup converges to $1/(1-f_{\text{parallel}})$. To see Amdahl's Law in action, suppose 5 percent of a training step is serial overhead (for example, Python global interpreter lock (GIL), kernel launch latency) and 95 percent is parallelizable matrix math:

- With $N_{\text{workers}} = 1$, speedup is 1.
- With $N_{\text{workers}} = 8$, speedup is $1/(0.05 + 0.95/8) \approx 5.9\times$.
- With $N_{\text{workers}} \to \infty$, speedup is capped at $1/0.05 = 20\times$.

No matter how many accelerators are added, this fixed workload cannot run faster than 20×. The same ceiling limits a single-node optimization: section 12.3.4 applies it to a measured pipeline, where an unchanged preprocessing stage caps the gain from a faster model.

D.2.3.2 Weak scaling (Gustafson's Law)

Instead of using 1,000 accelerators to finish a small training dataset in milliseconds, large-model training uses them to process a dataset 1,000× larger in the same wall-clock time. **Weak scaling** measures how much larger a problem can become while holding runtime fixed as processors are added.[5]

For N_{workers} processors, let $1-f_{\text{parallel}}$ be the serial fraction of execution time measured on those processors for the scaled workload, and f_{parallel} the parallel fraction. Gustafson's law (Gustafson 1988) derives "scaled speedup" by asking how long that scaled problem would take on a single processor. On N_{workers} processors, normalized runtime is $T(N_{\text{workers}}) = (1-f_{\text{parallel}}) + f_{\text{parallel}} = 1$. Executing the same total work on a single processor requires running the parallel fraction sequentially, taking $T(1) = (1-f_{\text{parallel}}) + N_{\text{workers}} \cdot f_{\text{parallel}} = N_{\text{workers}} - (1-f_{\text{parallel}})(N_{\text{workers}}-1)$. The resulting scaled speedup is:

$$\text{Scaled Speedup}(N_{\text{workers}}) = \frac{T(1)}{T(N_{\text{workers}})} = N_{\text{workers}} - (1-f_{\text{parallel}})(N_{\text{workers}}-1)$$

Because the parallel part grows linearly with N_{workers} while the serial fraction $1-f_{\text{parallel}}$ remains fixed, weak scaling can keep efficiency high as the problem grows. Using the same 5 percent serial overhead ($1-f_{\text{parallel}} = 0.05$), Gustafson's Law tells a very different story:

- With $N_{\text{workers}} = 1$, speedup is 1.
- With $N_{\text{workers}} = 8$, Scaled Speedup is $8 - 0.05 \times (7) = 8 - 0.35 = 7.65\times$.
- With $N_{\text{workers}} = 1000$, Scaled Speedup is $1000 - 0.05 \times (999) \approx 950\times$.

In weak scaling, efficiency remains high because the useful work (training the model) scales up to dwarf the fixed overheads. Section 8.7.1 shows how data-parallel training uses weak scaling to keep accelerators busy as the cluster grows.

[5] **John Gustafson**: A computer scientist known for his work in parallel computing and for introducing the Unum (universal number) format. His law was a direct response to the perceived "limits" of Amdahl's Law when applied to massive scale.

D.2.4 The training-time equation

Weak scaling explains why large training runs grow the dataset rather than shrink the wall-clock time. The training-time equation turns model size, data size, accelerator count, peak rate, and utilization into a single estimate of that wall-clock time. Section 8.2 applies it to the book's training workloads; the template below is its reference form.

Napkin Math D.1: The training time equation

Problem: How long does dense-transformer training take for a stated model size, token count, accelerator count, peak rate, and utilization?

Math:

$$T \approx \frac{6 \cdot P \cdot D}{N_{\text{GPU}} \cdot R_{\text{peak}} \cdot \eta_{\text{hw}}}$$

Variables:

- **Training FLOP factor**: The factor 6 derives from $2P$ FLOP/token for the forward pass and $4P$ FLOP/token for the backward pass ($2P$ for activation gradients and $2P$ for weight gradients), yielding $6PD$ FLOPs total across D training tokens.
- P: Number of model parameters.
- D: Number of training tokens.
- $N_{\textbf{GPU}}$: Number of accelerators.
- $R_{\textbf{peak}}$: Peak FLOP/s of one accelerator.
- $\eta_{\textbf{hw}}$: Hardware utilization, typically 30 percent–50 percent in this training estimate.

Example: Training a 1B parameter model on 20B tokens using 1 H100 (989 TFLOP/s) at 40 percent utilization. Total FLOPs $= 6 \times 1 \times 10^9 \times 2 \times 10^{10} = 1.2 \times 10^{20}$ FLOPs. Throughput $= 1 \times (9.89 \times 10^{14}) \times 0.40 \approx 3.956 \times 10^{14}$ FLOP/s. $T = \frac{1.2 \times 10^{20}}{3.956 \times 10^{14}} \approx 303,336.7$ seconds $\approx 5,055.6$ minutes.

Systems insight: Under these assumptions, training takes about 3.5 days. In D·A·M terms, this equation is the macroscopic product of Data (D tokens), Algorithm ($6P$ FLOPs/token), and Machine ($(N_{\text{GPU}} \cdot R_{\text{peak}} \cdot \eta_{\text{hw}})^{-1}$ s/FLOP): doubling the token count doubles the time, while doubling the accelerator count or the utilization halves it.

D.2.5 Little's Law

An inference server receiving 1,000 queries per second at a 50 ms average response time holds 50 requests in flight on average, and if each request occupies 1 GB of KV-cache state, a 24 GB accelerator runs out of memory before compute saturates. For capacity planning in stable inference systems, **Little's law** (Little 1961) relates long-run mean concurrency (Q_{req}), mean arrival rate (λ_{arr}), and mean time in system (T_{lat}):[6]

$$Q_{\text{req}} = \lambda_{\text{arr}} \times T_{\text{lat}}$$

[6] **John Little**: An Institute Professor at MIT and a pioneer in the field of operations research. His law, proved in 1961, is fundamental to queuing theory and is used across fields from manufacturing to computer network analysis.

The law follows from operational conservation of requests over any observation interval $[0, T_{\text{obs}}]$. Let $A(t)$ denote cumulative arrivals and $C(t)$ cumulative completions, so the instantaneous in-flight queue occupancy is $Q(t) = A(t) - C(t)$. The average number of requests in the system over $[0, T_{\text{obs}}]$ is $\bar{Q} = \frac{1}{T_{\text{obs}}} \int_0^{T_{\text{obs}}} Q(t)\, dt$. The total accumulated request-time $\int_0^{T_{\text{obs}}} Q(t)\, dt$ equals the sum of residence times $\sum_{i=1}^{N(T_{\text{obs}})} W_i$ of all $N(T_{\text{obs}})$ requests completed by time T_{obs} (plus boundary terms that vanish as $T_{\text{obs}} \to \infty$). Dividing both sides by T_{obs}:

$$\bar{Q} = \frac{1}{T_{\text{obs}}} \int_0^{T_{\text{obs}}} Q(t)\, dt = \frac{N(T_{\text{obs}})}{T_{\text{obs}}} \cdot \frac{1}{N(T_{\text{obs}})} \sum_{i=1}^{N(T_{\text{obs}})} W_i$$

In the limit as $T_{\text{obs}} \to \infty$ for a stable queue, $\lim_{T_{\text{obs}} \to \infty} \frac{N(T_{\text{obs}})}{T_{\text{obs}}} = \lambda_{\text{arr}}$ and $\lim_{N \to \infty} \frac{1}{N} \sum_{i=1}^{N} W_i = T_{\text{lat}}$, yielding $Q_{\text{req}} = \lambda_{\text{arr}} \times T_{\text{lat}}$ regardless of arrival distribution or service-time distribution. Because the identity requires no Poisson-arrival or exponential-service assumption, it applies directly to heavy-tailed large language model (LLM) generation workloads so long as the queue is stationary.

To see this in practice, consider sustaining 1,000 QPS with 50 ms average latency. The law dictates that the system must support 1000×0.05 s = 50 concurrent requests.

This sizes worker pools, but memory needs another assumption. If every in-system request simultaneously holds 1 GB of device state, the average population implies 50 GB; queued requests may instead stay in host memory or share batched state. If 24 device slots ($Q_{\text{req,max}}$, the most requests the device can hold at once) each remain occupied for 50 ms, their throughput proxy is $Q_{\text{req,max}}/T_{\text{lat}} = 24/0.05 = 480$ QPS; Little's law alone does not fix a maximum; device capacity does.

Serving systems use this relation to size request concurrency, and section 13.4.1 pairs it with a queueing model to show how latency degrades as utilization nears saturation. Together, these physics-based models (roofline, Amdahl, Gustafson, and Little) locate *where* a bottleneck lies; acting on that diagnosis requires the hardware structures that impose the bounds: the memory hierarchy, the links that move data between tiers, and the classes of hardware that package them.

D.3 Computer Architecture Essentials

A kernel can run at a small fraction of an accelerator's advertised peak when data movement, insufficient parallelism, synchronization, launch overhead, or software inefficiency stands in the way. Whereas physics sets the theoretical ceilings, computer architecture defines the machinery that determines how close a real workload can get to them across three structures: the memory hierarchy and its energy cost, the paths that move data between tiers, and the class of hardware that packages both.

D.3.1 The memory hierarchy

Computer systems rely on tiered storage architectures because no single physical medium simultaneously provides massive storage capacity and the lowest access latency. Faster, smaller, and costlier tiers sit close to the arithmetic units; larger and cheaper tiers sit farther away (figure D.2). When data movement sits on the critical execution path, staging tensors into the upper tiers avoids the orders-of-magnitude latency penalties of off-chip DRAM and persistent storage that table D.5 quantifies.

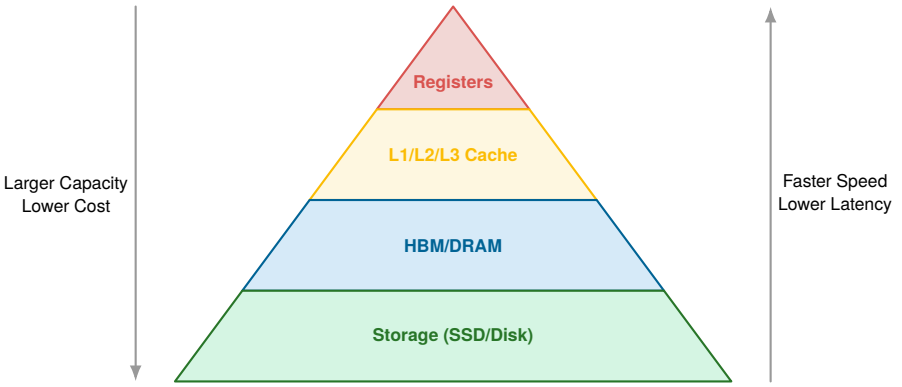

Figure D.2: The Memory Hierarchy: Performance depends on data proximity. Accessing HBM is roughly 1,000× slower than registers; accessing SSD is roughly 300,000× slower.

The memory hierarchy limits ML systems in both time and energy. Each access farther from the arithmetic units costs more energy, because the signal must drive longer, higher-capacitance wires (table D.7). Section 11.5.3 shows how accelerator design stages data in the upper tiers to avoid the off-chip cost.

Table D.7: Energy Across the Memory Hierarchy: Energy per 32-bit access in the cited 45 nm reference technology. The DRAM value is the Horowitz measurement; the register and SRAM values are illustrative hierarchy anchors. Absolute values fall with each process node, but the ordering and the gap between on-chip and off-chip access persist.

Tier	Technology	Energy per 32-bit Access	Relative to a Register
Register	Flip-flops	0.1 pJ	1×
L1 cache	SRAM	0.5 pJ	5×
L2 cache	SRAM	2 pJ	20×
Off-chip memory	DRAM/HBM	640 pJ	6,400×

Energy explains why data should stay high in the hierarchy. The table gives per-access costs, so the energy of a whole workload also depends on how many accesses reach each tier and how often data is reused. How long a transfer between tiers takes depends on two distinct properties of the path it crosses.

D.3.2 Bandwidth versus latency

Upgrading a 10 Gbps network link to 100 Gbps barely changes the delivery time of a 1 KB inference request, yet it cuts the transfer of a 1 GB checkpoint tenfold. Bandwidth (throughput) and latency

(delay) govern those two regimes as distinct constraints. For data volume D_{vol} sent over effective bandwidth BW with fixed path latency L_{lat}, and assuming the latency and serialization costs do not overlap, total transfer time is:

$$T = L_{\text{lat}} + \frac{D_{\text{vol}}}{\text{BW}}$$

The crossover point is the transfer size where the two terms are equal:

$$n^* = L_{\text{lat}} \times \text{BW}$$

For transfers below n^* (for example, small request or control messages), latency dominates. For transfers above it (for example, loading weights), bandwidth dominates.

Consider sending data over a 10 Gb/s link with 10 ms base request/response latency. The crossover size is 12.5 MB, so the dominant term depends on which side of that threshold the transfer falls.

- **Latency-dominated packet (1 KB)**: Transmission time is 1 KB $\times$ 8/10 Gb/s $\approx$ 0.8 µs. Total time is approximately 10 ms + 0.8 µs $\approx$ 10 ms. **Result**: Fixed path and protocol latency dominates; propagation is one component.
- **Bandwidth-dominated checkpoint (1 GB)**: Transmission time is 1 GB $\times$ 8/10 Gbps $\approx$ 800 ms. Total time is $\approx$ 10 ms + 800 ms = 810 ms. **Result**: Base latency is negligible; bandwidth is the bottleneck.

The classes of hardware that ML systems deploy on differ sharply in these properties. A data center accelerator and a microcontroller differ by orders of magnitude in memory bandwidth, compute, and power, and those differences decide which workloads each class can run.

D.3.3 Accelerator classes

The deployment paradigms of section 2.1 run on four classes of hardware that differ by orders of magnitude in peak rate, memory bandwidth, memory capacity, and power (table D.8). Each range spans representative devices in its class rather than any single product; section E.2.1 tabulates the products themselves.

Table D.8: Accelerator Classes: Order-of-magnitude ranges across representative devices in each class, rounded to one significant figure. Peak rate is the dense rate at each device's native ML precision (FP16 or BF16 for data center accelerators, mostly INT8 for edge, mobile, and microcontroller parts), so compare rates within a class rather than across classes. The ridge point is peak rate divided by memory bandwidth.

Class	Peak Rate	Memory Bandwidth	Memory Capacity	Power	Ridge Point
Datacenter accelerator	100–2,000 TFLOP/s	0.9–8 TB/s	30–200 GB	300–1,000 W	100–300 FLOP/byte
Edge module	4–300 TFLOP/s	8–200 GB/s	1–70 GB	2–60 W	100–1,000 FLOP/byte
Mobile SoC	20–40 TFLOP/s	50–80 GB/s	9–10 GB	5 W	300–700 FLOP/byte
Microcontroller	60–500 MFLOP/s	60–700 MB/s	0.2–4 MB	5–400 mW	0.2–6 FLOP/byte

Two patterns stand out across these classes: first, they span roughly 7 orders of magnitude in peak rate and 5 in power, so a model sized for one class rarely runs unchanged on another; second, whereas ridge points sit in the hundreds of FLOP per byte from data center to mobile, leaving the same low-intensity operations bandwidth bound on all three, a microcontroller's ridge sits within a few FLOP per byte, making nearly every layer of a keyword-spotting model compute bound and shifting the binding constraint to the power budget. Section 11.11 applies these classes to the choice of accelerator, while moving between classes also changes which numerical formats the hardware supports natively, and numerical precision directly controls *how much* data must move.

D.4 Numerical Representations

The numerical format decides how many bytes each value occupies and how much energy each operation costs. In ML systems, the choice of precision (FP32 vs. BF16 vs. INT8) is a direct trade-off between statistical fidelity and hardware throughput.

D.4.1 Floating-point formats

IEEE 754 standards and AI-specific numerical representations trade dynamic range (the span of representable values) against precision (the granularity of values within that range). Operational ranges and typical uses differ by format (table D.9), and the bit partitions of FP32, BF16, FP16, and INT8 show where each format spends its bits (figure D.3). BF16 retains FP32's full 8-bit exponent field, preserving the same dynamic range while truncating the mantissa to 7 bits, whereas FP16 widens the mantissa to 10 bits at the cost of a narrower 5-bit exponent.

Table D.9: Numerical Format Comparison: Each format trades off precision, dynamic range, memory footprint, and compute throughput.

Format	Bits	Exponent	Mantissa	Dynamic Range	Typical Use Case
FP32	32	8	23	$\sim 10^{-38}$ to 10^{38}	Training (full precision), reference inference
FP16	16	5	10	Normal: 6.10×10^{-5}–6.55×10^{4}	Training often with loss scaling, inference
BF16	16	8	7	FP32 normal exponent range	Training, usually without loss scaling
FP8	8	4 or 5	3 or 2	Varies	Training/inference on supported hardware
INT8	8	N/A	N/A	-128 to 127	Inference after quantization

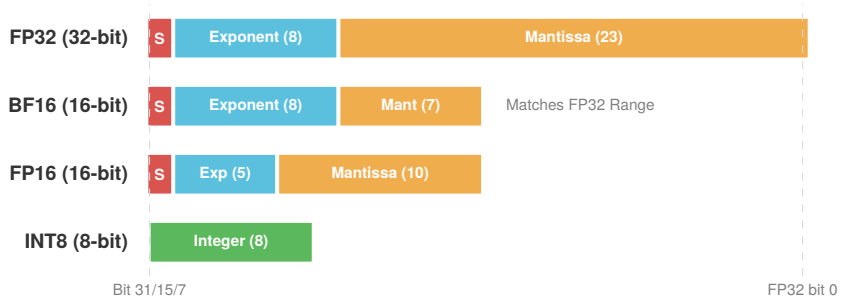

Figure D.3: Numerical Format Bit Layouts: A visual comparison of how FP32, BF16, FP16, and INT8 allocate their bits.

