Main Text

Chapter 1 Introduction 3
1.1 The AI Systems Moment . . . 4
1.2 From Code-Defined Logic to Data-Defined Behavior . . . 4
1.3 The Evolution of AI Bottlenecks . . . 7
1.4 The Bitter Lesson . . . 11
1.5 Defining ML Systems . . . 12
1.6 When ML Systems Fail Silently . . . 15
1.7 Iron Law of ML Systems . . . 16
1.8 Three Dimensions of ML Efficiency . . . 21
1.9 AI Engineering as a Discipline . . . 24
1.10 Book Organization . . . 26
1.11 Fallacies and Pitfalls . . . 27
1.12 Summary . . . 28

Part I: Foundations of ML Systems

Foundation Principles 33

Chapter 2 System Paradigms 35
2.1 Four Deployment Regimes Across Nine Orders of Magnitude . . . 36
2.2 Physical Constraints on Deployment . . . 37
2.3 Analyzing Workloads . . . 40
2.4 System Balance and Hardware . . . 43
2.5 Cloud ML: Computational Power . . . 47
2.6 Edge ML: Latency and Privacy . . . 51
2.7 Mobile ML: Offline Intelligence . . . 57
2.8 TinyML: Ubiquitous Sensing . . . 60
2.9 Choosing a Deployment Paradigm . . . 63
2.10 Hybrid Architectures . . . 67
2.11 What Every Tier Shares . . . 71

2.12 Fallacies and Pitfalls . . . 72
2.13 Summary . . . 74

Chapter 3 ML Lifecycle **77**
3.1 The Lifecycle as a Loop . . . 78
3.2 How Decisions Cascade: The Constraint Propagation Principle . . . 82
3.3 Where the Hours Go: Quantifying the ML Lifecycle . . . 83
3.4 Stage Ownership and Hand-offs . . . 84
3.5 Stage 1: Problem Definition . . . 87
3.6 Stage 2: Data Collection and Preparation . . . 89
3.7 Stage 3: Model Development and Training . . . 91
3.8 Stage 4: Evaluation and Validation . . . 94
3.9 Stage 5: Deployment and Integration . . . 97
3.10 Stage 6: Monitoring and Maintenance . . . 100
3.11 Systems Thinking Across the Lifecycle . . . 101
3.12 Fallacies and Pitfalls . . . 103
3.13 Summary . . . 104

Chapter 4 Data Engineering **107**
4.1 Data as Code . . . 108
4.2 How Data Fails . . . 109
4.3 Requirements and Data Budget . . . 113
4.4 Data Acquisition . . . 118
4.5 Ingestion and Validation . . . 123
4.6 Data Labeling . . . 131
4.7 Data Processing . . . 139
4.8 Dataset Release . . . 146
4.9 Physics of Data . . . 149
4.10 Storage and Delivery . . . 152
4.11 Accepting the Pipeline . . . 159
4.12 Operational Data Health . . . 160
4.13 Fallacies and Pitfalls . . . 165
4.14 Summary . . . 167

Part II: Development and Training

Development Principles **171**

Chapter 5 Neural Computation **173**
5.1 From Logic to Arithmetic . . . 174
5.2 Computing with Patterns . . . 176
5.3 Neural Network Fundamentals . . . 180
5.4 Learning Process . . . 192
5.5 Inference Pipeline . . . 217
5.6 Handwritten Digit Recognition . . . 220
5.7 D·A·M Reading of Neural Computation . . . 223
5.8 Fallacies and Pitfalls . . . 224
5.9 Summary . . . 225

Chapter 6 Network Architectures **227**
6.1 Architectural Principles . . . 228
6.2 MLPs: Dense Pattern Processing . . . 231
6.3 CNNs: Spatial Pattern Processing . . . 235
6.4 Skip Connections and Normalization . . . 246
6.5 RNNs: Sequential Pattern Processing . . . 249
6.6 Attention: Dynamic Processing . . . 254

6.7 Transformers: Parallel Sequence Processing . . . 260
6.8 Sparse Architectures: Recommendation Systems . . . 268
6.9 Comparing and Choosing Architectures . . . 272
6.10 Fallacies and Pitfalls . . . 282
6.11 Summary . . . 283

Chapter 7 ML Frameworks **285**
7.1 Three Framework Problems . . . 286
7.2 Evolution of Framework Abstractions . . . 288
7.3 Execution: From Graphs to Kernels . . . 290
7.4 Differentiation: Automatic Gradient Computation . . . 305
7.5 Abstraction: Tensors, Devices, and Operations . . . 316
7.6 Modules: From Operations to Models . . . 325
7.7 Anatomy of a Training Step . . . 330
7.8 Major Frameworks: TensorFlow, PyTorch, and JAX . . . 334
7.9 Choosing a Framework . . . 339
7.10 Fallacies and Pitfalls . . . 341
7.11 Summary . . . 342

Chapter 8 Model Training **345**
8.1 From One Step to a Training Run . . . 346
8.2 Training-Time Law . . . 349
8.3 Computation and Memory Costs of Training . . . 351
8.4 Pipeline Architecture . . . 365
8.5 Identifying Bottlenecks . . . 378
8.6 Pipeline Optimizations . . . 380
8.7 Scaling Training Systems . . . 404
8.8 Fallacies and Pitfalls . . . 410
8.9 Summary . . . 411

Part III: Optimization and Acceleration

Optimization Principles **417**

Chapter 9 Data Selection **421**
9.1 The Data Wall . . . 422
9.2 Measuring Data Value . . . 425
9.3 Static Pruning . . . 433
9.4 Dynamic Selection . . . 438
9.5 Synthetic Data Generation . . . 442
9.6 Learning from Unlabeled Data . . . 445
9.7 Selection Engineering . . . 448
9.8 Choosing a Selection Strategy . . . 455
9.9 Cross-Layer Interactions . . . 462
9.10 Fallacies and Pitfalls . . . 463
9.11 Summary . . . 464

Chapter 10 Model Compression **467**
10.1 Fitting the Deployment Budget . . . 469
10.2 Structural Optimization: Changing What the Model Computes . . . 474
10.3 Numerical Precision: Changing How Values Are Stored . . . 497
10.4 Hardware Implementation: Changing How the Model Executes . . . 517
10.5 Choosing and Combining Techniques . . . 522
10.6 Measuring Compression Gains . . . 529
10.7 Fallacies and Pitfalls . . . 533
10.8 Summary . . . 535

Chapter 11 Hardware Acceleration **537**
11.1 Anatomy of an Accelerator . . . 538
11.2 Hardware Specialization . . . 544
11.3 Compute Primitives . . . 549
11.4 Compute Units . . . 557
11.5 Memory Systems . . . 564
11.6 Performance Bounds . . . 574
11.7 Hardware Mapping . . . 584
11.8 Compilers and Runtimes . . . 600
11.9 Beyond One Accelerator . . . 607
11.10 Heterogeneous SoC Design . . . 607
11.11 Choosing an Accelerator . . . 611
11.12 Fallacies and Pitfalls . . . 613
11.13 Summary . . . 616

Chapter 12 Benchmarking **619**
12.1 The Benchmark–Production Gap . . . 620
12.2 Benchmark Carpentry . . . 624
12.3 Benchmarking Granularity . . . 632
12.4 Benchmark Suites . . . 640
12.5 Training Benchmarks . . . 646
12.6 Inference Benchmarks . . . 652
12.7 Power and Energy Measurement . . . 661
12.8 Benchmarking Best Practices . . . 667
12.9 Model and Data Evaluation . . . 673
12.10 Fallacies and Pitfalls . . . 683
12.11 Summary . . . 684

Part IV: Deployment and Operations

Deployment Principles **689**

Chapter 13 Model Serving **693**
13.1 The Serving Inversion . . . 694
13.2 Serving System Architecture . . . 699
13.3 Request Lifecycle . . . 702
13.4 Queuing Theory . . . 710
13.5 Throughput Optimization . . . 717
13.6 Inference Runtime Selection . . . 728
13.7 Node-Level Optimization . . . 734
13.8 Model Loading and Versioning . . . 738
13.9 LLM Serving . . . 742
13.10 Economics and Planning . . . 749
13.11 Fallacies and Pitfalls . . . 754
13.12 Summary . . . 755

Chapter 14 ML Operations **759**
14.1 Silent Failure in Production . . . 760
14.2 Technical Debt . . . 767
14.3 Development Infrastructure . . . 773
14.4 Releasing Models . . . 781
14.5 Production Monitoring . . . 787
14.6 Retraining Decisions . . . 798
14.7 Incident Response and Governance . . . 804
14.8 Operational Maturity . . . 810
14.9 Case Studies . . . 816

14.10 Fallacies and Pitfalls . . . 822
14.11 Summary . . . 824

Chapter 15 Responsible Engineering **827**
15.1 Responsibility as Systems Engineering . . . 828
15.2 Engineering Responsibility Gap . . . 830
15.3 Responsible Engineering Across the Lifecycle . . . 836
15.4 Environmental and Cost Awareness . . . 853
15.5 Data Governance and Compliance . . . 858
15.6 Fallacies and Pitfalls . . . 866
15.7 Summary . . . 867

Synthesis

Chapter 16 Conclusion **873**
16.1 The System Is the Model . . . 874
16.2 Lighthouse Models: Constraint Propagation . . . 875
16.3 Thirteen Quantitative Principles . . . 877
16.4 The Dual Mandate Revisited . . . 881
16.5 Future Directions . . . 883
16.6 The Engineering Responsibility . . . 886
16.7 Fallacies and Pitfalls . . . 886
16.8 Summary . . . 887

Foreword

David A. Patterson
Pardee Professor of Computer Science Emeritus
University of California, Berkeley
Distinguished Engineer, Google
ACM A.M. Turing Award Laureate
Berkeley, California

My career has been dedicated to understanding and improving the very foundations upon which computing operates – from the instruction set architectures that define processors to the storage systems that hold our data. I've seen firsthand how profound advancements are rarely about a single brilliant idea in isolation, but rather about the holistic integration of many ideas into a robust, efficient, and reliable system.

Today, we stand at another pivotal moment. Machine learning (ML) has transcended scientific curiosity to become a force reshaping industries, driving innovation, and transforming our daily lives. The intellectual power of the algorithms, the gains in accuracy, and the seemingly magical capabilities they unlock have rightly captured the world's imagination.

One concern is that much of this progress has been achieved by a community that, through no fault of its own, was never taught to think in systems terms about what it was building. Engineers who can call `model.fit()` but cannot explain why training is slow. Researchers who tune hyperparameters without understanding the memory bandwidth constraints that make certain choices impractical. Practitioners who deploy models into production without a framework for reasoning about latency, throughput, or failure modes.

A brilliant algorithm, without a well-engineered system to support it, is like a powerful engine without a chassis and brakes. It won't get you far, and it certainly won't get you there reliably.

This gap is not a talent deficit. It is a curriculum deficit. The field has simply not had the textbooks it deserves. This book, *Introduction to Machine Learning Systems*, arrives precisely at the right time to illuminate this critical, often overlooked, dimension of the ML revolution.

Why Systems Thinking Matters

My career has leveraged the power of systems thinking. Identify the bottlenecks, understand the interactions between components, and design for performance, reliability, cost-effectiveness, and ease of use across the entire stack. You could not reach the conclusion from first principles alone. You had to think about the system.

ML systems demand exactly the same discipline. A neural network is not a mathematical abstraction floating free of physical constraints. It is a computation that must execute on silicon with finite memory bandwidth, finite power budgets, and finite communication capacity. Arithmetic intensity, the Roofline Model, and memory hierarchy effects are not advanced topics to be addressed after students learn the basics. They are the basics.

Why ML Systems Deserve Serious Textbook Treatment

The purpose of a textbook is not just to catalog the current frontier. It is to provide the conceptual scaffolding that allows students to understand the frontier, and to advance it themselves. The neural network architectures covered in these pages will evolve. The hardware accelerators described will

be superseded. But some fundamentals will not change. We will still have memory hierarchies and arithmetic intensity will still be a critical measure. The principles of pipelining, of latency versus throughput trade-offs, of quantization and precision reflect physical and mathematical realities that do not go out of date. Anyone who genuinely understands them will be able to reason about whatever new system the field produces next year or ten years from now.

I am also struck by the scope of what this book attempts. It is not enough to explain how training works; one must also address data engineering, model optimization, hardware acceleration, deployment, benchmarking, responsible AI, and sustainability. These are not separate topics bolted together for completeness. They are interconnected aspects of a single engineering discipline. A decision made at the data layer has implications for model behavior, which has implications for inference latency, which has implications for deployment cost, which has implications for the communities that can and cannot access the resulting system. The book correctly treats this integration as a first-class concern.

I am particularly pleased to see the quantitative methodology that runs through every chapter. Claims are backed by measurements. Trade-offs are expressed numerically. Students are taught to estimate, measure, and verify rather than to rely on their gut. The difference between an engineer and a dilettante is precisely this capacity for rigorous, measurement-grounded reasoning.

Why Open Access Is Important for the Next Generation

I applaud the decision to make this invaluable resource freely available.

When I co-wrote *Computer Architecture: A Quantitative Approach* with John Hennessy, we debated how to make the material as accessible as possible. We lobbied our publisher to keep the price down and even came out with a low cost international student edition for sales outside North America. Those concerns have only grown more urgent as ML has become infrastructure—as consequential to the modern world as the electrical grid or the internet.

The decision to publish this book as a freely available educational resource is not a compromise. It is a statement of values. ML systems are being deployed in every sector of every economy on every continent. The engineers who build and maintain them will come from everywhere. If the foundational education required to do this work responsibly is available only to students at well-resourced institutions, we will contribute to an expertise gap that mirrors the societal concerns of who benefits from AI and who bears its costs.

What impresses me further is that this project has gone well beyond open access to a static text. The accompanying ecosystem—interactive laboratories, a build-from-scratch framework in TinyTorch, hardware deployment kits, instructor materials, a global network of adopting universities—reflects a familiar educational maxim: "I hear and I forget. I see and I remember. I do and I understand."

The open-source model also makes the curriculum itself better. Errors get corrected. Examples get sharpened. New chapters emerge in response to what the field actually needs. As we found with *Computer Architecture: A Quantitative Approach*, a community of contributors that forms around a book can offer a form of quality assurance that no single author team, however expert, can match alone.

A Final Word

The field of computer architecture has a tradition I am proud of: we build things, measure them honestly, share what we learn, and revise our philosophies when the measurements demand it. We do not hide behind the complexity of our systems to avoid accountability for whether they actually work. We do not conflate novelty with progress. We debate, rigorously, about what matters and why.

Hopefully, ML systems engineering will follow this tradition. It needs the habits of mind that come from taking systems seriously: thinking about interactions, measuring at the right level of abstraction, being honest about trade-offs, and holding oneself accountable to real-world performance rather than benchmark folklore. This book embodies those habits.

Introduction to Machine Learning Systems is more than just a textbook; it is a clarion call for systems thinking in the age of AI, a guide for building robust ML applications, and a testament to the power of open education.

We are at an extraordinary moment. Over my career there has been a major breakthrough every decade: the microprocessor in the 1970s, the personal computer in the 1980s, the Internet in the 1990s, the smartphone in the 2000s, and AI in the 2010s. The first four changed business and society, yet AI looks likely to have the largest impact of them all.

The systems being built today will shape how intelligence is deployed, who benefits from it, and what it costs—in money, in energy, and in carbon footprint. We need the engineers who build those systems to have the best possible systems skills.

This book is a significant step toward making it possible for anyone to learn them.

David A. Patterson

Author's Note

The world is rushing to build AI systems; it is not yet engineering them. That sentence is the reason this book exists. A model that wins on a benchmark is not yet a system, and the distance between the two is not a detail of implementation. It is engineering: the work of making something hold up under constraints that do not negotiate. A demo answers to no one. A system answers to latency budgets, memory limits, power envelopes, and the cost of being wrong in front of real users.

What makes this its own discipline is an unusual coupling. A processor answers to the physics of the machine, to clock cycles, cache lines, and the heat it can shed. A statistical model answers to the mathematics of learning, to bias, variance, and how generalization changes with data and model capacity. A machine learning system must answer to both at once, in the same decision, and the two do not always agree. A change that pleases the hardware can starve the model of the precision or throughput it needs to converge; a change that helps the model can ask the silicon for more memory or bandwidth than it can give. Hold that tension in view and the field stops looking like a pile of tools and starts looking like a structure you can reason about.

This book hands you that structure. Not the framework that is fashionable this year or the accelerator that is fastest this quarter, but the way of thinking that outlasts them. Frameworks change, hardware turns over every few years, and the benchmarks reset; the forces underneath stay the same. If the book works, you will finish it able to look at any machine learning system, from a sensor sipping microwatts to a server farm drawing megawatts, and see the same small set of forces deciding what is possible.

The textbooks that changed me when I was a student did not hand me facts. They handed me a way of seeing, and the facts arranged themselves around it. That is what I have tried to do here.

— Vijay Janapa Reddi
Cambridge, Massachusetts
2026

Preface

Who This Book Is For

A model that trains cleanly in a research notebook can still run out of memory on a server, miss its latency budget under live traffic, or cost ten times more to serve than the application can afford. Most readers will not become hardware architects or compiler writers, yet every practitioner who builds, trains, optimizes, or deploys a model makes choices whose outcome depends on the system beneath the code.

This book explains *how* machine learning systems work, from the mathematics that define a neural network to the hardware that runs it and the engineering trade-offs that make it fast and reliable. It builds that foundation for engineers meeting ML systems for the first time, practicing engineers who want to understand what happens below the framework API, and researchers who need to reason about runtime, memory, and deployment.

Prerequisites

Readers should bring two prerequisites:

- **Programming**: Fluency in Python, including functions, classes, and basic array manipulation with NumPy.
- **Mathematics**: Comfort with linear algebra, basic calculus, and probability at the introductory university level.

Two additional areas help but are not required:

- **Computer systems**: Prior familiarity with caches, memory bandwidth, and processor organization is useful, though the optimization and hardware chapters build every physical mechanism from first principles.
- **Machine learning basics**: Prior exposure to supervised learning gives helpful context, though Part II develops the required modeling foundations from the ground up.

Why a Systems Textbook

In 1968, a NATO conference in Garmisch, Germany, helped establish *software engineering* as a distinct discipline amid concern that software systems had grown too complex for ad hoc programming (Naur and Randell 1969). Reliable software required its own principles, methods, and rigor. Decades later, Hennessy and Patterson put quantitative analysis at the center of computer architecture education, giving engineers a shared way to measure, predict, and improve processor performance (Hennessy and Patterson 2017). Both moments turned a craft of rules of thumb into a teachable engineering discipline.

Machine learning faces its own Garmisch moment. For the past decade, ML research has been dominated by *model-centric* thinking focused on discovering new algorithms and architectures. That focus matters, but a model is not a system. A neural network that scores well on an offline benchmark fails in practice if it misses its latency deadline, if its data pipeline cannot keep accelerators fed, or if its energy bill exceeds the value of its predictions. The gap between a working model and a production system is not an implementation detail; it is a gap in engineering principles.

This book treats ML systems engineering not as a catalog of tools, such as Kubernetes, PyTorch, and CUDA, but as a discipline built on quantitative bounds, cost models, and design principles. Just

as civil engineers calculate loads before choosing materials, ML systems engineers need explicit laws that reveal which resource limits performance before they rewrite code. Four ideas anchor this book:

- **The D·A·M taxonomy**: Every bottleneck lives in the data, the algorithm, or the machine, and relieving one can expose another.
- **The iron law of ML systems**: Across the D·A·M axes, workload time factors as $(\text{Samples/Task}) \times (\text{FLOPs/Sample}) \times (\text{Seconds/FLOP})$ and unpacks on hardware into data movement, computation, and overhead; where stages run concurrently (such as transferring the next batch while computing the current one), elapsed time is governed by the critical path.
- **The bitter lesson**: General methods that exploit growing computation outpace hand-encoded expertise, which makes systems efficiency a lever of progress.
- **The energy-movement principle**: Fetching a value from off-chip memory can cost far more energy than computing with it, so per-event costs and event counts determine whether movement or computation dominates.

Each part adds its own governing principles, such as data gravity and Amdahl's law, at the point where they first bind. Together, the volume-wide anchors and part-level laws form a compact analytical toolkit that carries across every chapter.

Computer science studies what is computable. ML research studies what is learnable. AI engineering studies what is buildable, given the physics of real hardware and real data. I wrote this book to help build that foundation and to do for ML systems what Hennessy and Patterson (2017) did for computer architecture: replace guesswork with measurement, and folklore with engineering. The goal is to teach system-level reasoning before implementation, treating data, algorithms, and hardware not as separate silos but as a single, coupled design problem.

Consider a box of LEGO bricks. The same interlocking pieces build a spaceship, a castle, or an entire city. The sets change; the bricks do not. ML systems work the same way. A convolutional network for image classification, a transformer for language generation, and a reinforcement learning agent for robotics serve very different applications, but beneath them sit the same building blocks: computational graphs, memory hierarchies, data pipelines, training loops, and the trade-offs among latency, throughput, and energy. Once an engineer understands those building blocks, even an unfamiliar system becomes legible.

That is why this book teaches enduring principles rather than current tools. Dominant frameworks have shifted from Theano to TensorFlow to PyTorch in under a decade, and hardware has evolved from repurposed graphics processors to purpose-built tensor accelerators, with new architectures arriving every year. Because frameworks and hardware turn over so quickly, tool-specific advice ages fast, whereas the building blocks endure.

What This Book Covers

An engineer cannot diagnose why a thousand-GPU training cluster is stalling without first knowing how a single machine moves tensors through memory, feeds its data pipeline, and keeps its execution units busy. Even the largest warehouse-scale cluster is built out of individual compute nodes. This book therefore centers on the *single compute node*: one host with one to eight accelerators, each with its own discrete memory connected over a local link such as PCIe or NVLink. Multi-node execution enters only where it shapes single-node design; the distributed communication, scheduling, and fault-recovery problems that arise across a fleet build directly on the single-node foundations developed here.

The book is organized into four parts. Each part answers one question and hands the next part a concrete result:

- **Part I: Foundations of ML Systems** asks what is being built, under which constraints, and from what inputs. It develops the vocabulary, cost models, and end-to-end workflow that guide every ML project, from the traits that distinguish ML systems from traditional software to the data pipelines that feed them. It hands forward a design envelope and trustworthy data.
- **Part II: Development and Training** asks how a model computes, how it is structured, and how it learns. It connects mathematical foundations to working software and hardware through

neural network computation, model architectures, execution frameworks, and training loops. It hands forward a trained model whose memory, compute, and wall-clock costs are known.

- **Part III: Optimization and Acceleration** asks how to make that model cheaper to train or serve and how to prove the gain. Its chapters follow the D·A·M taxonomy in order: data selection cuts the samples a run must process, model compression shrinks the algorithm, hardware acceleration maps the remaining work onto the machine, and benchmarking tests whether the speedup holds up under honest measurement. It hands forward verified evidence for a deployment decision.
- **Part IV: Deployment and Operations** asks whether the system survives real users, shifting data, and its obligations to society. It covers serving infrastructure, production monitoring and retraining, and the engineering controls needed to keep deployed systems fair, safe, and accountable. It hands forward the tools to run and defend a system in production.

Each part builds on the previous one, following a single system through its life. The progression runs from problem and constraints through data, model, training, optimization, benchmarking, deployment, and operations.

Suggested Reading Paths

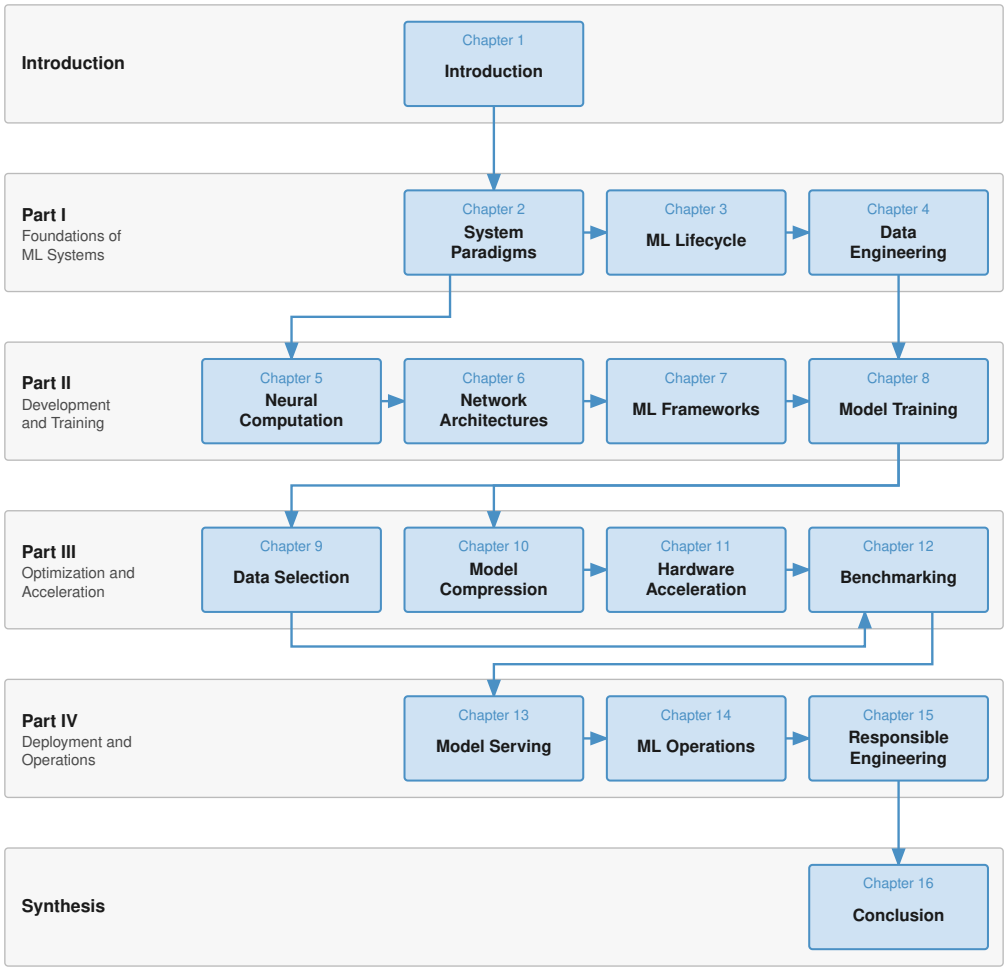
Reading the chapters in order gives the most complete foundation, because each part hands a concrete artifact and cost model to the next. Readers coming in with specific goals can take a more focused route:

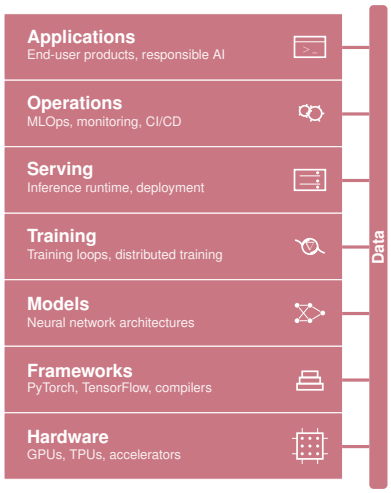
- **The Complete Path** (all chapters, in order): For engineers and researchers new to ML systems. Start with chapter 1, then read the four parts in sequence. This path builds every concept from first principles.
- **The ML Engineer's Path** (systems depth for practitioners): For engineers who already train and deploy models in Python but want to understand what happens underneath the framework API. Skim Part I for shared vocabulary, then focus on chapter 7, chapter 8, chapter 11, chapter 12, and chapter 13.
- **The Optimization Path** (efficiency-focused): For engineers working on model compression, kernel performance, edge deployment, or tight latency budgets. After Part I, review Part II's account of forward and backward passes, architecture costs, framework execution, and training bottlenecks before diving into Part III.

Whichever path a reader takes, figure P.1 shows which earlier chapters each chapter depends on. Readers who already know a prerequisite topic can skip ahead; others can follow the incoming arrows back to fill in the background. Model training sits at the center of the map, drawing on both data engineering and ML frameworks while feeding both data selection and model compression. The longest dependency chain runs through Part III, where model compression feeds hardware acceleration and benchmarking closes the loop before deployment.

How to Read This Book

The parts follow the lifecycle of a model rather than climbing the ML systems stack from the bottom, so each chapter touches several layers of that stack at once. Modeled on the classical computer systems hierarchy, each layer of the stack provides an interface to the layer above and builds on the layer below, from hardware at the bottom through frameworks, models, training, and serving, up to operations and applications at the top, while data runs alongside every layer like a system bus. Throughout the book, a recurring margin figure highlights which layers each chapter addresses:





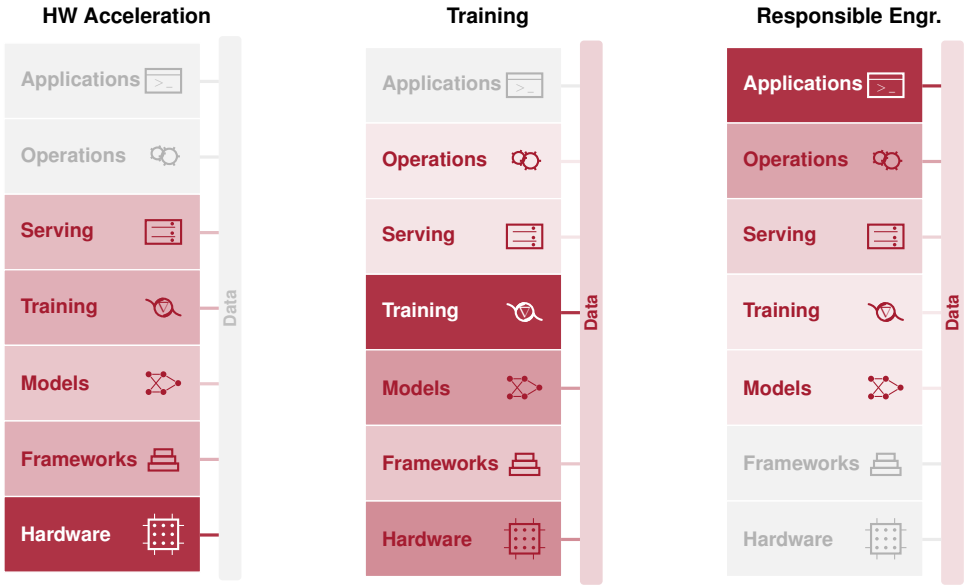


Figure P.1: Chapter Dependency Map: Each arrow points from a chapter to a later chapter that builds on its results, derived from the book's cross-references with transitive links omitted. The introduction frames every chapter; the arrow from it marks the chapter that draws on it directly.

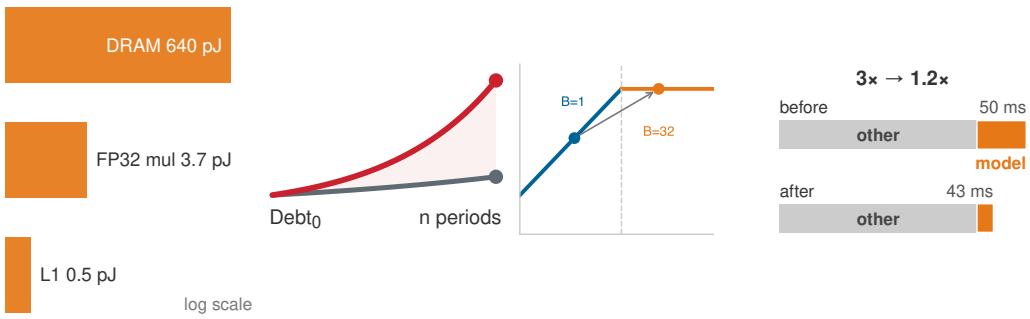


The vertical data bar alongside the stack tracks a separate dimension from the horizontal layers: its uniform shading reflects how central data is to the chapter as a whole, while the connecting wires mark which layers interact with data directly in that chapter's context. Three chapters show how this profile shifts across the book:

In chapter 11, the layer intensity concentrates at the bottom of the stack while the data bar is faint: the chapter focuses on hardware mechanisms rather than dataset construction. In chapter 8, the middle layers glow and the data bar is moderately lit, reflecting that training consumes data but is fundamentally about optimization. In chapter 15, the top layers dominate and the data bar carries a moderate tint, because biased training data surfaces as biased applications even though several layers sit between them. The same stack tells three different stories, with data as an independent dimension.

The margins also carry small visual notes at the point where a relationship is easiest to understand by sight. These are not numbered figures to cite later; they are reading aids. A ladder makes an energy or latency scale gap visible, a trend sketch shows direction, a roofline thumbnail shows whether memory bandwidth or compute throughput bounds performance, and a dominance bar shows which term controls total runtime. When a miniature uses a log scale, it says so inside the image.

Alongside these visual notes, unnumbered **marginal navigation pointers** connect an idea to the chapter that establishes it or builds on it, without interrupting the prose:

- ↩ **Backward pointer:** Directs the reader back to the earlier chapter where a principle, constraint, or cost model was established.
- ↪ **Forward pointer:** Directs the reader ahead to the later chapter, or to the appendix, where the current idea is developed, measured, or enforced.
- ⇄ **Contrast:** Marks a place where two chapters treat the same problem differently, so the comparison is visible at a glance.

A pointer only orients. When a sentence depends on another chapter, the reference stays in the text.

Conventions

This book uses a small set of typographic conventions to mark what each piece of prose is doing.

Bold marks first definitions

A term in **bold** within body prose is its formal first introduction in the volume. Each term receives this treatment exactly once. Subsequent appearances are unbolded; by then the term is part of the working vocabulary the chapter carries forward.

> Every machine learning system has a **dual mandate**: it must manage statistical uncertainty and physical constraints simultaneously.

Bold identifies a term that readers will use throughout the book. A matching index entry in the back of the book points to the defining occurrence (under the `definition` subentry), providing a way to return to it. Key technical terms are also compiled in the glossary.

Bold also appears in a second, structural role: as a functional label at the start of an item inside a callout box or a summary bullet—for example, **Recommendation**, **Trade-off**, or **Result**. In that context, the bold is scaffolding rather than a first definition.

Italics carry specific rhetorical jobs

Italics serve specific purposes rather than general emphasis. Common uses include:

- **Direct opposition**: *training* vs. *inference*, *logical* vs. *physical*.
- **Impossibility, stated as physical, mathematical, or logical law**: "sub-10 ms systems *cannot* use distant cloud infrastructure—physics forbids it."
- **Word used as word**: "the term *gradient* refers to a vector of partial derivatives."
- **Titles of works**: *Computer Architecture: A Quantitative Approach*.
- **Thesis punchline**: A single italicized sentence that captures the controlling insight of a section, for example, *Data is source code.*

Callouts have visual identities that match their job

Callout boxes are not decoration. Each type signals a specific kind of content, so the visual identity announces what the box contains before the reader engages with it.

Callout	Contains
Definition	Formal definition of a key term, with its significance, distinction from the nearest neighbor concept, and a common pitfall
Example	Historical case or concrete scenario, structured as context, insight, and systems lesson
Systems Perspective	Analytical observation or mathematical nuance that enriches the surrounding argument
Napkin Math	Worked calculation with assumptions and intermediate steps shown explicitly; intermediate tables and equations are the math itself
Checkpoint	Self-check questions to verify understanding of the preceding section
War Story	Documented engineering incident with a sourced failure mode, structured as context, failure, consequence, and lesson

Callout	Contains
Lighthouse	Recurring workloads characterized by a profile (parameters, FLOPs, dominant constraint), used as anchored case studies across multiple chapters
Principle	Canonical book principle or invariant referenced from later chapters
Theorem	Formal, equation-backed result or bound, stated with its conditions and applied in later quantitative analysis
Key Takeaways	Four to seven most important results from a chapter, in summary form
Learning Objectives	Skills and concepts that readers should be able to explain or apply after completing the chapter
What's Next	Bridge from the chapter just ended to the chapter beginning, naming the open question the next chapter addresses

When a callout contains a table, figure, or equation, that artifact is part of the callout's pedagogical unit, not decoration. A lighthouse's profile *is* its characterization. A napkin math box's intermediate tables *are* the worked math. Reading these as separated artifacts loses the teaching arc. Standalone reference tables, by contrast, sit between paragraphs as numbered artifacts the reader returns to through cross-references. Both forms are valid; the visual marker (callout vs. standalone) tells the reader which one they are looking at.

Companion Resources

Whichever path readers follow, this book is part of a broader learning ecosystem. The complete text, interactive notebooks, lecture slides, exercises, hands-on labs, and supplementary materials are available online at **mlsysbook.ai**.

This book is open source. The full text, figures, and build system are publicly available, and contributions from readers worldwide have materially improved every chapter. Visit **mlsysbook.ai/git** to report issues, suggest improvements, or contribute directly.

Using This Book in a Course

This book grew out of CS249r at Harvard University and the TinyML edX professional certificate program. Teaching ML systems on microcontrollers running on milliwatts and kilobytes of SRAM made one lesson unmistakable: the physical limits that govern a tiny sensor node—memory bandwidth, compute density, and energy per operation—are the exact same limits that govern a data center GPU. *The physics scales; only the numbers change.* That observation shaped the structure of this book.

An instructor teaching a one-semester course can keep the full sixteen-chapter arc while choosing how deeply to go inside each chapter. The core route below focuses on the engineering decisions every practitioner must be able to defend, using each chapter's purpose, learning objectives, worked examples, fallacies, and checkpoints as the spine of the syllabus:

1. **Part I (Foundations):** Ground the course in the iron law (section 1.7), then show how workload constraints dictate system architecture (section 2.3 and section 2.9). Trace the six lifecycle stages (section 3.4) from problem framing to holdout evaluation, and cover data collection, preprocessing pipelines, labeling, storage layout, and dataset health so students see how raw inputs become a reliable training feed.
2. **Part II (Development and Training):** Follow a neural network from forward and backward math (section 5.3) to end-to-end execution (section 5.5). Compare major architecture families by the operations they run, the state they store, and the data dependencies they impose. Then trace how frameworks lower a model graph into kernels, manage automatic differentiation and tensor memory, and execute a full training step (section 7.7), culminating in bottleneck diagnosis and single-node multi-GPU training (section 8.7.1).
3. **Part III (Optimization and Acceleration):** Teach students to optimize against measured bottlenecks across Data, Algorithm, and Machine. Start by scoring and pruning training data and deciding when a smaller dataset suffices (section 9.8). Move to pruning, distillation, and quantization alongside the hardware formats they require. Map those compressed models onto compute units and memory hierarchies using the roofline model (section 11.6), kernel

fusion, and compiler scheduling, and verify every claimed speedup with rigorous component, end-to-end, and power benchmarks (section 12.9).

4. **Part IV (Deployment and Operations):** Carry the verified model into production through request queuing, dynamic batching, serving runtimes, and cost modeling. Pair rollout and drift monitoring with the fairness, explainability, privacy, security, and energy controls summarized in section 15.3. Close with the coupled-budget synthesis in section 16.1, which ties the four parts back into a single engineering discipline.

Multi-node training (section 8.7.2), neural architecture search (section 10.2.5), the clinical deployment case study (section 14.9.2), and the appendix derivations work well as optional modules or project readings. Instructors teaching shorter terms or seminars can also split the book along its part boundaries:

- **Parts I–II** form an introductory half-semester on how ML systems are specified, built, and trained.
- **Parts III–IV** form an applied half-semester on optimizing, benchmarking, serving, and operating models in production.
- **The Part Introductions** alone offer a self-contained overview of the quantitative laws that govern ML systems for survey courses or executive seminars.

Lecture slides, assignments, and instructor resources are available at **mlsysbook.ai**.

Acknowledgments

Origins

This book owes its existence to a single conversation. During a sabbatical at Google, Pete Warden invited me to work on what seemed like an impossible moonshot for TinyML: running a small speech model on a microcontroller. That collaboration on TensorFlow Lite for Microcontrollers revealed something fundamental. The constraints that govern a device with 16 KB to 256 KB of memory are the same constraints that govern an accelerator in a data center, even when the scale is entirely different. Bandwidth, latency, energy, and memory obey the same physics across both settings. That insight became the seed of this book.

The TinyML work led to an online course on HarvardX, co-taught with Laurence Moroney, that grew to over 100,000 students worldwide. Brian Plancher helped build the TinyML curriculum. Marcelo Rovai, a professor who first encountered the material through the TinyML course, went on to develop the hands-on labs and kits that accompany this book. Zach Shelby opened the Edge Impulse platform for student use. Massimo Banzi and the Arduino team, along with Eric Pan and Seeed Studio, collaborated with us in developing and providing the hardware kits that made hands-on instruction possible. Marco Zennaro brought the material to developing countries through ICTP and planted the idea that these principles deserved a proper textbook. Teaching at that scale, without one, made the need undeniable.

That need turned into a book through CS249r at Harvard University. In 2023, the semester-long class project was to write the class notes: each student group took ownership of a topic, researched it, and worked with me to develop it into a chapter. That work seeded every chapter in this book. The premise was that writing forces you to think more deeply than reading alone. We then opened it all on GitHub, and what began as rough class notes has been rewritten and refined with every semester since.

Because that GitHub work continues, this book benefits from a community whose contributions evolve with the project. New contributors join as readers report issues, improve explanations, and extend the supporting materials. A printed acknowledgment can capture only one moment in that continuing history. The current contributor list and contribution guidelines are available at https://mlsysbook.ai/git.

Collaborators and Colleagues

Beyond the class and GitHub community, my earlier collaborations shaped the book's intellectual foundations. My time at Google informed much of the systems thinking in these pages. That period began with performance modeling for the first Pixel system on chip (SoC), drawing on my background in computer architecture. A collaboration with Mark Hill on roofline-style analytical modeling for heterogeneous SoCs taught me to reason about hardware from first principles, the kind of quantitative thinking that runs through every chapter. That emphasis on quantitative evaluation carried into my work on MLPerf. MLPerf involved many contributors across MLCommons, but I worked most closely with Peter Mattson, David Kanter, Carole-Jean Wu, Christine Cheng, Guenther Schmuelling, Cody Coleman, and Cliff Young. That collaboration shaped how I think about rigorous measurement of ML systems.

Boris Murmann and Song Han convinced me in the early stages that this project was worth pursuing. As I wrote, I sought feedback from colleagues in industry and academia alike. Practitioners at Arm, Google, Intel, Meta, Microsoft, Qualcomm, STMicroelectronics, and other organizations

offered perspectives grounded in production systems, while academic reviewers at universities across Europe, Asia, and the Americas stress-tested the material against their own research and teaching. Their combined feedback sharpened every chapter. Evgeni Gousev at Qualcomm and Pete Bernard at the Edge AI Foundation supported the project's outreach and helped build the community around it.

That feedback loop extended to classrooms around the world, where instructors put the material to the test when it was still rough. Sophia Shao at UC Berkeley, Xiaofan (Fred) Jiang at Columbia, Tushar Krishna and Divya Mahajan at Georgia Tech, and Wenkai Guan at the University of Minnesota Morris were among the first, and instructors at IIT Bombay, NUST Pakistan, De La Salle University in the Philippines, and universities across Europe, Latin America, and Africa have since adopted the book for their own courses. Their willingness to teach from an unfinished textbook provided invaluable feedback and confirmed that the need for this material was not limited to any one institution or any one country.

Students and Contributors

My students in the Edge Computing Lab at Harvard shaped this book in ways I cannot fully trace. Some did foundational work that helped establish TinyML as a field; their research and the ideas that emerged from years of collaboration informed the book's technical content. This cohort helped set the field in motion and then helped me write about it: Andy Cheng, Arya Tschand, Brian Plancher, Colby Banbury, Elizabeth Suitor, Emma Chen, Ikechukwu Uchendu, Jason Jabbour, Jason Yik, Jeffrey Ma, Jessica Quaye, Mark Mazumder, Matthew Stewart, Maximilian Lam, Radhika Ghosal, Shvetank Prakash, Srivatsan Krishnan, Yu-Shun Hsiao, and Zishen Wan. Kai Kleinbard, then at the Harvard Extension School, built the online generative AI SocratiQ tutor bot. Naeem Khoshnevis, from the Harvard Kempner Institute, established essential infrastructure including GitHub Actions and documentation standards. Željko Hrček produced the TikZ diagrams and contributed to the PDF layout, page composition, and final visual formatting of the book.

I am also grateful to the researchers whose work this book builds on and to the open-source community that helped improve it. Dozens of contributors caught errors, improved explanations, filed issues, and submitted pull requests. Some fixed a single typo; others rewrote entire sections. The book improved because people who owed it nothing chose to make it better. What kept me going, aside from stubbornness, was that community: every GitHub star was a signal that someone out there cared, that someone was learning, that the work mattered. I am grateful to every one of them.

Support

This work also depended on support from the Harvard Data Science Initiative, Harvard Extension School, and the National Science Foundation, as well as from the Edge AI Foundation and ICTP for educational outreach and scholarships. Arduino, Edge Impulse, Google, and Seeed Studio provided hardware, tooling, and infrastructure that enabled the practical labs.

At MIT Press, Susan Hartman believed in this project and guided it from an open-source experiment to a published textbook. Her support, editorial judgment, and friendship made this book real in a way that GitHub alone could not. I am equally grateful to MIT Press for agreeing to keep this book available as open access. A textbook about a discipline shaped by the open-source community should be accessible to everyone in it. That MIT Press shared this conviction made all the difference.

Finally, I thank my wife, Kari, and my daughters, Nora and Maya. This book was written in the hours that belonged to them: late nights that started at ten and ended at two or three in the morning, weekends that disappeared into revisions, years of mornings when I was present but not quite there. The cost was real, and they paid it with patience I did not always deserve.

A Note on AI Assistance

Every chapter of this book was researched, written, and rewritten by me. I also used AI tools throughout. What follows is more than the disclosure MIT Press requires of authors who use AI. It is a statement of the standard I held the book to, and a claim about what authorship means when the tools are this capable.

The standard is traceability. Derived quantities in these chapters are backed by Python computation cells whose source code ships with the book. Citations were checked against their sources, and cross-references are checked against stable anchors. The purpose-built infrastructure modeling engine used for the book's system calculations is available at https://mlsysbook.ai/mlsysim. A pre-commit test suite checks the machine-testable parts of these invariants on every commit, covering unit consistency, inline-reference resolution, cross-reference integrity, notation canonicality, and citation hygiene. AI tools helped me build and maintain this checking infrastructure, which makes the work auditable.

Authorship is thinking. Which concepts belong in this book and which do not. How to sequence the chapters so that each idea arrives only after the reader has the tools to understand it. Which worked examples to trace end-to-end, and which numbers to compute so the reader can verify the argument independently. What level to pitch each explanation at, rigorous enough for a graduate engineer and concrete enough for a student encountering systems thinking for the first time. Where students will get stuck, because I have taught this material and watched them get stuck. These judgments require knowledge of the reader and remain my responsibility. I used AI tools throughout this process to brainstorm framings, explore alternatives, and pressure-test my reasoning. The choices are mine.

In practice, AI was useful for writing code: the computation cells, the pre-commit checks, and the worked examples that are essentially programs. It helped me survey literature I then read in the original, draft passages I then rewrote substantially, and audit the manuscript for consistency across hundreds of cross-references, thousands of index entries, and tens of thousands of lines of prose. I reviewed the tools' suggestions and decided what to use.

AI-generated material can be plausible and still be wrong. Automated checks support review; they do not replace it. The standard I held this book to is the one I want us to demand of every system we ship. Tools can propose; engineers remain responsible for what they accept. MIT Press does not list AI tools as authors because they cannot assume ethical and legal responsibility for their work. The same is true of every engineered system. Authorship is the assumption of that responsibility, and it belongs to the human.

Notation

Machine learning systems span *machine learning* (computer science and statistics) and *systems* (computer architecture and hardware). Each field developed its notation independently, and many symbols mean different things across communities and publications. This collision creates real confusion when the disciplines merge. The notation below distinguishes quantities used in both fields.

Consider a simple statement: *"Increasing B improves throughput."* To an ML researcher, B means batch size. To a hardware engineer, B means bandwidth. Both interpretations are correct in their respective fields, but in machine learning systems we need both concepts in the same equation—hence the need for a single, consistent convention.

The Iron Law of ML Systems

Across the Data · Algorithm · Machine (D·A·M) axes, execution time factors into the product of workload scale, algorithmic operations per sample, and realized machine time per operation:

$$T = \underbrace{\left(\frac{\text{Samples}}{\text{Task}}\right)}_{\text{Data}} \times \underbrace{\left(\frac{\text{FLOPs}}{\text{Sample}}\right)}_{\text{Algorithm}} \times \underbrace{\left(\frac{\text{Seconds}}{\text{FLOP}}\right)}_{\text{Machine}}$$

where the first two factors multiply to set total floating-point operations O. For serialized execution phases on physical hardware, unpacking how the machine executes those operations gives the three-term iron-law performance decomposition, where each variable is chosen deliberately to avoid collision with standard ML terminology:

$$T = \underbrace{\frac{D_{\text{vol}}}{\text{BW}}}_{\text{Memory Time}} + \underbrace{\frac{O}{R_{\text{peak}} \cdot \eta_{\text{hw}}}}_{\text{Compute Time}} + \underbrace{L_{\text{lat}}}_{\text{Latency Overhead}}$$

Symbol	Definition	Unit	Notes
T	**Execution Time**	seconds	Total execution time in the iron-law performance decomposition.
D_{vol}	**Data Volume**	bytes	**Avoids collision with D (Dataset Size)**. In scaling laws and the D·A·M product, D counts logical training samples or tokens. Here we need physical bytes moved through memory. The subscript disambiguates.
BW	**Bandwidth**	bytes/s	**Avoids collision with B (Batch Size)**. Systems literature often uses B for bandwidth, while ML literature often uses B for batch size. The notation preserves the ML convention.
O	**Operations**	FLOPs	Total floating-point operations, the product of Samples/Task and FLOPs/Sample. Clean in equations (vs. "Ops").
R_{peak}	**Peak Rate**	FLOP/s	**Avoids collision with P (Parameters)**. Roofline presentations often use P for performance, while ML literature commonly uses P for parameter count. The notation preserves the ML convention.

Symbol	Definition	Unit	Notes
η_{hw}	**Efficiency**	—	Hardware utilization $(0 \leq \eta_{\text{hw}} \leq 1)$. Measures compute-unit utilization in the three-term decomposition, or end-to-end model FLOPs utilization when data movement and overhead are folded into the single-term training law (chapter 8). Avoids collision with learning rate (η).
L_{lat}	**Latency**	seconds	**Avoids collision with $\mathcal{L}$ (Loss).** Fixed overhead time (kernel launch, network RTT). The subscript distinguishes from the loss function.

Why these choices matter

Without careful notation, sentences become ambiguous:

> *"Reducing D improves performance."*

The sentence has two possible readings:

- Reducing **dataset size** (fewer training samples) can speed training but may reduce accuracy.
- Reducing **data volume moved** (for example, through compression or quantization) can speed inference, with accuracy effects that depend on the technique and calibration.

With our notation, we can write precisely and eliminate this ambiguity so that a statement like *"BW limits throughput"* has only one reading:

> *"Reducing D_{vol} through FP32-to-INT8 quantization cuts parameter memory traffic to one quarter while D (training data) remains unchanged."*

Subscripted variants

The root names the quantity, and an upright subscript names which instance of it is meant. The convention distinguishes closely related quantities:

- BW_{disk}, $\text{BW}_{\text{network}}$, $\text{BW}_{\text{accelerator}}$: bandwidth at three points on the data path
- D_{vol}, R_{peak}, L_{lat}, η_{hw}: iron-law terms, each held clear of a common ML symbol
- E_{move}, E_{compute}, E_{total}: one energy budget split into components

The subscript identifies where a measurement applies. Disk and accelerator bandwidth differ by orders of magnitude, so a reported bandwidth is meaningful only if readers know where it was measured.

The Degradation Equation

The degradation equation is an approximation fitted to observed outcomes over a limited range. Divergence alone does not determine whether accuracy rises or falls, so estimate λ from labeled outcomes. Some symbols below, such as τ, appear in chapter prose rather than in the equation.

$$\text{Accuracy}(t) \approx \text{Accuracy}_0 - \lambda \cdot \mathcal{D}(P_t \| P_0)$$

Symbol	Definition	Type or unit	Notes
$\textbf{Accuracy}(t)$	**Accuracy at Time t**	Scalar	Model accuracy after the model has been deployed for time t.
$\textbf{Accuracy}_0$	**Initial Accuracy**	Scalar	Model accuracy at deployment time.
λ	**Fitted Sensitivity**	Scalar	Local coefficient estimated from outcomes over a stated range; not a universal constant. *(Not wavelength.)*
P_t	**Current Distribution**	Distribution	The data distribution at time t. *(Not parameters—use P for parameter count.)*
P_0	**Training Distribution**	Distribution	The data distribution at training time.
$\mathcal{D}(P_t \| P_0)$	**Statistical Divergence**	Scalar ≥ 0	Measures how far P_t has drifted from P_0. Common choices: KL divergence, total variation, Wasserstein. *(Calligraphic to avoid collision with D = dataset size.)*

Symbol	Definition	Type or unit	Notes
τ	**Response Threshold**	Scalar > 0	Operational threshold for investigation; it does not automatically trigger retraining. The same symbol marks a classifier's decision threshold.
$\mathcal{D}$	**Divergence Measure**	Function	Divergence function that measures how far one probability distribution lies from another, with the specific measure left open.
$\mathcal{D}_{\mathbf{KS}}$	**Kolmogorov Smirnov Statistic**	Dimensionless	Two-sample Kolmogorov-Smirnov statistic, the largest absolute difference between two empirical cumulative distribution functions.
F_{P_0}	**Training Empirical CDF**	Function	Empirical cumulative distribution function of a feature in the training-baseline sample.
$x_{\mathbf{feat}}$	**Monitored Feature Level**	Varies	One value of a monitored feature, the argument at which its distribution or empirical cumulative distribution function is evaluated. The maximization variable of the Kolmogorov-Smirnov statistic.
F_{P_t}	**Serving Empirical CDF**	Function	Empirical cumulative distribution function of a feature in the current serving sample.
$c_{\mathbf{crit}}$	**Kolmogorov Smirnov Critical Threshold**	Dimensionless	Critical threshold that the two-sample Kolmogorov-Smirnov statistic must exceed to reject equal distributions at a given significance level.
n	**Drift Test Sample Size**	Integer	Number of observations in one of the two samples a two-sample drift test compares.
$\mathcal{D}_{\mathbf{KL}}$	**KL Divergence**	Function	Kullback-Leibler divergence, the expected extra code length from encoding one distribution with a code built for another.
H	**Shannon Entropy**	bits or nats	Average uncertainty of a probability distribution, the expected negative log probability of its outcomes. The log base sets the unit: base 2 gives bits, natural log nats.

The Energy Corollary

Effective costs per byte moved and per operation give the following approximation for workload energy. The symbols in the table below separate data-movement energy from arithmetic energy and list the circuit-level quantities that govern dynamic power:

$$E_{\text{total}} \approx D_{\text{vol}} \times E_{\text{move}} + O \times E_{\text{compute}}$$

Symbol	Definition	Unit	Notes
$E_{\mathbf{total}}$	**Total Energy**	joules	Total energy consumed by an ML workload, decomposed into data-movement and compute terms.
$E_{\mathbf{move}}$	**Energy per Byte Moved**	joules/byte	Effective movement cost; total energy also depends on bytes moved and operations executed.
$E_{\mathbf{compute}}$	**Energy per Operation**	joules/FLOP	Energy cost of a single arithmetic operation.
C	**Switched Capacitance**	farads	Capacitance of the wires and gates a circuit charges when it switches.
V	**Supply Voltage**	volts	Supply voltage that powers a digital circuit, the quantity dynamic voltage and frequency scaling lowers.
f	**Clock Frequency**	hertz	Rate at which a processor's clock ticks, setting how many switching cycles occur per second.
$P_{\mathbf{cluster}}$	**Cluster Power**	watts	Power drawn by a training cluster, including accelerators and hosts. Average power multiplied by training time gives training energy.
$P_{\mathbf{device}}$	**Device Power**	watts	Electrical power one device draws. Integrated over time it gives the device's energy.
$P_{\mathbf{dynamic}}$	**Dynamic Power**	watts	Power a chip draws switching its transistors, proportional to switched capacitance, supply voltage squared, and clock frequency.

Symbol	Definition	Unit	Notes
P_{avg}	**Average Power**	watts	Power drawn averaged over a stated period.

Deep Learning Notation

This book follows standard deep learning conventions (Goodfellow et al. 2016) with explicit disambiguation for systems variables. Where standard deep learning symbols would collide with hardware or serving quantities, the table below assigns distinct symbols and states the disambiguation rule explicitly.

Symbol	Definition	Type or unit	Notes
B	**Batch Size**	Integer	Number of examples grouped in a training or inference batch. *(Never bandwidth.)*
P	**Parameter Count**	Integer	The total count of scalar model parameters, including weights and biases. *(Never peak FLOP/s.)*
D	**Dataset Size**	Integer	Number of training samples or tokens. *(Never data volume in bytes—use D_{vol}.)*
S	**Sequence Length**	Integer	Number of tokens or time steps in an input sequence.
d	**Hidden Dimension**	Integer	Size of the hidden state vector of a layer or representation.
d_{in}	**Layer Input Width**	Integer	Number of input features in a layer.
d_{out}	**Layer Output Width**	Integer	Number of output features in a layer.
d_{head}	**Attention Head Dimension**	Integer	Per-head hidden dimension in attention layers.
N_L	**Number of Layers**	Integer	Total number of layers in a network.
N_{heads}	**Number of Attention Heads**	Integer	Number of attention heads in a multi-head attention layer.
H_{KV}	**Number of Key-Value Heads**	Integer	Number of key-value heads in grouped-query or multi-query attention.
ℓ	**Layer Index**	Integer	Index for a layer. Use instead of bare L when indexing layers, since L collides with loss and latency. A numeric subscript marks a norm instead (ℓ_1, ℓ_2).
$\mathcal{L}$	**Loss Function**	Scalar	The objective function minimized during training.
η	**Learning Rate**	Scalar	Step size for the optimizer. *(Never bare for hardware efficiency—use η_{hw}.)*
θ	**Model Parameters**	Vector	All learnable model parameters, treated as a vector.
g	**Gradient**	Vector	Gradient of the loss with respect to the parameters, $\nabla_\theta \mathcal{L}$; a subscript t marks the optimizer step.
$p(x)$	**Distribution**	Probability mass/density	Distribution for a random variable. Use lowercase $p(\cdot)$ for generic distributions to avoid collision with P (parameter count).
$p(y \mid x)$	**Conditional Distribution**	Conditional probability/density	Use this form for generic label relationships; reserve P_0 and P_t for the training/current distributions of drift analysis.
$\hat{\mathbf{y}}$	**Predicted Output**	Vector	A model's output for one example, such as class probabilities; $\mathbf{y}$ is the label vector.
T_{distill}	**Distillation Temperature**	Dimensionless	Softmax temperature in knowledge distillation. It is dimensionless, unlike execution time.
$\Pr(E)$	**Event Probability**	Probability	Probability of an event E. Use for event statements such as $\Pr(\text{batch} = 0)$; use $p(x)$ and $p(y \mid x)$ for distributions.
O_{train}	**Training Compute**	FLOPs	Total floating-point operations required for model training.
y	**Example Label**	Random variable	The label paired with one input, treated as a random variable.
x	**Model Input**	Random variable	Input of one example, the data a model receives to produce a prediction.