BF16[7] (Wang and Kanwar 2019; Kalamkar et al. 2019) occupies the same 16-bit storage class as FP16, yet the two formats behave very differently during training. Because BF16 allocates three more bits to the exponent than FP16, nominal bit width alone does not predict whether a training run will need gradient scaling.

7 **BF16 (brain floating point 16)**: Originally introduced with Google TPUv2 and later adopted by Intel, Arm, and NVIDIA, BF16 became a common training format across accelerator ecosystems. Its adoption made format support in hardware, kernels, and distributed-training libraries a portability concern rather than a vendor-specific feature.

> **Systems Perspective D.4: The dynamic range wall**
>
> The choice of numerical format is a direct application of the iron law of ML systems (principle 3). Reducing precision from FP32 to BF16 or FP16 halves the data volume term, potentially doubling throughput on memory-bound workloads. However, the *type* of 16-bit format determines the engineering complexity:
>
> - **Dynamic range (the exponent)**: BF16 preserves the eight-bit exponent of FP32 and therefore the same normal exponent range (Kalamkar et al. 2019).
> - **Precision (the mantissa)**: FP16 has a larger 10-bit mantissa than BF16 (7 bits), offering higher precision for values within its range. Its five-bit exponent, however, raises un-

derflow risk. FP16 training therefore often uses **loss scaling**, an operational step that multiplies gradients by a large constant to keep more values representable (Micikevicius et al. 2018); section 8.6.3 develops the full mixed-precision recipe.

- **Energy efficiency**: INT8 operations can be substantially more efficient than floating-point equivalents because they move less data and use simpler integer arithmetic paths. Moving to INT8 for inference is a primary lever for deploying neural networks under tight memory, latency, or power budgets (Jacob et al. 2018; Krishnamoorthi 2018); section 10.3.1 compares the formats on accuracy cost and hardware support.

D.4.2 Integer quantization

Storing weights and activations in 32-bit floating point spends four bytes per value and drives wide floating-point multipliers when 256 discrete levels often suffice for inference accuracy. Quantization cuts that cost by mapping continuous floating-point values to discrete integers, typically INT8, using either a symmetric or an asymmetric mapping to assign the floating-point range to 256 integer codes.

For symmetric quantization, let $\alpha_{\text{sym}} = \max|x|$ over the calibrated range, assume x is clipped to $[-\alpha_{\text{sym}}, \alpha_{\text{sym}}]$, and set the scale $s = \alpha_{\text{sym}}/127$. The signed INT8 code is:

$$x_q = \text{round}\left(\frac{x}{s}\right)$$

This symmetric mapping works well for weight distributions centered around zero, whereas asymmetric quantization handles distributions that are not centered (common after ReLU, which produces only nonnegative values) by shifting the range before scaling. Let α and β bound the calibrated range, clip x to $[\alpha, \beta]$, and set the scale $s = (\beta - \alpha)/255$. A common unsigned 8-bit mapping is:

$$x_q = \text{round}\left(\frac{x - \alpha}{s}\right)$$

The choice between symmetric and asymmetric quantization depends on the tensor's distribution and has measurable accuracy implications. Section 10.3 develops calibration, granularity, and the accuracy cost of each mapping on the book's workloads.

Summary

Machine-side diagnosis begins with units, ceilings, and working sets. The roofline model and the iron law identify which ceiling binds, and Amdahl's and Gustafson's laws, the memory hierarchy, the accelerator classes, and the numerical formats explain the gap between a measurement and that ceiling.

Treat peak specifications as ceilings, not predictions. Compare a measurement with the relevant ceiling, then trace the remaining gap to utilization, data movement, runtime overhead, architecture, or software. A back-of-envelope estimate is useful when it states its assumptions and units and makes the next measurement obvious. Chip specifications age with every product generation; the relationships here outlast them.

E

System Assumptions

A napkin calculation is only as trustworthy as the inputs behind it, and those inputs are easy to lose track of: an accelerator's peak rate, a model's parameter count, an electricity price, an energy cost per operation. This appendix gathers those canonical values and the unit conventions they depend on into a single reference sheet, so that a reader can check an estimate or substitute a newer figure. The chapters can then argue from numbers without restating where each one came from.

How to Use This Appendix

Every value here is dated: it belongs to a particular product, model, or price, and it changes when the next generation ships. Ratios and orders of magnitude, such as the energy gap between a DRAM access and an arithmetic operation, hold much longer, and section D.1 collects them. The NVIDIA H100 is the book's reference machine, so training and serving examples plug in the values of section E.2.2 unless a chapter names another device. Table E.1 maps each need to the section that holds the values. Section E.10 records where each value comes from, so a reader can substitute a current or local value and rerun the estimate without changing its method.

Table E.1: Where to Look: Each need maps to the section of this appendix that holds the values.

Need	Section
Convert a unit alias or check a decimal prefix	section E.1
Compare accelerator generations on one page	section E.2.1
Plug in the reference machine's peak rates, bandwidth, or ridge point	section E.2.2
Look up an older or alternative accelerator	section E.2
Size a mobile, edge, or microcontroller deployment	section E.2.9
Check which numeric formats a GPU generation supports	section E.2.10
Interpret an advertised peak-throughput claim	section E.2.11
Turn a list price into a price per unit of peak throughput	section E.2.12
Find a lighthouse's home regime and the resource that binds it	section E.3.1
Look up a model's parameters, operations, or training scale	section E.3.2
Size training-state memory per parameter	section E.4
Estimate the energy of an operation or a memory access	section E.5
Compare access latency and bandwidth across memory, links, and storage	section E.6.1
Estimate a transfer time over PCIe, NVLink, InfiniBand, or Ethernet	section E.6.2
Price electricity or data egress	section E.7
Anchor a production request volume or sensor data rate	section E.8
Follow a complete estimate built from these values	section E.9
Trace a value to its source	section E.10

E.1 Unit Conventions

Mixing binary (2^{30}-byte) capacities with decimal (10^9-byte) bandwidths shifts a memory or transfer estimate by 7 percent before any rounding, and confusing total FLOPs with FLOP/s turns a time

equation into a unit error. Every quantitative example in this book avoids those mismatches by using shared unit conventions: decimal data prefixes, distinct FLOPs and FLOP/s quantities, and the aliases in table E.2. Each row gives the multiplier k in `1 alias` $= k$ `base`. Data prefixes use decimal SI (KB $= 10^3$ bytes, not 1024). Binary IEC prefixes do not appear in the book's prose. Throughput quantities (FLOP/s, GB/s) combine these aliases with time; adding incompatible dimensions (bytes to FLOP/s) is a category error in napkin math, not a unit conversion.

Hardware capacity labels are the one deliberate exception. The reference tables retain vendor nameplate numbers and labels; the byte budgets used in calculations follow the book's device assumptions. For example, the book models an 80 GB accelerator with 80×2^{30} bytes and assigns 512×2^{10} bytes to a microcontroller with 512 KB of SRAM. These are modeled capacity assumptions, not universal guarantees inferred from the labels. Every other data quantity, including model footprints, activation sizes, and transfer volumes, uses the decimal prefixes above. Where a worked example subtracts a computed footprint from a device capacity, the capacity is converted to decimal units alongside the footprint, so that the arithmetic printed on the page is the arithmetic a reader can reproduce.

Table E.2: Unit Conventions: Decimal SI aliases and scale factors (book convention for napkin math). Throughput forms such as FLOP/s and GB/s divide work or data by time using the same conventions.

Alias	Multiplier	Base unit
`byte`	1	byte
`KB`	1000	byte
`MB`	1e+06	byte
`GB`	1e+09	byte
`TB`	1e+12	byte
`PB`	1e+15	byte
`flop`	1	flop
`GFLOPs`	1e+09	flop
`TFLOPs`	1e+12	flop
`ZFLOPs`	1e+21	flop
`param`	1	param
`Mparam`	1e+06	param
`Gbps`	1e+09	bit/s
`NS`	10^{-9}	second
`US`	10^{-6}	second
`MS`	10^{-3}	second
`second`	1	second
`hour`	3600	second
`day`	86400	second
`joule`	1	joule
`watt`	1	watt
`meter`	1	meter

E.2 Accelerator Specifications

Sizing a training cluster or a serving fleet requires a single set of per-chip ceilings so that estimates across chapters compare the workload rather than shifting hardware baselines. These **accelerator assumptions** supply the peak throughput, memory bandwidth, memory capacity, and thermal design power (TDP) for each generation the chapters cite. Values are vendor datasheet peaks, which serve as ceilings for napkin math rather than as sustained utilization, drawn from NVIDIA product documentation and IEEE Micro architecture articles (NVIDIA Corporation 2017, 2020b, 2020a, 2021a, 2018, 2024; Choquette et al. 2021; Choquette 2023), AMD MI300X documentation (AMD 2023), Google Tensor Processing Unit (TPU) publications (Jouppi et al. 2020; Jouppi et al. 2023), and Google

Cloud's current TPU v6e specification page (Google Cloud 2026b). Capacity rows keep the vendor's labeled capacity. The master matrix compares the generations on one page, and the sections after it give the per-chip values and three dated comparisons on precision support, advertised peaks, and price per unit of peak throughput. Section 11.6 develops the roofline analysis that turns these values into a regime for a given workload.

E.2.1 Master accelerator matrix

Side by side, the accelerators the book cites span more than an order of magnitude in peak rate, memory capacity, and power, yet most place their FP16 ridge point within a band of a few hundred FLOP per byte (table E.3). The ridge point divides peak FP16 throughput by memory bandwidth, so a workload whose arithmetic intensity falls below a chip's ridge is bandwidth bound on that chip and gains nothing from a faster datapath (section D.2.1 develops the model). Two chips sit far outside that band, at opposite ends. The first TPU paired an INT8-only datapath with DDR3 memory, which places its ridge point far above the band, and the wafer-scale engine keeps its weights in on-wafer SRAM, which places its ridge point far below it.

Table E.3: Master Accelerator Specification Matrix: Dense peak throughput, memory capacity and bandwidth, TDP, and FP16 ridge point (I_{ridge} = peak FP16 throughput divided by memory bandwidth) for each accelerator the book cites, read from the hardware registry. The FP8 or INT8 column gives each chip's dense low-precision peak where the registry lists one; TPU v1's ridge point uses its INT8 peak because it has no floating-point path. Memory is the vendor nameplate capacity.

Accelerator	Year	FP16/BF16 Peak	FP8 or INT8 Peak	Memory	Bandwidth	TDP	Ridge Point (I_{ridge})
NVIDIA V100	2017	125 TFLOP/s	—	32 GB	900 GB/s	300 W	138.9 FLOP/byte
NVIDIA T4	2018	65 TFLOP/s	130 TOPS (INT8)	16 GB	320 GB/s	70 W	203.1 FLOP/byte
NVIDIA A100	2020	312 TFLOP/s	624 TOPS (INT8)	80 GB	2,039 GB/s	400 W	153.0 FLOP/byte
NVIDIA H100	2022	989 TFLOP/s	1,979 TFLOP/s (FP8)	80 GB	3,350 GB/s	700 W	295.2 FLOP/byte
NVIDIA H200	2023	989 TFLOP/s	1,979 TFLOP/s (FP8)	141 GB	4,800 GB/s	700 W	206.0 FLOP/byte
NVIDIA B200	2024	2,250 TFLOP/s	4,500 TFLOP/s (FP8)	180 GB	8,000 GB/s	1,000 W	281.2 FLOP/byte
AMD Instinct MI300X	2023	1,307 TFLOP/s	2,614 TFLOP/s (FP8)	192 GB	5,300 GB/s	750 W	246.6 FLOP/byte
Intel Gaudi 2	2022	432 TFLOP/s	865 TFLOP/s (FP8)	96 GB	2,450 GB/s	600 W	176.3 FLOP/byte
Intel Gaudi 3	2024	1,835 TFLOP/s	1,835 TFLOP/s (FP8)	128 GB	3,700 GB/s	900 W	495.9 FLOP/byte
Google TPU v1	2017	—	92 TOPS (INT8)	8 GB	34 GB/s	75 W	2,705.9 FLOP/byte (INT8)
Google TPU v2	2017	46 TFLOP/s	—	16 GB	700 GB/s	280 W	65.7 FLOP/byte
Google TPU v3	2018	123 TFLOP/s	—	32 GB	900 GB/s	450 W	136.7 FLOP/byte
Google TPU v4	2021	275 TFLOP/s	—	32 GB	1,200 GB/s	200 W	229.2 FLOP/byte
Google TPU v5p	2023	459 TFLOP/s	918 TOPS (INT8)	95 GB	2,760 GB/s	300 W	166.3 FLOP/byte
Google TPU v6e	2024	918 TFLOP/s	—	32 GB	1,638 GB/s	300 W	560.4 FLOP/byte

Accelerator	Year	FP16/BF16 Peak	FP8 or INT8 Peak	Memory	Bandwidth	TDP	Ridge Point (I_{ridge})
Cerebras WSE-3	2024	125,000 TFLOP/s	—	44 GB SRAM	21 PB/s	23,000 W	6.0 FLOP/byte

E.2.2 NVIDIA H100 (reference machine)

The NVIDIA H100 is the default accelerator for the book's training and serving calculations, supplying a single baseline for peak FLOP/s, high-bandwidth memory (HBM) bandwidth, and capacity across chapters. It pairs Hopper-generation FP8 Tensor Cores and the Transformer Engine with HBM3 memory (Choquette 2023) (table E.4).

Table E.4: NVIDIA H100 (Hopper), the Reference Machine: Peak specifications from the Hopper architecture overview and datasheet (Choquette 2023), as recorded in the hardware registry. Ridge points divide each dense peak by HBM3 bandwidth. The list price is the representative range used in cost-performance examples, not a quote.

Assumption	Value
Release year	2022
Peak FP16/BF16 tensor throughput (dense)	989 TFLOP/s
Peak FP16/BF16 tensor throughput (2:4 sparse)	1,979 TFLOP/s
Peak FP8 tensor throughput (dense)	1,979 TFLOP/s
Peak INT8 tensor throughput (dense)	1,979 TOPS
Peak TF32 tensor throughput (dense)	494 TFLOP/s
Peak FP32 throughput (CUDA cores)	67 TFLOP/s
HBM3 capacity (nameplate)	80 GB
HBM3 bandwidth	3.35 TB/s
L2 cache	50 MB
Streaming multiprocessors	132
NVLink 4.0 bandwidth (bidirectional total)	900 GB/s
PCIe Gen5 x16 host link (per direction)	64 GB/s
TDP	700 W
Ridge point, FP16/BF16	295.2 FLOP/byte
Ridge point, FP8/INT8	590.7 FLOP/byte
List price (approximate)	~$25,000–30,000

The two ridge points turn these values into a classification. A kernel whose arithmetic intensity exceeds the FP16/BF16 ridge of 295.2 FLOP/byte is compute bound on the H100; one below it is bandwidth bound and runs no faster on a faster datapath. FP8 and INT8 double the peak rate while bandwidth stays fixed, so the ridge rises to 590.7 FLOP/byte and a layer that was compute bound at FP16 can fall below it after quantization. Section D.2.1.1 works the roofline example on these values, and section 11.6 develops the regimes.

E.2.3 NVIDIA V100

The Volta-generation V100 (table E.5) introduced Tensor Cores and is the accelerator of the GPT-3 training run that the book's cost and energy examples reconstruct. Its HBM2 bandwidth and power envelope serve as the early-generation baseline against which Ampere, Hopper, and Blackwell gains are measured.

Table E.5: NVIDIA V100 (Volta): Peak specs from NVIDIA's architecture whitepaper and product datasheet (NVIDIA Corporation 2017, 2020b). The V100 anchors baseline-generation comparisons.

Assumption	Value	Unit
Peak FP16 tensor throughput (V100)	125	TFLOP/s

Assumption	Value	Unit
Peak FP32 throughput (V100)	15.7	TFLOP/s
HBM bandwidth (V100)	900	GB/s
HBM capacity (V100)	32	GB
TDP (V100)	300	W

E.2.4 NVIDIA T4

Low-power inference comparisons use the Turing-generation T4 as their baseline (table E.6). Because the card fits within a low-power PCIe slot envelope without auxiliary power connectors, it anchors cost-per-query and edge-server comparisons across the serving chapters.

Table E.6: NVIDIA T4 (Turing): Peak specs from NVIDIA Tesla T4 product documentation (NVIDIA Corporation 2018). Its low TDP makes this inference accelerator a useful cost-per-inference anchor.

Assumption	Value	Unit
Peak FP16 tensor throughput (T4)	65	TFLOP/s
Peak INT8 throughput (T4)	130	TOPS
Memory bandwidth (T4)	320	GB/s
TDP (T4)	70	W

E.2.5 NVIDIA A100

The Ampere-generation A100 (table E.7) preceded the reference machine, and dated comparisons across generations use its values. It introduced TF32 and BF16 Tensor Cores alongside the HBM2e capacity tier that the H100 retained.

Table E.7: NVIDIA A100 (Ampere): Peak specs from NVIDIA's architecture whitepaper, 80 GB datasheet, and architecture article (NVIDIA Corporation 2020a, 2021a; Choquette et al. 2021). Ampere introduced TF32 Tensor Cores and the HBM capacity point that the H100 kept, with HBM3 in place of HBM2e.

Assumption	Value	Unit
Peak FP16 tensor throughput (A100)	312	TFLOP/s
Peak FP32 throughput (A100)	19.5	TFLOP/s
Peak INT8 throughput (A100)	624	TOPS
Peak TF32 throughput (A100)	156	TFLOP/s
HBM bandwidth (A100)	2039	GB/s
HBM capacity (A100)	80	GB
TDP (A100)	400	W

E.2.6 NVIDIA B200

Forward-looking capacity-planning examples rely on Blackwell-generation specs (table E.8). Its HBM3e bandwidth and native FP4 and FP8 Tensor Core rates show how memory capacity, bandwidth, and power continue to scale past Hopper.