Symbol	Definition	Type or unit	Notes
Δ	**Finite Change**	Operator	Finite change in the quantity it prefixes, between two states, configurations or points in time. Prefix operator, as in the return-on-compute ratio of accuracy change to compute-cost change.
k	**Batch Index**	Index	Position of one batch in the sequence delivered by a data loader or runtime.
p	**Probability Function**	Function	Probability mass or density function of a random variable, applied to its argument.
H	**Image Height**	Integer	Number of pixel rows in an image or its segmentation mask.
W	**Image Width**	Integer	Number of pixel columns in an image or its segmentation mask.
w	**Model Weight**	Dimensionless	Value of one learnable weight of a model, such as the weight on one input of a neuron.
x	**Layer Input Component**	Dimensionless	One component, or feature, of a layer's input vector.
$\mathbf{x}$	**Input Feature Vector**	Vector	Input feature vector of one example, written as a row vector.
b	**Neuron Bias**	Dimensionless	Bias term added to one neuron's weighted sum. Indexed by neuron: b_j.
z	**Neuron Preactivation**	Dimensionless	Preactivation of one neuron, its weighted input sum plus bias before the activation function. At the output layer, z_j is the logit for one class, the argument of softmax.
f	**Activation Function**	Function	Activation function of a neuron or layer, applied element-wise to the preactivation. A layer superscript names the layer (f^{(l)}); f′ is its derivative.
$\mathbf{w}$	**Weight Vector**	Vector	Weight vector of one neuron, one weight per input.
$\hat{y}$	**Predicted Output Component**	Dimensionless	One entry of a model's prediction, such as the predicted probability for one class.
$\mathbf{W}$	**Weight Matrix**	Matrix	Matrix of learned weights one layer multiplies its input by, or the kernel tensor of a convolution layer.
x	**Activation Input**	Dimensionless	Scalar argument an activation function is applied to in its defining formula.
σ	**Sigmoid Function**	Function	Logistic sigmoid function, one over one plus e to the minus x. Maps any real input to the open interval (0, 1).
K	**Class Count**	Integer	Number of classes a classifier distinguishes, or vocabulary entries it scores, the length of its softmax output.
$\mathbf{z}$	**Preactivation Vector**	Vector	Preactivation vector of one layer for one example, the logit vector at the output layer.
$\mathbf{b}$	**Bias Vector**	Vector	Vector of learned biases one layer adds to its weighted sums, one per neuron or output channel. Broadcast across the batch.
n	**Layer Width**	Integer	Number of units in the layer at a given position of the network, with n_0 the input width. Indexed by layer position.
$\mathbf{a}$	**Activation Vector**	Vector	Activation vector of one layer for one example.
$\mathbf{A}$	**Activation Matrix**	Matrix	Activation matrix of one layer for a batch, one example per row.
$\mathbf{y}$	**Label Vector**	Vector	True label of one example written as a vector, such as a one-hot class vector.
f	**Model Predictor**	Function	Trained model viewed as a function that maps an input to its prediction.
$\mathbf{Z}$	**Preactivation Matrix**	Matrix	Preactivation matrix of one layer for a batch, one example per row.
$\mathbf{X}$	**Layer Input Matrix**	Matrix	Input to a layer in matrix form, one row per example or token, or a single-channel image.
j	**Class Index**	Index	Index of an output class.
C_{in}	**Input Channel Count**	Integer	Number of channels in the feature map a convolution layer reads.
K	**Kernel Size**	Integer	Side length, in input positions, of a square convolution kernel.
$\mathbf{h}$	**Hidden Activation**	Vector	Activation vector a hidden layer outputs and passes to the next layer.

Symbol	Definition	Type or unit	Notes
C_{out}	**Output Channel Count**	Integer	Number of channels, one per filter, in the feature map a convolution layer produces.
f	**Layer Function**	Function	Function computed by a layer, operator, or recurrent cell, mapping inputs to outputs.
$\mathbf{x}$	**Layer Input Vector**	Vector	Vector of activations one layer receives as input.
H_{img}	**Feature Map Height**	Integer	Height, in pixels, of the image or feature map a convolution layer reads.
W_{img}	**Feature Map Width**	Integer	Width, in pixels, of the image or feature map a convolution layer reads.
H_{out}	**Output Feature Map Height**	Integer	Number of output rows a convolution produces.
W_{out}	**Output Feature Map Width**	Integer	Number of output columns a convolution produces.
$\mathbf{Q}$	**Attention Query Matrix**	Matrix	Matrix of query vectors, one row per token, in an attention layer.
$\mathbf{K}$	**Attention Key Matrix**	Matrix	Matrix of key vectors, one row per token, in an attention layer.
$\mathbf{V}$	**Attention Values Matrix**	Matrix	Matrix of value vectors, one row per token, that attention weights combine into the output.
$\mathbf{A}$	**Attention Weight Matrix**	Matrix	Matrix of attention weights, the row-wise softmax of scaled query-key scores.
$\mathbf{I}$	**Identity Matrix**	Matrix	Square matrix with ones on the diagonal and zeros elsewhere. Size follows from context.
$\mathcal{B}$	**Mini Batch Set**	Set	Set of examples processed together as one mini-batch.
γ	**Normalization Scale**	Dimensionless	Learned factor a normalization layer multiplies each normalized activation by.
$\boldsymbol{\gamma}$	**Normalization Scale Vector**	Vector	Vector of learned per-channel or per-feature factors a normalization layer multiplies its normalized output by.
$\boldsymbol{\beta}$	**Normalization Shift Vector**	Vector	Vector of learned per-channel or per-feature offsets a normalization layer adds to its scaled output.
v	**Trace Intermediate Variable**	Dimensionless	Intermediate variable in the evaluation trace of a differentiated program, its primal value.
$\bar{v}$	**Trace Intermediate Adjoint**	Dimensionless	Reverse-mode adjoint of an intermediate variable, the derivative of the output with respect to it.
$\mathbf{x}$	**Function Input Vector**	Vector	Vector a layer or differentiated function takes as input.
N	**Function Input Dimension**	Integer	Number of inputs of a differentiated function, the column count of its Jacobian.
x	**Function Input Element**	Dimensionless	One element of the input vector of a layer or elementwise function.
i	**Matrix Row Index**	Index	Position of a row within a matrix.
j	**Matrix Column Index**	Index	Column index of a matrix entry.
$\mathbf{S}$	**Attention Score Matrix**	Matrix	Matrix of attention scores, the scaled dot products of every query with every key before the softmax.
$\mathbf{x}$	**Softmax Input Vector**	Vector	Vector of scores an online softmax normalizes block by block.
m	**Softmax Running Maximum**	Dimensionless	Largest score seen so far in a block of the online softmax, subtracted before exponentiation. Superscripts (1), (2), new mark the block it covers.
z	**Softmax Normalizer**	Dimensionless	Sum of the max-shifted exponentials of a softmax row or block, the softmax denominator, kept as a running sum by online softmax. Not the class logit z of the data appendix.
$\mathbf{O}$	**Attention Head Output**	Matrix	Output of one attention head before the output projection, the attention weights applied to the value matrix. Distinct from the output-projection result of a whole attention layer.
β	**Data Scaling Exponent**	Dimensionless	Fitted power-law exponent at which loss falls as the training dataset or token count grows.
d	**Derivative Operator**	Operator	Differential operator d used in an ordinary derivative.

Symbol	Definition	Type or unit	Notes
t	**Optimizer Step Index**	Index	Position of one optimizer update in the sequence of training steps.
N_{epochs}	**Epoch Count**	Integer	Number of full passes a training run makes over its dataset. Training work scales with it times dataset size.
z	**Output Logit**	Dimensionless	Raw score a model outputs for one class before the softmax.
r	**Input Resolution**	Integer	Input image resolution of a convolutional model. Subscript 0 marks the base model in compound scaling.
s	**Quantization Scale**	Varies	Real-valued step between adjacent integer levels of a uniform quantizer.
x_q	**Quantized Integer Code**	Integer	Integer code a quantizer assigns to one real value.
W	**Layer Weight Entry**	Dimensionless	One scalar entry of a layer's weight matrix, picked out by a layer superscript and row and column subscripts.
W_{ij}	**Weight Matrix Entry**	Dimensionless	One entry of a weight matrix at a given row and column; italic because it is a scalar.
$\mathbf{W}_{\text{fused}}$	**Fused Convolution Weight**	Dimensionless	Convolution weights after the following batch normalization is folded into them, so inference runs one layer instead of two.
x	**Quantizer Input**	Varies	Full-precision real value, a weight or activation, that a quantizer maps to an integer code. Unit: units of the quantized tensor.
α	**Clipping Range Lower Bound**	Varies	Lower end of the real-valued range a quantizer represents, below which values are clipped. Calibration estimates it.
β	**Clipping Range Upper Bound**	Varies	Upper end of the real-valued range a quantizer represents, above which values are clipped.
b	**Quantization Bit Width**	Integer	Number of bits in each integer code a quantizer produces.
$\sigma_{\mathcal{B}}$	**Batch Norm Running Standard Deviation**	Vector	Per-channel square root of the running variance plus the numerical stabilizer that batch normalization uses at inference.
n_{keep}	**Structured Sparsity Nonzero Count**	Integer	Number of values kept nonzero in each group of an N:M structured-sparsity pattern.
m_{group}	**Structured Sparsity Group Size**	Integer	Number of consecutive values in one group of an N:M structured-sparsity pattern.
K_h	**Kernel Height**	Integer	Height of a convolution kernel, in input positions.
K_w	**Kernel Width**	Integer	Width of a convolution kernel, in input positions.
k	**Top Class Count**	Integer	Number of highest-scoring classes a top-k prediction returns or checks for the correct label.
μ	**Service Rate**	items/s	Rate at which one server, such as a worker, consumer, or model endpoint, completes items or calls.
$\hat{y}$	**Model Prediction**	Dimensionless	Prediction a model outputs for one example, compared with its label by the loss.
$\mathbf{Y}$	**Layer Output Matrix**	Matrix	Output matrix of a layer's matrix multiplication of the input matrix by the weight matrix, one row per example. Shape batch size by layer output width; before any bias or activation function.
m	**Softmax Row Maximum**	Dimensionless	Largest score in a softmax row or block, subtracted before exponentiation to prevent overflow.
x	**Softmax Input Score**	Dimensionless	One entry of the score vector the online softmax normalizes. Written with an index and a block superscript, $x_j^{(1)}$.
α_{sym}	**Symmetric Clipping Threshold**	Varies	Largest magnitude a symmetric quantizer represents, so values are clipped to plus or minus this bound.

Latin matrices and vectors are set in bold (**W**, **x**); scalars, dimensions, indices, and individual matrix entries stay italic (N, d, i, W_{ij}). The generic parameter symbol θ is the one conventional exception and stays italic.

Local matrix algebra follows the same bold rule. Matrix operands are bold (**A**, **B**, **C**), as in general matrix multiply (GEMM) $\mathbf{C} = \alpha\mathbf{AB} + \beta\mathbf{C}$. The bold form marks a matrix operand and is distinct from the italic scalar batch size B, which remains batch size in scalar contexts.

A GEMM's scalar dimensions are M, N, and K (**A** is $M \times K$, **B** is $K \times N$). Asymptotic cost is written $\mathcal{O}(\cdot)$, which keeps it distinct from the operation count O.

Performance, Serving, and Memory Notation

Reusable performance and serving quantities follow the same collision-avoidance rule as the iron law. Rates use R or descriptive Greek symbols; request counts use Q_{req} rather than overloading N; queue utilization uses a subscripted ρ so bare ρ remains available for other ratio models.

Symbol	Definition	Type or unit	Notes
I	**Arithmetic Intensity**	FLOP/byte	Workload FLOPs per byte moved. The Roofline Model uses I as the independent variable.
I_{ridge}	**Roofline Ridge Point**	FLOP/byte	$I_{\text{ridge}} = R_{\text{peak}}/\text{BW}$. Prefer this explicit form over starred shorthand so the meaning remains clear in prose.
R_{attain}	**Attainable Compute Rate**	FLOP/s	Roofline bound: $R_{\text{attain}} \leq \min(R_{\text{peak}}, I \times \text{BW})$. Uses R, not T, because this quantity is a rate.
MFU	**Model FLOPs Utilization**	Dimensionless	Useful model FLOP/s divided by available peak FLOP/s. Text acronym avoids overloading η.
Q_{req}	**Request Concurrency**	requests	Average in-flight requests in a stable serving system ($Q_{\text{req}} = \lambda_{\text{arr}} \cdot T_{\text{lat}}$ via Little's Law). Avoids overloading N, which counts devices, elements, or samples elsewhere.
λ_{arr}	**Arrival Rate**	requests/s	Request arrival rate. The subscript keeps bare λ free for fitted sensitivities.
T_{memory}	**Iron-Law Memory Time**	seconds	Data-movement term D_{vol}/BW in the iron law.
T_{compute}	**Iron-Law Compute Time**	seconds	Compute term $O/(R_{\text{peak}} \cdot \eta_{\text{hw}})$ in the iron law.
N_{GPU}	**Accelerator Count**	Integer	Number of accelerators in one job.
T_{lat}	**Request Time in System**	seconds	Average time a request spends queueing and being served, as used in Little's law. Distinct from L_{lat}, the fixed-latency term in the iron law.
$L_{\text{lat,total}}$	**End-to-End Request Latency**	seconds	Request-path latency budget, $L_{\text{lat,network}} + L_{\text{lat,pre}} + L_{\text{lat,infer}} + L_{\text{lat,post}} + L_{\text{lat,queue}}$. T_{lat} covers only the time inside the serving system.
$T_{\text{svc}}(B)$	**Batch Service Time**	seconds	Time to serve a batch of size B.
$\mu_{\text{eff}}(B)$	**Effective Service Rate**	requests/s	Batched service rate, typically $\mu_{\text{eff}}(B) = B/T_{\text{svc}}(B)$. The unbatched service rate is $\mu = \mu_{\text{eff}}(1)$.
ρ_{serv}	**Serving Utilization**	Dimensionless	Queue/server utilization. The subscript keeps bare ρ free for other ratio models.
M_{total}	**Total Memory Footprint**	bytes	Sum of explicit memory components; avoids bare M ambiguity.
M_{weights}	**Weight Memory**	bytes	Memory occupied by model weights ($P \times$ bytes-per-parameter).
$M_{\text{gradients}}$	**Gradient Memory**	bytes	Memory occupied by stored gradients.
$M_{\text{optimizer}}$	**Optimizer-State Memory**	bytes	Momentum, variance, master weights, and related optimizer buffers.
$M_{\text{activations}}$	**Activation Memory**	bytes	Retained activations for the backward pass or serving intermediates.
M_{KV}	**KV-Cache Memory**	bytes	Memory occupied by the key-value cache during autoregressive inference.
s_{elem}	**Element Storage Size**	bytes/element	Bytes per stored tensor element.
s_{sample}	**Sample Storage Size**	bytes/sample	Bytes per stored training or serving sample.
s_{loss}	**Loss-Scale Factor**	Dimensionless	Multiplier applied to the loss in reduced-precision training so small gradients stay representable.
$T_{\text{pipelined}}$	**Pipelined Execution Time**	seconds	Ideal steady-state execution time when data movement and computation overlap, approximated by the slower stage plus fixed latency.
G	**Accelerated Fraction Speedup**	Dimensionless	Speedup factor applied to the accelerated fraction of a workload in Amdahl's law, whether it comes from faster hardware or from more workers.
T_{train}	**Training Time**	seconds	Wall-clock time to complete one training run.
T_{IO}	**I/O Transfer Time**	seconds	Time to move a workload's data over a storage or network link, the input/output stage of a pipelined step. Overlaps with compute in the pipelined iron law; the step is I/O bound when it is the largest stage.

Symbol	Definition	Type or unit	Notes
$\mathbf{BW_{network}}$	**Network Bandwidth**	bytes/s	Sustained rate at which a network path delivers bytes between machines.
$L_{\text{lat,network}}$	**Network Latency**	seconds	Time a request and its response spend crossing the network, including propagation, routing, and protocol handling.
M_{device}	**Device Memory Capacity**	bytes	Total memory a device provides for a model's weights and activations.
G_{accel}	**Accelerator Gain**	Dimensionless	Speedup an optimization or accelerator gives the fraction of execution it applies to, in Amdahl's law.
a	**First Floating Point Addend**	Dimensionless	First of three floating-point numbers added in either grouping to show that floating-point addition is not associative.
b	**Second Floating Point Addend**	Dimensionless	Second of three floating-point numbers added in either grouping to show that floating-point addition is not associative.
c	**Third Floating Point Addend**	Dimensionless	Third of three floating-point numbers added in either grouping to show that floating-point addition is not associative.
$\mathbf{BW_{storage}}$	**Storage Bandwidth**	bytes/s	Sustained rate at which the storage system delivers bytes to the input pipeline.
T_{step}	**Training Step Time**	seconds	Wall-clock time of one training step, bounded below by the slower of compute and input I/O.
N	**Square GEMM Dimension**	Integer	Side length of the square matrices in a matrix multiply, the shared row, column, and inner dimension.
M	**GEMM Row Dimension**	Integer	Number of rows of the left operand and of the output in a matrix multiply.
K	**GEMM Inner Dimension**	Integer	Shared inner dimension of a general matrix multiply, the number of products summed per output element.
N	**GEMM Column Dimension**	Integer	Number of columns of the right operand and of the output in a matrix multiply.
µ	**Micro Unit Prefix**	Operator	SI unit prefix micro, one millionth, written before a unit such as seconds.
N	**Tensor Element Count**	Integer	Number of elements in one tensor.
n_{ops}	**Chained Operation Count**	Integer	Number of consecutive operations that read and write the same intermediate tensor and can be combined through kernel fusion.
T_{transfer}	**Batch Transfer Time**	seconds	Time to copy one batch of input data from host memory to the device that consumes it.
$\mathbf{C}$	**GEMM Output Matrix**	Matrix	Output matrix of a general matrix multiply, of size M by N, which the operation updates in place.
α	**GEMM Product Scale**	Dimensionless	Scalar multiplier applied to the matrix product in a general matrix multiply.
β	**GEMM Accumulator Scale**	Dimensionless	Scalar multiplier applied to the existing output matrix before the product is added in a general matrix multiply.
$\mathbf{A}$	**GEMM Left Operand**	Matrix	Left input matrix of a general matrix multiply, of size M by K.
$\mathbf{B}$	**GEMM Right Operand**	Matrix	Right input matrix of a general matrix multiply, of size K by N.
$\mathbf{BW_{disk}}$	**Disk Bandwidth**	bytes/s	Sustained rate at which a storage disk delivers bytes.
$R_{\text{sustained}}$	**Sustained Compute Rate**	FLOP/s	Operation rate an accelerator or system actually sustains on a workload.
T_{prep}	**Host Preparation Time**	seconds	Time the host takes to prepare one batch for the accelerator, from read through batching.
$\mathbf{BW_{accelerator}}$	**Accelerator Memory Bandwidth**	bytes/s	Sustained rate at which bytes move between an accelerator's own memory, such as HBM, and its compute units.
t	**Time Instant**	seconds	A point in continuous wall-clock time, the variable over which time-varying quantities are integrated.
$L_{\text{lat,infer}}$	**Inference Latency**	seconds	Time the model takes to compute a request's output.
M_{tensor}	**Intermediate Tensor Size**	bytes	Bytes in the intermediate tensor that a sequence of operations passes between its steps.
n_{nz}	**Nonzero Count**	Integer	Number of nonzero values a sparse matrix format stores.
n_{rows}	**Sparse Matrix Row Count**	Integer	Number of rows in a sparse matrix. Compressed sparse row (CSR) storage uses one more row pointer than the number of rows.
T_{token}	**Decode Token Time Floor**	seconds	Lower bound on the time to generate one token at batch one, bytes streamed per step divided by memory bandwidth.
$L_{\text{lat,queue}}$	**Queueing Latency**	seconds	Time a request waits in queues before it is served.

Symbol	Definition	Type or unit	Notes
$L_{\text{lat,pre}}$	**Preprocessing Latency**	seconds	Time spent preparing a request's input before inference.
$L_{\text{lat,post}}$	**Postprocessing Latency**	seconds	Time spent turning a model's output into the response.
b	**Numeric Bit Width**	Integer	Number of bits used to represent one numeric value, such as an arithmetic operand or a quantized weight or activation.
T	**Dataset Transfer Time**	seconds	Ideal line-rate time to move a dataset over a network or storage path: data volume divided by bandwidth.
T_{GPU}	**Accelerator Batch Time**	seconds	Time the accelerator takes to run one training step on one batch, excluding input preparation.

Statistical and Operational Notation

Statistical thresholds, workload fractions, and system constraints follow standard statistical and operational conventions. Each symbol in the table below carries an explicit domain and unit so that hypothesis tests, queueing bounds, and fairness metrics can be combined without ambiguity:

Symbol	Definition	Type or unit	Notes
κ	**Cohen's Kappa**	Dimensionless	Inter-annotator agreement coefficient $\kappa \in [-1, 1]$.
T_{deadline}	**Deadline**	seconds	Latency deadline for query completion or batch execution.
f_{overhead}	**Operational Overhead Fraction**	Dimensionless	Fraction of wall time spent outside productive step execution (f_{overhead}).
f_{parallel}	**Parallel Fraction**	Dimensionless	Fraction of workload execution that can be parallelized in Amdahl's Law ($0 \leq f_{\text{parallel}} \leq 1$).
α	**Significance Level**	Dimensionless	Statistical significance threshold α for hypothesis tests.
ϵ	**Numerical Stability Constant**	Scalar	Small numerical constant $\epsilon > 0$ for numerical stability.
N_{workers}	**Worker Count**	Integer	Number of parallel worker threads, processes, or devices.
t_{obs}	**Observation Timestamp**	seconds	Time at which a labeled observation, such as a churn event, occurred. Upper bound on the feature timestamps an as-of join may use.
C_{error}	**Erroneous Prediction Cost**	dollars	Average business cost incurred by one erroneous prediction. Multiplies the skew rate and query volume in the training-serving skew cost.
F_{access}	**Storage Access Factor**	Dimensionless	Fraction of peak storage throughput a workload's access pattern achieves.
g	**Subgroup Index**	Index	Label of one population subgroup whose outcomes are compared against a reference group.
k	**Feedback Interval Count**	Integer	Number of fixed feedback intervals, such as retraining cycles, elapsed since the disparity was first measured.
α_{fb}	**Bias Feedback Factor**	Dimensionless	Factor by which a group's disparity is multiplied over one feedback interval, fitted from observed disparities. Above 1 the feedback loop is self-reinforcing; at or below 1 it is stable or damped.
Δ_g	**Group Disparity**	Dimensionless	Size of the performance gap between one group and a reference group; the feedback analysis tracks how it grows from one feedback interval to the next.
k_{anon}	**Anonymity Set Size**	Integer	Smallest number of records that share every quasi-identifier value in a k-anonymous release.
p_{deploy}	**Deployment Distribution**	Distribution	Joint distribution of inputs and labels a deployed model must serve, the population a verification guarantee is stated over.
d_{task}	**Task Distance**	Function	Task-specific distance between a model's prediction and the correct label, the error measure a verification guarantee bounds.
τ_{tol}	**Task Error Tolerance**	Dimensionless	Largest task distance between a prediction and its label that still counts as an acceptable output.

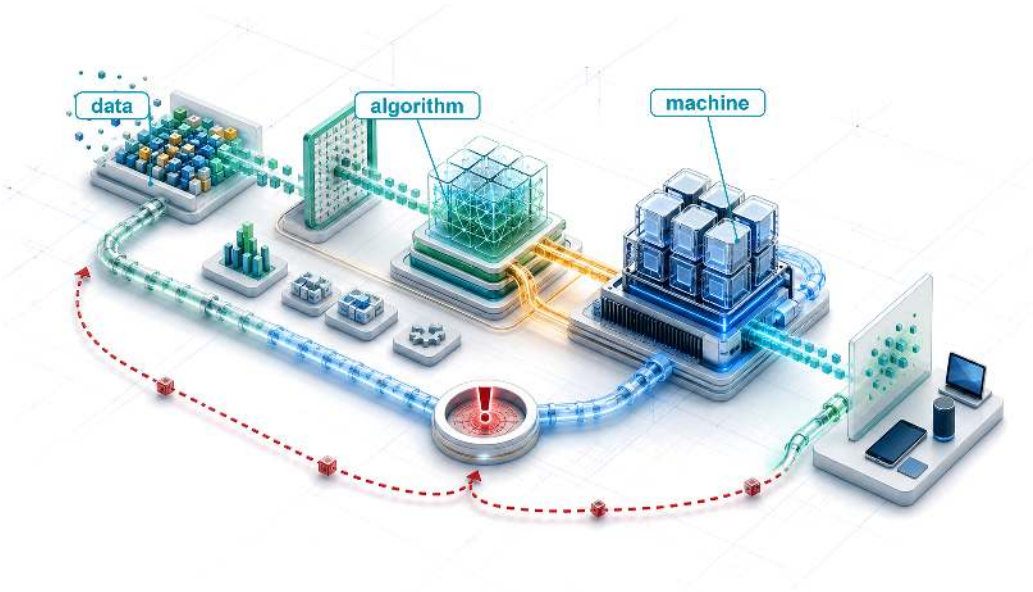
Symbol	Definition	Type or unit	Notes
ϵ	**Tolerated Failure Probability**	Dimensionless	Maximum allowed probability that a deployed model exceeds its task error tolerance. The confidence level used to estimate this probability is specified separately.
S_{skew}	**Training Serving Skew**	Dimensionless	Expected absolute difference between the serving-path and training-path model scores on the same inputs, over a stated comparison-input distribution. Measurable without labels; a risk signal, not an accuracy-loss equation.
f_{serve}	**Serving Path Predictor**	Function	Serving code path viewed as a function from a raw input to the model's output, including its preprocessing and runtime.
f_{train}	**Training Path Predictor**	Function	Training code path viewed as a function from a raw input to the model's output, as offline validation evaluates it.
q	**Target Completion Quantile**	Dimensionless	Required probability that a request completes within its latency deadline, the completion quantile a service level states.

Units and Precision

- **Physical units**: This book uses SI (metric) units throughout, including meters, kilograms, seconds, watts, and °C, consistent with standard engineering and scientific practice. Where source data was originally reported in imperial units, the book converts to SI and notes the original values parenthetically. A space always separates the number from the unit (for example, 100 ms, 2 TB/s).
- **Data and memory**: This book uses **decimal SI prefixes only**: KB = 10^3 bytes, MB = 10^6, GB = 10^9, TB = 10^{12}. Binary-prefixed units do not appear in prose; model sizes, activation footprints, throughputs, and transfer volumes are reported in decimal units (for example, 2 TB/s, 102 MB). Hardware memory capacities retain the vendor's nameplate figure and label. Calculations requiring an exact byte count use the device's documented capacity.
- **Compute**: The notation distinguishes operation counts from rates. Total work uses FLOPs (for example, GFLOPs, TFLOPs), while throughput uses FLOP/s with decimal prefixes (for example, GFLOP/s, TFLOP/s).
  - 1 TFLOP = 10^{12} FLOPs
  - 1 TFLOP/s = 10^{12} FLOPs per second
  - Arithmetic intensity conventionally uses FLOP/byte as a unit ratio (floating-point operations per byte moved). This is a ratio unit, not a total-work symbol or throughput symbol.

- **Power**: Power carries a subscript (P_{avg}, P_{device}, P_{cluster}); bare P remains parameter count.
- **Latency percentiles**: Written p50, p95, and p99 in upright type, inside math as well as in prose.
- Currency: Dollar amounts use the dollar sign (`$`); unless otherwise noted, dollar-denominated costs are U.S. dollars (USD).
- **Precision**:
  - **FP64**: Double precision (8 bytes)
  - **FP32**: Single precision (4 bytes)
  - **TF32**: TensorFloat-32 (19-bit Tensor Core compute mode; inputs and storage remain FP32)
  - **FP16**: Half precision (2 bytes, standard range)
  - **BF16**: Brain float (2 bytes, wide dynamic range)
  - **FP8**: Quarter precision (1 byte, E4M3 or E5M2 format)
  - **FP4**: 4-bit floating-point format
  - **INT8**: 8-bit integer (1 byte)
  - **INT4**: 4-bit integer; lower integer precisions follow the same uppercase `INTn` pattern (for example, INT3, INT2)

Quick Reference: Resolving Collisions



ML conventions generally take precedence for single letters, while systems quantities use subscripts or descriptive symbols. This preserves familiar ML notation while distinguishing systems quantities across the most common notation collisions in machine learning systems literature:

Symbol	ML Meaning	Systems Meaning	Book Convention
B	Batch Size	Bandwidth	**Batch Size**. Use BW for bandwidth.
P	Parameter Count	Peak FLOP/s	**Parameter Count**. Use R_{peak} for peak rate.
D	Dataset Size	Data Volume	**Dataset Size**. Use D_{vol} for bytes moved.
L	Loss	Latency	**Loss** ($\mathcal{L}$). Use L_{lat} for latency.
η	Learning Rate	Efficiency	**Learning Rate**. Use η_{hw} for efficiency.

1.12 Summary

Purpose

Why does an accurate machine learning model not guarantee a reliable, efficient system?

Machine learning systems have a physics. Data moves through memory hierarchies governed by bandwidth, arithmetic executes on silicon governed by power, and predictions must arrive within strict latency windows. These constraints are not secondary implementation details. Moving an operand from main memory can cost far more energy than performing arithmetic on it, and a prediction that arrives a few hundred milliseconds late can be worth nothing to the real-time process waiting for it. An architecture that fits comfortably in a data center is useless on a mobile phone, and a training pipeline that converges in days on high-bandwidth accelerators can stall for weeks on standard hardware. These systems also diverge from conventional software because empirical data, rather than explicit logic alone, defines their behavior. When a conventional program misbehaves, it often crashes or throws an exception. When an ML system misbehaves, the runtime may operate flawlessly while learned predictions fail because the input distribution has shifted or the training data was unrepresentative. No assertion fails and no exception is raised; the only symptom is deteriorated decisions, discovered weeks later through lost revenue, erroneous predictions, or compromised safety. Testing, version control, and profiling remain necessary but are no longer sufficient. A unit test confirms that code computes what it was written to compute, but it cannot establish that learned behavior still matches a non-stationary world, and optimizing one component in isolation frequently moves the bottleneck to another layer of the stack. In D·A·M terms, data, algorithm, and machine must be engineered together as one problem.