Table E.8: NVIDIA B200 (Blackwell): Peak specs from NVIDIA Blackwell product documentation (NVIDIA Corporation 2024). Forward-looking capacity-planning examples use its HBM3e bandwidth and FP8 throughput.

Assumption	Value	Unit
Peak FP16 tensor throughput (B200)	2250	TFLOP/s
Peak FP8 tensor throughput (B200)	4500	TFLOP/s
Peak FP4 throughput (B200)	9000	TFLOP/s

Assumption	Value	Unit
HBM bandwidth (B200)	8	TB/s
HBM capacity (B200)	180	GB
TDP (B200)	1000	W

E.2.7 AMD Instinct MI300X

The MI300X capacity, bandwidth, throughput, and power specifications give a cross-vendor comparison with the H100 used elsewhere (table E.9). Its larger HBM3 capacity and memory bandwidth illustrate how an accelerator tuned for memory-bound serving shifts the single-device capacity ceiling.

Table E.9: AMD Instinct MI300X: Peak specs from AMD Instinct MI300X product documentation (AMD 2023). Its HBM capacity and bandwidth make it a cross-vendor baseline for bandwidth-bound and capacity-bound workloads.

Assumption	Value	Unit
Peak FP16 tensor throughput (MI300X)	1307	TFLOP/s
HBM bandwidth (MI300X)	5.3	TB/s
HBM capacity (MI300X)	192	GB
TDP (MI300X)	750	W

E.2.8 Google TPU v4, v5p, and v6e

When comparing training economics across accelerator families, TPUs, Google's custom application-specific integrated circuit (ASIC) accelerators, offer the main alternative to GPUs (table E.10). Each chip couples its systolic arrays to HBM and to neighboring chips over the Inter-Chip Interconnect (ICI), the TPU counterpart of NVLink.

Table E.10: Google TPU v4, v5p, and v6e (Trillium): TPU v4 values come from Google TPU publications (Jouppi et al. 2023), TPU v6e values from Google Cloud's Trillium specification page (Google Cloud 2026b), and TPU v5p values from Google Cloud's v5p specification as recorded in the hardware registry. ICI bandwidth for v5p and v6e is the bidirectional total per chip.

Assumption	TPU v4	TPU v5p	TPU v6e
Peak BF16 throughput	275 TFLOP/s	459 TFLOP/s	918 TFLOP/s
Peak INT8 throughput	—	918 TOPS	—
HBM capacity	32 GB	95 GB	32 GB
HBM bandwidth	1,200 GB/s	2,760 GB/s	1,638 GB/s
On-chip vector memory (VMEM)	—	128 MB	—
ICI bandwidth	300 GB/s	1,200 GB/s	800 GB/s
TDP	200 W	300 W	300 W

E.2.9 CPU and mobile/edge processors

Edge and mobile ML examples rely on a different performance baseline (table E.11), well below data center throughput. The microcontroller rows describe the ESP32-S3, the board on which the book's keyword-spotting examples run.

Table E.11: CPU, Mobile NPU, Edge, and Microcontroller Specs: Illustrative reference points for edge, mobile, and microcontroller examples (not vendor peaks for a single SKU, except the ESP32-S3 rows). The contrast with data-center accelerators shows why deployment target shapes every design decision.

Assumption	Value	Unit
Peak FP32 throughput (reference CPU)	1	TFLOP/s

Assumption	Value	Unit
DRAM bandwidth (reference server)	50	GB/s
Reference NPU throughput (iPhone 15 Pro)	35	TOPS
Memory bandwidth (iPhone 15 Pro)	51.2	GB/s
TDP (mobile device, reference)	5	W
Power (edge object detector, reference)	2	W
Battery capacity (phone, reference)	15	Wh
On-chip SRAM (microcontroller, ESP32-S3)	520	KiB
TDP (microcontroller, ESP32-S3)	0.4	W

E.2.10 Precision support by generation

Tensor Core format support widened with each NVIDIA generation from Volta through Ampere (table E.12). Volta supported little below FP16, whereas Ampere introduced TF32, which combines the exponent range of FP32 with the mantissa width of FP16 (NVIDIA 2020b), alongside broader support for BF16, INT8, and INT4 (NVIDIA Corporation 2017, 2018, 2020a). Later generations narrow the formats further, with FP8 on Hopper and FP4 on Blackwell (table E.4; table E.8). Section 11.4.5.1 explains why each narrower format raises peak throughput on the same silicon.

Table E.12: Precision Support Evolution: From Volta through Ampere, Tensor Core support expanded from FP16 to TF32, BF16, and integer formats, broadening the precision choices available to training and inference; the CUDA-core column shows the separate scalar/vector formats each generation supports.

Architecture	Year	Tensor Core Formats	CUDA Core Formats
Volta	2017	FP16	FP64, FP32, FP16
Turing	2018	FP16, INT8, INT4, INT1	FP64, FP32, FP16, INT8
Ampere	2020	FP64, TF32, BF16, FP16, INT8, INT4	FP64, FP32, FP16, BF16, INT8

E.2.11 Advertised peak throughput across generations

Advertised single-chip GPU throughput rose by more than three orders of magnitude across the generations plotted in figure E.1, which combine architectural scaling with lower numerical precisions and structured sparsity (NVIDIA Corporation 2017, 2020a, 2024; Choquette 2023). Because the points mix precision formats, combine FLOP/s with INT8 operations per second, and assume structured sparsity for the A100, H100, and B200, they do not measure one consistent quantity; instead, the curve compares each generation's most prominent advertised path rather than same-precision application performance. Table E.3 gives the same chips' dense, precision-specific peaks, bandwidths, and power limits.

E.2.12 Accelerator cost worksheet

An illustrative cost worksheet divides an approximate list price by a representative peak for three accelerator generations (table E.13). Because list prices vary across vendor, region, contract terms, and procurement volume while the throughput rows use distinct numerical precision modes, the resulting price-per-peak-operation ratio is meaningful within a single row to show how a price assumption enters the arithmetic, rather than as a cross-device ranking. Section 11.11.2 states the durable rule the worksheet supports, which divides cost by the throughput a workload delivers on its binding resource rather than by the advertised peak.

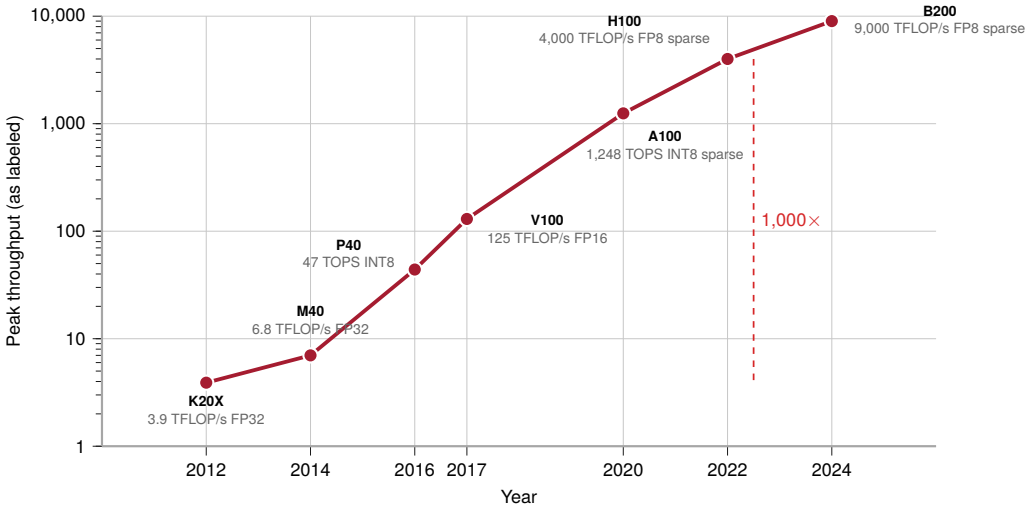

Figure E.1: Advertised GPU Peak Capability Across Generations: Single-chip values are plotted on a logarithmic axis. The precision label at each point matters because the curve does not measure same-precision scaling. The series follows Dally (2023; NVIDIA Corporation 2017, 2020a, 2024; Choquette 2023).

Table E.13: Illustrative Accelerator Cost Worksheet: Each row divides an approximate acquisition-price assumption by the representative peak mode shown. Because precision, sparsity assumptions, and price sources differ, the ratios are not comparable as workload performance. Total cost also includes utilization, memory capacity, power, cooling, interconnect, software, and infrastructure.

Accelerator	List Price	Representative Peak (precision shown)	Memory Bandwidth	Price per Peak TFLOP/s
NVIDIA V100	~$10,000	125 TFLOP/s (FP16)	900 GB/s	$80/(TFLOP/s)
NVIDIA A100	~$15,000	312 TFLOP/s (FP16)	2,039 GB/s	$48.1/(TFLOP/s)
NVIDIA H100	~$25,000–30,000	494 TFLOP/s (TF32)	3,350 GB/s	~$50.6/(TFLOP/s)

E.3 Model Specifications

The book's quantitative examples run on a small set of recurring workloads. The first table places the five lighthouse workloads in the regimes they occupy on their machines; the second gives the parameter counts, operation budgets, and training-scale anchors of every model the chapters cite.

E.3.1 Lighthouse workloads

Five lighthouse workloads recur through the book, each introduced in the regime it typifies (section 1.7.1; section 2.3.2). Because a regime belongs to a workload on a machine rather than to a model name, each row of table E.14 is keyed by model, phase, and batch, with the second GPT-2 XL row recording a crossing out of the model's home regime. Across those rows, four regimes appear: compute-bound and bandwidth-bound workloads are separated by the roofline's ridge point, whereas capacity-bound and power-bound workloads are constrained before either time term applies because the working set must fit in memory and the energy budget must cover the run. For the compute- and bandwidth-bound rows, the last column compares the time a step spends on arithmetic at peak FP16 throughput with the time it spends reading the weights once at peak HBM bandwidth on one H100, and whichever is larger names the regime; a fifth regime, overhead-bound, arises when the iron law's fixed latency term dominates and belongs to a deployment choice such as batch-one serving rather than to a lighthouse (section A.7.2).

Table E.14: Lighthouse Workloads by Model, Phase, and Batch: Each row's regime on its machine, with the registry quantities that set it. Times are idealized lower bounds at peak FP16 throughput and peak HBM bandwidth of one H100 (the phone NPU's INT8 peak for MobileNetV2); activation traffic is excluded, so the comparison establishes a regime only where the two times differ by orders of magnitude. Training costs about three forward passes, and decode costs two FLOPs per parameter per token.

Light-house	Phase	Batch	Machine	Regime	Binding Resource	What Sets the Regime
ResNet-50	Training	256 images	H100	Compute-bound	Tensor throughput	6.4 ms of arithmetic against 15.3 µs of weight reads per step
Mo-bileNetV2	Inference	1 image	Phone NPU	Compute-bound (efficient regime)	Arithmetic within a phone's power envelope	17.1 µs of arithmetic at the NPU's 35 TOPS peak, inside a 5 W device envelope
GPT-2 XL	Decode	1 sequence	H100	Bandwidth-bound	HBM bandwidth	3.0 µs of arithmetic against 0.90 ms of weight reads per token
GPT-2 XL	Training	32 sequences of 1,024 tokens	H100	Compute-bound (crossing)	Tensor throughput	298.2 ms of arithmetic against 0.90 ms of weight reads per step
Llama 3 8B	Decode, 8,192-token context	1 sequence	H100	Bandwidth-bound	HBM bandwidth and KV-cache capacity	5.1 ms reading 16.1 GB of weights and 1.07 GB of KV cache, against 16.2 µs of arithmetic per token
DLRM	Inference	Any	H100	Capacity-bound	Memory capacity	100 GB of embedding tables against 80 GB of HBM
KWS (DS-CNN)	Inference	1 audio window	ESP32-S3	Power-bound	Energy per inference	200 KB INT8 model in 520 KB of SRAM, on a board drawing 50 mW to 1.2 W

The same model changes regime when phase or batch changes. GPT-2 XL streams every weight to produce one decode token, but a training step amortizes one weight read over tens of thousands of tokens and becomes arithmetic-dominated, while Llama 3 8B's KV cache adds bytes to every decode step as the context grows. Section 11.6 places these workloads on the H100 roofline, section 6.7.4.2 sizes the KV cache that makes decode bandwidth bound, and section 13.9.5 budgets that cache against serving capacity.

E.3.2 Reference model specifications

Parameter counts, per-inference FLOP budgets, and published training-scale anchors form the **reference model assumptions** behind training-cost, memory-footprint, and inference-workload examples (table E.15). Published model sizes follow primary papers, model reports, and official documentation (Devlin et al. 2019; Radford et al. 2019; Brown et al. 2020; Dubey et al. 2024; He et al. 2016a; Sandler et al. 2018; Ultralytics 2023; Naumov et al. 2019; C. Banbury, Reddi, Torelli, Holleman, Jeffries, Kirber, et al. 2021), whereas the inference FLOP budgets are book-derived from sequence length 128 for BERT-Base, 224×224 images for ResNet-50 and MobileNetV2, and 640×640 images for YOLOv8-Nano, counting two FLOPs per multiply-add in the vision models. For large-scale training anchors, GPT-3 training FLOPs follow (Brown et al. 2020) while its duration and accelerator count come from the published carbon reconstruction (Patterson et al. 2021), and because the GPT-4 technical report does not disclose architecture size, the GPT-4 parameter count and training GPU-days use public third-party mixture of experts (MoE) estimates (Patel and Wong 2023). Finally, the DLRM row represents the book's reference configuration, whose FP32 embedding values exceed one accelerator's memory, rather than a single production recommender.

Table E.15: Reference Model Specifications: Parameter counts and FLOP budgets for worked examples, with sources as given in the text above. GPT-4 rows cite (OpenAI et al. 2023) for the official model family and (Patel and Wong 2023) for the public MoE parameter and GPU-day estimates used in this edition.

Assumption	Value	Unit
Inference FLOPs (BERT-Base)	2.2e+10	flop
Parameters (BERT-Base)	1.1e+08	param
Parameters (Llama 3 8B)	8.03e+09	param
Hidden dimension (GPT-2 XL)	1600	-
Layers (GPT-2 XL)	48	-
Parameters (GPT-2 XL)	1.5e+09	param
Parameters (GPT-3)	1.75e+11	param
Reference training duration (GPT-3)	14.8	d
Reference training accelerators (GPT-3)	10,000	V100 GPUs
Reference training FLOPs (GPT-3)	3.14e+23	flop
Parameters (GPT-4, public MoE estimate)	1.76e+12	param
Reference training GPU-days (GPT-4)	2.5e+06	GPU-days
Inference FLOPs (ResNet-50)	8.2e+09	flop
Parameters (ResNet-50)	2.56e+07	param
Inference FLOPs (MobileNetV2)	6e+08	flop
Parameters (MobileNetV2)	3.50487e+06	param
Inference FLOPs (YOLOv8-Nano)	8.7e+09	flop
Embedding table size (DLRM, reference)	100	GB
Embedding values (DLRM, reference)	2.5e+10	embedding values
Parameters (KWS DS-CNN)	200000	param
Inference FLOPs (KWS DS-CNN)	2e+07	flop

E.4 Training Memory Conventions

Training-memory napkin math assumes the mixed-precision Adaptive Moment Estimation (Adam) storage model used in the worked training-memory estimate and several training chapters: BF16 weights, BF16 gradients, and FP32 master weights plus Adam first- and second-moment buffers (16 bytes per parameter in total). This is a book convention, not a measured hardware constant. The BF16 data path uses standard BF16 mixed-precision training (Kalamkar et al. 2019), the FP32 master copy of the weights follows earlier FP16 work (Micikevicius et al. 2018; NVIDIA 2017), and Adam's first- and second-moment buffers follow (Kingma and Ba 2015). Multiplying the bytes per parameter by the parameter count gives the nonactivation training-state footprint, and table E.16 lists the per-component byte widths. Section C.3.3 derives each component and the activation memory that adds to it, and section 8.3.2 applies the convention to the book's training runs.

Table E.16: Training Memory Conventions: Per-parameter storage for mixed-precision Adam, 16 bytes before activations. Book convention for napkin math; see (NVIDIA 2017) for mixed-precision training context.

Assumption	Value	Unit
Weight/gradient width (BF16)	2	bytes
Master weight width (FP32)	4	bytes
Master + Adam states per parameter (FP32)	12	bytes
Bytes per parameter (mixed-precision Adam)	16	bytes

E.5 Energy Constants

The specifications above bound how fast a chip can run; **energy assumptions** determine whether the design is thermally and economically viable at the level of the operation and the memory

access. Horowitz's 45 nm arithmetic and 32-bit DRAM estimates (Horowitz 2014), together with illustrative book anchors for register and SRAM access, MobileNetV2 inference, and 5G transfer, underpin the book's efficiency comparisons but are not process-independent. Access energy rises from registers through DRAM, and the arithmetic energy of an add and a multiply falls with operand width (table E.17). The access hierarchy quantifies why data reuse dominates kernel design, and section D.3.1 explains the physics behind it as ratios that hold across process nodes.

Table E.17: Energy per Operation and Access: Arithmetic and 32-bit DRAM estimates use Horowitz's 45 nm model (Horowitz 2014), and the per-byte DRAM row is derived from that estimate. Register, SRAM, MobileNetV2, and 5G rows are illustrative book anchors. The roughly 6,400× gap between a 0.1 pJ register access and a 640 pJ DRAM access explains why data reuse dominates ML kernel optimization.