Learning Objectives

- Explain why data-defined behavior lets predictive quality decline while model code and execution remain unchanged
- Apply a data-algorithm-machine lens to diagnose a system bottleneck and reassess it after an intervention
- Calculate execution time with the iron law and assess how a component improvement changes end-to-end time
- Analyze when scalable search and learning can benefit from additional computation within data and machine constraints
- Compare algorithmic, compute, and data-selection efficiency by the iron-law term each changes and the accuracy gained per added cost
- Evaluate whether predictive quality and resource use meet deployment requirements using evaluation and lifecycle monitoring

1.1 The AI Systems Moment

Artificial intelligence is no longer confined to research demonstrations. When a user queries a smartphone voice assistant, learned components convert speech to text, interpret intent, retrieve information, and generate a response within seconds. Search engines rank results, recommendation systems decide what people see, lenders use models to assess risk, and driver-assistance systems detect hazards. In each case, a prediction participates in a larger decision that can affect attention, money, access, or safety. Even a single voice query is therefore a chain of models and services operating in the world.

Modern AI systems became practical when three forces converged: digital services generated large datasets, learning algorithms extracted predictive structure from those examples, and parallel hardware made the resulting computation feasible. Yet the most consequential change was conceptual. Data stopped being merely an input to software; it became a mechanism defining program behavior. Instead of hand-coding every decision rule, engineers build a training process through which examples shape the behavior a system learns.

This convergence creates a **dual mandate**. Every ML system must establish that its learned behavior is trustworthy and that the machine can produce that behavior within the available time, memory, energy, and cost. A model that is accurate but too slow is unusable; a fast model trained on unrepresentative data is wrong at machine speed. At scale, both obligations span the entire stack. Conversational services coordinate pools of GPUs[1] while managing memory, networks, and cooling. Driver-assistance systems must fuse sensor streams within milliseconds. A search service processing more than 13.7B queries per day (Srinivasan 2025) must also meet strict latency targets. These systems succeed only when learned behavior and physical execution are engineered together. That co-design begins with the shift from code-defined logic to data-defined behavior.

1.2 From Code-Defined Logic to Data-Defined Behavior

An email spam filter built from hand-written rules fails as soon as attackers rephrase their messages or disguise forbidden keywords. Instead of encoding those decision rules directly into source code, an ML team pairs historical emails with binary spam labels and runs an optimization procedure that adjusts millions of numerical weights[2] until the model's predictions align with the labels. Live inference[3] then applies those trained weights to incoming messages whose labels are unknown, and evaluation against a separate test set checks whether the learned decision boundary generalizes reliably beyond the training corpus.

Andrej Karpathy[4] framed this transition from code-defined logic to data-defined behavior as the shift from **Software 1.0** to **Software 2.0** (Karpathy 2017). As summarized in table 1.1, Software 1.0 encodes procedural logic in human-written instructions, whereas Software 2.0 searches a high-dimensional parameter space for a model configuration that satisfies an empirical objective.

Software 2.0 does not eliminate traditional software engineering. Engineers still write data ingestion pipelines, loss functions, distributed training loops, and low-latency serving harnesses.

[1] **GPU (graphics processing unit)**: Originally designed to render graphics by performing many calculations in parallel. Neural networks also require large numbers of similar arithmetic operations, especially matrix multiplications, making this hardware useful for training. Keeping those operations supplied with data remains a separate engineering challenge.

[2] **Model weights**: The learned numerical parameters of a neural network. They must be stored and accessed during execution, so their number and numerical representation affect memory use, data movement, and cost.

[3] **Inference**: Applying a trained model to inputs, whether during evaluation or deployment. Interactive serving often imposes a response-time limit, whereas offline inference may prioritize the total number of examples processed per second. These workloads can require different execution choices even for the same model (see chapter 13).

[4] **Andrej Karpathy**: A founding member of OpenAI and former director of AI at Tesla. His "Software 2.0" essay described neural network weights as a new form of "source code" (Karpathy 2017). The analogy shifts debugging attention toward the examples that shaped those weights and the conditions under which the model is evaluated.

However, the core operational logic no longer resides in human-readable control flow, but in millions of numerical weights shaped by data. Static analysis and manual code review cannot reveal what decision the system will make for a novel input. Both paradigms can suffer from undetected faults, but learned systems add a distinct failure mode in which predictive accuracy falls silently even when source code, compiler binaries, and execution environments remain unchanged.

Table 1.1: The Paradigm Shift from Software 1.0 to Software 2.0: In Software 2.0, the "programmer" curates the dataset and designs the training process that shapes learned behavior. Debugging expands to include the data. The "compiler" analogy is approximate: unlike a deterministic compiler, the training process is stochastic and may produce different learned weights from the same training data.

Feature	Software 1.0 (Traditional)	Software 2.0 (Machine Learning)
Source Code	C++, Python, Java	Learned weights, shaped by training data
Compiler	GCC, LLVM	Training loop (stochastic gradient descent)
Logic	Explicit (Hand-coded)	Implicit (Learned)
Failure Mode	Crashes or silent logic errors	Also statistical quality loss
Debugging	Trace execution and inputs	Also inspect data and learned behavior

The data-centered workflow changes what engineers must build and maintain. Sculley and colleagues described how model code occupies only a small fraction of a production ML system (Sculley et al. 2015). The surrounding system includes data collection, verification, feature extraction, resource management, serving, and monitoring, each with its own maintenance obligations.

That imbalance creates hidden technical debt, the accumulating cost of maintaining undocumented dependencies and brittle infrastructure around the model. Each surrounding component encodes assumptions about how an example is sampled, what a label means, when a feature is computed, which version reaches serving, and how degradation is detected. None of those assumptions appears in the matrix multiplication that produces a prediction, yet any of them can change the result. Improving the model alone cannot repair a measurement that no longer tracks its target, a broken feature pipeline, or a missing feedback signal.

Production ML work is mostly the surrounding system, not the model code alone.

Production data is therefore not a passive input. It is a measurement of the world, collected through a particular product and transformed by a changing pipeline. If that measurement stops representing the intended target, the model can remain numerically healthy while the system becomes wrong. Google Flu Trends had an enormous, timely stream of search data, but the meaning of that data changed beneath the model.

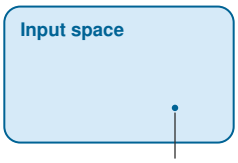
War Story 1.1: When search logs mistook attention for illness (2013)

Context: Google Flu Trends (GFT) estimated influenza activity from patterns in aggregated search queries (Ginsberg et al. 2009; Lazer et al. 2014). Its attraction came from the speed and scale at which searches arrived relative to clinical reports. If people searched for flu symptoms when they became ill, query volume appeared to offer a timely proxy, or indirect measurement, for infection.

Failure mode: The proxy was not stable. News coverage could change what people searched for, and autocomplete could change how they expressed those searches. Query volume could therefore reflect public attention and product behavior as well as illness. During the 2012–2013 season, GFT estimated roughly twice the CDC-reported proportion of doctor visits for influenza-like illness, and from August 2011 onward it overestimated in 100 of 108 weeks.

Systems lesson: The remedy was not simply a larger search dataset or a better-tuned model. Researchers combined search signals with U.S. Centers for Disease Control and Prevention (CDC) sentinel clinical data and recalibrated the relationship over time. Data volume is not ground truth. A behavioral proxy needs a feedback loop to a trusted measurement and continual evidence that the proxy still represents the quantity the system claims to estimate.

In Google Flu Trends, predictive quality deteriorated while the software kept operating. The input distribution, meaning the kinds of inputs and how frequently they occur, and the relationship between proxy and target can change. Under the **data-as-code principle**, training data does not merely enter a fixed program; it helps determine the operational logic that the model implements. Engineers still write the optimization procedure, but the examples shape the model weights through stochastic gradient descent[5] and related methods. Changing the dataset can therefore change system behavior as surely as changing source code.



Data-defined behavior is a property of machine learning; *data-centric* AI is a development strategy for improving that behavior (Ng 2021). A model-centric approach holds the data comparatively fixed and improves the model, whereas a data-centric approach holds the model comparatively fixed and makes data curation an explicit route to better predictions.

Data-defined behavior adds a testing obligation: assessing predictive quality over the population of inputs the system will encounter. Conventional software can also have input spaces too large to enumerate, so exhaustive testing is not a realistic expectation for either kind of system. In the 2012 ImageNet challenge, AlexNet's decisive win[6] helped set the deep learning era in motion, yet the benchmark could evaluate only a vanishing fraction of the inputs the model might encounter. Each input is a 224×224 RGB image with $256^{150,528}$ possible pixel configurations, a number with 362,508 digits. Real photographs occupy only a tiny region of that space, but even that region is far too large to enumerate. The ImageNet Large Scale Visual Recognition Challenge (ILSVRC) validation set contains only 50,000 images (Krizhevsky et al. 2012; Russakovsky et al. 2015). The ratio of evaluated inputs to possible configurations (Test Set Coverage/Total Input Space) is effectively zero. That disparity between what any test set can cover and what a deployed system will meet is the **verification gap**.

This disparity does not make evaluation futile; it changes what testing can establish. Predeployment evaluation provides statistical evidence over sampled inputs, while continuous production monitoring verifies whether the operating population and observed outcomes continue to support that empirical baseline. Statistical confidence replaces any expectation of exhaustive proof. The chapters on deployment and operations return to this gap and bound it statistically over a specified operating population.

A unit assertion verifies that a given input and state follow an explicit execution path, while a machine learning claim describes aggregate performance over a population that changes over time. Robustness therefore cannot mean immunity to change. It means instrumenting the system to detect when production evidence no longer supports the model, and acting on that evidence.

Debugging an ML system therefore starts with inspecting datasets and pipeline transformations rather than tracing Python call stacks alone. Version control must record dataset snapshots and feature configurations alongside source-code commits, and evaluation harnesses must measure statistical distribution shifts and subpopulation outcomes rather than branch coverage. These practices establish reproducibility and provenance, even though they cannot transform empirical sampling into formal verification.

Test coverage is a vanishing fraction of the input space.

↪ Versioning training datasets so that a model can be reproduced and traced to its inputs is developed in section 4.8.2.

Checkpoint 1.1: The paradigm shift

Before tracing the history of AI, verify your understanding of the paradigm shift in how software is built:

- ☐ **Software 1.0 vs. 2.0**: can you distinguish Software 1.0 (explicit instructions) from Software 2.0 (behavior learned from data)?
- ☐ **Debugging shift**: can you identify which dataset evidence to inspect when accuracy falls without a code change?
- ☐ **Verification gap**: can you explain why finite test coverage can provide statistical evidence but never exhaustive proof, and why production monitoring must continue gathering that evidence?

Learning behavior from data can seem inevitable in hindsight, but its adoption also reflects the scaling limits of earlier approaches. Many AI systems attempted to program intelligence directly

[5] **Stochastic gradient descent (SGD)**: A training algorithm, descended from the stochastic approximation method of Robbins and Monro (1951), that repeatedly adjusts model parameters using small, randomly sampled groups of examples, called batches, rather than processing the entire dataset for each update.

[6] **AlexNet**: Alex Krizhevsky, Ilya Sutskever, and Geoffrey Hinton trained this image-recognition network across two GPUs. At ILSVRC 2012, its 15.3 percent top-5 error, meaning the correct class was absent from its five highest-scoring predictions, substantially beat the second-place system's 26.2 percent (Krizhevsky et al. 2012). Section 1.3.3 returns to its architecture and systems co-design.

through hand-crafted symbols and rules. Reading that history through a systems lens reveals recurring binding constraints, the limits whose relaxation would most improve the whole system: logic, knowledge acquisition, feature design, and the physical infrastructure that the rest of this book studies.

1.3 The Evolution of AI Bottlenecks

Each era of AI history encountered a different limit, in representation, data, or computing resources. When Alan Turing[7] proposed evaluating machine intelligence through observable responses (Turing 1950), computing machinery had little memory or processing capacity. Early systems pursued two contrasting paths: Frank Rosenblatt's Perceptron (1958) (Rosenblatt 1958) attempted to learn weights directly from sensory inputs, whereas Joseph Weizenbaum's ELIZA[8] (Weizenbaum 1966) executed hand-coded pattern substitutions. Both soon met structural limits, as a single-layer perceptron could separate classes only with a linear boundary (Minsky and Papert 1969) while practical methods for training deeper networks remained out of reach, and ELIZA's scripts broke whenever inputs strayed from their hand-written templates. Four eras organize this history around recurring bottlenecks (symbolic AI, expert systems, statistical learning, and deep learning), although the approaches overlapped in time.

Figure 1.1 traces attention to AI across seven decades of published literature and shades two "AI winter" intervals (1974–1980 and 1987–1993) marked by funding cuts and unmet expectations.[9] These setbacks reflected gaps between expectations and what systems could deliver. Later advances combined changes in algorithms, data, and computing resources; the sections below examine how those changes shifted the limiting constraint.

1.3.1 Rule-based approaches: Logic and knowledge bottlenecks

Rule-based approaches attempted to build intelligent systems by making knowledge explicit. Symbolic AI encountered a *logic bottleneck* when its rules could not capture real-world ambiguity. Expert systems narrowed the task to a domain but encountered a *knowledge bottleneck*: acquiring and maintaining the rules required extensive expert effort.

1.3.1.1 The symbolic AI era and the logic bottleneck

Early AI research (1950s–1970s) pursued **symbolic AI**, representing knowledge and reasoning through explicit symbols and rules, an approach later crystallized in the physical-symbol-system hypothesis (Newell and Simon 1976). Researchers at the 1956 Dartmouth Conference[10] (McCarthy et al. 1955) hypothesized that aspects of intelligence could be precisely described and simulated by machines. Even then, Arthur Samuel at IBM demonstrated a different path in 1959 when a checkers program improved through self-play. His work coined the term "**machine learning**" (Samuel 1959), though the dominant paradigm remained symbolic. Daniel Bobrow's STUDENT[11] system (Bobrow 1964) took this approach to algebra word problems.

These systems could produce impressive demonstrations, yet they were operationally brittle. Their success depended on manually coded rules that mapped each acceptable input form to a symbolic representation. STUDENT could solve an algebra problem once it translated English into equations, but a minor variation in phrasing could prevent that translation. The difficulty extended beyond language to perception and movement.[12]

> Example 1.1: STUDENT (1964)
>
> STUDENT separated language interpretation from algebra:
>
> ```
> language  "Two numbers sum to 30; one is twice the other."
> parse     x + y = 30, x = 2y
> solve     x = 20, y = 10
> ```
>
> Once the equations were written, solving was routine. The bottleneck was the translation. Each unfamiliar phrasing needed another hand-written rule, so linguistic coverage grew only as fast as the rule base.

7 | **Alan Turing**: His "Imitation Game" approached machine intelligence through observable responses rather than a definition of its internal nature (Turing 1950). It provides an early example of evaluating a system through what it does.

8 | **ELIZA**: A natural-language program whose scripts could store selected inputs and reuse them in later responses (Weizenbaum 1966). This limited memory was programmed explicitly rather than learned from conversations. Extending its coverage required changing the scripts, even when the existing program ran correctly.

9 | **AI winters as systems failures**: The first AI winter (1974–1980) unfolded amid funding cuts; the 1973 Lighthill Report criticized the gap between AI promises and delivered results (Lighthill 1973). The second winter (1987–1993) involved a market and funding collapse around expert systems and specialized Lisp machines as general-purpose workstations undercut their economics (Hendler 2008). These episodes involved technical limitations, unmet expectations, and economics; hardware capacity alone does not explain them.

10 | **Dartmouth Conference (1956)**: The workshop organized around the term "artificial intelligence," already used in its 1955 proposal (McCarthy et al. 1955). The proposal discussed limits in computer speed and memory while treating programming as the larger obstacle. Physical capacity was part of the problem from the outset, even as researchers focused on language, abstraction, problem solving, and self-improvement.

11 | **STUDENT**: An early program that translated algebra word problems into equations using hand-written language rules (Bobrow 1964). Its success depended on the wording fitting those rules; an algebra solver could solve the resulting equations without establishing that the program had interpreted the original problem correctly.

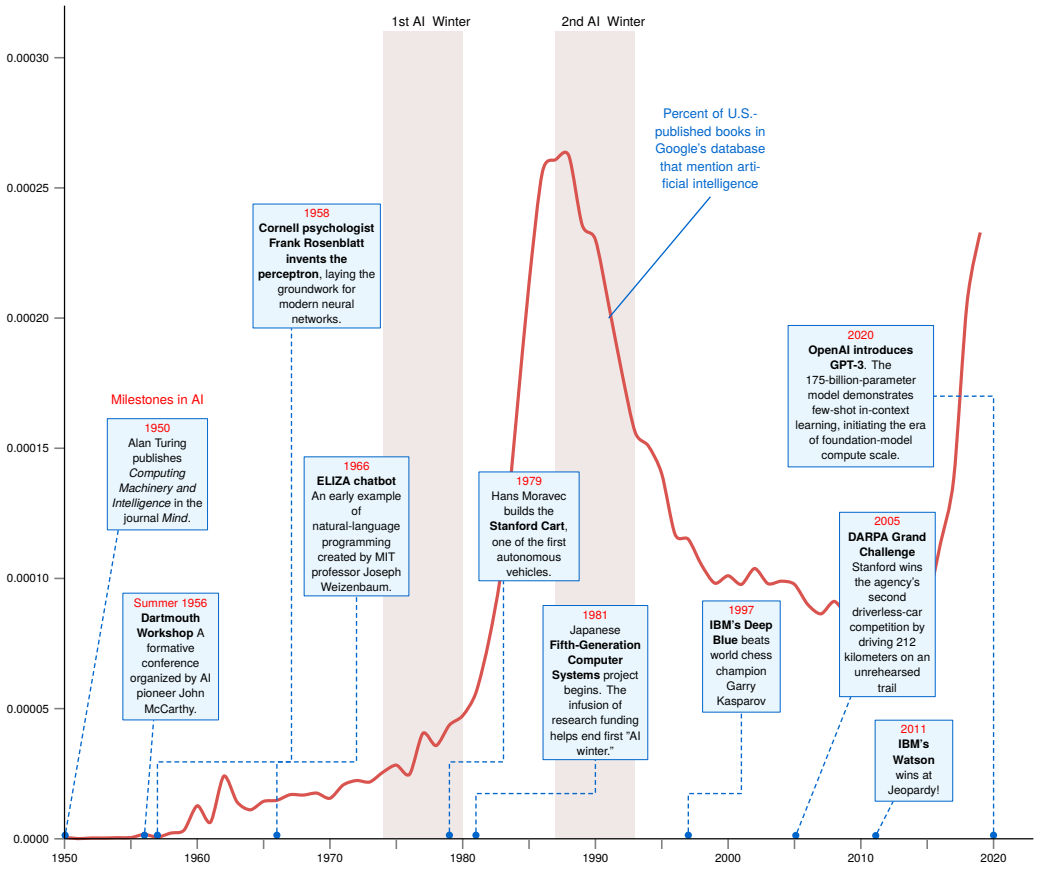


Figure 1.1: AI Development Timeline: The red curve tracks how often published books mention artificial intelligence, a measure of attention rather than capability, and the light-brown bands mark the two AI winters. Callout boxes place milestones such as Turing's 1950 paper (Turing 1950), the Dartmouth conference (McCarthy et al. 1955), the Perceptron (Rosenblatt 1958), ELIZA (Weizenbaum 1966), Deep Blue (Campbell et al. 2002), and GPT-3 (Brown et al. 2020) against that curve. Adapted from Michel et al. (2011).

12 **Moravec's paradox**: Hans Moravec observed that skills people acquire with little conscious effort, such as perception and movement, can be harder to reproduce computationally than formal reasoning tasks (Moravec 1988). Human familiarity with a task is therefore a poor guide to its engineering difficulty or resource requirements.

1.3.1.2 The expert systems era and the knowledge bottleneck

In the expert-systems era, engineers narrowed the problem. Instead of constructing general reasoning systems, they encoded deep knowledge from a specific domain. MYCIN, designed to diagnose blood infections, let medical knowledge be expressed as production rules (Shortliffe et al. 1975).

> Example 1.2: MYCIN (1975)
>
> MYCIN made its reasoning explicit. Patient facts triggered readable production rules:
>
> ```
> facts  stain=gram-positive, shape=coccus, arrangement=clumps
> rule   IF facts match THEN organism=staphylococcus (certainty=0.7)
> cycle  match facts -> fire rule -> update certainty -> repeat
> ```
>
> An inference engine repeated this match-and-fire cycle across hundreds of rules and propagated certainty factors (numerical confidence weights) toward a diagnosis. A physician could inspect every step, but coverage still grew one rule at a time: each exception had to be elicited, encoded, and reconciled with the existing rule base.

MYCIN performed well in specific tests, but its success exposed the **knowledge acquisition bottleneck**.[13] The problem was no longer whether a rule could express expertise. It was how tacit judgment entered the system and remained consistent as the rule base grew.

Faster machines could evaluate production rules at higher frequencies, but raw processor speed could not accelerate the extraction or maintenance of human expertise. Scaling meant learning decision boundaries from examples instead of asking domain specialists to enumerate every contingency. This transition did not eliminate human design; it relocated engineering effort. Instead of hand-coding decision logic, engineers shifted to curating datasets, selecting mathematical representations, and formulating learning objectives from which models could optimize their own parameters. The next era exchanged the knowledge acquisition bottleneck for a new one, the manual design of features extracted from raw data.

[13] **Knowledge acquisition bottleneck**: Feigenbaum (1984) treated extracting and representing expert knowledge as a central challenge in building applied AI systems. Experts could exercise judgment without being able to state every rule behind it, so acquiring knowledge required more than transcribing a ready-made list.

1.3.2 The statistical learning era and the feature engineering bottleneck

The 1990s marked the shift to **statistical learning** and probabilistic systems. Instead of hard-coded logic, systems estimated probabilities from data, such as the conditional distribution $p(y \mid x)$ of a label y given an input x. This transition was driven by the availability of digital data and the "unreasonable effectiveness"[14] of large datasets. Early spam filters illustrated the change: rather than maintaining lists of forbidden words, statistical filters learned the probability that a word implies spam from millions of examples.

[14] **Unreasonable effectiveness of data**: The observation that a simple statistical model with abundant data can outperform a more sophisticated model with less data (Halevy et al. 2009). The benefit depends on the task, model, and data quality. This makes collecting and preparing useful examples part of the engineering work, rather than merely a preliminary step.

Example 1.3: Early spam detection systems

Statistical filters shifted the decision from a hand-written rule to a probability estimated from labeled messages:

```
rules: if "free" or "winner" appears -> spam
learn: labeled email -> word likelihoods -> Pr(spam | email)
```

Maintenance did not disappear. It moved from editing keyword lists to curating representative examples and checking whether the learned probabilities still tracked current email.

Learning the decision boundary from data reduced one source of manual work but exposed another. Many statistical classifiers relied on engineers to convert raw inputs into features, measurable properties such as word counts or image edges. In computer vision, engineers designed feature extractors such as SIFT (Scale-Invariant Feature Transform) (Lowe 1999) and HOG (Histogram of Oriented Gradients) (Dalal and Triggs 2005) to summarize local image patterns. Classifiers such as support vector machines (SVMs) (Cortes and Vapnik 1995) then learned decision boundaries from those features. The learner adjusted the boundary; engineers decided which evidence it could see. Extending the system to a new problem often meant rebuilding the preprocessing stack, creating the **feature engineering bottleneck**.

This hybrid approach combined human-engineered features with statistical learning. The Viola-Jones algorithm[15] (Viola and Jones 2001), typical of this era, achieved real-time frontal-face detection using simple rectangular features and cascaded classifiers. It showed that well-engineered features could enable practical low-latency applications, but only within narrow domains where experts could hand-craft the right representations. A conventional vision pipeline makes that manual effort visible, because several hand-crafted stages preceded any learning at all.

[15] **Viola-Jones algorithm**: The detector applied a sequence of classifiers, rejecting likely nonface regions early and spending more computation on promising regions. On the reported test set, it evaluated an average of ten features per candidate image region, although the complete cascade contained over 6,000 features (Viola and Jones 2001). Its speed depended on how little work most inputs required, not just on how fast each operation ran.

Example 1.4: Traditional computer vision pipeline

A conventional vision system separated representation from classification:

```
image -> resize -> HOG/SIFT features -> SVM -> label
```

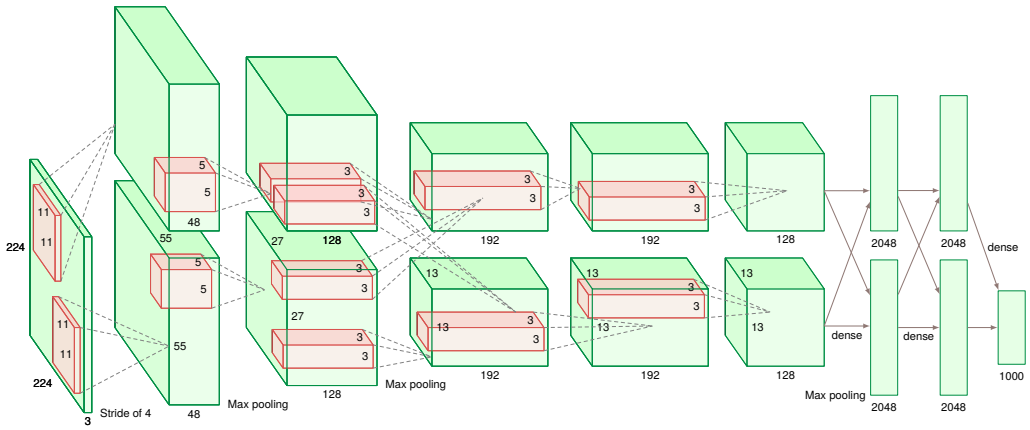

Figure 1.2: AlexNet Architecture: Two parallel GPU streams process 224×224 input images through convolutional layers (green blocks) that extract spatial features at decreasing resolutions, converging through three fully connected layers to 1,000 output classes. Because each stream holds half of the network, the figure also shows how the model was partitioned across two GPUs. Adapted from Krizhevsky et al. (2012).

> Moving from faces to pedestrians or another domain meant redesigning the feature extractor and often the entire preprocessing stack.

1.3.3 The deep learning era and the infrastructure bottleneck

Redesigning hand-crafted feature extractors for every new domain could not scale, so **deep learning** (LeCun et al. 2015) moved feature extraction inside the model itself. A neural network computes in layers, stages of arithmetic on learned weights in which each layer transforms the output of the one before. Instead of receiving features designed by humans, deep networks with many such layers learned representations directly from raw inputs such as pixels and audio waveforms. The training process could now shape both the representation and the decision boundary, enabling "end-to-end" learning.

The breakthrough was not algorithmic alone. Convolutional neural networks (CNNs), whose convolutional layers slide small learned weight patterns called filters across an image to detect the same feature at every position, existed earlier (LeCun, Boser, et al. 1989; LeCun et al. 1998); AlexNet paired architecture and training with **systems co-design**, choosing the model, training procedure, and hardware mapping together (Krizhevsky et al. 2012). Its parallel matrix operations matched GPU capabilities. With 60 million parameters distributed across two GTX 580 GPUs, AlexNet achieved 15.3 percent top-5 error, a 41.6 percent relative improvement over the next-best entry that year. The hardware partition in figure 1.2 carries the immediate systems lesson: the network divided work between the two GPUs and exchanged intermediate results only at selected layers to limit communication across the link between them (Krizhevsky et al. 2012). Model structure and machine organization were designed together.

Hardware still shaped what could be learned. In 2012, storing AlexNet's 60 million 32-bit parameters required roughly 240 megabytes, well within a single card's capacity. Training also needs working storage for intermediate results and for calculating and retaining parameter updates. These quantities, developed later as activations, gradients, and optimizer state, make training memory larger than the stored model alone, and the intermediate results grow with the number of images processed together. Each GTX 580 offered only 3 GB of video random-access memory (VRAM), and the original paper reports that this limit made the network too large to train on one card (Krizhevsky et al. 2012). AlexNet therefore divided convolutional and dense layers between two GPU streams communicating over the PCIe bus, the host's general-purpose peripheral interconnect. This early model-parallel design foreshadowed modern multi-GPU training. Deep learning reduced the need for hand-crafted features, but it moved the binding constraint to the infrastructure required to store data, move parameters, and coordinate computation.

↪ Model parallelism, which partitions a model across accelerators when it outgrows one device's memory, as AlexNet's two-GPU split did, is developed in section 8.7.1.2.

This shift produced the **infrastructure bottleneck**, in which physical memory capacity, interconnect bandwidth, and hardware orchestration dictate the boundaries of what models can learn. GPT-3 (Generative Pre-trained Transformer 3), with 175 billion parameters, was trained on roughly 300 billion tokens (the word fragments a language model reads and predicts) curated from filtered web text, books, and Wikipedia (Brown et al. 2020). The dense-training approximation (Kaplan et al. 2020) ($O \approx 6 \cdot P \cdot D$ operations for a model with P parameters trained on D tokens, counting both the forward and backward passes) agrees with the roughly 314 zettaFLOPs of total computation that the GPT-3 authors report, where one zettaFLOP is 10^{21} floating-point operations (FLOPs). A retrospective audit by Patterson et al. (2021) estimated that this single training run consumed roughly 405 V100 GPU-years. The hard part had moved from designing edge detectors to keeping some 10,000 accelerators running in parallel across high-speed fabrics without failures that halt training midway. Viewed through this systems lens, each transition traded one binding constraint for the next, first in human effort (rules, knowledge, features) and then in physical infrastructure (table 1.2).

↪ The dense-training approximation used for this operation count is developed in section 8.1.1.

Table 1.2: AI Paradigm Evolution: Each era is viewed through a recurring systems bottleneck. Deep learning (far right) reduced the need for manual feature engineering while increasing demands on computing infrastructure.