Assumption	Value	Unit
Register access energy	0.1	pJ
L1 SRAM access energy	0.5	pJ
L2 SRAM access energy	2	pJ
DRAM access energy (32-bit)	640	pJ
DRAM access energy (per byte)	160	pJ/byte
FP32 add energy (45 nm)	0.9	pJ/add
FP16 add energy (45 nm)	0.4	pJ/add
INT32 add energy (45 nm)	0.1	pJ/add
INT8 add energy (45 nm)	0.03	pJ/add
FP32 multiply energy (45 nm)	3.7	pJ/multiply
FP16 multiply energy (45 nm)	1.1	pJ/multiply
INT8 multiply energy (45 nm)	0.2	pJ/multiply
MobileNetV2 inference energy (reference)	0.1	mJ
5G transfer energy per MB	100	mJ/MB

The arithmetic rows carry two orderings that hold at every process node. A multiply costs several times an add at the same precision, because multiplier area grows roughly with the square of the operand bit width b while an adder grows linearly in it, and both fall as the operand narrows (Horowitz 2014; Dally et al. 2021). Newer nodes lower every absolute value in the table, so the 45 nm figures are upper anchors for current silicon, and the orderings, not the absolute values, are what precision and reuse arguments depend on.

E.6 Interconnect and Network Bandwidth

Energy costs operate at the chip level, but real ML systems also move data across interconnects, between accelerators, across racks, and over wide-area networks. These **bandwidth assumptions** apply when chapters reason about gradient synchronization, pipeline bubbles, checkpoint I/O, or cross–data center latency. The first table gives the latency and bandwidth of each tier of one H100 node, from registers to local storage; the second gives the link families that connect accelerators, hosts, and nodes.

E.6.1 Latency and bandwidth by tier

Access latency rises by five orders of magnitude from a register to an NVMe read, while bandwidth falls from terabytes per second at HBM to single gigabytes per second at local storage (table E.18). Section D.1.1 expresses the same tiers as decades and as multiples of a register access, which change more slowly than the values here.

Table E.18: Latency and Bandwidth by Tier (H100 Node): Representative access latency and bandwidth from registers to local storage. Register, L1, and L2 latencies are generic on-chip anchors; the HBM row uses a generic off-chip DRAM latency. NVLink bandwidth is the bidirectional total; other bandwidths are per direction. Host DRAM latency is not recorded, so that cell is left empty.

Tier	Technology	Latency	Bandwidth
Registers	Flip-flops	0.3 ns	—
L1 cache	SRAM	1 ns	—
L2 cache	SRAM	4 ns	—
Accelerator memory	HBM3 (H100)	300 ns	3,350 GB/s
Accelerator link	NVLink 4.0 (H100)	500 ns	900 GB/s
Host link	PCIe Gen5 x16	1,000 ns	64 GB/s
Host memory	DDR4/DDR5	—	50 GB/s
Network	InfiniBand NDR	5 µs	50 GB/s
Local storage	NVMe SSD (Gen4)	100 µs	7 GB/s

E.6.2 Interconnect specifications

On the reference node, NVLink runs more than an order of magnitude faster than the PCIe host link, and the host link runs faster than the node's InfiniBand NDR port, so the boundary a transfer crosses sets its cost before its size does (table E.19). Every rate is quoted in GB/s for comparison, with the direction convention each vendor uses; a bidirectional total halves for a one-way transfer. NVLink and PCIe rates follow accelerator product documentation (NVIDIA Corporation 2017, 2020a; Choquette 2023); the InfiniBand architecture specification anchors the protocol family (InfiniBand Trade Association 2000), while current high-speed product families and Ethernet roadmaps anchor modern link-rate examples (NVIDIA 2026f; Ethernet Alliance 2025). Section 11.5.4 develops the transfer-time model these rates feed, and the speed of light in fiber, which bounds every cross–data center round trip, is a physical constant kept with the other durable values in section D.1.

Table E.19: Interconnect Specifications: Link-family bandwidths from accelerator product documentation, the InfiniBand architecture specification, and current product and roadmap documentation (NVIDIA Corporation 2017, 2020a; Choquette 2023; InfiniBand Trade Association 2000; NVIDIA 2026f; Ethernet Alliance 2025), as recorded in the hardware and systems registries. Network ports are converted from line rate at eight bits per byte. Latencies are representative end-to-end values where the registry records one: a generic NVLink and PCIe hop and a fabric-level network latency.

Link	Device or Generation	Bandwidth	Convention	Latency
PCIe Gen3 x16	Host link (V100)	15.75 GB/s	Per direction	—
PCIe Gen4 x16	Host link (A100)	32 GB/s	Per direction	—
PCIe Gen5 x16	Host link (H100, B200)	64 GB/s	Per direction	1,000 ns
CXL memory over PCIe Gen5	Memory expansion	64 GB/s	Per direction	—
NVLink 2.0	V100	300 GB/s	Bidirectional total	500 ns
NVLink 3.0	A100	600 GB/s	Bidirectional total	500 ns
NVLink 4.0	H100	900 GB/s	Bidirectional total	500 ns
NVLink 5.0	B200	1,800 GB/s	Bidirectional total	500 ns
ICI	TPU v4	300 GB/s	Per direction	—
ICI	TPU v5p	1,200 GB/s	Bidirectional total	—
ICI	TPU v6e	800 GB/s	Bidirectional total	—
InfiniBand EDR	Network port	12.5 GB/s	Per direction	—
InfiniBand HDR	Network port	25 GB/s	Per direction	7 µs
InfiniBand NDR	Network port	50 GB/s	Per direction	5 µs
InfiniBand XDR	Network port	100 GB/s	Per direction	5 µs
RoCE (100 GbE)	Network port	12.5 GB/s	Per direction	10 µs

Link	Device or Generation	Bandwidth	Convention	Latency
RoCE (400 GbE)	Network port	50 GB/s	Per direction	10 µs
10 GbE	Network port	1.25 GB/s	Per direction	50 µs
100 GbE	Network port	12.5 GB/s	Per direction	50 µs
400 GbE	Network port	50 GB/s	Per direction	50 µs
800 GbE	Network port	100 GB/s	Per direction	50 µs
NVMe SSD (Gen3)	Local storage	3.5 GB/s	Sequential read	—
NVMe SSD (Gen4)	Local storage	7 GB/s	Sequential read	—
NVMe SSD (Gen5)	Local storage	14 GB/s	Sequential read	—

E.7 Economic Constants

Converting a training run's megawatt-hours or a dataset's cross-region transfer volume into dollars requires baseline utility and network rates. These **pricing assumptions** underpin total cost of ownership (TCO) and energy-cost napkin math in table E.20. They are illustrative hyperscaler-order rates for ratio analysis (similar in spirit to carbon accounting examples in (Patterson et al. 2021)), not quotes for a specific region or contract. Local values should replace these anchors when absolute price dominates. Accelerator list prices are kept with each chip, in table E.4 and table E.13.

Table E.20: Economic Assumptions: Illustrative cloud electricity and egress rates for TCO napkin math (2024–2025 order of magnitude). On-premise cost structures differ.

Assumption	Value	Unit
Cloud electricity price	0.12	dollar/kWh
Cloud egress price per GB	0.09	dollar/GB

E.8 Scale References

Capacity-planning examples need request rates and data rates, so the **scale assumptions** in table E.21 fix illustrative order-of-magnitude baselines for email and search volume, autonomous-vehicle sensor streams, and standard 1080p and 4K video formats. They are magnitude anchors, not audited statistics for a specific year.

Table E.21: Production Scale and Data Rate References: Illustrative workload and sensor-rate anchors, plus standard 1080p and UHD 4K video parameters.

Assumption	Value	Unit
Gmail emails per day	1.21e+11	-
Google searches per day	1.37e+10	-
Waymo sensor data rate (low)	1	TB/h
Waymo sensor data rate (high)	19	TB/h
1080p frame width	1920	-
1080p frame height	1080	-
4K frame width	3840	-
4K frame height	2160	-
Bytes per RGB pixel	3	bytes
Video frame rate (standard)	30	Hz

E.9 Worked Estimates

A table of peak rates, byte widths, and utility prices does not by itself tell an engineer whether a kernel is bandwidth bound, whether a fine-tuning job fits on one GPU, or what a training run's electricity bill covers. The three worked estimates below combine the tables above to answer those

performance, capacity, and cost questions, and each names the section that develops its method so a reader can rerun it with substituted values.

The first estimate places two operations on the reference machine's roofline, using the method of section D.2.1. Comparing the ridge point against each operation's arithmetic intensity separates compute-bound matrix multiplies from bandwidth-bound token generation.

Napkin Math E.1: Classify a roofline regime

Problem: For the stated H100 and workload intensities, which operations are compute bound and which are bandwidth bound?

Variables: For an H100 at FP16/BF16 peak, use 989 TFLOP/s peak compute and 3.35 TB/s memory bandwidth.

Math: Divide peak FLOP/s by memory bandwidth to get the roofline ridge point: 989 TFLOP/s/3.35 TB/s $\approx$ 295.2 FLOP/byte. A large general matrix multiply (GEMM) with $N = 4096$ has intensity $N/3 \approx 1{,}365.3$ FLOP/byte.

Result: Operations above 295.2 FLOP/byte are compute bound; operations below it are bandwidth bound. The GEMM example is compute bound, while a single-token autoregressive decode at FP16, with intensity of about 1 FLOP/byte, is deeply bandwidth bound.

Systems insight: The same accelerator can be compute rich and memory constrained. Arithmetic intensity determines which resource the workload actually consumes.

The second estimate sizes training state with the convention of table E.16. Section C.3.3 derives the components, and section 8.3.3.3 shows how parameter-efficient fine-tuning brings the same model onto one accelerator.

Napkin Math E.2: Estimate training-state memory

Problem: How much model-state memory is required to fully fine-tune Llama 3 8B with mixed-precision Adam?

Variables: Mixed-precision Adam stores BF16 weights, gradients, FP32 master weights, momentum, and variance. The model-state budget is 16 bytes per parameter.

Math: For 8.03B parameters, model state is 8.03B $\times$ 16 bytes = 128.5 GB.

Result: An H100 has 80 GB of HBM, so the model state alone exceeds a single accelerator before accounting for activations.

Systems insight: Optimizer state, not weights alone, sets the floor for training memory. Capacity planning that starts from parameter bytes underestimates the real requirement.

The third estimate converts power and time into energy and cost. Section D.2.2 checks that the units of such a product reduce to energy, and section 15.4.2.1 applies the same accounting to cost and carbon at deployment scale.

Napkin Math E.3: Estimate accelerator electricity cost

Problem: What is the accelerator-only electricity cost of the GPT-3 training run?

Variables: Use 10,000 V100s, 300 W per accelerator, ~14.8 days wall-clock, and \$0.12/kWh electricity (Patterson et al. 2021).

Math: The run requires roughly 3.14×10^{23} FLOPs. The accelerator-only electricity-cost estimate is ~14.8 days wall-clock $\times$ 10,000 V100s $\times$ 24 h/day $\times$ 0.3 kW $\times$ \$0.12/kWh = ~\$127,872.

Result: The accelerator-only electricity cost is roughly \$128,000. This TDP-only estimate excludes host CPUs, networking, storage, cooling, and facility overhead. The 1,066 MWh of accelerator energy behind it covers about 83 percent of the 1,287 MWh reported for the run, which also counts host power and data center overhead. The GPU count and duration are a

published reconstruction from measured per-GPU throughput, so only their product is firm (Patterson et al. 2021).

Systems insight: Energy follows directly from power and time, while the dollar figure depends on the electricity rate assumed.

E.10 Assumption Provenance

Each assumption has a provenance record that lets readers trace the number back to its primary source. The appendix's quantitative inputs fall into evidence classes, each with its primary references (table E.22). Vendor specifications and standards define published limits, peer-reviewed measurements provide empirical anchors, and explicitly marked editorial scenarios supply illustrative values where no durable universal constant exists. Every value is read from the book's hardware, model, systems, and infrastructure registries, which record the same provenance per entry. A reader should check the class before trusting a number, because vendor peaks are ceilings, measurements are anchors, and scenarios are placeholders.

Table E.22: Assumption Provenance Catalog: Quick map from appendix section to source class and bibliography.

Appendix section	Source type	Primary references
Accelerator specifications	Vendor datasheet peaks and list-price ranges; editorial CPU/mobile anchors; release-year format support; advertised marketing peaks	(NVIDIA Corporation 2017, 2018, 2020a, 2024; NVIDIA 2020b; Choquette et al. 2021; Choquette 2023; AMD 2023; Jouppi et al. 2023; Google Cloud 2026b); editorial for CPU/mobile rows
Model specifications	Published papers, model reports, benchmark references, and official docs; GPT-3 run reconstruction; GPT-4 size from public analysis	(Devlin et al. 2019; Radford et al. 2019; Brown et al. 2020; Patterson et al. 2021; Dubey et al. 2024; He et al. 2016a; Sandler et al. 2018; Ultralytics 2023; Naumov et al. 2019; C. Banbury, Reddi, Torelli, Holleman, Jeffries, Kirber, et al. 2021; OpenAI et al. 2023; Patel and Wong 2023)
Training memory conventions	Book convention (mixed-precision Adam layout)	(Kingma and Ba 2015; Kalamkar et al. 2019; Micikevicius et al. 2018; NVIDIA 2017)
Energy constants	Published 45 nm arithmetic/DRAM estimates; add-versus-multiply scaling	(Horowitz 2014; Dally et al. 2021) for arithmetic/DRAM; editorial for register/SRAM, MobileNetV2, and 5G rows
Interconnect bandwidth	Vendor specs; InfiniBand standard; product and roadmap documentation; representative latency tiers	(NVIDIA Corporation 2017, 2020a; Choquette 2023; InfiniBand Trade Association 2000; NVIDIA 2026f; Ethernet Alliance 2025)
Economic assumptions	Illustrative cloud/utility rates	(Patterson et al. 2021) (methodology context)
Scale references	Illustrative workload rates; standard video conventions	Editorial for workload rates; standard format definitions for video
Unit conventions	Decimal SI; book notation	Editorial
Worked estimates	Derived from the rows above	As for the inputs they use

E.11 Summary

This appendix is the reference catalog for the dated quantitative inputs used throughout the book. It runs from unit conventions and accelerator specifications through model, energy, interconnect, and cost assumptions, and closes with three worked estimates and a provenance map. The values come from vendor peaks, published measurements, standards, and editorial scenarios, so they carry different evidentiary weight and age at different rates.

Use these tables as starting inputs, not universal constants. For each estimate, record the table row, unit convention, and provenance; replace time-sensitive peaks, prices, and rates with local values; distinguish a physical ceiling from a measured operating point and a scenario assumption; and report which assumptions dominate the result. This keeps napkin math reproducible and makes clear which input controls the conclusion.

Glossary

This glossary defines key terms used throughout this book and gathers them as a compact reference. Terms are organized alphabetically so they can be consulted alongside the chapters.

3

3DMark Graphics performance benchmark suite that evaluates real-time 3D rendering capabilities, measuring triangle throughput, texture fill rates, and modern features like ray tracing and DLSS performance.

A

A/B testing A controlled experimental method for comparing two versions of a system or model by randomly dividing users into groups and measuring performance differences between the variants.

ablation study An experiment that removes, disables, or isolates one component at a time to measure its contribution to model or system behavior.

activation-based pruning A pruning method that evaluates the average activation values of neurons or filters over a dataset to identify and remove neurons that consistently produce low activations and contribute little information to the network's decision process.

activation checkpointing A memory optimization technique that reduces memory usage during backpropagation by selectively discarding and recomputing activations instead of storing all intermediate results.

activation function A mathematical function applied to the weighted sum of inputs in a neural network neuron to introduce nonlinearity, enabling the network to learn complex patterns beyond simple linear combinations.

activation memory Memory used to store intermediate layer outputs needed for gradient computation during training, scaling with batch size, sequence length, and model depth.

active learning An approach that intelligently selects the most informative examples for human annotation based on model uncertainty, reducing the amount of labeled data needed for effective training.

Adam optimization An adaptive learning rate optimization algorithm that combines momentum and RMSprop by maintaining exponentially decaying averages of both gradients and squared gradients for each parameter.

AdamW A variant of Adam that decouples weight decay from the adaptive gradient update, improving regularization while keeping the optimizer's adaptive moments.

alerting Automated notification systems that inform teams when metrics exceed predefined thresholds or anomalies are detected in production ML systems.

AlexNet A landmark convolutional neural network architecture that won the 2012 ImageNet challenge, reducing error rates from 26 percent to 16 percent and sparking the deep learning renaissance.

AllReduce A collective communication operation in distributed computing where each process contributes data and all processes receive the combined result, commonly used for gradient aggregation in distributed training.

all-to-all communication A communication pattern where every device or process exchanges data with every other device, common in sharded embedding and expert-parallel workloads.

AlphaFold A landmark AI system developed by DeepMind that predicts the three-dimensional structure of many proteins from their amino acid sequences, achieving breakthrough accuracy without solving every folding problem and demonstrating how large-scale ML systems can accelerate scientific discovery. Its predictions still require confidence interpretation and, for many uses, experimental validation.

Amdahl's Law A speedup bound showing that overall improvement is limited by the portion of a workload or pipeline that remains serial or unoptimized.

AOT compilation Ahead-of-time compilation that converts a model, graph, or program into optimized executable code before deployment or execution, trading flexibility for lower runtime overhead.

Apache Kafka A distributed streaming platform that handles real-time data feeds using a publish-subscribe messaging system, commonly used for building ML data pipelines with high throughput and fault tolerance.

Apache Spark An open-source distributed computing framework that enables large-scale data processing across clusters of computers, revolutionizing ETL operations with in-memory computing capabilities.

application-specific integrated circuit (ASIC) Custom chips designed for specific computational tasks that offer superior performance and energy efficiency compared to general-purpose processors by abandoning general-purpose flexibility. Examples include Google's TPUs, Cerebras Wafer-Scale Engine, and Bitcoin mining ASICs.

arithmetic intensity The ratio of floating-point operations to bytes of memory accessed (FLOP/byte), used in roofline analysis to determine whether workloads are memory bound or compute bound and to guide optimization priorities.

artificial general intelligence AI systems intended to match human-level performance across a broad range of cognitive tasks; the term has no universally accepted capability threshold and implies no particular architecture.

artificial intelligence The field of computer science focused on creating systems that can perform tasks typically requiring human intelligence, such as perception, reasoning, learning, and decision-making.

artificial neural network A computational model inspired by biological neural networks, consisting of interconnected nodes (neurons) organized in layers that can learn patterns from data through adjustable weights and biases.

artificial neurons Basic computational units in neural networks that mimic biological neurons, taking multiple inputs, applying weights and biases, and producing an output signal through an activation function.

attention mechanism A neural network component that computes weighted connections between elements based on their content, allowing dynamic focus on relevant parts of the input rather than fixed architectural connections.