Aspect	Symbolic AI	Expert Systems	Statistical Learning	Deep Learning
Key Strength	Logical reasoning	Domain expertise	Versatility	Pattern recognition
Bottleneck	Brittleness (Rules break)	Knowledge Acquisition (Experts are scarce)	Feature Engineering (Manual preprocessing)	Infrastructure (Compute and data scale)
Data Handling	Minimal data needed	Domain knowledge-based	Moderate data required	Massive data processing

Across the four eras, engineering effort migrated from handcrafting domain heuristics toward building scalable compute and data pipelines. The bitter lesson explains why this shift recurred.

1.4 The Bitter Lesson

Expert systems invested engineering effort in encoding domain knowledge; deep learning systems invest much of that effort in learning from data at scale. The **bitter lesson** captures the historical advantage of general methods, especially search and learning, that can make effective use of increasing computation. Richard Sutton[16] crystallized this insight in his 2019 essay "The Bitter Lesson" (Sutton 2019). Sutton wrote, "The biggest lesson that can be read from 70 years of AI research is that general methods that leverage computation are ultimately the most effective, and by a large margin."

Training scale at the frontier is often stated in **accelerator-days** (GPU-days when the accelerator is a GPU): one reference accelerator running continuously for 24 hours. Table 1.3 pairs representative benchmark milestones with their hardware. Its final column runs from CPU-based learning to multi-thousand-accelerator clusters, using 2.5 million reference GPU-days as an estimated frontier-training anchor (Patel and Wong 2023).

[16] **Richard Sutton**: A reinforcement learning pioneer whose essay emphasizes search and learning as methods that scale with computation (Sutton 2019). The lesson is "bitter" because carefully encoded human knowledge has repeatedly been overtaken by more general methods. It is a lesson about long-term progress, not a claim that domain knowledge has no engineering value.

Table 1.3: AI Performance Evolution Across Paradigms: Representative systems illustrate the growth in computational scale across eras. GPT-4 training details are estimated reference anchors rather than official disclosures.

Era	Approach	Representative Task	Performance	Computational Resources
Statistical ML (1990s–2000s)	Feature engineering + learning	Handwritten digit recognition	about 98–99% on MNIST-era benchmarks (LeCun et al. 1998)	CPU-era feature pipelines; resources varied by implementation
Deep Learning (2012)	End-to-end neural networks	ImageNet top-5 accuracy	84.7% (AlexNet)	6 days on 2 GPUs
Modern Deep Learning (2020+)	Large-scale transformers (Vaswani et al. 2017)	ImageNet top-1 accuracy	88.55% (ViT-H/14) (Dosovitskiy et al. 2021)	Large-scale Tensor Processing Unit (TPU) pretraining
Modern Deep Learning (2023)	Foundation models	MMLU benchmark	86.4% (GPT-4) (OpenAI et al. 2023)	Estimated ~2.5 million reference GPU-days (on the order of 25,000 reference GPUs run for 100 days) (Patel and Wong 2023)

Digit recognition, ImageNet classification, and Massive Multitask Language Understanding (MMLU) measure different capabilities under separate metrics, so table 1.3 does not compare methods on one task. It shows instead that each new capability threshold demanded orders of magnitude more hardware, from single-node CPU routines to multi-megawatt accelerator clusters. Testing Sutton's lesson, whether general methods powered by raw computation surpass hand-engineered representations, requires holding the task fixed and comparing competing approaches within one domain.

Game playing separates the roles of search and learning. In chess, IBM's Deep Blue[17] defeated world champion Garry Kasparov in 1997 by combining custom chess hardware, large-scale search, and chess-specific evaluation knowledge. In Go, DeepMind's AlphaGo learned from expert games and self-play, using neural networks to guide tree search, but still used some engineered input features (Silver et al. 2016). AlphaGo Zero[18] provides the clearer example of Sutton's lesson: it learned through self-play without human game records or those hand-engineered features (Silver et al. 2017). The advance depended on methods that could turn computation into improved play, not merely on a faster machine.

The lesson is "bitter" because encoding human expertise can appear to be the most direct path to a solution. Sutton's examples show how scalable search and learning repeatedly overtook such approaches. More computation does not guarantee better results; the method must use it productively, and the data and objective must support the intended task.

Modern language models such as GPT-4 (OpenAI et al. 2023) and image generation systems such as DALL-E (Ramesh et al. 2021) illustrate the engineering demands of learning at scale. Much of their behavior is learned from large datasets rather than expressed as explicit linguistic or artistic rules. Training GPT-3 alone was estimated to consume roughly 1.3 GWh of energy[19] (Patterson et al. 2021), and serving these models to millions of users turns inference into a continuous data-center power, cooling, and capacity-planning problem.

When model capability scales with raw computation, the binding limits shift to physical infrastructure: memory bandwidth,[20] interconnect latency, thermal dissipation, and data pipeline throughput. Data movement, arithmetic throughput, and operational reliability must therefore be designed as one problem. Designing for continuous computational growth is the responsibility that defines AI engineering, which section 1.9 formalizes once its system boundaries and quantitative foundations are in place.

1.5 Defining ML Systems

Absorbing computational growth takes a working system, not only a model, and even a familiar service shows how many parts such a system has. A production spam filter needs more than a model that recognizes unwanted messages. It needs representative training data, a way to update learned behavior as attacks change, and infrastructure that classifies incoming mail within the delivery budget. Global email traffic is measured in hundreds of billions of sent and received messages

[17] **Deep Blue**: Its 480 custom chess chips worked alongside general-purpose processors, searching about 100 million positions per second in tactical positions and approaching 200 million in quieter positions (Campbell et al. 2002). The hardware accelerated chess-specific search and evaluation; it did not remove the system's reliance on encoded chess knowledge.

[18] **AlphaGo Zero**: After three days of self-play training, it defeated AlphaGo Lee, the version that had beaten Lee Sedol, by 100 games to 0 (Silver et al. 2017). Self-play generated the training examples, allowing search and learning to improve play without a dataset of human games.

[19] **GPT-3 training energy**: Patterson et al. (2021) estimated that GPT-3's training consumed approximately 1,287 MWh and produced 552 metric tons of CO_2-equivalent emissions. The energy estimate corresponds to the annual electricity use of about 120 US households at a baseline of 10.7 MWh/household-year. Emissions also depend on how that electricity is generated.

[20] **Memory bandwidth**: The rate at which a memory interface transfers data, measured in bytes per second. A processor must receive the values an operation needs before it can perform the arithmetic. When moving those values takes longer than computing with them, faster arithmetic alone cannot remove the delay; reducing transfers or increasing the available bandwidth addresses the limiting resource.

per day (Statista Research Department 2024), making this a substantial systems problem for large providers.

The challenge begins with data. The filter is trained on labeled examples and needs updated training data and periodic retraining as spam tactics change. It is also an algorithmic problem, because the model must generalize from those examples to messages it has never seen before. Precision measures the fraction of flagged messages that are actually spam; recall measures the fraction of all spam messages that the filter catches. Flagging more messages may catch more spam while also hiding legitimate mail, so the system must evaluate both consequences. Finally, it is an infrastructure problem. Providers must handle incoming traffic, store and update models, and return predictions within their delivery latency budget. The classifier is therefore only one component of an evolving data, software, and hardware system.

When a new phishing template appears, the data layer must capture representative messages, the algorithm must learn to separate attacks from legitimate mail, and the infrastructure must deploy and serve the updated model. Any layer can fail while the others continue working, so the full chain from measurement through learning to execution is the right unit of analysis.

Definition 1.1: Machine learning systems

Machine learning systems combine models that learn from data with the software and hardware needed to train, deploy, and maintain them. Their performance depends jointly on data quality, algorithm choice, and machine capacity.

1. **Significance**: Requirements are end to end, so a failure in any layer changes the user-visible result even while the other layers operate correctly.
2. **Distinction**: The system includes every path an input travels, not only the model. A feature computed one way in training and another in serving changes what the system predicts even when the model and its weights are identical.
3. **Common pitfall**: The model is not the system. Data pipelines, feature transformations, serving infrastructure, monitoring, and feedback loops surround the learned parameters and often dominate the engineering burden (Sculley et al. 2015).

The definition exposes three diagnostic axes: the data that describes the task, the algorithm that turns examples into behavior, and the machine that executes that behavior within the operating budget. The same user-visible symptom can originate in any of the three. Treating every miss as a model problem risks improving the wrong component. The D·A·M taxonomy separates these causes for diagnosis.

Each explanation calls for different evidence. The data hypothesis sends the engineer to coverage, labels, and distribution shift. The algorithm hypothesis sends the engineer to error slices (errors grouped by input type), model capacity, and the learning objective. The machine hypothesis sends the engineer to latency, throughput, memory, and utilization. These investigations are not interchangeable. Faster hardware cannot supply examples that were never collected, while a larger dataset cannot repair a serving path that misses its deadline because memory is saturated.

The relevant constraint is the one whose relaxation improves the end-to-end result. This idea of a **binding constraint**, used informally in the history above, prevents teams from optimizing the most visible component instead of the component that governs the outcome. The purpose of D·A·M is therefore operational: it identifies the next hypothesis to test and the class of intervention capable of changing system behavior. The diagnosis is provisional. Once an intervention relaxes one limit, the system must be measured again because a different axis may now bind. D·A·M is a loop, not a one-time label.

Definition 1.2: D·A·M taxonomy

D·A·M taxonomy is a diagnostic framework for examining machine learning system bottlenecks along three axes. Data determines what examples and bytes the system must process, Algorithm

determines the model structure and work required to learn or predict, and Machine determines the hardware capacity available to execute that work. The goal is to identify which axis is the binding constraint.

1. **Significance**: The diagnostic power is concrete even before detailed hardware arithmetic enters the story. If the spam filter misses a new phishing campaign because the training set never contained that tactic, the binding axis is Data. If the training examples are adequate but the model cannot express the pattern, the binding axis is Algorithm. If both are adequate but the service cannot classify messages quickly enough during a traffic spike, the binding axis is Machine. Quantitative diagnosis begins by asking which axis is limiting the system.
2. **Distinction**: The D·A·M taxonomy connects predictive quality to physical execution. Algorithm choice shapes both the data needed to learn useful behavior and the machine resources needed to run it. Those requirements depend on the task and training procedure, so model size alone does not determine either generalization or runtime.
3. **Common pitfall**: A frequent misconception is that the three axes are independent. Changing from a simple classifier to a larger model can require more memory, different serving infrastructure, and a broader data distribution. Because changing one of Data, Algorithm, and Machine can change the requirements imposed on the other two, every edge of the triangle in figure 1.3 points both ways.

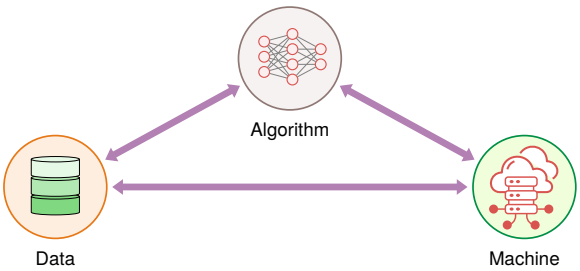

Figure 1.3: The D·A·M Axis Triad: Each vertex is one diagnostic axis, and each double-headed edge is a path along which a relaxed bottleneck can reappear on the neighboring axis.

An operational diagnosis earns confidence only when an intervention validates it, that is, when relaxing the identified constraint improves full-system behavior. Resolving one bottleneck frequently migrates the binding constraint across an adjacent edge of figure 1.3, so interventions rarely end the optimization process. Upgrading to faster accelerators (Machine) leaves execution units idling if storage I/O cannot stream input batches quickly enough (Data); conversely, expanding dataset volume (Data) exposes model architectures that lack the expressive capacity to absorb new patterns (Algorithm), and scaling model capacity to close that gap (Algorithm) soon exceeds accelerator memory, triggering out-of-memory faults or expensive paging across the PCIe bus (Machine). Engineering an ML system therefore requires identifying the currently binding constraint while anticipating where the bottleneck will migrate once that constraint is relaxed.

While the triad separates the three axes to simplify initial diagnosis, practical systems operate at their boundaries. Data formats govern memory traffic, model architectures dictate hardware functional unit utilization, and deployment budgets reshape both data representation and algorithmic design. Figure 1.4 partitions these interfaces into a three-set Venn diagram whose pairwise overlaps each pose one question: what the system can learn from ($D \cap A$), how information moves ($D \cap M$), and how computation executes efficiently ($A \cap M$).

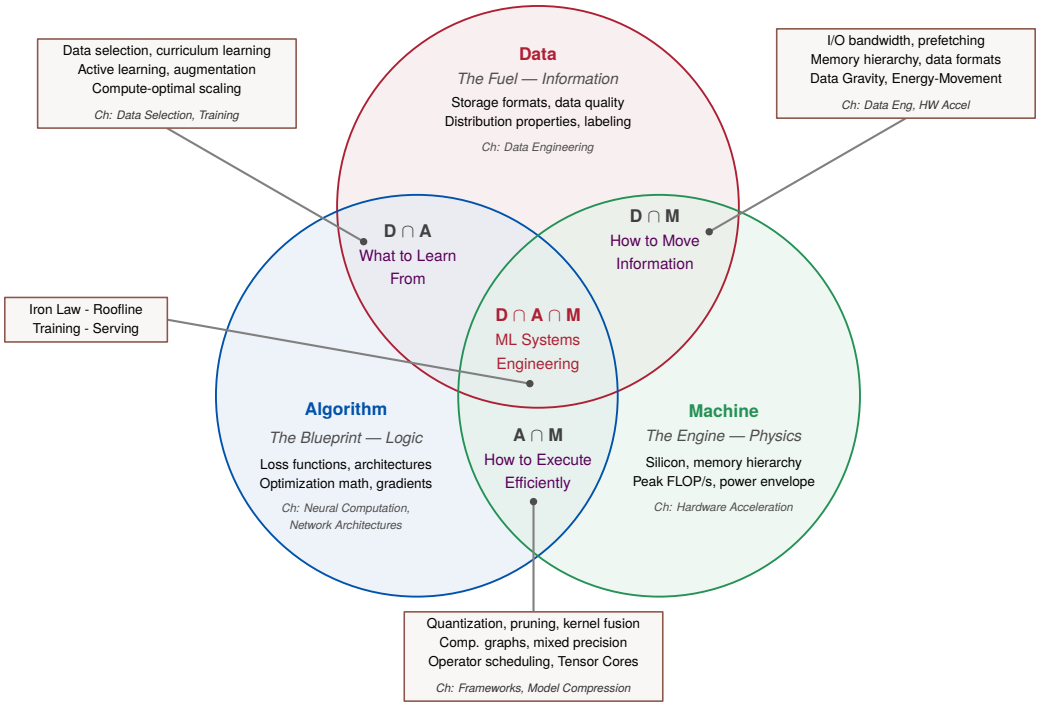

Figure 1.4: The D·A·M Intersection Landscape: Each circle lists the concerns that belong to one axis, and each pairwise overlap is titled with the question that axis pair must answer jointly. The central region, where all three circles overlap, is labeled ML systems engineering.

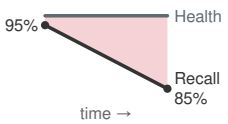


At the center, all three questions must be answered together: data selection and training determine which examples help the model learn useful behavior, data engineering and hardware acceleration deliver that information to the machine at speed, and frameworks and execution techniques turn the model's computations into efficient work on that silicon. Pruning a model (Algorithm), which removes parameters that contribute little to its predictions, alters its memory footprint and how much of it stays in fast on-chip memory (Machine). Compressing input features can likewise reduce transfers while adding preparation work (Data). These changes must be evaluated across the interfaces, because a local improvement may leave the end-to-end result unchanged, and even when every component executes without error, a shift on the data axis can still degrade predictions silently.

1.6 When ML Systems Fail Silently

In an automotive driver-assistance system, diagnostic trouble codes and hardware watchdog timers expose hardware or communication faults, yet they do not measure how often a perception model detects pedestrians. When seasonal conditions introduce low-angle winter sunlight, heavy precipitation, or bulky clothing underrepresented in training, pedestrian recall can decline from 95 percent to 85 percent even while the accelerator processes images at full frame rate without raising a hardware fault. Correct execution and predictive quality are separate properties, and an ML system must be engineered and monitored for both.

Crashes, unhandled exceptions, and failed health checks make some software defects directly observable, though conventional software can also produce silent numerical errors or logic bugs. Machine learning adds another route to **silent degradation**: learned behavior loses predictive quality as the operating population changes, even while the runtime executes instructions without error, memory allocations succeed, and inference servers return predictions well within latency service level agreements (SLAs).

↪ How pruning shrinks a model's memory footprint, and why its effect on speed depends on the sparsity pattern the hardware can exploit, is developed in section 10.2.1.

Recall falls while health metrics stay flat.

In this example, the miss rate triples, from 1 in 20 pedestrian frames to 3 in 20. That is a substantial change in detection quality, but it does not imply a tripling of vehicle-level safety risk, because temporal filtering, sensor fusion, and downstream control affect how missed detections influence a driving decision.

Input distributions can drift as environmental conditions, user behavior, or sensor calibrations change (Gama et al. 2014; Quiñonero-Candela et al. 2009). A model may then apply its fixed weights to inputs unlike those on which it was evaluated. The machine can execute every operation correctly while producing predictions whose quality no longer meets the requirement.

Outcome measurements establish whether predictive quality has fallen; distribution-divergence signals can prompt investigation before those outcomes arrive. When both are observed, model degradation can be approximated locally as a function of distribution shift. Let Accuracy_0 denote the baseline accuracy at deployment, $\mathcal{D}(P_t \| P_0)$ represent the statistical divergence between current production distribution P_t and training distribution P_0, and λ denote the locally fitted sensitivity to that shift measure, so that $\text{Accuracy}(t)$ is the accuracy after the model has been deployed for time t. This relationship, formalized in equation 1.1, is the **degradation equation**:

$$\text{Accuracy}(t) \approx \text{Accuracy}_0 - \lambda \cdot \mathcal{D}(P_t \| P_0) \tag{1.1}$$

This approximation describes a local trend fitted from observed inputs and labeled outcomes; it is not a universal law of accuracy loss. The chapters on deployment return to it as a statistical drift diagnostic. **Data drift** occurs when P_t differs from P_0. Such a shift can reduce inference quality even when the model and execution environment remain unchanged, but the shift alone does not establish a quality loss. Large changes may fall outside the range where the fitted relationship holds. The divergence measure $\mathcal{D}(\cdot \| \cdot)$ is left general here.

↪ The statistics that measure distribution shift and detect drift in production data are developed in section 4.12.1.

The equation separates baseline quality from sensitivity to shift. Better data, objectives, and architectures can change both quantities, so an improved baseline does not by itself establish robustness to drift. For the driving example, training on representative winter images may reduce sensitivity to seasonal conditions; evaluating pedestrian recall under those conditions establishes whether it does. Monitoring $\mathcal{D}(P_t \| P_0)$ provides a warning that prompts engineers to seek outcome evidence. That evidence determines whether retraining or another intervention is needed. *Knowing when to reevaluate is as important as knowing how to train.*

↪ How drift signals and labeled outcomes become an operational decision to retrain, made only when the expected benefit exceeds the cost, is developed in section 14.6.1.

Silent degradation can also originate inside the system through **training-serving skew**. Training and serving may use separate implementations to transform raw inputs into model features. If those transformations differ, for example by resizing images with a different interpolation method or applying different missing-value defaults, the model receives inputs unlike those used in training. The model can execute cleanly and return predictions on time while accuracy falls. This is a software consistency defect whose consequence is degraded learned behavior.

↪ Keeping transformation code and its fitted parameters identical across training and serving is developed in section 4.7.1.

Host-health signals such as CPU utilization, memory residency, network I/O, and HTTP status codes remain necessary, but do not measure whether predictions are useful. Machine learning operations must track these infrastructure metrics alongside data quality, feature distributions, and prediction accuracy. Because an ML system can fail silently while infrastructure metrics appear nominal, system design must integrate continuous evaluation from data ingestion through inference serving.

Useful predictions satisfy the first half of the ML systems mandate. The second half requires producing them within the available latency, memory, energy, and cost budgets. Meeting those budgets requires a quantitative account of where execution time goes.

1.7 Iron Law of ML Systems

Computational scale has a physical cost, and it shows up as two familiar failures. A training job stalls when storage cannot feed an accelerator; an inference path misses its deadline when model state moves too slowly through memory or across the network. Their symptoms differ, but both are governed by how the three D·A·M axes combine to consume wall-clock time. Across Data (D), Algorithm (A), and Machine (M), every ML task completes by processing a set of samples (examples in vision or tabular workloads, tokens in language models) through an algorithm's operations on

hardware. By dimensional cancellation, total execution time T (seconds) is the product of these three factors (equation 1.2):

$$T = \underbrace{\left(\frac{\text{Samples}}{\text{Task}}\right)}_{\text{Data}} \times \underbrace{\left(\frac{\text{FLOPs}}{\text{Sample}}\right)}_{\text{Algorithm}} \times \underbrace{\left(\frac{\text{Seconds}}{\text{FLOP}}\right)}_{\text{Machine}} \tag{1.2}$$

The same equation governs both training and inference because only the definition of the task and the scale of each factor change. The product of the first two factors sets the total arithmetic work O (FLOPs), while the third factor (Seconds/FLOP) is the realized time the machine takes per operation:

- **Training**: A task is a training run (or an optimization step), where Samples/Task is the corpus token budget D (billions to trillions of tokens) and FLOPs/Sample spans the forward and backward passes ($\approx 6P$ FLOPs per token for a dense transformer, giving $O \approx 6PD$). Because large training batches reuse model weights across thousands of tokens per step, the machine amortizes memory transfers and dispatch overhead, keeping realized Seconds/FLOP low and near the hardware's compute ceiling.
- **Inference**: A task is serving a request or generating a response, where Samples/Task shrinks to a small request batch (B) or a stream of generated tokens, and FLOPs/Sample covers only the forward pass ($\approx 2P$ FLOPs per token). With far fewer samples per invocation to amortize weight reads and orchestration, realized Seconds/FLOP rises sharply as memory bandwidth and fixed latency overtake arithmetic.

A real machine does not run at its datasheet peak rate $1/R_{\text{peak}}$ because physical execution requires moving data across memory and interconnect buses, driving arithmetic units at some realized utilization, and paying fixed control overheads. Assuming these three physical costs occur sequentially, the **iron law of ML systems** unpacks total execution time T (seconds) into their sum (equation 1.3):

$$T = \underbrace{\frac{D_{\text{vol}}}{\text{BW}}}_{\text{Memory Time}} + \underbrace{\frac{O}{R_{\text{peak}} \cdot \eta_{\text{hw}}}}_{\text{Compute Time}} + \underbrace{L_{\text{lat}}}_{\text{Latency Overhead}} \tag{1.3}$$

Together, equation 1.2 and equation 1.3 account for the physical-execution half of the dual mandate introduced in section 1.1:

1. **The memory term** $(D_{\text{vol}}/\text{BW})$ represents the physical cost of moving bits. D_{vol} is the volume of data moved (bytes), and BW is the memory or network bandwidth (bytes/s). Whether loading terabytes from cloud storage or fetching weights from high-bandwidth memory (HBM), the stacked dynamic random-access memory (DRAM) packaged beside an accelerator, performance is often limited by I/O physics. Part I develops this foundation.
2. **The compute term** $(O/(R_{\text{peak}} \cdot \eta_{\text{hw}}))$ represents the cost of arithmetic. O is the number of floating-point operations (FLOPs) set by the product of Samples/Task and FLOPs/Sample, R_{peak} is the hardware's theoretical peak throughput (FLOP/s), and η_{hw} is dimensionless realized compute utilization $(0 \leq \eta_{\text{hw}} \leq 1)$. Parts II and III develop this term.
3. **The latency term** (L_{lat}) represents orchestration, networking, and serialization overhead (seconds), treated as fixed for the modeled execution. Engineering changes can reduce this overhead, which can dominate small, latency-critical requests where little data moves and little arithmetic runs. Part IV develops this term.

Consider a hypothetical task that spends 2 seconds moving data, 8 seconds computing, and 1 second on overhead. Its total is 11 seconds. Doubling the arithmetic rate reduces computation to 4 seconds, but leaves movement and overhead unchanged. The task now takes 7 seconds, rather than half its original time. A faster component helps only through the portion of the time budget it changes.

Data enters equation 1.2 and equation 1.3 in two distinct ways: logical samples versus physical bytes. In equation 1.2, the Data factor counts how many examples or tokens the task processes (such as the dataset size D in the $6 \cdot P \cdot D$ training estimate), which multiplies FLOPs/Sample to fix

total arithmetic work O. In equation 1.3, by contrast, D_{vol} counts the physical bytes moved across a memory or interconnect bus, including model weights (P), activations, cached sequence state, and gradients alongside the raw inputs. When a language model decodes a single token at batch size one, the logical input is one token (Samples/Task $= 1$), yet D_{vol} spans gigabytes of model weights streamed from high-bandwidth memory.

Systems Perspective 1.1: The iron law analogy

The name "iron law" follows the processor performance equation of Patterson and Hennessy (2017), Time/Program $=$ (Instructions/Program) $\times$ (Cycles/Instruction) $\times$ (Seconds/Cycle). Equation 1.2 is the direct ML counterpart: the Data (Samples/Task) and Algorithm (FLOPs/Sample) factors multiply to set total operations O just as program path length and instruction set determine instruction count, while the Machine factor (Seconds/FLOP) mirrors cycles per instruction times clock period. Reducing FLOPs/Sample (for example, through unstructured sparsity) can still slow down execution if irregular memory accesses inflate Seconds/FLOP, just as complex CPU instructions that cut instruction count can lose performance by inflating cycles per instruction. Equation 1.3 then takes the same second step that computer architects take when decomposing processor time into compute cycles, memory-stall cycles, and pipeline overhead.

The additive form assumes sequential execution. When movement and computation overlap, the critical-path lower bound replaces the sum in equation 1.4:

$$T_{\text{pipelined}} \geq \max\left(\frac{D_{\text{vol}}}{\text{BW}}, \frac{O}{R_{\text{peak}} \cdot \eta_{\text{hw}}}\right) + L_{\text{lat}} \tag{1.4}$$

This max-based formulation reflects hardware that transfers the next block of data while computing on the current one, so the slower of the two stages hides the faster. Equality requires ideal overlap and assumes that L_{lat} remains outside the overlapped phases.

Even as a sum, the iron law identifies which physical constraint dominates before any optimization begins. Amdahl's law (Amdahl 1967) plays the same role for speedups. Accelerating only part of a task leaves the untouched remainder in place, and that remainder caps the whole task's speedup however fast the accelerated part becomes; equation 11.1 states that cap quantitatively as a bound on overall speedup. Section A.3.2 presents the refined treatment, including pipelining and overlap techniques that transform the additive model into the max-based formulation used in practice.

Diagnosing the limiting term requires comparing the workload with the machine. Arithmetic intensity ($I = O/D_{\text{vol}}$) counts the operations performed per byte moved. Each machine has an intensity at which its memory and compute terms balance, set by its peak compute rate divided by its memory bandwidth. A workload below that balance point waits on memory; one above it waits on arithmetic. Improving the smaller of the two terms yields a limited end-to-end gain. Actual performance also depends on realized utilization, and overhead (L_{lat}) sits outside this comparison and can dominate small requests. A single-accelerator estimate applies these ideas below.

↪ The roofline model, which bounds attainable throughput by arithmetic intensity and locates the ridge point, is developed in section 11.6.

Napkin Math 1.1: Estimating one local execution

Problem: A hypothetical workload on one accelerator moves 2 GB at 100 GB/s, performs 1 GFLOP at an effective arithmetic rate of 100 GFLOP/s, and incurs 5 ms of fixed overhead. Movement precedes computation. What execution time does the iron law predict, and which rate should be improved first?

Math: Dividing bytes by bytes/s gives a movement time of 20 ms. Dividing FLOPs by FLOP/s gives a compute time of 10 ms; the supplied effective rate already includes η_{hw}, so it must not be

multiplied by efficiency again. Adding these durations and overhead gives 35 ms. Movement is the largest term.

Result: Raising bandwidth to 200 GB/s reduces movement to 10 ms and total sequential time to 25 ms. Arithmetic and overhead remain unchanged, so doubling bandwidth does not halve the total.

Systems insight: If movement and computation could instead overlap ideally, with overhead still outside both phases, the lower bound would be 25 ms before the upgrade and 15 ms afterward. The upgrade balances the two stages; further bandwidth increases alone would leave that ideal bound unchanged. Whether the sum or the bound describes a measured run depends on its execution schedule.

A larger training estimate returns to equation 1.2 under an explicit compute-dominated assumption, folding all non-arithmetic delays into an effective end-to-end utilization factor η_{hw} so that the realized machine factor across N_{GPU} parallel accelerators is $(N_{\text{GPU}} \cdot R_{\text{peak}} \cdot \eta_{\text{hw}})^{-1}$ seconds per FLOP. Its efficiency factor accounts for the losses involved in coordinating many accelerators, beyond the local execution just calculated. A multi-machine cluster of that kind lies outside this book's single-machine scope; the estimate appears here only to show the scale the compute term can reach.

↪ The training-time form of the iron law, which converts an operation count into days of training at a realized utilization, is developed in section 8.2.

Napkin Math 1.2: Training GPT-3

Problem: How long would a GPT-3-class model take to train on a hypothetical modern cluster of 1,024 accelerators? This reference cluster uses A100-class accelerators, a generation newer than the V100 GPUs of the original run estimated earlier at roughly 405 V100 GPU-years, so the result shows what the same work could cost on newer hardware at the utilization assumed below. The original run achieved lower utilization, so part of the speedup comes from that assumption rather than from the hardware.

Given:

- **Operations** (O): $\approx 3.14 \times 10^{23}$ FLOPs (the product of the Data factor, 300 billion tokens, and the Algorithm factor, $6P$ FLOPs/token for 175 billion parameters)
- **Peak Rate** (R_{peak}): 312 TFLOP/s
- **Efficiency** (η_{hw}): $\approx$ 45 percent (an assumed planning value for large-scale distributed training, where communication and stalls keep realized throughput well below peak)
- **Accelerator Count** (N_{GPU}): 1,024 accelerators

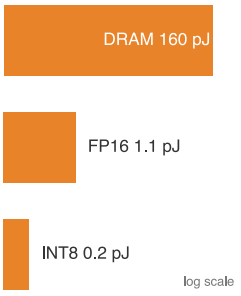
Math:

Assume that the training workload reuses data sufficiently to make arithmetic dominant and overlaps data loading with computation. Under this compute-dominated approximation, folding remaining communication and memory stalls into the effective end-to-end utilization η_{hw} across N_{GPU} parallel accelerators yields the training time T_{train}:

- $T_{\text{train}} \approx \frac{O}{N_{\text{GPU}} \cdot R_{\text{peak}} \cdot \eta_{\text{hw}}} \approx \frac{3.14 \times 10^{23}}{1024 \times 312 \times 10^{12} \times 0.45} \approx 25$ days

Result: 25 days.

Systems insight: If hardware utilization (η_{hw}) improves from 45 percent to 60 percent through better scheduling and more efficient execution, training time drops to 19 days, saving 6 days of expensive compute time.



Each term of the iron law resolves to seconds, making the equation dimensionally consistent, yet execution time is not the only physical constraint. For battery-powered edge devices and warehouse-scale accelerator clusters alike, energy dissipation and thermal limits often bind the system before throughput limits are reached. Moving bits across the memory hierarchy exacts an **energy tax** that parallels the delay of the memory term.

↪ The term-by-term unit check behind this statement, and its use as a test for any performance equation, are collected for reference in section D.2.2.

Let D_{vol} be the total data volume moved (bytes), E_{move} the energy per byte moved, O the total operation count, and E_{compute} the energy per operation. Equation 1.5 formalizes this relationship, following the hardware-energy observation that data movement can dominate arithmetic energy (Horowitz 2014):

$$E_{\text{total}} \approx \underbrace{D_{\text{vol}} \times E_{\text{move}}}_{\text{Movement Term}} + \underbrace{O \times E_{\text{compute}}}_{\text{Compute Term}} \tag{1.5}$$

The energy comparison depends on the transfer size and arithmetic operation being counted. Under the energy constants used in this text, moving one byte from off-chip DRAM consumes roughly 145× the energy of a 16-bit floating-point (FP16) multiply and 800× that of an INT8 (8-bit integer) multiply (Horowitz 2014). Whether movement dominates a complete workload also depends on the number and width of transfers relative to its operation count. The physical reason for the per-access gap is that data movement requires charging and discharging wires over longer distances, while arithmetic occurs locally within a processing unit's circuits. Minimizing avoidable data movement (D_{vol}) can therefore improve both speed and energy efficiency.

Moving a byte from DRAM costs about 145 times the energy of a 16-bit floating-point multiply, so data movement, not arithmetic, dominates the energy cost.

↪ The energy ladder from on-chip arithmetic to off-chip memory, and why its gap makes data movement a primary target for accelerator design, are developed in section 11.2.3.

Checkpoint 1.2: The iron law

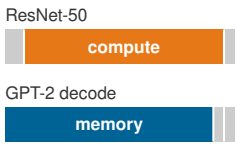
Before proceeding, verify that you can manipulate both forms of the iron law (equation 1.2 and equation 1.3, where $T = \frac{D_{\text{vol}}}{\text{BW}} + \frac{O}{R_{\text{peak}} \cdot \eta_{\text{hw}}} + L_{\text{lat}}$):

- ☐ **D·A·M product (equation 1.2)**: identify which two factors multiply to set O, and explain the difference between logical samples or tokens (D) in the Data factor and physical bytes moved (D_{vol}) in the memory term.
- ☐ **Memory term** (D_{vol}/BW): identify the physical resource that bounds this term and name one workload regime where it dominates.
- ☐ **Compute term** ($O/(R_{\text{peak}} \cdot \eta_{\text{hw}})$): identify the hardware quantity and utilization factor that bound this term.
- ☐ **Latency term** (L_{lat}): identify which costs remain after data movement and arithmetic have been optimized.
- ☐ **Peak throughput**: holding the other quantities fixed, if you double R_{peak}, which term improves, and why does total execution time fall by less than half when movement and overhead also contribute?

1.7.1 Lighthouse models put the iron law into practice

Each term of the iron law suggests an engineering intervention. The memory term can be reduced by moving fewer bytes or increasing effective bandwidth. The compute term can be reduced by performing fewer operations or using arithmetic units more effectively. The latency term calls for reducing orchestration and communication overhead. The equation alone does not say which intervention a system needs; that depends on its measured workload and whether the required data fits in memory.

Concrete workloads answer that question. Five recurring **lighthouse models** serve as diagnostic probes for the iron law throughout this book; later chapters explain the model structures and execution mechanisms behind their constraints. Each is a distinct stress case under the workload conditions stated for it:



- **Image classification (ResNet-50)** (He et al. 2016a) probes compute throughput. With sufficient reuse of learned filters across image positions and batched inputs, the arithmetic term ($O/(R_{\text{peak}} \cdot \eta_{\text{hw}})$) can dominate execution time.
- **Text generation (GPT-2/Llama)** probes memory bandwidth, with GPT-2 (Radford et al. 2019) anchoring the lighthouse and Llama (Touvron, Lavril, et al. 2023) representing its larger successors. Generating text token by token, the phase called decode, for one request at a time offers little weight reuse per token, so fetching weights from memory (D_{vol}/BW) can become the binding constraint.

- **Recommendation (DLRM)**, the Deep Learning Recommendation Model (Naumov et al. 2019), probes memory capacity, which determines whether the model can run at all. Embedding tables store numerical vectors for user and item IDs. Large tables can reach about a hundred gigabytes in reference models (Naumov et al. 2019), and terabytes in production (Mudigere et al. 2022), exceeding single-accelerator device memory.
- **Mobile vision (MobileNetV2)** (Sandler et al. 2018) probes compute throughput within a power envelope. Its efficient operators cut arithmetic far enough that a phone-class processor can classify frames in real time while sharing a battery and thermal budget with other applications.
- **Keyword spotting (KWS)** probes the power envelope, because an always-on microcontroller[21] must listen continuously for a wake word within a milliwatt budget and kilobytes of memory (Y. Zhang et al. 2017).

[21] **Microcontrollers**: Single-chip computers integrating a processor, memory, and interfaces to sensors or other devices. The keyword-spotting lighthouse has a kilobyte-scale memory budget and a milliwatt-scale power budget. A candidate model must fit those limits as well as meet its prediction-quality requirement.

These five are deliberately not the newest models. Each marks a point where the field turned and isolates one binding constraint in its cleanest form. ResNet-50 made deep convolutional training on accelerators routine and became a reference workload of the MLPerf training benchmark (Mattson et al. 2020). GPT-2 showed that scaling a decoder-only language model changes what it can do. DLRM represents the recommendation models that accounted for most AI inference cycles in Facebook's data centers when it was introduced (Gupta et al. 2020). Later models grow in scale, but the same terms of the iron law bind them, so the analysis in this book should transfer to models that do not yet exist.

The iron law makes these differences actionable under the stated workload conditions. Raising peak compute R_{peak} helps convolutions when arithmetic dominates, while increasing memory bandwidth BW helps generation when weight transfers dominate. Batch size, reuse, and serving patterns can change that diagnosis, so the bottleneck belongs to the workload on a particular machine rather than to the model name alone, which is why table 1.4 identifies each lighthouse by the regime it probes.

Same iron law, opposite dominant term, opposite fix.

Table 1.4: Lighthouse Models as Reference Workloads: Each workload illustrates a resource constraint under the stated conditions, providing a concrete setting for investigating how system constraints affect architectural choices. Each model's architectural background appears in chapter 6, and its quantitative specifications in section 6.9.1.

Lighthouse Model	System Bottleneck	What It Reveals	Diagnostic Target
ResNet-50	Compute throughput under reuse	GPU utilization, batching	Arithmetic throughput versus memory stalls
GPT-2/Llama	Memory bandwidth	Weight and sequence-state movement	Weight and cached-context transfer rates
Deep Learning Recommendation Model (DLRM)	Memory capacity	Embedding tables, memory budgeting	Device memory capacity and partitioning
MobileNetV2	Compute within a power envelope	Efficient operator design	Real-time latency deadlines within battery limits
Keyword spotting (KWS)	Power envelope	Tiny memory and energy budgets	Continuous inference within milliwatt power budgets

The lighthouse models supply the book's recurring workloads; the deployment paradigms described later in this chapter supply the operating envelopes those workloads must fit. The iron law estimates the execution time of one run on one machine. Over the past decade, however, training workloads grew faster than hardware improvements alone could accommodate, making efficiency a central concern.

1.8 Three Dimensions of ML Efficiency

Because training compute grew faster than hardware, every term of the iron law also had to shrink through better algorithms, better utilization, and better data. AlexNet's 2012 run is where that pressure began. Read through the D·A·M taxonomy, its breakthrough was coordination across all three axes rather than algorithmic novelty in isolation: a convolutional architecture whose parallel matrix operations matched GPU capabilities, the 1.3M labeled images of the 2012 ImageNet challenge training split[22] (Deng et al. 2009), and two consumer GPUs running for about six days. A university

[22] **ImageNet**: The full image collection grew from 3.2 million images reported in the initial paper to about 14.2 million across thousands of labeled categories (Deng et al. 2009; Russakovsky et al. 2015). The 2012 challenge used a subset of this collection; AlexNet's training split contained about 1.3M labeled images. Distinguishing the full collection from a benchmark split matters when comparing dataset sizes and training costs.

laboratory could afford that budget. Modern foundation models demand training compute roughly 8 orders of magnitude larger.

Scale drives AI progress, as the bitter lesson (section 1.4) argued, but ever-larger datasets and compute budgets narrow participation to the most resource-rich organizations. Even those organizations eventually meet physical limits in data center power, memory bandwidth, and the diminishing returns of adding more parameters. Using existing compute more efficiently is therefore a complementary path to progress.

Efficiency offers three complementary choices that align with the three factors of equation 1.2: perform less computation per sample, execute that computation in fewer seconds per FLOP, or choose more informative examples so the task needs fewer samples. **Algorithmic efficiency** reduces computational requirements (FLOPs/Sample) through model design and training procedures. **Compute efficiency** lowers realized machine time per operation (Seconds/FLOP) by raising hardware utilization η_{hw} and cutting memory and latency stalls, turning more of the machine's theoretical capacity into useful work. **Data selection** identifies examples that contribute useful learning signal, reducing Samples/Task (and therefore O) when training processes fewer examples; under a fixed computation budget, it can instead redirect work toward more informative examples.

Choosing among them calls for a bottleneck diagnosis across the interfaces in figure 1.4. All three must account for information movement: reducing FLOPs/Sample alone has little effect on wall-clock time when the memory term D_{vol}/BW dominates Seconds/FLOP.

Part III develops these dimensions in the order work flows through a system. Data selection asks which examples merit training computation. Model compression[23] asks how much storage and arithmetic a trained model requires. Hardware acceleration explains how the remaining operations map onto memory and compute units. This teaching order does not prescribe an optimization sequence. The measured binding constraint and deployment budget determine where to intervene first, and hardware limits inform data and model choices from the outset.

The historical trajectory of computer vision models isolates the compounding effect of architectural design. Hernandez and Brown (2020) held accuracy fixed at the AlexNet level and asked how much training computation successive architectures needed to reach it. Because they counted operations rather than seconds, hardware speed does not enter the measurement. Between AlexNet in 2012 and EfficientNet in 2019, the required compute fell by 44×, a halving roughly every 15 months between those two endpoints (figure 1.5). The dashed line in the figure is an exponential fit to those measured points. The reduction measures algorithmic progress at fixed task quality. Comparing it with hardware progress would require a matching measure of useful throughput or energy efficiency; Moore's law describes transistor integration,[24] which alone does not determine either quantity.

Architecture-by-architecture gains tell only half the story, because over the same years aggregate training compute in published frontier runs climbed far faster than algorithms could offset. Figure 1.6 charts that climb on a logarithmic scale, from early deep learning models near 10^{18} FLOPs to frontier systems beyond 10^{25} FLOPs. Sevilla et al. (2022) measured a doubling time of roughly six months across the deep learning era, and a least-squares fit to the runs in the figure gives a similar cadence. An earlier study over 2012 through 2018 found a 3.4-month doubling (Amodei and Hernandez 2018b); different windows and sets of runs yield different estimates. Both studies found training compute growing faster than the roughly two-year doubling associated with Moore's law. This divergence motivates efficiency improvements across algorithms, software runtimes, and hardware architectures, helping keep useful systems within reach as workload demands grow.

The two plots show how efficiency gains can coexist with growth in training scale. Figure 1.5 reports a 44× reduction in compute for a fixed accuracy target, while figure 1.6 illustrates roughly 8 orders of magnitude of growth in selected training runs. They measure different quantities and include contextual estimates, so they do not by themselves establish an economic cause. Efficiency makes a given capability less expensive; organizations can use the savings to reduce spending, broaden access, or pursue more demanding targets.

[23] **Model compression**: A family of techniques that reduces model storage or computation, including quantization (storing values in fewer bits), pruning (removing parameters that contribute little), and distillation (training a smaller model to imitate a larger one). Its size and accuracy effects depend on the model, method, workload, and target hardware.

[24] **Moore's law**: Gordon Moore's 1965 observation described rapid growth in the number of components that could be economically integrated on a chip (Moore 1998); later industry summaries often expressed the cadence as roughly a two-year doubling.

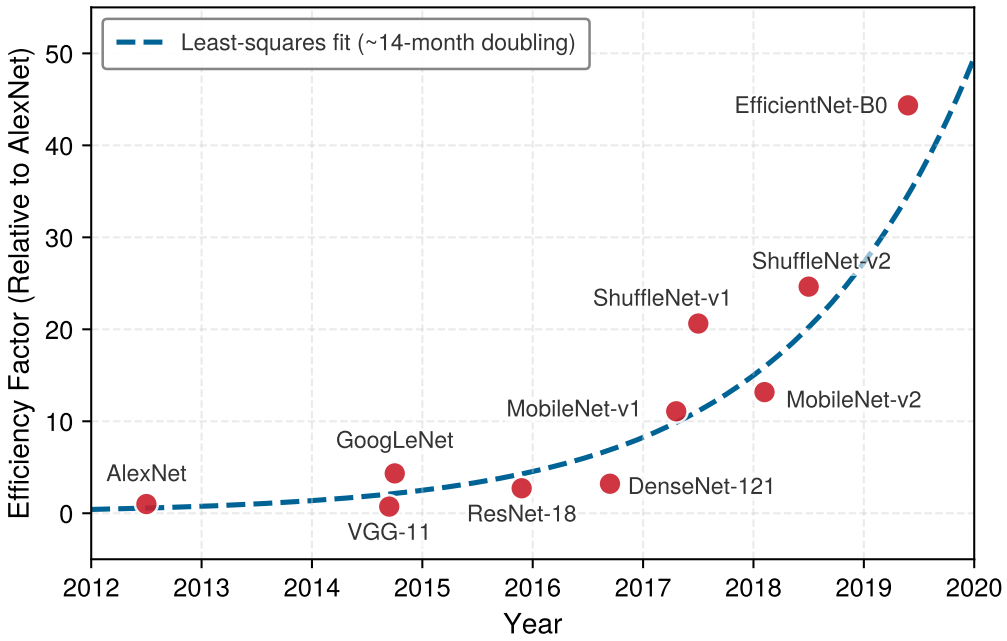


Figure 1.5: Algorithmic Efficiency Trajectory: Each point shows how much less training compute an ImageNet architecture needed than AlexNet to reach AlexNet-level accuracy, so height measures algorithmic progress with hardware speed held out. Most later architectures sit well above AlexNet, although individual points vary; VGG-11 needed more compute than AlexNet. The dashed line is a least-squares exponential fit to the measured points. Data from Hernandez and Brown (2020).

Systems Perspective 1.2: The efficiency paradox

Jevons paradox (Jevons 1865) describes cases in which more efficient resource use leads to greater total consumption because demand expands. A similar response is possible in AI. If EfficientNet needs 44× less compute than AlexNet to reach the same accuracy, an organization can reinvest the savings in larger models or more experiments. It can also choose a smaller budget or serve more users at the same cost. Reinvestment is a possible consequence of efficiency, not an inevitable one, and the plotted trends alone do not establish it.

Whether reinvestment pays is an economic question. The same physical terms that determine time and energy also determine cost: every byte moved, operation executed, and millisecond of latency consumes infrastructure budget. The test is whether added compute buys enough model improvement to justify the expenditure.

1.8.1 Return on compute: Weighing accuracy against cost

A model upgrade that raises accuracy by 1 percentage point can still be the wrong choice if it requires a 10× increase in O (total operations) whose cost exceeds the application's budget or the gain's value. **Return on compute (RoC)** measures the incremental accuracy gain per added dollar of infrastructure investment, in accuracy points per dollar:

$$\text{RoC} = \frac{\Delta\text{Accuracy}}{\Delta\text{Compute Cost}} \tag{1.6}$$

The RoC test compares that ratio against what each point of accuracy is worth to the application. Each alternative is compared against the same baseline, and the ratio is defined only when the added cost is positive. The GPT-3 estimate above demonstrates a different benefit: assuming scheduling changes preserve model quality, raising η_{hw} from 45 percent to 60 percent saves 6 days of cluster

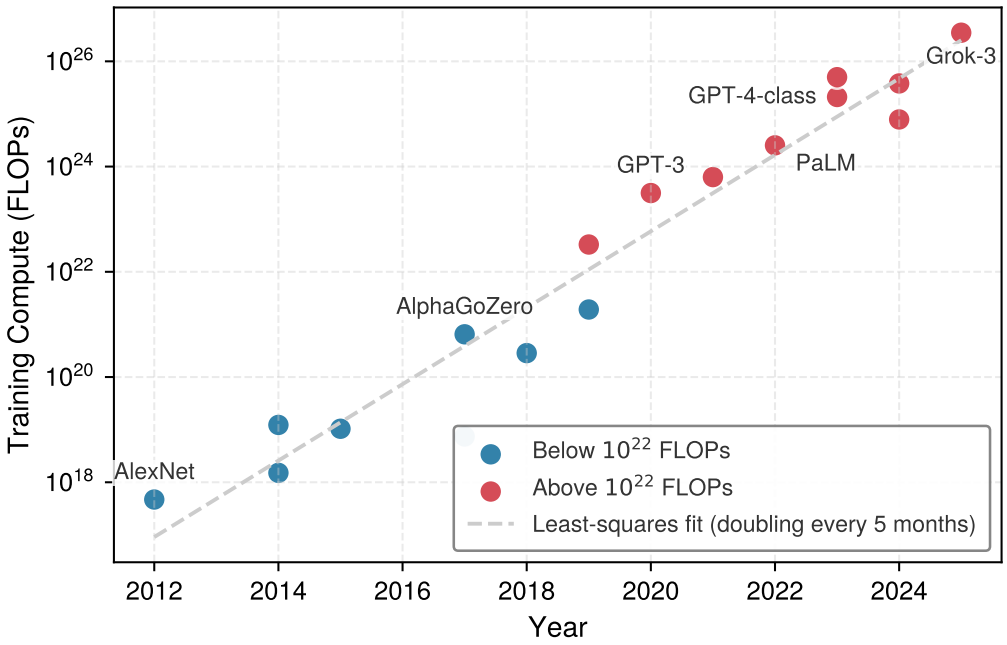

Figure 1.6: The Era of Scale: Each point plots a third-party training-compute estimate (FLOPs) for a notable model against its publication year on a log scale. Runs below 10^{22} FLOPs appear in blue; larger runs appear in red. The dashed line is a least-squares fit to these points and doubles every 5 months. From AlexNet (2012) to GPT-4-class training scale (2023), compute requirements increased by roughly 8 orders of magnitude (about 44.7M times). This endpoint comparison is distinct from training-compute trend studies (Amodei and Hernandez 2018b; Sevilla et al. 2022) and is used here to motivate the specialized infrastructure described in this book. Data from Epoch AI's Notable AI Models database (Epoch AI 2026c).

time for the same training work. This is a cost saving, not an accuracy gain. It can free budget for another experiment, whose incremental accuracy and cost must then be measured. The iron law helps estimate what computation costs; RoC asks whether an additional investment is worthwhile. Efficiency choices must therefore be evaluated against the system's goals and deployment constraints.

1.9 AI Engineering as a Discipline

A cloud service may optimize throughput across racks of accelerators, while an edge device must remain within a strict battery and thermal envelope, so the same model can be efficient in one setting and unusable in another. Holding predictive quality and resource cost to one specification across such different operating budgets requires combining the three quantitative tools developed above: the degradation equation judges predictive quality in both settings, the iron law judges execution time and energy, and the efficiency framework judges the cost of improving either. Applying them draws on computer science, electrical engineering, statistics, and established software and systems engineering practice.

Definition 1.3: AI engineering

AI engineering is the discipline of designing, deploying, and maintaining ML systems whose predictive quality and execution meet stated deployment requirements. It integrates decisions about data, algorithms, and machines, using statistical evidence to assess learned behavior and measurements to assess resource use.

1. **Significance**: A model improvement must still satisfy the other system requirements. AI engineering jointly considers data quality and governance, prediction quality, execution

time, memory, energy, and cost. A model that achieves 95 percent accuracy in research but violates a 100 ms deployment latency requirement does not meet the system specification.

2. **Distinction**: A model-level evaluation establishes evidence under a stated dataset and protocol. AI engineering must carry that evidence into a complete system whose latency, throughput, accuracy, cost, fairness, and robustness meet deployment requirements, and reassess it when operating conditions change.
3. **Common pitfall**: A frequent misconception is that AI engineering is just "software engineering for ML." Software correctness remains necessary, but the system specification also includes statistical claims about learned behavior over an operating population. Code tests cannot establish those claims by themselves, making continuing evaluation and monitoring part of the system design.

A requirement can be fixed while the evidence for meeting it remains uncertain. Pedestrian recall of at least 95 percent over a stated population is a fixed target; evaluation estimates recall from sampled outcomes, with uncertainty that must be reported and reassessed as conditions change. Execution requirements also need a defined workload and measurement protocol. Sampled response times support a statistical latency claim; a hard bound requires assumptions and analysis covering the specified execution conditions. Combining these obligations resembles the earlier convergence of computing and electrical engineering in computer engineering.[25] In this book's usage, AI engineering names the discipline and its shared principles, while ML systems engineering names the work of applying them to build and operate a specific system under its deployment constraints.

[25] **Computer engineering**: A discipline spanning digital circuits, processor design, and the software that runs on them. Moving a function from software into specialized hardware can change its speed, power use, and flexibility. ML systems engineering extends this shared design problem to include learned behavior and the data that shapes it.

1.9.1 Engineering across the ML lifecycle

Shipping a trained model to production does not end the engineering work, because the first shift in user behavior or upstream data can force a deployed system back into data collection and training. Putting an algorithmic advance into service requires data ingestion and preprocessing, computation within the available machine budget, reliable serving, and ongoing evidence of real-world performance. These obligations form a recurring lifecycle rather than a linear sequence that ends at deployment, and the engineering object is no longer only code but also data, model behavior, deployment context, and monitoring evidence evolving together.

At the project level, six responsibilities organize this work: problem definition, data collection and preparation, model development and training, evaluation and validation, deployment and integration, and monitoring and maintenance. Problem definition sets the task and acceptance requirements before any data is collected, so figure 1.7 begins after it and splits the data stage into collection and preparation to show where each feedback path re-enters.

The structural difference shows up first in tooling. Version control, continuous integration, and static analysis have long supported code-defined behavior. For learned behavior, these practices must also track dataset and model versions and test predictive quality, because source-code changes alone do not describe changes to the deployed system.

Feedback must therefore assess learned behavior as well as software execution. In figure 1.7, a failed evaluation sends work back to data preparation, while degraded production performance sends it back to data collection. Feedback determines which work must be repeated; it does not make every alert a retraining instruction. The six stages and the feedback paths that join them into a loop are developed in section 3.1.

↪ The workflow controls that learned behavior adds to established software practice are developed in section 3.1.1.

Each stage of this cycle carries resource demands of its own. Those demands are not uniform, because the binding physical constraints depend on where the system is deployed.

1.9.2 Deployment context shapes the lifecycle

Deployment context determines which lifecycle pressures dominate. The same stages apply across ML systems, but a megawatt-scale data center and a milliwatt-scale embedded device impose different bottlenecks on data collection, model updates, monitoring, and serving. Four **deployment paradigms** span that range (cloud, edge, mobile, and TinyML), and their envelopes sit orders of magnitude apart.

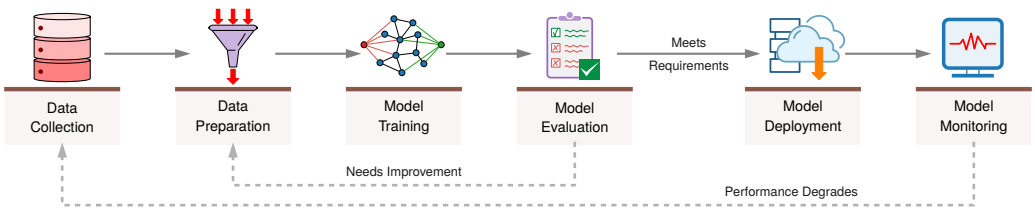

Figure 1.7: ML System Lifecycle: Forward arrows carry work from data collection to monitoring, and the two labeled return arrows mark where evidence sends it back. The return arrows end at different stages, so a failed evaluation and a confirmed production problem trigger different amounts of rework.

From cloud to TinyML, the endpoints differ by roughly 10^5 in memory and 10^6 in compute. Because a cloud model cannot fit directly on a microcontroller, moving down that scale requires compression, a smaller architecture, or a narrower task. At the upper end, cloud ML systems offer large computing budgets alongside capacity limits, operational complexity, and substantial infrastructure bills; at the lower end, TinyML systems on microcontrollers make memory and energy feasibility an immediate concern, as a sensor may need to detect anomalies on a single battery for years. Between these poles, placement determines where work and resource demands fall: edge ML systems move computation toward data sources to reduce latency[26] and network traffic, mobile ML systems share memory, thermal headroom, and battery power with foreground applications, and hybrid systems split work across tiers to balance latency, privacy, bandwidth, and update control.

Tight response deadlines or unreliable connectivity can require local execution, as in vehicle control, whereas fraud detection can run on cloud infrastructure whenever network and service latency fit the decision budget, and large language-model services rely on centralized clusters to accommodate their memory and compute footprint. In turn, cloud capacity and cost govern how often models are retrained, what historical data is retained, and how inference load is distributed, while edge and mobile limits constrain model size and update frequency.

As computation spreads across tiers, operational complexity grows alongside it. Edge and hybrid deployments must coordinate data collection across sensors with intermittent connectivity, track model versions across thousands of devices, push remote updates with safe rollback, and aggregate monitoring signals from distant endpoints. Data pressures pull in opposite directions at the same time: privacy rules and data sovereignty push computation toward the edge, whereas training high-capacity models pulls data back toward centralized clusters. Production architectures resolve this tension by running inference locally at the edge while routing sampled telemetry to cloud clusters for retraining.

In every deployment context, the model eventually meets inputs its evaluation never sampled. Autonomous driving illustrates this hybrid loop, running perception on the vehicle while cloud clusters train updated weights on logged fleet data. Because the Waymo Open Dataset shows pronounced domain gaps among San Francisco, Phoenix, and Mountain View (Sun et al. 2020), and because models that score well on benchmarks often lose accuracy when deployment inputs shift (Koh et al. 2021), every remote update must be revalidated against the population it will actually serve. Beyond predictive accuracy and latency, deployed systems must also satisfy fairness, interpretability, and privacy requirements across data, models, and governance: training sets can encode societal biases, regulated fields such as healthcare and finance require decisions that auditors and clinicians can interpret, and inference attacks[27] can leak sensitive information from trained weights. Meeting these technical, operational, and governance obligations across all four deployment regimes sets the structure of the book that follows.

1.10 Book Organization

Production ML work divides into responsibilities that engineering teams own: data engineering, training systems, deployment infrastructure, operations and monitoring, and ethics and governance (Paleyes et al. 2022). Those boundaries leak. Upstream data pipelines limit what training can reach, training choices fix the memory and latency footprint at serving time, and governance constrains every stage, so the book does not follow an organization chart. Its four parts follow the order in which constraints must be understood. The organizing principle is *context before theory*: physical

[26] **Latency at the edge**: Every millisecond of delay is distance traveled before a decision takes effect. A vehicle traveling at 30 m/s moves 3 cm during each millisecond of delay. Sensing, communication, computation, and actuation all contribute to the time before braking can begin, so reducing network delay addresses only part of the response budget.

↪ The light barrier, power wall, and memory wall that shape these operating envelopes are developed in section 2.2.

[27] **Inference attack**: An attempt to deduce sensitive information about training data from a model's outputs. Memorization can expose information, but the risk depends on the data, training procedure, and access available to the attacker. Defensive techniques include adding calibrated noise during training (differential privacy) and restricting the information returned by the system.

hardware limits and data ingestion bottlenecks constrain algorithmic choices, whose resource demands must in turn be checked against the machine. Readers establish operational boundaries and vocabulary (Part I) before constructing models (Part II), optimizing computational efficiency (Part III), and deploying systems under production service-level agreements (Part IV), the progression summarized in table 1.5.

Table 1.5: Book Organization: The four parts progress from foundations through model construction and training to optimization, deployment, and operations. This introduction precedes them and chapter 16 follows them. Each part builds on the vocabulary and methods of its predecessors.