AUC Area under the ROC curve, a threshold-independent classification metric that compares true positive and false positive rates across decision thresholds.

audit trail An append-only record of who accessed or changed data, models, or system artifacts and when, supporting accountability, debugging, and compliance.

autograd tape A transient record of operations and saved values built during forward execution so reverse-mode automatic differentiation can compute gradients during the backward pass.

automatic differentiation A computational technique that automatically calculates exact derivatives of functions implemented as computer programs by systematically applying the chain rule at the elementary operation level, essential for training neural networks through gradient-based optimization.

automatic mixed precision A training technique that automatically manages the use of different numerical precisions (FP16, FP32) to optimize memory usage and computational speed while maintaining model accuracy.

AutoML Automated machine learning that automates model design decisions, including architecture search, hyperparameter optimization, and feature selection, to reduce manual effort.

autoscaling Dynamic adjustment of compute resources based on workload demand, auto-

matically scaling up during peak usage and scaling down during low usage to optimize costs and performance.

B

backpropagation An algorithm that computes gradients of the loss function with respect to network weights by propagating error signals backward through the network layers, enabling systematic weight updates during training.

backward pass The training phase that propagates gradients from the loss back through the network to compute parameter gradients, pairing with the forward pass.

bandwidth The maximum rate of data transfer across a communication channel or memory interface, typically measured in bytes per second and critical for optimizing data movement in AI accelerators.

batch inference The process of running inference on a large dataset in bulk, typically as a scheduled job, as opposed to real-time inference on individual requests. Batch inference enables higher throughput by amortizing overhead across many inputs.

batch ingestion A data processing pattern that collects and processes data in groups or batches at scheduled intervals, suitable for scenarios where real-time processing is not critical.

batch normalization A technique that normalizes inputs to each layer to have zero mean and unit variance, which stabilizes training and often allows for higher learning rates and faster convergence, and subsequently applies a learnable scale and shift to preserve representational power.

batch processing The technique of processing multiple data samples simultaneously to amortize computation and memory access costs, improving overall throughput in neural network training and inference.

batch size The number of training examples processed simultaneously during one iteration of neural network training, affecting both computational efficiency and gradient estimation quality.

batch throughput optimization Techniques for maximizing the number of samples processed per unit time when handling multiple inputs simultaneously, using parallelism and batching efficiencies.

batched operations Matrix computations that process multiple inputs simultaneously, converting matrix-vector operations into more efficient matrix-matrix operations to improve hardware utilization.

benchmark engineering The systematic design and development of performance evaluation frameworks, involving test harness creation, metric selection, and result interpretation methodologies.

benchmark harness Systematic infrastructure component that controls test execution, manages input delivery, and collects performance measurements under controlled conditions to ensure reproducible evaluations.

benchmarking Systematic evaluation of compute performance, algorithmic effectiveness, and data quality in machine learning systems to optimize performance across diverse workloads and ensure reproducibility.

BERT Bidirectional Encoder Representations from Transformers, a transformer-based language model introduced by Google in 2018 that revolutionized natural language processing through masked language modeling pretraining.

BF16 A 16-bit floating-point format developed by Google Brain that maintains the same dynamic range as FP32 but with reduced precision, making it particularly suitable for deep learning training.

bias A learnable parameter added to the weighted sum in each neuron that shifts the activation function, allowing neurons to activate even when all inputs are zero and providing additional flexibility for the network to fit complex patterns.

binarization A 1-bit quantization technique that reduces neural network weights, activations, or both to binary values (typically -1 and +1), achieving maximum compression but often requiring specialized training procedures and hardware support.

biological neuron A cell in the nervous system that receives, processes, and transmits information through electrical and chemical signals, serving as inspiration for artificial neural networks.

bitter lesson Richard Sutton's 2019 observation that general methods using computation consistently outperform approaches encoding human expertise, suggesting that systems engineering enabling computational scale is central to AI advancement.

black box A system whose inputs and outputs are observable but whose internal workings are inaccessible or opaque. This opacity is particularly problematic when the system makes consequential decisions without explaining its reasoning.

BLAS Basic Linear Algebra Subprograms, a specification for low-level routines that perform common linear algebra operations such as vector addition, scalar multiplication, dot products, and matrix operations, forming the computational foundation of modern ML frameworks.

block sparse matrix A sparse matrix whose nonzero values appear in dense blocks rather than isolated elements, preserving structure that hardware kernels can exploit efficiently.

blue-green deployment A deployment strategy using two production environments so traffic can switch to a validated new version while the old version remains available for rollback.

bounding box A rectangular annotation that identifies object locations in images by drawing a box around each object of interest, commonly used in computer vision training datasets.

brittleness The tendency of rule-based AI systems to fail completely when encountering inputs that fall outside their programmed scenarios, no matter how similar those inputs might be to what they were designed to handle.

C

caching A technique for storing frequently accessed data in high-speed storage systems to reduce retrieval latency and improve system performance in ML pipelines.

caching allocator A framework memory manager that reuses device-memory blocks instead of calling the hardware allocator for every tensor, reducing allocation latency and fragmentation.

calibration The process in post-training quantization of analyzing a representative dataset to determine optimal quantization parameters, including scale factors and zero points, that minimize accuracy loss when converting from high to low precision.

canary deployment A deployment strategy where new model versions receive a small percentage of production traffic to validate behavior before full rollout, enabling early detection of issues with minimal user impact.

CAP theorem A distributed systems principle stating that, during a network partition, a data store cannot guarantee both linearizable consistency and availability for every request.

carbon footprint The total greenhouse gas emissions, typically measured in CO_2 equivalent, produced directly and indirectly by training and operating an ML system.

carbon intensity The emissions produced per unit of energy, usually measured as kg CO_2e per kWh, used to convert ML energy use into carbon impact.

Cerebras Wafer-Scale Engine In the CS-2 generation, a single-wafer processor containing 2.6 trillion transistors and 850,000 cores, designed to eliminate inter-device communication bottlenecks in large-scale machine learning training.

chain rule The calculus rule enabling computation of derivatives for composite functions, fundamental to backpropagation.

channelwise quantization A quantization granularity approach where each channel in a layer uses its own set of quantization parameters, providing more precise representation than layerwise quantization while maintaining hardware efficiency.

CI/CD pipelines Continuous Integration and Continuous Delivery automated workflows that streamline model development by integrating testing, validation, and deployment processes.

circuit breaker pattern A resilience pattern that stops or redirects calls to an unhealthy service after repeated failures to prevent cascading failure and enable fallback behavior.

classification labels Simple categorical annotations that assign specific tags or categories to data examples, representing the most basic form of supervised learning annotation.

CloudSuite Benchmark suite developed at EPFL that addresses modern data center workloads including web search, data analytics, and media streaming, measuring end-to-end performance across network, storage, and compute dimensions.

cold-start performance Time required for a system to transition from idle state to active execution, particularly important in serverless environments where models are loaded on demand.

collaborative filtering A technique used in recommendation systems that predicts user preferences by identifying patterns in interactions from many users, using the collective behavior of the crowd rather than just item properties.

communication overhead The time a distributed system spends synchronizing state between nodes rather than computing, set by the latency and bandwidth of the links between them.

compound AI systems AI architectures that combine multiple specialized models and components working together, rather than relying on a single monolithic model, enabling modularity, specialization, and improved interpretability.

compressed sparse row (CSR) A memory-efficient storage format for sparse matrices that uses three arrays (values, column indices, row pointers) to store only nonzero elements, reducing memory from $\mathcal{O}(n_{\text{rows}}^2)$ (for a square matrix with n_{rows} rows) to

$\mathcal{O}(n_{\text{nz}} + n_{\text{rows}})$ where n_{nz} is the number of nonzeros.

computational graph A directed graph representing the sequence of operations in neural network computation, enabling automatic differentiation.

computer engineering An engineering discipline that emerged in the late 1960s to address the growing complexity of integrating hardware and software systems, combining expertise from electrical engineering and computer science to design and build complex computing systems.

concept drift The phenomenon where $p(y \mid x)$, the statistical relationship between inputs and targets, changes over time, distinct from data drift in $p(x)$; this can, but need not, degrade a fixed model's performance. Detecting it typically requires outcome labels because input drift alone does not establish a conditional change.

conditional computation A dynamic optimization technique where different parts of a neural network are selectively activated based on input characteristics, reducing computational load by skipping unnecessary computations for specific inputs.

consensus labeling A quality control approach that collects multiple annotations for the same data point to identify controversial cases and improve label reliability through inter-annotator agreement.

containerization Packaging applications and their dependencies into portable, isolated containers using tools like Docker to ensure consistent execution across different environments.

continuous batching An LLM serving technique that adds and removes requests from an inference batch between token-generation steps as sequences start and finish.

continuous integration A software development practice where code changes are automatically integrated, tested, and validated multiple times per day to detect issues early in the development cycle.

convolution A mathematical operation that slides a filter (kernel) across input data to extract features such as edges, textures, or patterns. Convolution is fundamental to convolutional neural networks and particularly effective for processing images and spatial data.

convolutional neural network A specialized neural network architecture designed for processing grid-like data such as images, using convolutional layers that apply filters to detect local features.

coreset A small subset of a dataset selected to preserve important statistical or training properties of the full dataset while reducing training or evaluation cost.

correction cascade An ML technical-debt pattern where fixing one component creates new failures or redesign needs elsewhere because data and model dependencies propagate through the system.

covariate shift A distribution shift where input feature distributions change while the relationship between features and labels remains stable.

CP decomposition CANDECOMP/PARAFAC decomposition that expresses a tensor as a sum of rank-one components, used to compress neural network layers by reducing the number of parameters while preserving computational functionality.

credit assignment problem The challenge of determining which weights in a multi-layer network contributed to prediction errors.

CRISP-DM Cross-Industry Standard Process for Data Mining, a structured methodology developed in 1996 that defines six phases for data projects: business understanding, data understanding, data preparation, modeling, evaluation, and deployment.

critical batch size The batch size beyond which larger batches provide diminishing optimization benefit and may reduce generalization, limiting simple linear learning-rate scaling.

cross-entropy loss A loss function commonly used in classification tasks that measures the difference between predicted probability distributions and true class labels, providing strong gradients for effective learning.

crowdsourcing A collaborative data collection approach that uses distributed individuals via the internet to perform annotation tasks, enabling scalable dataset creation through platforms like Amazon Mechanical Turk.

cuBLAS NVIDIA's CUDA Basic Linear Algebra Subprograms library that provides GPU-accelerated implementations of standard linear algebra operations, enabling high-performance matrix computations on NVIDIA graphics processing units.

CUDA (Compute Unified Device Architecture) NVIDIA's parallel computing platform and programming model that enables general-purpose computing on graphics processing units (GPUs), allowing machine learning frameworks to use massive parallelism for accelerated tensor operations.

CUDA stream An ordered queue of GPU work used to schedule kernels, memory transfers, and synchronization events so independent operations can overlap.

D

D·A·M taxonomy A diagnostic framework that analyzes ML system bottlenecks through three interacting axes: Data (information flow, bounded by bandwidth), Algorithm (mathematical logic, bounded by total operations), and Machine (physical execution, bounded by peak throughput).

Dartmouth conference The legendary 8-week workshop at Dartmouth College in 1956 where AI was officially born, organized by John McCarthy, Marvin Minsky, Nathaniel Rochester, and Claude Shannon, following their 1955 proposal, which introduced the term artificial intelligence.

data as source code The Software 2.0 principle that training data defines ML system behavior, so dataset changes act like behavior-changing code changes.

data augmentation The process of artificially expanding training datasets by creating modified versions of existing data through transformations like rotation, scaling, or noise injection.

data cascades Systemic failures where data quality issues compound over time, creating downstream negative consequences such as model failures, costly rebuilding, or project termination.

data center A facility that houses computer systems and associated components such as telecommunications and storage systems, typically containing thousands of servers for cloud computing operations.

data-centric approach A machine learning paradigm that prioritizes improving data quality, diversity, and curation rather than solely focusing on model architecture improvements to achieve better performance.

data-centric computing Systems optimized for the efficient ingestion of data and iterative refinement of model parameters, where the programmer's job is to curate data.

data contracts Explicit agreements between data producers and consumers defining schema, quality expectations, and service levels to prevent downstream breakage.

data curation The process of selecting, organizing, and maintaining high-quality datasets by removing irrelevant information, correcting errors, and ensuring data meets specific standards for machine learning applications.

data debt Accumulated data quality, documentation, schema, lineage, or freshness liabilities that compound over time and degrade model behavior.

data drift The phenomenon where the input distribution $p(x)$ changes over time even though code remains unchanged; this may affect model performance but does not guarantee degradation. It can be monitored without labels, although labels are needed to measure its effect on quality.

data echoing A training input-pipeline technique that reuses batches, often with fresh augmentation, when data preparation is slower than accelerator consumption.

data governance The framework of policies, procedures, and technologies that ensure data security, privacy, compliance, and ethical use throughout the machine learning pipeline.

data gravity The architectural pull created by large data volumes, transfer time, bandwidth limits, and egress cost, which tends to draw computation toward the data.

data ingestion The process of collecting and importing raw data from various sources into a system where it can be stored, processed, and prepared for machine learning applications.

data lake A storage repository that holds structured, semi-structured, and unstructured data in its native format, using schema-on-read approaches for flexible data analysis.

data lakehouse A storage architecture that combines data lake flexibility with warehouse-style query semantics, schema management, and transactional guarantees.

data lineage The documentation and tracking of data flow through various transformations and processes, providing visibility into data origins and modifications for compliance and debugging.

data locality The principle that data and computation should be colocated when transfer latency, bandwidth, or cost dominates remote processing.

data parallelism A distributed training strategy that splits the dataset across multiple devices while each device maintains a complete copy of the model, enabling parallel computation of gradients.

data pipeline The infrastructure and workflows that automate the movement and transformation of data from sources through processing stages to final storage or consumption.

data quality The degree to which data meets requirements for accuracy, completeness, consistency, and timeliness, directly impacting machine learning model performance.

data quality multiplier The idea that improvements in data quality can amplify gains from model and system changes because all downstream stages depend on the data.

data validation The systematic verification that collected data meets quality standards, is properly formatted, and contains accurate information suitable for machine learning model training and evaluation.

data versioning The practice of tracking and managing different versions of datasets over time, similar to code versioning, to ensure

reproducibility and enable rollback to previous data states when needed.

data warehouse A centralized repository optimized for analytical queries (OLAP) that stores integrated, structured data from multiple sources in a standardized schema.

dataflow architecture Specialized computing architecture where instruction execution is determined by data availability rather than a program counter, enabling highly parallel processing of neural network operations.

dataflow challenges Technical difficulties in managing data movement and dependencies in hardware accelerators, including memory bandwidth limitations and synchronization requirements.

datasheets for datasets Documentation for training data that captures provenance, collection methodology, demographic composition, and known limitations affecting model behavior.

dead letter queue A separate storage mechanism for data that fails processing, allowing for later analysis and potential reprocessing of problematic data without blocking the main pipeline.

deduplication The removal of exact, near-duplicate, or semantically redundant samples from a dataset to reduce storage, training compute, and leakage risk.

deep learning A subfield of machine learning that uses artificial neural networks with multiple layers to automatically learn hierarchical representations from data without explicit feature engineering.

demographic parity A fairness criterion requiring that the probability of receiving a positive prediction is independent of group membership across protected attributes.

Dennard scaling The observation that as transistors became smaller, their power density remained constant, enabling higher performance at the same power envelope. Its breakdown around 2005 ended the era of free frequency scaling.

dense layer A fully-connected neural network layer where each neuron receives input from all neurons in the previous layer, enabling comprehensive information integration across features.

deployment constraints Operational limitations such as hardware resources, network connectivity, regulatory requirements, and integration requirements that influence how machine learning models are implemented in production environments.

deployment paradigm A distinct approach to hosting and executing ML models characterized by specific resource constraints and operational properties, such as Cloud ML, Edge ML, Mobile ML, or TinyML.

depthwise separable convolution A convolution factorization that applies spatial filtering independently per channel and then mixes channels with a pointwise convolution to reduce computation.

DevOps Software development practice that combines development and operations teams to shorten development cycles and deliver high-quality software through automation and collaboration.

Dhrystone Integer-based benchmark introduced in 1984 that measures integer and string operations in DMIPS (Dhrystone MIPS), designed to complement floating-point benchmarks with typical programming constructs.

diabetic retinopathy A diabetes complication that damages blood vessels in the retina, serving as a leading cause of preventable blindness and a key application area for medical AI screening systems.

differential privacy A mathematical framework for quantifying and limiting privacy loss when releasing statistical information about datasets by bounding how much the output distribution can change when any one individual's data is added or removed.

direct memory access (DMA) A mechanism that lets a device move data to or from memory without CPU-managed copying for each transfer, enabling overlap and reducing host overhead.

disaggregated evaluation The practice of breaking down model performance metrics by demographic groups or other factors to reveal disparities that are hidden by aggregate measures.

dispatch overhead Runtime overhead from launching and orchestrating many small operations through the host framework instead of executing fused or compiled graph regions.

distributed computing An approach that processes data across multiple machines or processors simultaneously, enabling scalable handling of large datasets through frameworks like Apache Spark.

distributed intelligence The placement of computational capabilities across multiple devices and locations rather than relying on a single centralized system, enabling local processing and decision-making.

distributed training A method of training machine learning models across multiple machines or devices to handle larger datasets and models that exceed single-device computational or memory capacity.

distribution shift A change in the statistical properties of data between training and deployment, or over time during deployment. Types include covariate shift (input distribution changes), label shift (output distribution changes), and concept drift (relationship between inputs and outputs changes).

DLRM Deep Learning Recommendation Model, an architecture developed by Meta that combines categorical embeddings with a bottom multi-layer perceptron (MLP) and top MLP to handle the massive scale and sparsity of recommendation system workloads.

domain-specific architecture Hardware designs tailored to optimize specific computational workloads, trading flexibility for improved performance and energy efficiency compared to general-purpose processors.

dropout A regularization technique that randomly sets a fraction of input units to zero during training to prevent overfitting and improve generalization.

dying ReLU problem A failure mode where ReLU neurons become permanently inactive and output zero for all inputs, preventing them from contributing to learning when weighted inputs consistently produce negative preactivations.

dynamic batching A serving technique that waits briefly to group independent requests into a batch, improving throughput while adding controlled batch-formation latency.

dynamic graph A computational graph that is built and modified during program execution, allowing for flexible model architectures and easier debugging but potentially limiting optimization opportunities compared to static graphs.

dynamic pruning A pruning approach that changes which parameters or units are inactive in response to input data or training dynamics, rather than relying only on a fixed pruning decision.

dynamic quantization The process of storing neural-network weights at lower precision and determining activation quantization parameters at runtime, reducing memory use while requiring supported low-precision kernels for speedup.

dynamic random-access memory (DRAM) A type of volatile memory that stores data in capacitors and requires periodic refresh cycles, commonly used as main memory in computer systems.

dynamic voltage and frequency scaling (DVFS) Power management technique that adjusts processor voltage and clock frequency based on workload demands to optimize energy consumption while maintaining performance.

E

eager execution An execution mode where operations are evaluated immediately as they are called in the code, providing intuitive debugging and development experience but potentially sacrificing some optimization opportunities available in graph-based execution.

early exit architectures Neural network designs that include multiple prediction heads at different depths, allowing samples to exit early when confident predictions can be made, reducing average computational cost per inference.

edge computing A distributed computing paradigm that brings computation and data storage closer to the sources of data, reducing latency and bandwidth usage.

edge deployment A deployment strategy where machine learning models run locally on devices at the network edge rather than in centralized cloud servers, reducing latency and enabling operation without constant internet connectivity.

efficiency frontier The optimal trade-off curve between accuracy and computational cost (latency, energy, or memory), where no model exists that is both more accurate and more efficient.

EfficientNet A family of neural network architectures discovered through neural architecture search that achieves better accuracy-efficiency trade-offs by using compound scaling to balance network depth, width, and input resolution.

EL2N (Error L2-Norm) A sample-scoring method that ranks examples by the L2 norm of prediction error early in training, often using a proxy model, to guide data selection.

ELIZA One of the first chatbots created by MIT's Joseph Weizenbaum in 1966 that could simulate human conversation through pattern matching and substitution, notable because people began forming emotional attachments to this simple program.

embedded systems Computer systems with dedicated functions within larger mechanical or electrical systems, typically designed for specific tasks with real-time computing constraints.

embedding sharding Splitting large embedding tables across devices or nodes so they fit in aggregate memory, while adding communication to gather embeddings for each batch.

embedding table A lookup table that maps discrete IDs or tokens to dense vectors, often dominating memory in recommendation models and large vocabularies.

emergent behaviors Unexpected system-wide patterns or characteristics that arise from the interaction of individual components, often becoming apparent only when systems operate at scale or in real-world conditions.

encoder-decoder An architectural pattern where an encoder processes input into an intermediate representation and a decoder generates output from this representation, commonly used in sequence-to-sequence tasks.

end-to-end benchmarks Comprehensive evaluation methodology that assesses entire AI system pipelines including data processing, model execution, postprocessing, and infrastructure components.

energy efficiency The measure of computational work performed per unit of energy consumed, typically expressed as operations per joule and crucial for battery-powered and data center deployments.

energy per inference The total energy consumed to produce one model prediction, including model execution and relevant system overhead.

epoch One complete pass through the entire training dataset during neural network training, consisting of multiple batch iterations depending on dataset size and batch size.

equal opportunity A fairness criterion requiring equal true positive rates across different demographic groups.

equalized odds A fairness criterion requiring that both true positive and false positive rates are equal across different demographic groups.

expected calibration error (ECE) A metric measuring the gap between predicted confidence and observed accuracy across confidence bins, used to assess probability calibration.

experiment tracking The systematic recording and management of machine learning experiments, including hyperparameters, model versions, training data, and performance metrics, to enable comparison and reproducibility.

expert systems AI systems first developed in the mid-1960s that captured human expert knowledge in specific domains, exemplified by MYCIN for diagnosing blood infections, representing a shift from general AI to domain-specific applications.

extract, load, transform (ELT) A data processing paradigm that first loads raw data into the target system before applying transformations, providing flexibility for evolving analytical needs.

extract, transform, load (ETL) A traditional data processing paradigm that transforms data before loading it into a data warehouse, resulting in ready-to-query formatted data.

F

fairness laundering A failure mode where removing explicit protected attributes makes a system appear compliant while correlated proxy variables still reproduce discriminatory outcomes.

false positive rate (FPR) The proportion of actual negative cases incorrectly classified as positive, computed as false positives divided by false positives plus true negatives.

FarmBeats A Microsoft Research project that applies machine learning and IoT technologies to agriculture, using edge computing to collect real-time data on soil conditions and crop health while demonstrating distributed AI systems in challenging real-world environments.

feature engineering The process of manually designing and extracting relevant features from raw data to improve machine learning model performance, largely automated in deep learning systems.

feature map The output of a convolutional layer representing the response of learned filters to different spatial locations in the input, capturing detected features at various positions.

feature store A specialized data storage system that provides standardized, reusable features for machine learning, enabling feature sharing across multiple models and teams.

federated learning A machine learning approach that trains algorithms across decentralized edge devices or servers holding local data samples, without exchanging the raw data.

feedback loop A cyclical process where outputs influence future inputs. In ML, this includes both beneficial cycles (where model outputs inform system improvement) and harmful ones (where a model's predictions influence its own future training data, potentially reinforcing and amplifying initial biases over time).

feedforward network A neural network architecture where information flows in one direction from input to output layers without cycles, forming the foundation for many deep learning models.

field-programmable gate array (FPGA) A reconfigurable integrated circuit that can be programmed after manufacturing to implement custom digital circuits and specialized computations, offering flexibility between general-purpose processors and ASICs.

fine-tuning Adapting a pretrained model to a target task or domain by continuing training on task-specific data.

FlashAttention An IO-aware attention algorithm that tiles computation to avoid materializing the full attention matrix in high-bandwidth memory, reducing memory traffic and enabling longer sequences.

floating-point unit (FPU) A specialized processor component designed to perform arithmetic operations on floating-point numbers with high precision and efficiency.

FLOP/s Floating-Point Operations per Second, a measure of computational throughput that quantifies the number of floating-point operations a system can perform per second.

forgetting events Events where a model changes from classifying an example correctly to misclassifying it later in training, marking difficult or informative samples.

forward pass The process of computing neural network predictions by passing input data through successive layers, applying weights, biases, and activation functions at each stage to produce outputs. Also called *forward propagation*.

foundation model Large-scale machine learning models trained on broad data that can be adapted to a wide range of downstream tasks, serving as a base for specialized applications.

four pillars framework A data engineering framework organizing concerns into Quality, Reliability, Scalability, and Governance to manage the data lifecycle.

FP16 16-bit floating-point numerical representation that reduces memory usage and accelerates computation on modern hardware accelerators while maintaining acceptable precision for many machine learning applications.

FP32 32-bit floating-point numerical representation that provides standard precision for mathematical computations but requires more memory and computational resources than lower-precision formats.

FP32 to INT8 A common quantization transformation that converts 32-bit floating-point weights and activations to 8-bit integers, achieving roughly 4× memory reduction while maintaining acceptable accuracy for many models.

FP8 An 8-bit floating-point format family used on newer accelerators for high-throughput training and inference, requiring careful scaling because of limited precision and range.

framework decomposition The systematic breakdown of neural network frameworks into hardware-mappable components, enabling efficient distribution of operations across processing elements.

G

GEMM General Matrix Multiply operations that follow the pattern $\mathbf{C} = \alpha\mathbf{AB} + \beta\mathbf{C}$, representing the fundamental computational kernel underlying most neural network operations including fully connected layers and convolutional layers.

GEMV General Matrix-Vector multiplication operations that compute the product of a matrix and a vector, commonly used in neural network computations and requiring careful optimization for memory access patterns.

generalization The ability of a machine learning model to perform well on unseen data that differs from the training set, often improved through diverse and high-quality training data.

generalization gap The difference between a model's performance on training data and its performance on held-out data. A large generalization gap can indicate overfitting to the training data.

generative AI A category of artificial intelligence systems capable of creating new content such as text, images, audio, or video based on learned patterns from training data.

Goodhart's Law The observation that when a measure becomes an optimization target, it can stop representing the underlying goal.

GPT-2 A 1.5-billion parameter autoregressive language model released by OpenAI in 2019, serving as a primary lighthouse model for analyzing memory bandwidth constraints in transformer inference.

graceful degradation A system design principle where services continue functioning with reduced capabilities when faced with partial failures or data unavailability.

gradient accumulation A technique that simulates larger batch sizes by accumulating gradients from multiple smaller batches before updating model parameters, enabling training with limited memory.

gradient-based pruning A pruning method that uses gradient information to rank parameters, neurons, or filters as candidates for removal.

gradient clipping An optimization technique that mitigates exploding gradients by limiting their magnitude during backpropagation, typically by scaling gradients when their norm exceeds a threshold.

gradient compression A technique used in distributed training to reduce the communication overhead by compressing gradient information exchanged between computing nodes.

gradient descent An optimization algorithm that iteratively adjusts neural network parameters in the direction that minimizes the loss function, using gradients to determine update directions and magnitudes.

gradient synchronization The process in distributed training where locally computed

gradients are aggregated across devices to ensure all devices update their parameters consistently.

GraNd (Gradient Normed) A data selection score based on the norm of an example's gradient during early training, identifying samples with larger learning signal.

graph break A point where a compiler cannot capture part of a program and must fall back to eager execution, splitting optimized graph regions.

graphics processing unit (GPU) A specialized processor originally designed for rendering graphics that provides massive parallel computing capabilities essential for efficient neural network computation, training, and inference.

Green AI A movement in AI research and practice that prioritizes computational efficiency and energy consumption as primary metrics alongside traditional performance metrics like accuracy.

Green500 Ranking system that evaluates the world's most powerful supercomputers based on energy efficiency measured in FLOP/s per watt rather than raw computational performance.

ground truth The reference target treated as correct for training or evaluation, often derived from measurement or annotation and therefore not necessarily identical to objective reality.

GRU Gated Recurrent Unit, a simplified variant of LSTM that uses fewer gates while maintaining the ability to capture long-term dependencies in sequential data.

H

hardware abstraction The layer in ML frameworks that provides a unified interface to diverse computing hardware (CPUs, GPUs, TPUs, accelerators) while handling device-specific optimizations and memory management behind the scenes.

hardware acceleration The use of specialized computing hardware to perform certain operations faster and more efficiently than software running on general-purpose processors.

hardware accelerator Specialized computing hardware designed to efficiently execute specific types of computations, such as GPUs for parallel processing or TPUs for machine learning workloads.

hardware-aware design The practice of designing neural network architectures specifically optimized for target hardware platforms, considering factors like memory hierarchy, compute units, and data movement patterns to maximize efficiency.

hidden layer An intermediate layer in a neural network between input and output layers that learns abstract representations by transforming data through learned weights and activation functions.

hidden state The internal memory of recurrent neural networks that carries information from previous time steps, enabling the network to maintain context across sequential inputs.

hierarchical processing A multi-tier system architecture where data and intelligence flow between different levels of the computing stack, from sensors to edge devices to cloud systems.

high-bandwidth memory (HBM) An advanced memory technology that provides much higher bandwidth than traditional DRAM by using 3D stacking and wide interfaces, critical for data-intensive AI workloads.

horizontal scaling Increasing system capacity by adding more machines or instances rather than upgrading existing hardware, providing better fault tolerance and load distribution.

hybrid machine learning The integration of multiple ML paradigms such as cloud, edge, mobile, and TinyML to form unified distributed systems that combine complementary strengths.

hybrid parallelism A distributed training approach that combines data parallelism and model parallelism to use the benefits of both strategies for training very large models.

hyperparameter A configuration setting that controls the learning process but is not learned from data, such as learning rate, batch size, or network architecture choices.

hyperscale data center Large-scale data center facilities containing thousands of servers and covering extensive floor space, designed to efficiently support massive computing workloads.

I

I/O bottleneck A performance limit where storage, decoding, preprocessing, or data transfer cannot supply data fast enough to keep compute resources busy.

idempotent transformation A data transformation that has the same effect when applied repeatedly as when applied once, supporting safe retries and reprocessing.

im2col A convolution-lowering technique that unfolds image patches into matrix columns so convolution can execute as GEMM.

ImageNet A massive visual database containing over 14 million labeled images across 20,000+ categories, developed by a team led by Fei-Fei Li and introduced in 2009, whose annual challenge became instrumental in driving breakthrough advances in computer vision.

imperative programming A programming paradigm in which programs specify sequences of commands that update state and direct control flow; it is distinct from whether operations execute eagerly or are staged for later execution.

inductive bias A structural assumption built into a model or architecture that restricts the functions it can learn efficiently, such as locality in CNNs.

inference The operational phase where trained neural networks make predictions on new data using fixed parameters, without weight updates.

InfiniBand A high-throughput, low-latency networking technology commonly used for multi-node accelerator clusters and distributed training.

information-compute ratio (ICR) A metric quantifying the efficiency of data selection, defined as the ratio of model performance gain to the computational cost (FLOPs) required to achieve it. Maximizing ICR is the primary goal of data selection strategies.

infrastructure as code Practice of managing and provisioning computing infrastructure through machine-readable configuration files rather than manual processes, enabling version control and automation.

INT8 An 8-bit signed-integer representation used to quantize weights, activations, or both. Each INT8 value occupies one quarter the storage of an FP32 value, and supported hardware can accelerate applicable operations, with accuracy depending on the quantization scheme.

intermediate representation (IR) A compiler-internal representation between frontend model code and backend hardware code generation, used by ML frameworks for optimization and portability.

internet of things A network of physical objects embedded with sensors, software, and other technologies that connect and exchange data with other devices and systems over the internet.

intersectional analysis Evaluation that considers combinations of demographic attributes (for example, race and gender simultaneously) to detect concentrated harms not visible in single-factor analysis.

IOPS Input/Output Operations Per Second; a storage performance metric measuring the number of read/write operations a device can handle per second, critical for random access workloads like training data loading.

Iron Law of ML Systems A quantitative framework relating workload execution time to the D·A·M taxonomy and hardware bottlenecks. Across the D·A·M axes, time factors multiplicatively as $T = (\text{Samples/Task}) \times (\text{FLOPs/Sample}) \times (\text{Seconds/FLOP})$, where the first two factors set total operations O; on physical hardware, execution unpacks into Data Movement (limited by bandwidth), Computation (limited by sustained FLOP/s), and Latency (limited by fixed overhead) as $T = D_{\text{vol}}/\text{BW} + O/(R_{\text{peak}} \cdot \eta_{\text{hw}}) + L_{\text{lat}}$.

iterative pruning A gradual pruning strategy that removes parameters in multiple stages with fine-tuning between each stage, allowing the model to adapt to reduced capacity and typically achieving better accuracy than one-shot pruning.

J

JAX A numerical computing library developed by Google Research that combines NumPy's API with functional programming transformations including automatic differentiation, just-in-time compilation, and automatic vectorization for high-performance machine learning research.

JIT compilation Just-In-Time compilation that analyzes and optimizes code at runtime, enabling frameworks to balance the flexibility of eager execution with the performance benefits of graph optimization by compiling frequently used functions.

K

k-anonymity A privacy technique that ensures each record in a dataset is indistinguishable from at least $k_{\text{anon}} - 1$ other records by generalizing quasi-identifiers.

kernel A small matrix of learnable weights used in convolutional layers to detect specific features through the convolution operation, also called a filter. In GPU programming, the term also denotes a function launched for parallel execution by a grid of threads.

kernel fusion An optimization technique that combines multiple computational operations into a single kernel to reduce memory transfers and improve performance on parallel processors.

keyword spotting (KWS) A technology that detects specific wake words or phrases in audio streams, typically used in voice-activated devices with constraints on power consumption and latency.

knowledge distillation A model compression technique where a smaller "student" network learns to mimic the behavior of a

larger "teacher" network by training on the teacher's soft output probabilities rather than just hard labels.

Kolmogorov-Smirnov test (K-S test) A nonparametric test that measures the maximum distance between two cumulative distributions, often used to compare feature distributions for drift.

Kullback-Leibler divergence (KL divergence) An asymmetric information-theoretic measure of how one probability distribution differs from another, used in monitoring and drift analysis.

KV cache Stored key and value tensors from previous transformer tokens used during autoregressive inference to avoid recomputing attention history.

L

L0 norm The count of nonzero elements in a vector or tensor, used in pruning to express sparsity or a target budget for remaining weights.

label quality drift Degradation in the reliability or consistency of labels over time, even when the underlying input distribution remains stable.

label shift A distribution shift where label frequencies change while the feature patterns conditioned on labels remain stable.

LAPACK Linear Algebra Package that extends BLAS with higher-level linear algebra operations including matrix decompositions, eigenvalue problems, and linear system solutions, providing essential mathematical foundations for machine learning computations.

latency The time delay between a request or event and the corresponding response or completion, critical in real-time applications where prompt responses are required.

latency constraints Real-time requirements that limit the maximum acceptable delay for model inference, driving optimization decisions in deployment scenarios where response time is critical.

layer normalization A normalization technique that normalizes inputs across the features dimension for each sample, commonly used in transformer architectures to stabilize training.

layerwise quantization A quantization granularity where all parameters within a single layer share the same quantization parameters, providing computational efficiency but potentially limiting representational precision compared to finer-grained approaches.

learning rate A hyperparameter that determines the step size for weight updates during gradient descent optimization, critically affecting training stability and convergence speed.

learning rate scheduling The systematic adjustment of learning rates during training, using strategies like step decay, exponential decay, or cosine annealing to improve convergence and final model performance.

lifecycle coherence The principle that all stages of ML development should align with overall system objectives, maintaining consistency in data handling, model architecture, and evaluation criteria.

linear scaling failure The phenomenon where increasing computing resources (for example, doubling accelerators) results in sublinear performance gains due to communication overhead and synchronization costs.