Part	Question It Answers	Key Chapters
I: Foundations of ML Systems	What is being built, under which constraints, and from what inputs?	chapter 2, chapter 3, chapter 4
II: Development and Training	How does a model compute, how is it structured, and how is it trained?	chapter 5, chapter 6, chapter 7, chapter 8
III: Optimization and Acceleration	How can the model be made cheaper, and how is the gain proven?	chapter 9, chapter 10, chapter 11, chapter 12
IV: Deployment and Operations	Does the system survive real users, changing data, and its obligations?	chapter 13, chapter 14, chapter 15

Each part opens with the named principles it develops. These are numbered across the book so later chapters can refer back to them. The deployment part, for example, opens with the verification gap stated over a deployment population.

This book focuses on the **single-node** regime of one host with one to eight accelerators, each typically using local device memory and communicating through an on-node interconnect such as PCIe or NVLink. The binding constraint depends on the workload and may be memory capacity, memory bandwidth, compute throughput, or communication. Larger fleets add coordination and network constraints across many hosts. For reading paths, learning outcomes, prerequisites, and guidance on using the textbook, the preface provides the orientation.

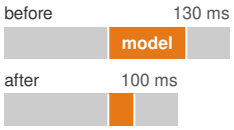
1.11 Fallacies and Pitfalls

A passing code test, a high held-out score, and a faster inference stage each provide useful evidence, but none alone establishes that an ML system meets its requirements. Mistaking code-level checks for validation of learned behavior overlooks the verification gap and silent degradation, treating a held-out score as proof of deployment readiness ignores distribution shift and execution budgets, and extrapolating a component speedup to the whole system overlooks the untouched costs captured by Amdahl's law. Each of these errors applies evidence beyond the conditions that support it.

Fallacy: *Better algorithms automatically produce better systems.*

A more accurate spam classifier can still be a worse production choice if it needs too much memory or cannot classify incoming messages within the delivery budget. The iron law (section 1.7) explains why algorithmic quality alone does not settle that decision. Model selection must maximize task quality subject to latency, memory, energy, cost, and reliability requirements. A simpler model supported by representative data and reliable infrastructure can meet those requirements more effectively than a sophisticated model whose surrounding system is inadequate.

Pitfall: *Treating ML systems as traditional software that happens to include a model.*



Established testing and deployment practices remain necessary for ML systems, but code-level checks alone cannot validate learned behavior (section 1.6). Both conventional and ML software can fail silently. In the driver-assistance example, pedestrian recall can fall from 95 to 85 percent while the accelerator keeps its full frame rate and raises no fault. ML systems additionally require outcome monitoring to detect declining predictive quality, with observation windows and sample sizes sufficient to resolve relevant differences across subpopulations. Teams deploying ML with only continuous integration and continuous deployment (CI/CD) pipelines risk silent failures, in which test suites and health checks report green while user-facing prediction quality degrades.

Fallacy: *High accuracy on benchmark datasets indicates production readiness.*

A benchmark score describes performance on a stated dataset under an evaluation protocol; it does not establish deployment readiness (section 1.9.2). The ILSVRC validation set holds 50,000 images, while the number of possible inputs has 362,508 digits, so even a perfect score is evidence about a sample, not proof about the population. A sentiment model may lose accuracy when users employ slang or context absent from the test set. Deployment also introduces resource requirements: mobile memory and latency limits may make a multi-model ensemble impractical, while network round trips can consume the response budget. Production validation must cover the intended operating conditions, relevant subgroups, resource use, and monitoring needed to detect change.

Pitfall: *Optimizing individual components without considering system interactions.*

Amdahl's law, which holds that the untouched share of a task caps the speedup of the whole, explains why improving inference alone may produce a small end-to-end gain. Consider a team that reduces model inference from 45 ms to 15 ms, expecting proportional improvement. Preprocessing still consumes 60 ms and postprocessing adds 25 ms, so total latency drops only from 130 ms to 100 ms. That is a 23 percent improvement in total latency rather than the 67 percent improvement of the inference stage alone. Most of the request path was untouched. Measuring the whole request prevents a component speedup from being mistaken for a system speedup; the bound in equation 11.1 computes the overall speedup from the share of time a component occupies and its local gain.

Making the model three times faster trims end-to-end latency by only 23 percent.

Fallacy: *ML systems can be deployed once and left to run indefinitely.*

Deployed ML systems cannot assume static performance over time: environmental distribution shifts can degrade a frozen model even when underlying execution code remains untouched. In this illustrative scenario, a recommendation system deployed at 85 percent accuracy drops to 80.2 percent within 6 months as purchasing patterns shift, losing 4.8 percentage points without any code changes. The ML lifecycle (section 1.9.1) therefore treats outcome monitoring and evidence-based retraining as operational requirements. Without continuous monitoring, systems can appear healthy while prediction quality silently erodes.

Pitfall: *Assuming that ML expertise alone is sufficient for ML systems engineering.*

Production ML (section 1.9.2) requires expertise across algorithms, software, systems, and operations. A team with strong ML skills can still miss throughput targets if storage layout or serving infrastructure is inadequate. Conversely, infrastructure built without attention to model inputs can introduce preprocessing defects that degrade predictions. Deployment case studies show the need for coordinated attention to data, models, infrastructure, and organizational workflow (Paleyes et al. 2022). Failures can arise at the boundaries, where one team's assumptions become another team's inputs.

1.12 Summary

Machine learning systems must satisfy two obligations at once: learned behavior must remain trustworthy, and the machine must deliver that behavior within physical and economic limits. Every ML system answers to three questions: what shapes its predictions, what limits its execution, and what evidence supports its deployment. The D·A·M taxonomy organizes that diagnosis, the degradation equation and the iron law quantify the trade-offs, and efficiency together with return on compute guides the choice of interventions. Because data and operating conditions keep changing, those answers never stay fixed, and five lighthouse models (ResNet-50, GPT-2/Llama, DLRM, MobileNetV2, and keyword spotting) recur throughout the book to ground these methods in concrete workloads.

Return to the smartphone interaction that opened the chapter. What appeared to be one intelligent action depended on representative data, a learned model, a machine within its operating budget, and feedback that could reveal changing behavior. That chain answers the question posed at the outset: an accurate model alone does not establish a reliable, efficient system. AI engineering coordinates these decisions and uses measured evidence to assess whether the complete system meets its requirements.

Key Takeaways: Constraints drive architecture

- **Relieving a bottleneck can expose another**: Data, Algorithm, and Machine constraints interact. After an intervention, measure the complete system again to determine which constraint now limits the result.
- **Learned behavior can decay silently**: ML systems can lose predictive quality while code and infrastructure stay fixed because deployment inputs change. Drift metrics prompt investigation; labeled outcomes establish whether prediction quality has fallen.
- **End-to-end time is the whole path**: Data movement, computation, and overhead all spend from the same time budget. Cutting inference from 45 ms to 15 ms gives only 23 percent improvement when preprocessing (60 ms) and postprocessing (25 ms) dominate, so optimize the term that binds end-to-end behavior.
- **Scale needs useful computation**: The bitter lesson emphasizes search and learning methods that can use increasing computation effectively. Their benefit depends on data, objectives, and a supporting machine. Efficiency gains of 44× at a fixed accuracy target coexisted with roughly 8 orders of magnitude of growth in selected training runs.
- **AI engineering is continuous co-design**: Deployment requirements guide decisions about data, models, and execution. Evaluation and lifecycle monitoring provide evidence that predictive quality and resource use continue to meet those requirements.

An intended capability becomes an engineering result only when measured behavior meets the goal within a feasible resource budget. Data, learning objectives, design choices, and hardware all shape that result. The first engineering act is therefore a measurement of the complete system, not an optimization of its most visible part.

What's Next: From vision to architecture

This chapter asserted that the four deployment paradigms have operating envelopes orders of magnitude apart without deriving the gap. Chapter 2 derives it from physical limits and turns it into a decision framework for choosing among them when requirements conflict.

I

FOUNDATIONS OF ML SYSTEMS

Part I

Foundation Principles

Complexity in a machine learning system often moves rather than disappearing, although good design can remove accidental complexity. Complexity flows among the three domains of the D·A·M taxonomy: Data as information, Algorithm as logic, and Machine as physics. Simplifying one domain can burden the others. A hand-crafted feature pipeline reduces algorithmic complexity but demands more data engineering effort. A larger model absorbs messy data but shifts complexity onto the hardware that must train and serve it. This conservation-of-complexity heuristic recurs throughout this book. The quantitative bounds, models, and principles introduced throughout the book describe constraints that emerge from where complexity currently resides.

Architectures, frameworks, and optimizations succeed only when they respect constraints imposed by hardware, mathematics, and information theory. Just as civil engineers cannot ignore gravity, ML engineers cannot ignore the physical laws that govern data, computation, and system throughput. The introduction argued, through the bitter lesson, that progress comes from general methods that scale with data and computation, and it named the iron law that accounts for the cost of that scale. Part I establishes the foundations on which that pricing rests: where a system can physically run, when its constraints must be known, and how the data it learns from is engineered. The principles in this book are not best practices that evolve with frameworks or opinions that differ between teams, and they are not universal laws either. Each principle box opens by naming its kind (bound, decomposition, fitted model, policy, or heuristic), and each holds only under the assumptions it states. Part I's two principles concern data, which every Part I chapter must account for. Chapter 2 uses data gravity to decide where computation runs, and chapter 4 turns the pair into the two bounds data places on a system, data as code governing what a model can learn and data gravity grounding the physics of moving bytes that bounds how fast the machine can learn it.

Principle 1: The data-as-code principle

Heuristic: Data functions as the source code of the ML system. A change to the training dataset can alter the system's learned behavior. Here, learned behavior means the trained input-output mapping; Train denotes the training process, and $\approx$ marks a qualitative dependency rather than a predictive equality. Model architecture, initialization, optimizer configuration, and training stochasticity are included in the training procedure.

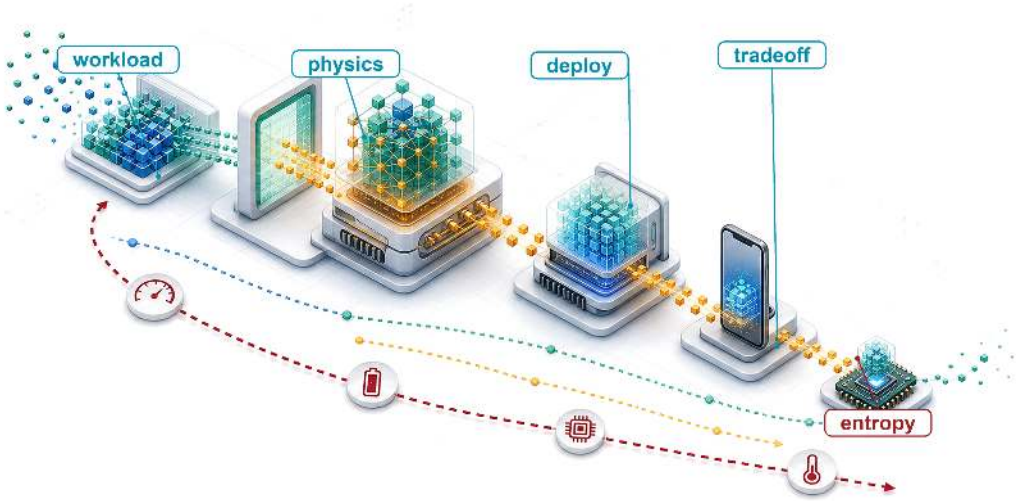
$$\text{Learned Behavior} \approx \text{Train}(\text{Training Data}, \text{Training Procedure})$$

Implication: Data engineering requires the same rigor as software engineering. Datasets should be versioned (like Git), unit-tested (data quality checks), and debugged. Deleting a row of training data can alter the rebuilt model just as deleting a line of code can alter a compiled artifact.

If data functions as source code, then it is not merely a logical artifact; it also has physical properties that constrain system architecture when data and computation occupy different locations. Moving terabytes of raw sensor or text data across a constrained link costs far more time and energy than shipping the training or query logic to where those bytes already reside.

Principle 2: The data-gravity principle

Heuristic: As data volume (D_{vol}) grows, transferring the dataset can cost more than sending a much smaller query or code payload over the same constrained link (McCrory 2010). Here, cost denotes one transfer metric at a time, such as elapsed transfer time or bytes sent, under identical link conditions; it does not combine latency and bandwidth into one quantity.



$$\text{Cost to transfer dataset} \gg \text{Cost to transfer query or code} \quad \text{in this regime}$$

Implication: Large datasets can become the gravitational center of the architecture. Systems may move compute to data by shipping queries or code to the storage layer rather than moving data to compute by repeatedly downloading large datasets.

Together, these two principles establish that data can be both the logical program and a physical anchor of an ML system. Part I develops these implications as a dependency chain. Chapter 2 derives from physical limits where a system can execute; chapter 3 carries those constraints around the lifecycle, where a constraint discovered late invalidates every artifact built before it; and chapter 4 builds the pipeline that meets both data bounds, versioning what the model learns from and delivering it as fast as the accelerator consumes it. Ignoring any link returns complexity as integration cost: an accurate model that cannot execute, a workflow that cannot reproduce its inputs, or a pipeline whose outputs no longer match deployment conditions.

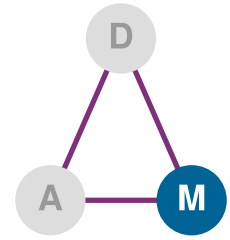
Purpose

Why does deploying the same model to a phone vs. a data center demand fundamentally different engineering?

The defining insight of ML systems engineering is that constraints drive architecture. The speed of light sets an absolute floor on how quickly distant servers can respond, thermodynamics limits how much computation can occur in a given volume before heat becomes unmanageable, and memory physics makes moving data more expensive than processing it. Because these physical limits persist as technology improves, deployment categories organize recurring constraint regimes rather than divide hardware into fixed, mutually exclusive classes. A data center can train billion-parameter models yet cannot guarantee low-latency responses to users thousands of miles away; a smartphone can respond immediately yet holds a fraction of the memory budget and must share a small battery with the rest of the phone; and a microcontroller can run on a coin-cell battery for years while offering barely enough compute for a simple keyword detector. Across these regimes, power budgets span roughly nine orders of magnitude, from megawatts in a data center to milliwatts on a microcontroller, while memory capacity spans from terabytes to kilobytes. The same model applied to the same data therefore demands radically different engineering in each regime, not because the physics changes, but because different constraints dominate. The engineering task is not to identify a universally best deployment, but to locate the constraint that binds in the intended operating regime. In D·A·M terms, understanding these regimes turns deployment from an operational afterthought into a co-design problem in which data locality, algorithm structure, and machine constraints jointly determine what is possible.

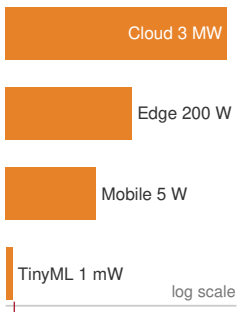
Learning Objectives

- Explain how physical constraints shape deployment paradigms from cloud to TinyML
- Diagnose which term of a tier's silicon contract binds a workload, separating iron-law limits from memory and energy feasibility
- Match workload demands to deployment budgets using lighthouse model examples
- Compare cloud, edge, mobile, and TinyML by operational constraints and quantitative trade-offs
- Apply the decision framework to select paradigms by privacy, latency, resource, and cost constraints
- Analyze hybrid patterns that combine paradigms to satisfy system constraints
- Evaluate deployment placements against data-locality deadlines, energy per inference, and lifecycle cost



2.1 Four Deployment Regimes Across Nine Orders of Magnitude

Consider two extremes: a wake-word detector on a smartwatch and a recommendation engine in a data center. The wake-word detector represents a TinyML workload operating under milliwatt power budgets and kilobyte memory limits; the recommendation engine exemplifies a cloud ML workload requiring terabytes of embedding tables and megawatt-scale infrastructure. These systems solve different problems under opposite physical constraints, and their supporting infrastructure differs sharply in scale and design. The introduction's D·A·M taxonomy (figure 1.4) treated the machine as one of three interacting components. Between these two extremes, the machine is the component that changes most, and its physical limits decide which data and algorithmic choices remain open.



Physical constraints determine where an ML model can run and shape what is possible in ways no algorithmic choice can override. They bind the whole system, not only the weights: data ingestion pipelines, feature extraction, serving runtimes, telemetry, and hardware resource managers must all fit the host platform's physical envelope.

Three physical constraints (latency, power dissipation, and memory) organize four deployment paradigms.[1] The categories overlap—edge describes proximity to data, while mobile and TinyML further distinguish local devices by their resource envelopes—and the combination of a workload and its target platform determines which constraint binds first. Centralizing computation in Cloud ML provides elastic compute and large memory capacity at the cost of wide-area network latency on every inference; moving workloads to Edge ML eliminates that network round trip and keeps sensitive data on premises (Shi et al. 2016), but caps available compute at local site power and cooling budgets. Stepping onto battery-powered devices, Mobile ML delivers responsive interaction directly on handsets and tablets within a passive thermal envelope where sustained computation triggers throttling, and at the low-power extreme, TinyML runs on microcontrollers (Janapa Reddi, Plancher, et al. 2022) whose milliwatt power budgets and kilobyte memories require compact models and integer arithmetic. Along the way, the memory constraint changes form: in the data center it usually binds as bandwidth, whereas on a microcontroller it binds first as capacity. Arranged along one physical continuum, these tiers run from warehouse-scale megawatts in data centers down to milliwatts on embedded microcontrollers (figure 2.1).

While figure 2.1 traces the continuous progression from embedded sensors to data centers, table 2.1 quantifies conceptual operating envelopes across processing location, round-trip latency, power draw, and memory capacity. The cloud row describes facility power; the other rows describe local systems or devices. These envelopes compare deployment scales, whose physical basis is developed in section 2.2.

The machine axis sets the deployment envelope.

Deployment paradigm: A distinct operating regime defined by latency, power, memory, and connectivity constraints. The Cloud-to-TinyML spectrum changes which resources bind; optimizing within an infeasible regime cannot satisfy the application's deployment budget. Raising a cloud model's throughput by 5 percent, for example, cannot rescue an application whose 10 ms latency budget the network round trip alone exceeds.

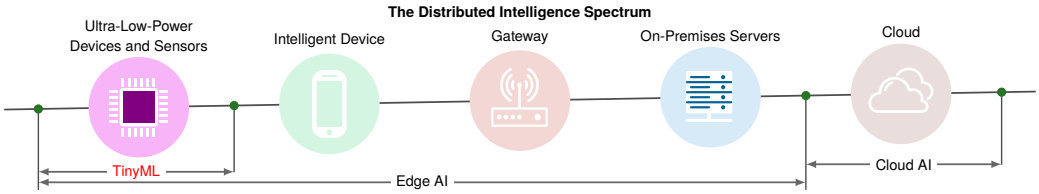


Figure 2.1: Distributed Intelligence Spectrum: Deployment tiers form a continuum governed by physical constraints, spanning nine orders of magnitude in power. Moving from centralized cloud infrastructure to on-device TinyML trades raw computational capacity and elastic scale for shorter communication paths, data locality, and network independence.

Table 2.1: The Deployment Spectrum (Conceptual): Four paradigms span nine orders of magnitude in power (MW to mW) and memory (TB to KB). This conceptual overview defines each paradigm by its operating regime, and each power entry names a typical class rather than a bound; the concrete hardware spectrum in table 2.4 grounds these categories in specific platforms and quantitative decision thresholds. The hardware specifications and physical constants underpinning these numbers are catalogued in Appendix E.

Paradigm	Where	Latency (ms)	Power	Memory	Best For
Cloud ML	Data centers	100-500	MW	TB	Training, complex inference
Edge ML	Local servers	10-100	100 W	GB	Real-time inference, privacy
Mobile ML	Smartphones	5-50	3–5 W	GB	Personal AI, offline
TinyML	Microcontrollers	1-10	mW	KB	Always-on sensing

At every tier, the hardware offers a **silicon contract**: a compute rate, a memory bandwidth, and an execution overhead. Different tiers offer different budgets for these resources, and the contract also carries a memory capacity, which is not a term of execution time but a precondition that decides whether a workload fits on the tier at all. Physical constraints set those budgets, and each budget enters one term of the iron law of ML systems, which decomposes end-to-end execution time into data movement, computation, and system overhead. The speed of light, thermal dissipation, and memory signaling shape those terms, which is why deployment paradigms exist as distinct engineering regimes rather than arbitrary points on a continuous slider.

2.2 Physical Constraints on Deployment

A safety system with a 10 ms reaction budget cannot wait for a cross-country round trip, and a billion-parameter model cannot be squeezed into a microcontroller by better code alone. Both follow directly from the physical laws governing the speed of light, power thermodynamics, and memory signaling. The light barrier limits remote responsiveness, the power wall restricts sustained throughput, and the memory wall caps data transfer. Where a system runs changes the operational terms the hardware offers, which changes what the hardware can offer the model.

↩ A first sketch of the deployment spectrum and its three walls is established in section 1.9.2.

The light barrier

Sending a sensor packet from California to a cloud data center in Virginia (~3,600 km straight-line) requires ~36 ms round-trip in optical fiber before a single floating-point operation begins, and real networks add routing, protocol, queuing, and processing delays on top. Any application that requires a sub-10 ms response *cannot* rely on distant cloud infrastructure, no matter how fast the remote accelerators are. The **light barrier** sets this absolute latency[2] floor. Let Distance denote the one-way path length and c_{fiber} the propagation speed in optical fiber. Equation 2.1 gives the minimum round-trip time:

$$L_{\text{lat,min}} = \frac{2 \times \text{Distance}}{c_{\text{fiber}}} \approx \frac{2 \times \text{Distance}}{200{,}000 \text{ km/s}} \tag{2.1}$$

For optical fiber, $c_{\text{fiber}} \approx 200{,}000$ km/s, roughly two-thirds of its vacuum value because light travels more slowly through glass than through a vacuum. This propagation floor directly motivates edge ML: when a tight latency budget rules out the round trip, computation must move closer to the data source.

The power wall

Doubling a processor's clock frequency to finish a model's arithmetic in half the time does not merely double its power draw; because higher frequencies typically require higher supply voltages to switch transistors reliably, dynamic power can jump roughly eightfold, turning every extra watt into heat that the package and chassis must carry away. That thermal ceiling is the **power wall**, which limits how much computation can occur in a given volume. Dynamic CMOS power follows equation 2.2, where C is capacitance, V is supply voltage, and f is clock frequency. Under the illustrative assumption that voltage rises proportionally with frequency ($V \propto f$), dynamic power rises cubically (Power $\propto f^3$). The exact voltage-frequency relationship varies by device, but increasing both consumes thermal headroom rapidly.

$$\text{Power} \propto C \times V^2 \times f \quad \text{where } V \propto f \implies \text{Power} \propto f^3 \tag{2.2}$$

When broad voltage scaling broke down in the mid-2000s,[3] that cubic penalty ended "free" frequency speedups and forced hardware designers toward parallelism (multi-core CPUs) and domain-specific specialization (GPUs and Tensor Processing Units (TPUs)[4]). Figure 2.2 records that turn across five decades of processors. From the mid-2000s to the early 2020s the largest chips gained about 190× more transistors, yet the fastest clock stayed near 4.7 GHz and single-thread performance rose only 5×, against 21× in the decade before; the added transistors went into more cores and specialized units rather than a faster single thread.

The same limit is tightest on mobile devices, which hit a thermal ceiling at 3–5 W; exceeding it causes "throttling," where the device reduces performance to prevent overheating, a trace worked through in notebook 2.9. This physical limit gives rise to mobile ML: battery-powered devices cannot simply run cloud-scale models locally.

The memory wall

An accelerator's matrix units can finish a block of multiplications in nanoseconds, yet spend most of an inference step sitting idle while weights and activations trickle in from off-chip DRAM. The **memory wall** (Wulf and McKee 1995) names this widening gap between processor speed and memory delivery, which shows up in ML chiefly as a bandwidth[5] shortfall. A rough sketch with representative annual growth factors shows why the gap compounds:

$$\frac{\text{Compute Growth Rate}}{\text{Memory Bandwidth Growth Rate}} \approx \frac{1.6}{1.2} \approx 1.33 \tag{2.3}$$

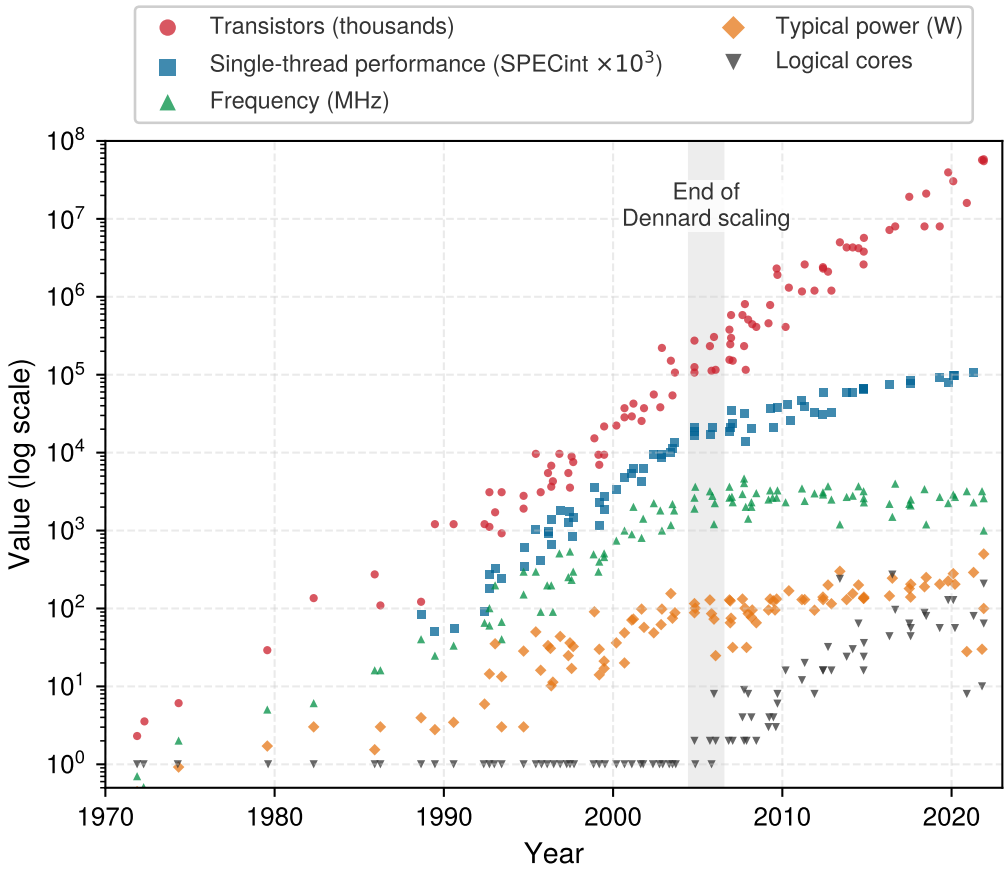
In equation 2.3, the numerator and denominator are dimensionless annual growth factors. A ratio above 1 means compute capability is pulling away from memory bandwidth, so each hardware generation makes data movement a larger share of the performance problem unless the workload increases locality or arithmetic intensity (operations performed per byte moved).

[2] **Latency**: The time between issuing a request and receiving a result, corresponding to T in the iron law, where propagation delay enters through the fixed-overhead term L_{lat}. The light barrier makes that propagation floor irreducible, as equation 2.1 quantifies. Every millisecond consumed by distance is a millisecond unavailable for model inference, which is why the light barrier forces paradigm selection rather than mere optimization.

[3] **Dennard scaling**: Named after Robert Dennard, whose IBM team described MOSFET scaling relationships under which shrinking devices could reduce voltage and current while keeping power density approximately controlled (Dennard et al. 1974). As voltage scaling slowed and energy became a first-order architectural constraint, performance growth shifted toward parallelism and specialization: multi-core processors, GPUs, and TPUs (Hennessy and Patterson 2019; Esmaeilzadeh et al. 2011).

[4] **Tensor processing unit (TPU)**: An application-specific integrated circuit (ASIC) designed for operations common in ML, especially matrix multiplication. PFLOP/s-to-EFLOP/s figures describe aggregated TPU systems rather than one chip. Specialization trades general-purpose flexibility for workload-dependent efficiency; its advantage over a GPU depends on the model, numerical format, and systems being compared (Jouppi et al. 2023).

[5] **Memory bandwidth (the memory wall)**: The term "memory wall" comes from Wulf and McKee (1995), who predicted that the processor-memory performance gap would eventually dominate system performance, a prediction borne out for ML workloads in which weight or activation movement can bind performance. Whether bandwidth binds a given workload depends on arithmetic intensity, batch size, data reuse, access pattern, and hardware balance rather than model size alone.



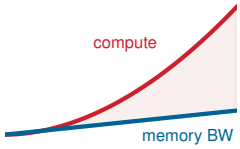


Figure 2.2: Fifty Years of Microprocessor Trends: Transistor count, single-thread performance (SPECint benchmark score), clock frequency, typical power, and logical core count of microprocessors from 1971 to 2021 on a logarithmic axis. Transistor counts keep rising after the mid-2000s while frequency and typical power level off and single-thread performance slows; the gray band marks the end of Dennard scaling, after which added transistors went into more cores. Data from Karl Rupp (2022).

This illustrative trend comparison assumes that compute capacity doubles every 18 months, about 1.6× per year (the numerator of equation 2.3), while memory bandwidth grows by ~20 percent annually (the denominator). These assumed rates illustrate the widening gap rather than a forecast for every hardware generation. Sustained for a decade, those rates leave compute about 16× further ahead of bandwidth than at the start. This widening gap makes data movement a frequent bottleneck, in both time and energy, for ML workloads. An on-chip arithmetic logic unit (ALU) operates over short local connections, whereas an off-chip DRAM access also drives memory interfaces and longer interconnects. In representative hardware, fetching operands from DRAM can cost orders of magnitude more energy than the arithmetic performed on them (Horowitz 2014). The ratio depends on the operation, numerical precision, memory technology, and amount of data transferred. The constraint affects all paradigms, and it takes a different form on TinyML devices, where capacity, not bandwidth, is usually exhausted first.