LINPACK Benchmark developed at Argonne National Laboratory that measures system performance by solving dense systems of linear equations, famous for its use in TOP500 supercomputer rankings.

Little's Law A queuing relationship stating that average concurrency equals arrival rate times average time in the system, linking throughput, latency, and capacity.

Llama Large Language Model Meta AI, a family of open foundation models that popularized efficient architectural choices like RMSNorm and SwiGLU, serving as a modern reference point for large-scale transformer efficiency.

load balancing Distribution of incoming requests across multiple server instances to prevent bottlenecks, improve response times, and ensure high availability.

locality-sensitive hashing (LSH) A hashing family that maps similar items to the same buckets with high probability, enabling scalable approximate similarity search.

logits The raw, unnormalized scores output by the last layer of a neural network before the activation function (like softmax) converts them into probabilities.

loss function A mathematical function that measures how well model outputs satisfy a training objective, providing the objective minimized by the training algorithm.

loss scaling A technique used in mixed-precision training that multiplies the loss by a large factor before backpropagation to prevent gradient underflow in reduced precision formats.

Lottery Ticket Hypothesis The theory that large neural networks contain sparse subnetworks that, when trained in isolation from proper initialization, can achieve comparable accuracy to the full network while being significantly smaller.

low-rank factorization A matrix decomposition technique that approximates large weight matrices as products of smaller matrices, reducing the number of parameters and computational operations required for neural network layers.

LSTM Long Short-Term Memory, a type of recurrent neural network architecture designed to handle long-term dependencies through gating mechanisms that control information flow.

M

machine learning A subset of artificial intelligence that enables systems to automatically improve performance on tasks through experience and data rather than explicit programming.

machine learning framework A software platform that provides tools and abstractions for designing, training, and deploying machine learning models, bridging user applications with infrastructure through computational graphs, hardware optimization, and workflow orchestration. Examples include TensorFlow, PyTorch, and JAX.

machine learning lifecycle A structured, iterative process that encompasses all stages involved in developing, deploying, and maintaining machine learning systems, from problem definition through ongoing monitoring and improvement.

machine learning operations (MLOps) The engineering discipline and set of tools focused on deploying and operating machine learning models through automation, monitoring, and management of the entire ML pipeline from development to production.

machine learning systems engineering The engineering discipline focused on building reliable, efficient, and scalable AI systems across computational platforms, spanning the entire AI lifecycle from data acquisition through deployment and operations with emphasis on resource-awareness and system-level optimization.

macro benchmarks Evaluation methodology that assesses complete machine learning models to understand how architectural choices and component interactions affect overall system behavior and performance.

magnitude-based pruning The most common pruning method that removes parameters with the smallest absolute values, based on the assumption that weights with smaller magnitudes contribute less to the model's output.

masking An anonymization technique that alters or obfuscates sensitive values so they cannot be directly traced back to the original data subject.

membership inference attack A privacy attack that tries to determine whether a specific record was included in a model's training data.

memory bandwidth Rate at which data can be read from or written to memory, measured in bytes per second, which often becomes a bottleneck in memory-intensive machine learning workloads.

memory hierarchy The organization of memory systems with different access speeds and capacities, from fast on-chip caches to slower off-chip main memory.

memory wall The widening performance gap between processor speed and memory bandwidth, where computational capacity outpaces the rate at which data can be delivered to the processor, becoming a primary bottleneck for large ML models.

metadata Descriptive information about datasets that includes details about data collection, quality metrics, validation status, and other contextual information essential for data management.

micro-batch A smaller slice of an effective batch processed sequentially for gradient accumulation or pipeline parallelism to reduce peak memory.

micro benchmarks Specialized evaluation tools that assess individual components or specific operations within machine learning systems, such as tensor operations or neural network layers.

microcontroller A small computer on a single integrated circuit containing a processor core, memory, and programmable input/output peripherals, commonly used in embedded systems.

MinHash A sketching method that approximates set similarity with compact signatures, commonly used for scalable near-duplicate detection.

mini-batch gradient descent A training approach that computes gradients and updates weights using a small subset of training examples simultaneously, balancing computational efficiency with gradient estimation quality.

mini-batch processing An optimization approach that computes gradients over small batches of examples, balancing the computational efficiency of batch processing with the memory constraints of stochastic methods.

mixed-precision computing A technique that uses different numerical precisions at various stages of computation, such as FP16 for matrix multiplications and FP32 for accumulations.

mixed-precision training A training methodology that combines different numerical precisions (typically FP16 and FP32) to optimize memory usage and computational speed while maintaining training stability.

ML node A single production ML application treated as an operational unit, including data pipelines, feature computation, model training, serving infrastructure, and monitoring.

ML systems Integrated computing systems comprising three core components: data that guides algorithmic behavior, learning algorithms that extract patterns from data, and computing infrastructure that enables both training and inference processes.

ML systems spectrum The range of machine learning system deployments from cloud-based systems with abundant resources to tiny embedded devices with severe constraints, each requiring different optimization strategies and trade-offs.

ML Test Score A production-readiness rubric for ML systems that evaluates data, model, infrastructure, and monitoring tests.

MLCommons Organization that develops and maintains industry-standard benchmarks for machine learning systems, including the MLPerf suite for training and inference evaluation.

MLPerf Industry-standard benchmark suite that provides standardized tests for training and inference across various deep learning workloads, enabling fair comparisons of machine learning systems.

MLPerf execution scenarios Standard MLPerf inference traffic scenarios that model sequential, synchronized, server, batch, and interactive workloads with different latency and throughput requirements.

MLPerf Inference Benchmark framework that evaluates machine learning inference performance across different deployment environments, from cloud data centers to mobile devices and embedded systems.

MLPerf Mobile Specialized benchmark that extends MLPerf evaluation to smartphones and mobile devices, measuring latency and responsiveness under strict power and memory constraints.

MLPerf Power An MLPerf methodology for measuring power and energy efficiency of ML workloads alongside performance.

MLPerf Tiny Benchmark designed for embedded and ultra-low-power AI systems such as IoT devices, wearables, and microcontrollers operating with minimal processing capabilities.

MLPerf Training Standardized benchmark that evaluates machine learning training performance by measuring time-to-accuracy, throughput, and resource utilization across different hardware platforms.

mobile machine learning The execution of machine learning models directly on portable, battery-powered devices like smartphones and tablets, enabling personalized and responsive applications.

model cards A standardized format for documenting machine learning models, capturing information essential for responsible deployment, including intended use, performance factors, and ethical considerations.

model-centric AI A research paradigm where the dataset is treated as fixed and engineering effort focuses on optimizing model architecture.

model compression Techniques used to reduce the size and computational requirements of machine learning models while seeking to preserve accuracy, enabling deployment on resource-constrained devices.

model deployment The process of integrating trained machine learning models into production systems where they can make predictions on new data and provide value to end users.

model drift The degradation of machine learning model performance over time due to changes in data patterns, user behavior, or environmental conditions that differ from the original training conditions.

model evaluation The systematic assessment of machine learning model performance using various metrics and validation techniques to determine whether the model meets requirements and is ready for deployment.

model FLOPs utilization (MFU) The ratio of the model FLOPs per second implied by observed throughput to the hardware's theoretical peak FLOPs per second, measuring how effectively a workload uses available compute for model computation.

model optimization The systematic refinement of machine learning models to enhance their efficiency while maintaining effectiveness, balancing trade-offs between accuracy, computational cost, memory usage, latency, and energy efficiency.

model parallelism A distributed training strategy that splits a neural network model across multiple devices, with each device responsible for computing a portion of the network.

model quantization The process of reducing numerical precision in machine learning models, typically from FP32 to INT8, to decrease model size and memory traffic; speed increases only with efficient low-precision kernels.

model registry Centralized repository for storing, versioning, and managing trained machine learning models with associated metadata to support model governance and deployment.

model serving Infrastructure and systems that expose deployed machine learning models through APIs to handle prediction requests at scale with appropriate latency and throughput.

model training The process of using machine learning algorithms to learn patterns from training data, adjusting model parameters to minimize prediction errors and create a functional predictive system.

model validation The process of testing machine learning models on independent datasets to assess their generalization ability and ensure they perform reliably on unseen data.

model versioning The systematic tracking and management of different versions of machine learning models, including their parameters, training data, and performance metrics, to enable comparison and rollback capabilities.

momentum An optimization technique that accumulates a velocity vector across iterations to help gradient descent navigate through local minima and accelerate convergence in consistent gradient directions.

monitoring The continuous observation and measurement of machine learning system performance, data quality, and operational metrics in production to detect issues and trigger maintenance actions.

multi-head attention An attention mechanism that uses multiple parallel attention heads, each focusing on different aspects of the input to capture diverse types of relationships simultaneously.

multilayer perceptron (MLP) A feedforward neural network with one or more hidden layers between input and output layers, capable of learning nonlinear mappings through dense connections and activation functions.

multiply-accumulate (MAC) The operation of multiplying two values and accumulating the result into a running sum, dominating linear layers and accelerator datapaths.

MYCIN One of the first large-scale expert systems developed at Stanford beginning in 1972 to diagnose blood infections, representing the shift toward capturing human expert knowledge in specific domains rather than pursuing general artificial intelligence.

N

N:M sparsity A structured sparsity pattern where exactly N of every M values are nonzero, giving hardware more regular zero patterns to exploit.

neural architecture search An automated approach that searches possible combinations of layers, connections, and architectural hyperparameters to find neural network architectures that perform well under specified objectives and constraints.

neural network A computational model consisting of interconnected nodes organized in layers that can learn to map inputs to outputs through adjustable connection weights.

neural processing unit (NPU) Specialized processors designed specifically for accelerating neural network operations and machine learning computations, optimized for parallel processing of AI workloads.

neuromorphic computing A computing approach that mimics the structure and function of biological neural networks, potentially offering more energy-efficient processing for AI applications.

NoSQL A category of database systems designed to handle large volumes of unstructured or semi-structured data with flexible schemas, often used in big data applications.

numerical precision optimization The dimension of model optimization that addresses how numerical values are represented and processed, including quantization techniques that map high-precision values to lower-bit representations.

NVLink NVIDIA's high-bandwidth GPU interconnect for intra-node communication, useful for gradient synchronization and model-parallel activation transfers.

O

observability Comprehensive monitoring approach that provides insight into system behavior through metrics, logs, and traces, enabling understanding of internal states from external outputs.

on-chip memory Fast memory integrated directly onto the processor chip, including caches and scratchpad memory, providing high bandwidth and low latency data access.

on-device learning The capability for machine learning models to adapt and learn directly on edge devices without requiring data transmission to external servers.

one-hot encoding A representation where categorical labels become vectors with a single 1 and remaining 0s.

one-shot pruning A pruning strategy where a large fraction of parameters is removed in a single step, typically followed by fine-tuning to recover accuracy, offering simplicity but potentially requiring more aggressive fine-tuning.

online analytical processing (OLAP) A database approach optimized for complex analytical queries across large datasets, typically used in data warehouses for business intelligence.

online inference Real-time prediction serving that processes individual requests with low

latency, suitable for interactive applications requiring immediate responses.

online transaction processing (OLTP) A database approach optimized for frequent, short transactions and real-time processing, commonly used in operational applications.

ONNX Open Neural Network Exchange, a standardized format for representing machine learning models that enables interoperability between different frameworks, allowing models trained in one framework to be deployed using another.

ONNX Runtime Cross-platform inference engine that optimizes machine learning models through techniques like operator fusion and kernel tuning to improve inference speed and reduce computational overhead.

optimizer An algorithm that adjusts model parameters during training to minimize the loss function, with common examples including SGD (Stochastic Gradient Descent), Adam, and RMSprop, each with different strategies for parameter updates.

optimizer state Auxiliary values maintained by an optimizer in addition to model parameters, such as Adam's momentum and variance tensors, often dominating training memory for large models.

orchestration Coordination and management of complex workflows and distributed computing tasks, often using platforms like Kubernetes for container management.

outlier detection The process of identifying data points that significantly deviate from normal patterns, which may represent errors, anomalies, or valuable rare events.

overfitting A phenomenon where a model learns specific details of training data so well that it fails to generalize to new, unseen examples, typically indicated by high training accuracy but poor validation performance.

P

padding A technique in convolutional networks that adds zeros or other values around the input borders to control the spatial dimensions of the output feature maps.

PagedAttention A KV-cache memory-management technique that stores attention context in fixed-size pages rather than contiguous per-request blocks to reduce fragmentation.

paradigm shift A structural change in scientific approach, like the shift from symbolic reasoning to statistical learning in AI during the 1990s, and from shallow to deep learning in the 2010s, requiring researchers to abandon established methods for markedly different approaches.

parallelism The simultaneous execution of multiple computational tasks or operations, central to achieving high performance in neural network processing.

parameter A learnable component of a neural network, including weights and biases, that gets adjusted during training to minimize the loss function.

Pareto frontier The set of configurations where improving one objective requires worsening another, used to reason about accuracy, latency, memory, and energy trade-offs.

partitioning A database technique that divides large datasets into smaller, manageable segments based on specific criteria to improve query performance and system scalability.

perceptron The basic building block of neural networks, consisting of weighted inputs, a bias term, and an activation function that produces a single output.

performance insights Analytical observations derived from monitoring production machine learning systems that reveal opportunities for improvement in model accuracy, system efficiency, or user experience.

performance-per-data (PPD) A metric measuring the accuracy gain per training sample, used to evaluate the quality of a dataset or selection strategy. High PPD indicates a dataset rich in information and low in redundancy.

pinned memory Page-locked host memory that enables direct, asynchronous transfers between CPU and GPU, improving data-loading throughput at the cost of reserving system memory.

pipeline jungle Anti-pattern where complex, interdependent data processing pipelines become difficult to maintain, debug, and modify, leading to technical debt and operational complexity.

pipeline parallelism A form of model parallelism where different layers of a model are placed on different devices and data flows through them in a pipeline fashion, allowing multiple batches to be processed simultaneously.

point-in-time correctness The guarantee that training examples use only feature values that would have been available at the historical prediction time, preventing leakage.

pooling A downsampling operation in convolutional networks that reduces spatial dimensions while retaining important features, commonly using max or average operations over local regions.

population stability index (PSI) A binned distribution-shift metric that compares current feature distributions against a baseline to detect population drift.

positional encoding A method used in transformer architectures to inject information about the position of tokens in a sequence, since transformers lack inherent sequential processing.

post-training quantization A quantization approach applied to already-trained models without modifying the training process, typically involving calibration on representative data to determine optimal quantization parameters.

power usage effectiveness (PUE) Metric used in data centers to measure energy efficiency, calculated as the ratio of total facility power consumption to IT equipment power consumption.

power wall The technological barrier reached around 2005 where increasing processor frequency no longer yielded performance gains without unsustainable increases in power density and heat generation, forcing a shift to parallel and specialized architectures.

precision In numerical computing, the number of significant bits or digits used to represent values, affecting computational accuracy and resource requirements in machine learning systems.

prefetching A system optimization technique that loads data into memory before it is needed, overlapping data loading with computation to reduce idle time and improve training throughput.

problem definition The initial stage of machine learning development that involves clearly specifying objectives, constraints, success metrics, and operational requirements to guide all subsequent development decisions.

processing element (PE) A repeated accelerator building block containing compute units and local storage, with arrays of PEs providing parallel tensor execution.

programmable logic controller (PLC) Industrial control systems used in manufacturing and IoT environments that can be integrated with ML models for automated decision-making in operational technology contexts.

protein folding problem The scientific challenge of predicting the three-dimensional structure and dynamics of proteins from their amino acid sequences and environments, a longstanding problem on which systems such as AlphaFold achieved breakthrough accuracy without resolving every folding question.

proxy variable A feature that indirectly carries signal about a protected or sensitive attribute even when that attribute is removed.

pseudonymization A privacy technique that replaces direct identifiers with artificial identifiers while maintaining the ability to trace records for analysis purposes.

PyTorch A deep learning framework developed by Facebook's AI Research lab that emphasizes dynamic computational graphs, eager execution, and intuitive Python integration, particularly popular for research and experimentation.

Q

quantization A model-compression technique that represents parameters or activations at lower precision, such as FP32 to INT8, reducing storage and data movement without reducing mathematical operation count; speedups require supported hardware and kernels.

quantization-aware training A training approach where quantization effects are simulated during the training process, allowing the model to adapt to reduced precision and typically achieving better accuracy than post-training quantization.

quantization granularity The level at which quantization parameters are applied, ranging from per-tensor (coarsest) to per-channel or per-group (finer), with finer granularity typically preserving more accuracy but requiring more storage.

queries per second (QPS) Performance metric that measures how many inference requests a system can process in one second, commonly used to evaluate throughput in production deployments.

query-key-value The three components of attention mechanisms where queries determine what to look for, keys represent what is available, and values contain the actual information to be weighted and combined.

R

real-time processing Processing data as it becomes available under application timing constraints; hard real-time systems guarantee worst-case deadlines, while soft real-time systems tolerate occasional misses.

receptive field The region of the input that influences a particular neuron's output, determining the spatial extent of patterns that can be detected by that neuron.

recurrent neural network A type of neural network designed for sequential data processing, featuring connections that create loops allowing information to persist across time steps.

Red AI AI research and development that prioritizes maximizing accuracy or performance without regard for the increasing computational and environmental costs required.

regularization Techniques used to prevent overfitting in neural networks by adding constraints or penalties, including methods like dropout, weight decay, and data augmentation.

ReLU Rectified Linear Unit activation function defined as $f(x) = \max(0, x)$ that introduces nonlinearity while maintaining computational efficiency and helping mitigate vanishing gradients for positive inputs.

residual connection A skip connection that adds the input of a layer to its output, enabling the training of very deep networks by mitigating the vanishing gradient problem.

ResNet Residual Network, a deep convolutional architecture built from residual blocks with skip connections, enabling the training of networks with hundreds of layers and achieving breakthrough performance.

ResNet-50 A specific 50-layer variant of the Residual Network architecture that serves as the canonical lighthouse model for compute-bound workloads, balancing depth and computational cost for vision benchmarks.

retinal fundus photographs Medical images of the interior surface of the eye, including the retina, optic disc, and blood vessels, commonly used for diagnosing eye diseases and training medical AI systems.

reverse-mode differentiation An automatic differentiation technique that computes gradients by traversing the computational graph in reverse order, highly efficient for functions with many inputs and few outputs, making it ideal for neural network training.

ridge point The arithmetic intensity at which a workload transitions from memory-bound to compute bound on a given hardware platform, calculated as peak FLOP/s divided by memory bandwidth. The inflection point on the Roofline Model diagram.

Ring AllReduce A bandwidth-efficient AllReduce algorithm where devices pass chunks around a ring and accumulate results for distributed gradient synchronization.

RMSprop An adaptive learning rate optimization algorithm that maintains a moving average of squared gradients to automatically adjust learning rates for each parameter during training.

role-based access control (RBAC) An access-control model that grants permissions according to user, service, or team roles rather than ad hoc individual grants.

rollback Process of reverting to a previous stable version of a model or system when issues are detected in production, ensuring service continuity.

roofline analysis A performance modeling technique that plots attainable performance against operational intensity, with peak compute and bandwidth forming the ceilings, to identify whether a system is memory bound or compute bound.

S

scalability The ability of machine learning systems to handle increasing amounts of data, users, or computational demands without significant degradation in performance or user experience.

scale and zero-point Quantization parameters that map real-valued tensors to integer values and back, where scale controls step size and zero-point maps real zero into the quantized range.

schema The structure and format definition of data that specifies data types, field names, and relationships, essential for data validation and processing consistency.

schema evolution The process of modifying data schemas over time while maintaining backward compatibility and ensuring continued functionality of dependent systems and applications.

schema-on-read An approach used in data lakes where data structure is defined and enforced at the time of reading rather than when storing, providing flexibility for diverse data types.

scratchpad memory Fast software-managed local memory used by accelerators to stage predictable data movement under compiler or runtime control.

segmentation maps Detailed annotations that classify objects at the pixel level, providing the most granular labeling information but requiring significantly more storage and processing resources.

self-attention An attention mechanism where queries, keys, and values all come from the same sequence, allowing each position to attend to all positions including itself.

semi-supervised learning A machine learning approach that uses both labeled and unlabeled data for training, using structural assumptions to improve model performance with limited labels.

sensitivity The proportion of actual positive cases correctly identified by a classification model, also known as true positive rate or recall; critical in medical applications where missing positive cases has severe consequences.

serverless Cloud computing model where infrastructure is automatically managed by the provider, allowing code execution without server management concerns.

service level agreement (SLA) A formal external contract specifying service commitments, often through one or more SLOs, and the consequences or penalties for noncompliance.

service-level objective (SLO) An internal measurable target for a service-level indicator such as latency, error rate, or availability that guides operations and may underpin an external SLA.

shadow deployment A deployment strategy where a new model runs in parallel with the production model, making predictions that are logged but not served to users, enabling validation without user impact.

shallow learning Machine learning approaches that use algorithms with limited complexity, such as support vector machines and decision trees, which require carefully engineered features but cannot automatically discover hierarchical representations like deep learning methods.

SHAP values Feature-attribution scores based on Shapley values that estimate each feature's contribution to a model prediction.

sigmoid An activation function that maps input values to a range between 0 and 1, historically popular but prone to vanishing gradient problems in deep networks.

silent bias Model unfairness that produces valid-looking but discriminatory outputs, evading traditional error monitoring and requiring disaggregated evaluation to detect.

silent degradation The gradual decline in ML system performance that occurs without triggering errors, exceptions, or alerts. An ML system can continue operating while producing increasingly inaccurate predictions.

silent failure A system failure mode where an ML model continues to produce plausible-looking outputs that are gradually less accurate or contextually relevant without triggering conventional error alerts.

SIMD (Single Instruction, Multiple Data) A parallel computing architecture that applies the same operation to multiple data elements simultaneously, effective for regular data-parallel computations.

SIMT (Single Instruction, Multiple Threads) An extension of SIMD that enables parallel execution across multiple independent threads, each maintaining its own state and program counter.

singular value decomposition A matrix factorization technique that decomposes a matrix into the product of three matrices, commonly used in low-rank approximations to compress neural network layers by retaining only the most significant singular values.

skip connection A direct connection that bypasses one or more layers, allowing gradients to flow more easily through deep networks and enabling better training of very deep architectures.

soft targets Teacher-model probability distributions used as supervision in knowledge distillation, carrying class-similarity information beyond hard labels.

softmax An activation function that converts logits into a probability distribution where outputs sum to 1, used in multi-class classification.

sparse Tensor Core A Tensor Core variant that accelerates supported structured sparsity patterns such as 2:4 sparsity by skipping constrained zero values.

sparsity The property of tensors in which many values are exactly zero, which can improve computational efficiency when the zeros have suitable structure and specialized sparse kernels or hardware support them; near-zero values count only after pruning.

SPEC CPU Standardized benchmark suite developed by the System Performance Evaluation Cooperative that measures processor performance using real-world applications rather than synthetic tests.

special function unit (SFU) Dedicated hardware for specialized operations such as exponentials, reciprocals, roots, and some activation-function primitives that do not map cleanly to ordinary arithmetic or matrix multiply units.

specificity The proportion of actual negative cases correctly identified by a classification model, also known as true negative rate; important for avoiding overwhelming referral systems with false positives.

SPECpower Benchmark methodology that measures server energy efficiency across varying workload levels, enabling direct comparisons of power-performance trade-offs in computing systems.

speculative decoding An optimization technique for autoregressive language models where a smaller model generates draft tokens that are then verified by a larger model, accelerating inference while maintaining quality.

speed of light (latency) The physical speed limit of information transmission (approx. 200,000 km/s in fiber), creating an irreducible lower bound on network latency that requires edge computing for applications needing sub-10 ms response times over long distances.

state dict A framework serialization mapping from module or optimizer names to tensors, used to save, load, and checkpoint models and optimizer state.

static graph A computational graph that is defined completely before execution begins, enabling comprehensive optimization and efficient deployment but requiring all oper-

ations to be specified upfront, limiting runtime flexibility.

static quantization A quantization approach where quantization parameters are determined once during calibration and remain fixed during inference, providing computational efficiency but less adaptability than dynamic approaches.

statistical learning The era of machine learning that emerged in the 1990s, shifting focus from rule-based symbolic AI to algorithms that could learn patterns from data, laying the groundwork for modern data-driven approaches to artificial intelligence.

stochastic gradient descent A variant of gradient descent that estimates gradients using individual training examples or small batches rather than the entire dataset, reducing memory requirements and enabling online learning.

Straight-Through Estimator (STE) A gradient approximation that lets training pass gradients through nondifferentiable operations such as rounding, often used in quantization-aware training.

stream ingestion A data processing pattern that handles data in real-time as it arrives, essential for applications requiring immediate processing and low-latency responses.

stream processing Real-time data processing approach that handles continuous flows of data as it arrives, enabling immediate responses to events and pattern detection.

stride The step size by which a convolutional filter moves across the input, controlling the spatial dimensions of the output and the degree of overlap between filter applications.

structured pruning A pruning approach that removes entire computational units such as neurons, channels, or layers, producing smaller dense models that are more hardware-friendly than the sparse matrices created by unstructured pruning.

supervised learning A machine learning approach where models learn from labeled training examples to make predictions on new, unlabeled data.

symbolic AI An approach to artificial intelligence that uses high-level symbolic representations of problems, logic, and search algorithms, dominant before the deep learning revolution and characterized by expert systems and rule-based reasoning.

synthetic benchmark Artificial test program designed to measure specific aspects of system performance, as opposed to benchmarks based on real-world applications and workloads.

synthetic data Artificially generated data created using algorithms, simulations, or generative models to supplement real-world datasets, addressing limitations in data availability or privacy concerns.

system entropy The tendency of ML systems to degrade over time as the world changes (drift) or as hidden dependencies accumulate (technical debt), requiring active energy (ops) to maintain order.

System-on-Chip (SoC) An integrated circuit that incorporates most or all components of a computer or electronic system, including CPU, GPU, memory, and specialized processors on a single chip. Commonly used in mobile devices and embedded systems for space and power efficiency.

systems co-design Joint design of algorithms, software, and hardware so model structure and execution fit physical capabilities and constraints.

systems integration The process of combining various components and subsystems into a unified, functional system that operates efficiently and reliably as a whole.

systems thinking An approach to understanding complex systems by considering how individual components interact and affect the whole system, particularly important in ML where data, algorithms, hardware, and deployment environments must work together effectively.

systolic array A specialized hardware architecture that efficiently performs matrix operations by streaming data through a grid of processing elements, minimizing data movement and energy consumption.

T

tail latency High-percentile response time in a system, typically measured as p95 or p99 latency, important for characterizing slow requests under peak load but not equivalent to the absolute worst case. It complements median and mean latency rather than replacing them.

tailored inference benchmarks Specialized performance tests designed for specific deployment environments or use cases, accounting for unique constraints and optimization requirements.

tanh Hyperbolic tangent activation function that maps inputs to (-1, 1), providing zero-centered outputs.

technical debt Long-term maintenance cost accumulated from expedient design decisions during development, particularly problematic in ML systems due to data dependencies and model complexity.

telemetry Automated collection and transmission of performance data and metrics from distributed systems, enabling remote monitoring and analysis.

tensor A multi-dimensional array used to represent data in neural networks, generalizing scalars (0D), vectors (1D), and matrices (2D) to higher dimensions.

Tensor Core A specialized GPU matrix unit for accelerated mixed-precision multiply-accumulate operations on tensor tiles.

tensor decomposition The extension of matrix factorization to higher-order tensors, used to compress neural network layers by representing weight tensors as combinations of smaller tensors with fewer parameters.

tensor parallelism A model parallelism strategy where individual tensor operations (like matrix multiplication) are split across multiple devices, reducing memory per device and potentially reducing large-layer latency when the reduction in computation time exceeds the added communication time.

tensor processing unit (TPU) Google's custom application-specific integrated circuit designed specifically for machine learning workloads, optimized for matrix operations and featuring systolic array architecture.

TensorFlow A comprehensive machine learning framework developed by Google that provides tools for the entire ML pipeline from research to production, featuring both eager execution and graph-based computation with extensive ecosystem support.

TensorRT NVIDIA's inference optimization library that applies techniques like operator fusion and precision reduction to accelerate deep learning inference on GPU hardware.

ternarization A low-bit quantization technique that constrains weights to three values (typically -1, 0, +1), providing significant compression while maintaining more representational capacity than binary quantization.

thermal design power (TDP) The sustained power and heat level a device or cooling system is designed to dissipate under typical maximum workload.

thermal throttling A protective mechanism in mobile and embedded devices that reduces processor clock speed and performance to prevent overheating, often limiting the sustained performance of on-device ML inference.

throughput The rate at which a system can process data or complete operations, typically measured in operations per second and a primary metric for training large models.

time per output token (TPOT) The per-token latency during autoregressive decode after the first token, reflecting decode throughput and memory-bandwidth limits.

time-to-accuracy The wall-clock time required to train a model to a specified validation accuracy.

time to first token (TTFT) The time from request arrival to the first generated token in streaming LLM serving, including prefill, scheduling, and initial response latency.

TinyML A field focused on deploying machine learning models on ultra-constrained embedded devices such as microcontrollers and sensors, operating in the milliwatt to sub-watt power range, with severe limitations on memory, power, and computational capacity. Also called *tiny machine learning*.

TOPS Tera Operations Per Second, an operation-rate unit indicating how many trillion operations a system can execute in one second. It is commonly reported for low-precision integer workloads, so the operation type and precision must be specified.

total cost of ownership (TCO) A comprehensive financial metric for ML systems encompassing training, inference, and operational costs over the system's entire lifecycle.

train-serve split A hybrid architecture pattern where computationally intensive model training occurs on powerful cloud infrastructure, while the trained model is optimized and deployed for inference on resource-constrained edge or mobile devices.

training The process of adjusting neural network parameters using data or interaction experience and an optimization procedure to minimize a loss or maximize a reward.

training-serving skew A mismatch between how features or data are computed during model training vs. serving in production, which can degrade model performance. Common causes include different preprocessing pipelines, feature computation timing, or data sources between training and inference.

transfer learning A machine learning technique that uses knowledge gained from pretrained models on related tasks, allowing faster training and better performance on new tasks with limited data by reusing learned features and representations.

transformer A neural network architecture built from attention, feed-forward blocks, residual connections, and normalization; the original design eliminates recurrence and convolution, though later variants may incorporate them.

translation equivariance A property where shifting the input causes a corresponding shift in the output feature map, distinct from invariance which discards position.

translation invariance The property that a model's output remains unchanged when the input shifts. Convolution is translation-

equivariant; pooling or global aggregation can produce approximate invariance.

Tucker decomposition A tensor decomposition method that generalizes singular value decomposition to higher-order tensors using a core tensor and factor matrices, commonly used for compressing convolutional neural network layers.

TV white spaces Unused broadcasting frequencies that can be repurposed for internet connectivity, as employed by systems like FarmBeats to extend network access to remote agricultural sensors and IoT devices.

U

uniform quantization A quantization approach where the range of values is divided into evenly spaced intervals, providing simple implementation but potentially suboptimal for nonuniform value distributions.

universal approximation theorem A theoretical result proving that neural networks with sufficient width and a suitable nonlinear activation function can approximate any continuous function on a compact domain to arbitrary accuracy.

unreasonable effectiveness of data The empirical observation that for many problems, adding more data is more effective than improving algorithms, driving the data-centric AI paradigm.

unstructured pruning A pruning approach that removes individual weights while preserving the overall network architecture, creating sparse weight matrices that require specialized hardware support to realize computational benefits.

unstructured sparsity A form of model sparsity where individual weights are set to zero without following any particular pattern, creating irregular sparsity patterns that require specialized hardware support to realize computational benefits.

V

validation issues Problems identified during model testing that indicate poor performance, overfitting, data quality problems, or other issues that must be resolved before deployment.

vanishing gradient problem A problem in deep neural networks where gradients become exponentially smaller as they propagate backward through layers, making it difficult for early layers to learn effectively.

vector operations Computational operations that process multiple data elements simultaneously, enabling efficient parallel execution of element-wise transformations in neural networks.

verification gap The mismatch between finite test-set coverage and the much larger input space an ML system may encounter in production.

versioning The practice of tracking changes to datasets, models, and pipelines over time, enabling reproducibility, rollback capabilities, and audit trails in ML systems.

virtuous cycle The self-reinforcing process in deep learning where improvements in data availability, algorithms, and computing power each enable further advances in the other areas, accelerating overall progress.

Von Neumann bottleneck The performance limitation caused by the shared bus between processor and memory in traditional computer architectures, where data movement becomes more expensive than computation.

W

warehouse-scale computer (WSC) A data center operated as a single programmable computer, treating compute, storage, networking, and failures as system-level resources.

warp A group of 32 threads on NVIDIA GPUs whose active threads execute one common instruction at a time; the fundamental unit of thread scheduling on NVIDIA GPUs.

Waymo A subsidiary of Alphabet Inc. that represents a leading deployment of machine learning systems in autonomous vehicle technology, demonstrating how ML systems can span from embedded systems to cloud infrastructure in safety-critical environments.

weak supervision An approach that uses lower-quality labels obtained more efficiently through heuristics, distant supervision, or programmatic methods rather than manual expert annotation.

web scraping An automated technique for extracting data from websites to build custom datasets, requiring careful consideration of legal, ethical, and technical constraints.

weight A learnable parameter that determines the strength of connection between neurons in different layers, adjusted during training to minimize the loss function.

weight matrix An organized collection of weights connecting one layer to another in a neural network, enabling efficient computation through matrix operations.

weight sharing The practice of using the same parameters across different spatial locations, as in convolutional networks, reducing the number of parameters while maintaining pattern detection capabilities.

Whetstone Early benchmark developed at the UK National Physical Laboratory by Curnow and Wichmann, first published as an ALGOL 60 program in 1972 and later as the canonical FORTRAN version in 1976. It measured floating-point arithmetic performance in MWIPS (millions of Whetstone instructions per second), becoming one of the first widely-adopted standardized performance tests.

workflow orchestration Automated coordination and management of complex ML pipeline sequences, ensuring proper execution order, dependency management, and error handling across distributed systems.

X

XLA Accelerated Linear Algebra, a domain-specific compiler for linear algebra operations that optimizes TensorFlow and JAX computations by generating efficient code for various hardware platforms including CPUs, GPUs, and TPUs.

Y

YOLO You Only Look Once, a family of single-stage object detection models that reframes detection as a spatial regression problem, predicting bounding boxes and class probabilities in a single forward pass to achieve high throughput on edge accelerators.

Z

zero-copy memory A memory allocation pattern that allows accelerator execution units to directly read or write host pinned memory across the system bus without an explicit staging transfer, trading bus bandwidth for reduced memory allocation footprint.

ZeRO Zero Redundancy Optimizer, a memory-efficient distributed training paradigm that partitions optimizer states, gradients, and model parameters across data-parallel ranks to eliminate memory redundancy while maintaining communication efficiency.

zero-shot learning A deployment paradigm where a pretrained model performs inference on tasks or classes unseen during supervised training, relying on learned semantic representations without fine-tuning.