Compute capacity outruns memory bandwidth; the widening gap is the memory wall.

> Checkpoint 2.1: Physical constraints and deployment
>
> Deployment choices are governed by physics, not just preference. Check your understanding:
>
> - ☐ **Light barrier**: Can you use the cross-country propagation bound to explain why that distant cloud path cannot meet a < 10 ms safety deadline?

↪ The architectural responses to the memory wall, high-bandwidth memory (HBM) and on-chip SRAM hierarchies, are developed in section 11.5.3.

- ☐ **Power wall**: Can you explain why a workload that exceeds a phone's sustained heat-dissipation budget cannot maintain its initial performance?
- ☐ **Memory wall**: Can you explain why data movement is often more expensive (in time and energy) than computation?

These physical laws explain the trade-offs behind the four paradigms. Physical limits decide which designs can work at all; privacy regulation, economic incentives, and data sovereignty requirements further restrict the choices within those limits. No regulation can make the speed of light faster, and no economic model can repeal thermodynamics. Nor do those walls act in isolation: in practice, an ML system is limited by whichever physical boundary binds on its primary resource first. Evaluating these limits quantitatively requires analytical tools: the iron law to decompose execution time into its components, the bottleneck principle to identify the rate-limiting stage, and workload archetypes to classify the model's resource demands.

2.3 Analyzing Workloads

A vision model that saturates accelerator compute units during batched training can stall on memory bandwidth when serving one image at a time, and a model that runs effortlessly in a data center can overheat a phone in under a minute. Deciding which physical resource binds first on the target hardware—whether for a recommendation engine or a wake-word detector—requires the iron law of ML systems from section 1.7, restated here in the same notation because every tier in this chapter is analyzed through it. For a serialized execution path, equation 2.4 adds three costs:

$$T = \frac{D_{\text{vol}}}{\text{BW}} + \frac{O}{R_{\text{peak}} \cdot \eta_{\text{hw}}} + L_{\text{lat}} \tag{2.4}$$

Equation 2.4 decomposes total latency into three terms: data movement (D_{vol}/BW), compute ($O/(R_{\text{peak}} \cdot \eta_{\text{hw}})$), and fixed overhead ($L_{\text{lat}}$). For an inference path that executes these stages sequentially, their times add. A single request can also contain overlapping work, so its latency must follow the actual dependencies. In production systems, however, tasks are processed continuously as a stream, and the analysis shifts from single-task latency to identifying which term limits the system. The answer depends on the workload, its execution conditions, and the deployment hardware. A workload is **compute bound** when its compute term $O/(R_{\text{peak}} \cdot \eta_{\text{hw}})$ exceeds its data term D_{vol}/BW, and bandwidth-bound in the reverse case.

2.3.1 The bottleneck principle

Adding a twice-as-fast accelerator to a serving pipeline does nothing for steady-state throughput if the processor spends half of every step waiting for the memory bus to deliver the next batch of weights. Where the iron law quantifies the cost of each stage, the **bottleneck principle** identifies which stage governs continuous throughput. Section 1.7 gave the overlapped form of the iron law for **pipelined execution**, in which the memory system prefetches batch $k+1$ while the accelerator computes on batch k. The slowest stage then hides the others and sets the interval between completions, so speeding a nonlimiting stage does not raise ideal steady-state throughput while the system bottleneck remains unchanged. Deployment adds one more overlapped stage, T_{IO}, the time to transfer data over a storage or network link, including offloading a request to a remote server. Equation 2.5 extends the pipelined form with that stage. Here the left-hand side is the steady-state time per completed task, with fixed overhead treated as nonoverlapped; equality requires ideal overlap of the other stages:

$$T_{\text{pipelined}} \geq \max\left(\frac{D_{\text{vol}}}{\text{BW}}, \frac{O}{R_{\text{peak}} \cdot \eta_{\text{hw}}}, T_{\text{IO}}\right) + L_{\text{lat}} \tag{2.5}$$

When a system is bandwidth-bound ($D_{\text{vol}}/\text{BW} > O/(R_{\text{peak}} \cdot \eta_{\text{hw}})$), faster processors ($R_{\text{peak}}$) do not raise ideal pipeline throughput while memory remains the slowest stage, just as widening a highway cannot help traffic constrained by a narrow bridge. Shortening a sequential compute stage can still reduce an individual request's latency. Engineers must identify the dominant term before

optimizing. The *additive form* in equation 2.4 describes a single task's serialized path and the *max form* in equation 2.5 an ideally overlapped continuous stream; the actual dependencies determine which stages can overlap.

2.3.2 Workload archetypes

The bottleneck principle reduces optimization to identifying the dominant constraint for a given workload. The answer depends on all three D·A·M axes at once: the data a request carries, the algorithm's arithmetic and memory demands, and the machine that executes it. Different deployment environments create different bottlenecks along these axes, so the same model family can require different engineering when it moves from a cloud server with terabytes of memory to a microcontroller with kilobytes. Classifying workloads by what binds them first yields four **workload archetypes**.[6] Each archetype is a recurring physical bottleneck that determines which engineering moves can help. Two of them correspond to terms of the iron law. The other two are bound by preconditions the time equation assumes are already met, namely that the working set fits in memory and that the energy budget can pay for the run. A capacity or energy limit can therefore decide feasibility before any term of equation 2.4 is evaluated.

[6] **Workload archetype**: A classification of ML workloads by their dominant bottleneck rather than by their model family. Misidentifying the archetype wastes optimization effort on the wrong term of the iron law, as when teams add accelerator FLOP/s to a bandwidth-bound inference pipeline and obtain little improvement while memory transfer remains dominant.

The first split, between the two iron-law terms, separates arithmetic-bound systems from data-movement-bound systems. A **compute-bound** workload performs many calculations per byte loaded, so progress comes from higher arithmetic throughput, better utilization, and more parallel execution; large neural-network training is the canonical case. A **bandwidth-bound** workload, by contrast, waits on dense weight or activation movement, so wider memory buses and better data reuse matter more than additional peak FLOP/s; autoregressive text generation illustrates this regime. The roofline literature calls this regime *memory-bound*; this book says bandwidth-bound to keep it distinct from running out of memory capacity, which is the next archetype.

The second split covers workloads where the binding constraint is not a term of the time equation at all. **Capacity-bound** workloads are dominated by irregular table lookups and poor cache locality, so memory capacity, access latency, and communication shape performance in recommendation systems with massive embedding tables. **Power-bound** workloads face the opposite envelope: energy per inference and memory footprint, not raw speed, determine whether always-on sensing can run at all.

Lighthouse 2.1: Five reference workloads

The introduction (section 1.7.1) introduced five lighthouse models by the system bottleneck each isolates (table 1.4); table 2.2 pairs each with a representative workload archetype and deployment paradigm. The classifications describe operating regimes: batched image processing can emphasize arithmetic, single-request text generation can emphasize weight transfers, and a large recommendation table can exceed local memory capacity. Changing batch size, model size, or hardware can change the binding constraint. MobileNetV2 shows why. In table 2.2, it sits with the compute-oriented vision workloads because its pointwise convolutions carry most of its arithmetic, sized down to fit mobile thermal and energy envelopes. Its depthwise layers, however, perform few operations per byte and are often bandwidth-bound on mobile accelerators. Whether arithmetic throughput or memory bandwidth ultimately binds MobileNetV2 on a specific device depends on target hardware balance, precision, and batching, as the roofline analyses in section 2.4 demonstrate. Chapter 6 opens up the architecture behind each lighthouse.

Table 2.2: Five Lighthouse Models: Five recurring workloads ground the iron law in concrete practice throughout the book. Each lighthouse pairs a home regime (compute-bound, bandwidth-bound, capacity-bound, power-bound) with the deployment paradigm where it predominantly runs, illustrating a distinct resource constraint under representative execution conditions.

Lighthouse	Archetype	Deployment Paradigm
ResNet-50	Compute-bound	Cloud training, edge inference
GPT-2/Llama	Bandwidth-bound (decode)	Cloud inference
DLRM	Capacity-bound	Cloud for large tables
MobileNetV2	Compute-bound (efficient regime)	Mobile, edge
Keyword Spotting (KWS)	Power-bound	TinyML, always-on

Large-scale compute-bound training and capacity-bound workloads gravitate to cloud data centers; compact vision workloads operating in efficient compute-bound regimes such as MobileNetV2 can fit mobile and edge devices; bandwidth-bound decoding runs in the cloud unless a smaller model fits locally; and power-bound workloads belong on microcontrollers. Those placements become concrete once each lighthouse is given its cost. The image classifier **ResNet-50** spends approximately 8.2 GFLOP per image on 25.6 million parameters, which occupy 102.4 MB at FP32 (He et al. 2016a). That regular, compute-dense structure makes it the canonical benchmark for hardware accelerator performance.

The language models **GPT-2/Llama** exemplify autoregressive text generation (Radford et al. 2019; Touvron, Lavril, et al. 2023; Touvron, Martin, et al. 2023). These models generate text one token at a time. Because multi-billion parameter models exceed on-chip cache, weights reside in external memory; generating text token-by-token for one request at a time forces the processor to stream the weights across the memory bus for each token with little reuse across inputs (1.5 billion parameters for GPT-2, 7 billion–70 billion parameters for Llama). This sequential access pattern creates an autoregressive bottleneck that shapes serving cost (Pope et al. 2023).

↪ Continuous batching and KV-cache paging, the runtime mechanisms that serve token-by-token generation, are developed in section 13.9.4.

The recommendation lighthouse, **DLRM**[7], represents the embedding-heavy recommendation workload behind large-scale "You might also like" systems (Naumov et al. 2019). It maps users and items to embedding vectors stored in tables that can exceed 100 GB of embeddings, making memory capacity rather than computation the binding constraint.

The mobile lighthouse, **MobileNetV2**, performs the same image classification task as ResNet-50 while cutting its computation by 13.7× (Sandler et al. 2018). It gets there by restructuring the image-filtering layers, splitting each expensive filtering step into two much cheaper ones (depthwise separable convolutions). That reduction makes it a candidate for real-time inference within a smartphone's 3–5 W envelope; the implementation and workload determine whether it meets the deadline.

The TinyML lighthouse, **keyword spotting (KWS)**, represents the always-on sensing archetype. KWS systems detect short trigger phrases with compact models built for resource-constrained microcontrollers (Y. Zhang et al. 2017). The lighthouse workload has approximately 200K parameters, about 200 KB at INT8 (stored in flash), placing it in the kilobyte-memory, milliwatt-budget TinyML regime.

A smart doorbell, a TinyML scenario that recurs through later chapters alongside the five lighthouses, applies the same always-on pattern to vision. A visual wake-word model (Chowdhery et al. 2019), a small classifier that answers only whether a person is in view, runs on an ESP32-S3 microcontroller, the TinyML platform of table 2.4. Its feasibility is screened in two levels, storage first and latency second. At level 1, the 0.5 MB of 16-bit weights occupy 11.9 percent of the 4.2 MB flash. Passing this storage check does not establish complete memory fit, because intermediate results and runtime state must also fit in SRAM, the two-tier split that section 2.8.1 develops. Level 2 applies the iron law. The model needs 25 MFLOP per frame, and the microcontroller sustains about 0.25 GFLOP/s at this precision, so compute takes 100 ms; about 1 ms of fixed overhead brings the total to 101 ms. That estimate clears the scenario's canonical 200 ms budget; sensor acquisition and any data movement omitted by the estimate must still be checked. A more responsive chime with a 50

[7] **Deep learning recommendation model (DLRM)**: Meta's 2019 architecture that exemplifies the capacity-bound archetype. At that scale, memory capacity and communication BW can constrain execution more than raw R_{peak}. These demands motivate specialized cluster designs where memory, not arithmetic, is the scarce resource.

↪ How depthwise separable convolutions factor one filtering step into two cheaper ones is developed in section 6.3.5.

ms budget changes the verdict without changing the model, and figure 2.3 plots that tightened case. In the plot, flash stays far below the saturation line while latency reaches 202 percent of its budget. Flash storage was not the binding constraint; latency is, and on-chip SRAM still has to be checked separately.

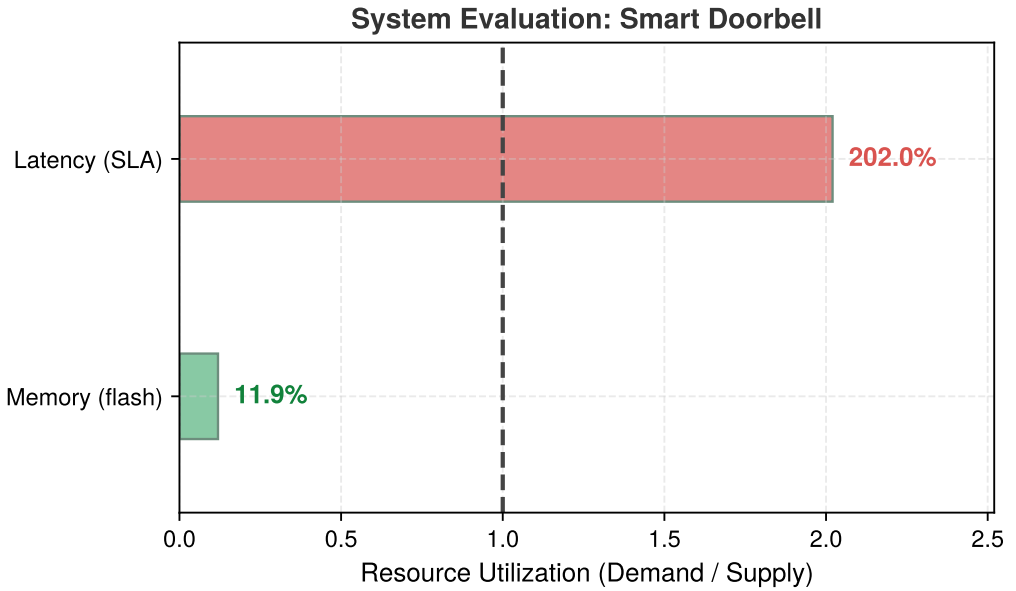

Figure 2.3: Smart Doorbell Constraint Scorecard: Each bar is demand over supply, so the dashed line marks the point where a level is exactly saturated. The model occupies a small fraction of the ESP32-S3's 4 MB flash budget (Level 1: PASS), but its 101 ms latency (25 MFLOP of compute plus fixed overhead) is twice a tightened 50 ms budget for a responsive chime (Level 2: FAIL), even though it clears the scenario's canonical 200 ms budget.

The range in compute requirements and memory footprints explains why no single deployment paradigm fits all workloads. A keyword spotter can operate with roughly 20 MFLOP per inference and about 200 KB of INT8 weights, while ResNet-50 requires about 8.2 GFLOP per image and roughly 102.4 MB of FP32 weights. The reference DLRM example already reaches 100 GB, and Meta has demonstrated scaling recommendation models to 100 TB using embedding offloading (Park et al. 2024). Language models add a bandwidth-dominated regime, with billions of parameters streamed repeatedly from memory during autoregressive inference. Whether each of these demands is affordable depends on the compute, bandwidth, and memory a given platform supplies.

2.4 System Balance and Hardware

A model that clears its latency budget on paper can still stall on a real host if PCIe transfers between CPU and GPU memory choke the pipeline or if single-sample inference leaves the accelerator's matrix units starved for bytes. Checking the iron law and workload archetypes against real hardware means tracing a request through every layer of one host, from the application's latency or throughput target down to the silicon that must meet it.

2.4.1 Inside one machine: The single-node stack

When an application issues an inference request or a training step on a single machine, that work travels down a four-layer **single-node stack**, which refines the machine side of the D·A·M taxonomy for one host while data and algorithm enter through workload requirements. At the top of the stack, the application defines the mission through a training-throughput or inference-latency target, and the ML framework below it translates model code into executable operations that aim to meet that target. Those operations then pass through the operating system, drivers, and runtime, which coordinate resources and move tensors between host memory and accelerator memory, down to

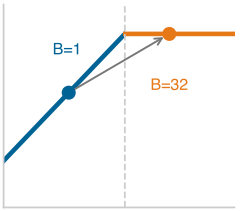
the hardware itself—where HBM capacity, memory bandwidth, intra-node interconnects such as NVLink, and compute throughput set the physical limits, with the memory wall as a recurring constraint.

The hardware layer fixes the terms on offer to any model: a memory bandwidth (BW), a peak compute rate (R_{peak}), and a fixed overhead (L_{lat}). These are the terms of the silicon contract. The hardware offers them, and the workload and its execution conditions determine which resource limits progress first. Deployment analysis works with the hardware's half, asking which term a given platform makes scarce; the model architecture's half, the choice of which resource to saturate, belongs to chapter 6.

↪ How an ML framework turns model code into executed operations, eagerly or through a captured graph, is developed in section 7.3.

↩ The iron law of ML systems and its decomposition of end-to-end latency are established in section 1.7.

2.4.2 Matching workloads to hardware



Before profiling cache reuse or arithmetic intensity, an engineer can rule out impossible hardware placements with a two-step test that proceeds from coarse to fine. The coarse test asks whether an operation can fit inside the latency budget at all. The fine test asks which hardware resource limits the operations that do fit, and its answer depends on system balance, the ratio of peak compute throughput to memory bandwidth and I/O capacity on a given platform.

Operation latencies supply the coarse test, and they turn latency-vs-throughput trade-offs into decisions through concrete numbers. They span roughly eight orders of magnitude, from about a nanosecond for an on-chip cache hit or a single accelerator multiply, through milliseconds for one mobile vision inference, to tens or hundreds of milliseconds for a cross-region network call. Section D.1 collects the memory-hierarchy and network round-trip anchors along with illustrative application latency budgets. The span matters because of one strict rule: an operation with latency $> T_{\text{deadline}}$ *cannot* appear on the critical path of a system whose latency budget is T_{deadline} ms.[8]

For the operations that pass the latency test, system balance decides which resource limits them. Roofline analysis classifies bottlenecks by comparing a workload's arithmetic intensity, the operations it performs per byte moved (FLOP/byte), against the hardware machine balance point ($R_{\text{peak}}/\text{BW}$), the ridge point (Williams et al. 2009) introduced with the iron law in section 1.7. The framing is informal here; section 11.6 develops the model and the ridge point that separates the memory-bound and compute-bound regimes, with a worked derivation collected for reference in section D.2.1. In that framing, the same ResNet-50 model can shift from compute-bound training behavior at high batch sizes to more memory-sensitive single-image inference at batch=1. Deployment paradigm selection must account for this shift.

The batch-size shift is one instance of a broader change between execution phases, in which physical constraints reconfigure all three D·A·M axes at once. Training updates model weights from batches of examples; serving applies fixed weights to new inputs. Table 2.3 contrasts typical training and latency-sensitive serving demands; cloud serving can also batch requests for throughput.

8 | **Critical path**: The longest sequential chain of dependent operations in a pipeline. The decision rule in the triggering sentence is strict: if a 200 ms cross-region network call appears anywhere on the critical path, a system with a 100 ms total budget is guaranteed to fail regardless of how fast every other stage runs. Model inference need not be the longest stage; preprocessing and postprocessing can dominate, making the critical path longer than model execution alone suggests.

In this example, batching moves the workload from the memory-bound side toward the compute ceiling.

Table 2.3: D·A·M × Phase: The same model imposes starkly different demands on Data, Algorithm, and Machine depending on whether the system is training or serving. When bottlenecks shift unexpectedly, check which phase is currently being optimized.

Component	Training (Mutable)	Inference (Immutable)
Data	Massive throughput: large batches, shuffling, augmentation	Low latency: single samples, freshness, speed
Algorithm	Learning phase: update model parameters from examples	Prediction phase: apply fixed weights to new inputs
Machine	Throughput-optimized: high-bandwidth clusters, large memory	Latency-optimized: edge devices, inference accelerators

ResNet-50 inference on a high-end data center accelerator and on a mobile neural processing unit (NPU)[9] puts numbers on this analysis. The hardware figures are point-in-time anchors; the reasoning rests on compute rate, memory bandwidth, and batch size, which outlast any one product.

9 | **Neural processing unit (NPU)**: A dedicated hardware block on a mobile system-on-chip whose circuits are designed for low-precision tensor operations. This specialization can improve energy efficiency relative to CPU execution, helping AI workloads fit within mobile power budgets.

Napkin Math 2.1: ResNet-50 on cloud vs. mobile

Problem: Is ResNet-50 inference compute-bound or bandwidth-bound on (a) a high-end data center accelerator (an NVIDIA A100) and (b) a flagship mobile NPU?
Given (from lighthouse models):

- ResNet-50: 8.2 GFLOP per inference, 25.6 million parameters (102.4 MB FP32, 51.2 MB FP16)

Analysis:
(a) Cloud data-center accelerator (batch=1, FP16)
The analytical model assumes 56.3 MB moved per inference, including weights and activation traffic. This is a modeled transfer volume, not the stored parameter footprint; reuse and runtime choices can change it.

- Peak compute: 312 TFLOP/s (FP16)
- Memory bandwidth: 2.04 TB/s
- Compute time: $T_{\text{compute}} = \frac{8.20 \times 10^9}{3.12 \times 10^{14}} = 0.026$ ms
- Memory time (weights plus activations): $T_{\text{memory}} = \frac{5.63 \times 10^7}{2.04 \times 10^{12}} = 0.028$ ms
- **Result**: Bottleneck = Memory (1.1× slower than compute)
- **Ridge point**: $R_{\text{peak}}/\text{BW}$ = 312 TFLOP/s ÷ 2.04 TB/s ≈ 153 FLOP/byte.
- **Analysis**: Arithmetic intensity = $\frac{8.20 \times 10^9}{5.63 \times 10^7} = 146$ FLOP/byte, just below the ridge point, so the workload is bandwidth-bound; above the ridge it would be compute bound. For single-image inference, the low batch size yields limited reuse, explaining why even high-throughput accelerators can be bandwidth-bound at batch = 1. Both times use peak rates (efficiency $\eta_{\text{hw}} = 1$ and full bandwidth), so they are lower bounds; because this workload sits close to the ridge, the efficiencies a real kernel achieves decide which term dominates in practice.

(b) Mobile: Flagship NPU (batch=1, INT8)
At INT8, the analytical model assumes 28.2 MB moved per inference, including weights and activation traffic. The INT8 weight footprint below is only one component of that transfer volume.

- Peak compute: ~35 TOPS (INT8), representative of modern mobile NPUs
- Memory bandwidth: ~51.2 GB/s (LPDDR5)
- Model size: 25.6 MB (INT8 quantized)
- Compute time: $T_{\text{compute}} = \frac{8.20 \times 10^9 \text{ INT8 ops}}{3.50 \times 10^{13} \text{ INT8 ops/s}} = 0.23$ ms
- Memory time (weights plus activations): $T_{\text{memory}} = \frac{2.82 \times 10^7}{5.12 \times 10^{10}} = 0.55$ ms
- **Result**: Bottleneck = Memory (2.3× slower than compute)

Systems insight: Under these peak-rate assumptions, both platforms are bandwidth-bound for single-image inference. The A100's faster memory bandwidth (2.04 TB/s vs. 51.2 GB/s = 39.8×) gives roughly 19.9× lower modeled memory-transfer time under the stated FP16 and INT8 traffic assumptions; this ratio is not a measured end-to-end inference speedup. Byte-reduction and lower-precision techniques can therefore beat simply buying more peak FLOP/s for deployment.
ResNet-50 becomes compute bound when batching and data reuse raise computation per byte moved above the hardware balance point, $I > R_{\text{peak}}/\text{BW}$, where $I = O/D_{\text{vol}}$. With ideal reuse during batched inference, each weight is transferred across the memory bus once and used across all B samples in the batch. This amortizes the weight transfer over B inputs, increasing the arithmetic intensity until computation time overtakes memory-transfer time. The crossover is architecture- and implementation-dependent because activation traffic, input/output movement, cache reuse, and runtime execution details all change the effective bytes moved per inference.

The four deployment paradigms gain precision when grounded in concrete hardware. Where table 2.1 defined the paradigms by operating regime, table 2.4 places one real platform in each and pairs it with the per-device envelope that marks the tier.[10] The example-platform and power columns describe complete systems, including a cloud pod, while the tier compute and bandwidth columns describe per-device envelopes. The following spans compare those complete examples, not equivalent individual chips. Memory drops from 128 TB (cloud) to 512 KB (TinyML), a 250 million-fold reduction. Power runs from about 3 MW for the cloud pod to the TinyML tier's average-power target of < 1 mW, and hardware cost spans six orders of magnitude, from multimillion-dollar clusters to $10 microcontrollers. Together with facility overheads such as power usage effectiveness (PUE),[11] these spreads decide which paradigm can serve a workload economically, and they explain why model compression becomes essential as the budget tightens.

The hardware spectrum turns the bottleneck diagnosis into a fit test, in which each workload must be matched to the tier whose compute, bandwidth, power, and cost envelope it can satisfy. These platforms are products of decades of hardware evolution, from floating-point coprocessors in the 1980s through graphics processors in the 2000s to today's domain-specific AI accelerators.

[10] **ML hardware cost spectrum**: The million-fold cost range makes deployment paradigm selection an economics decision as well as a physics decision. The same accuracy target may be achievable on a low-cost microcontroller only after substantial model reduction, or on an expensive data-center accelerator with a much larger resource budget, and the two designs carry fundamentally different latency, power, and operational cost profiles.

[11] **Power usage effectiveness (PUE)**: Total facility energy divided by IT equipment energy over the same period (The Green Grid 2007), developed in section 12.7. It captures facility overhead, including cooling and power distribution. Even a PUE of 1.06 leaves substantial noncompute power at data-center scale. TinyML does not require dedicated facility cooling, although sensing, communication, conversion losses, and sleep power still contribute to its complete system-energy budget. These device-level costs sit outside PUE.

↪ The progression from floating-point coprocessors to domain-specific AI accelerators is developed in section 11.2.1.

Table 2.4: Hardware Spectrum (Concrete Platforms): Each paradigm in table 2.1 is represented by one platform, paired with the per-device compute and memory-bandwidth envelope that marks the tier and the constraint that usually binds first there: an iron-law term for cloud and edge, a precondition outside the time equation for mobile (energy) and TinyML (memory capacity). Envelope figures mark a paradigm's typical class rather than a hard ceiling. The DGX Spark sits at the high end of the edge spectrum as a compact workstation example; most edge deployments use far smaller devices. BF16 and FP4 are reduced-precision number formats (16 and 4 bits per value; "sparse" rates count skipped zero-valued operations); HBM2 and LPDDR5x are high-bandwidth and low-power memory types; NVMe is solid-state storage.

Paradigm	Example Platform	Tier Compute	Tier Memory BW	Power	Price	Binding Constraint
Cloud ML	Google TPU v4 Pod: 4,096 TPU v4 chips, 1.1 EFLOP/s BF16, 128 TB HBM2	> 1000 TFLOP/s	> 1000 GB/s	~3 MW per pod; PUE 1.1–1.3	Rental	Compute (training); memory bandwidth (LLM decode)
Edge ML	NVIDIA DGX Spark: GB10 Grace Blackwell (1 PFLOP/s sparse FP4), 128 GB LPDDR5x, 4 TB NVMe	~1 PFLOP/s	> 270 GB/s	~200 W; 100 W class typical	~$3,000–$5,000	Memory bandwidth
Mobile ML	Flagship smartphone: mobile SoC (CPU + GPU + NPU), 8–16 GB RAM, 128 GB-1 TB storage	15–45 TOPS	51.2–77 GB/s	3–5 W	$999+	Energy (battery and heat)
TinyML	ESP32-S3: dual-core @ 240 MHz, 512 KB SRAM, 4.2 MB flash	< 1 TOPS	—	0.05 W–1.2 W active; < 1 mW average target	$10	Memory capacity (working state must fit in SRAM)

Systems Perspective 2.1: System balance across paradigms

The last column of table 2.4 reads each tier through the pipelined bound in equation 2.5. For cloud and edge the binding constraint is a term of that bound, whereas for mobile and TinyML it is a limit the time equation leaves out, and in every tier the dominant constraint sets the optimization strategy. Compute-bound cloud training rewards higher accelerator utilization and larger batches, while bandwidth-bound large language model (LLM) decode (token-by-token generation) and bandwidth-bound edge inference reward moving fewer bytes—through smaller models, lower precision, and more reuse per loaded weight—so a faster accelerator helps them little. Moving to battery-powered devices adds an implicit energy term: mobile systems integrate power over time under a tight thermal cap, which makes lower precision and duty cycling pay off in both battery life and sustained speed, while TinyML faces a strict memory precondition before any time or energy term applies, because weights and code must fit in flash and activations and runtime state must fit in SRAM through compact models and

low-precision arithmetic. Section A.5.3 maps each dominant term to the optimizations that work and the ones that are wasted, turning this diagnosis into an action plan.

Each paradigm is therefore an operating envelope with different resource budgets, and moving from warehouse data centers down to microcontrollers traces a physical gradient that trades raw compute throughput for energy and memory efficiency. The four sections that follow walk that gradient one tier at a time, and each asks the same four questions, which the constraint map in each section draws as four branches: which constraint binds, how the system responds, where the paradigm fails, and which workloads fit. Because that structure is shared, each section concentrates on what is distinctive about its tier and on the one or two calculations that decide whether a workload belongs there.

2.5 Cloud ML: Computational Power

Consider the estimated resources needed to train GPT-3 (Brown et al. 2020): 3,634 PFLOP-days of computation, equivalent to 10,000 V100 GPUs running for approximately 15 days at the reported sustained rate, and about 1.3 GWh of electricity (Patterson et al. 2021). A PFLOP-day is 10^{15} FLOP/s sustained for one day, about 8.6×10^{19} FLOPs, so this total is the same few hundred zettaFLOPs estimated from the model's parameter and token counts in section 1.3.3. At the hardware rates used in that estimate, a smartphone or edge server could not have completed this training run on a practical schedule. It required a data-center-scale cluster with enough aggregate compute, memory, and storage. The bitter lesson shows up here as hardware. General methods that improve with computation keep winning, and the computation they consume concentrates wherever power, cooling, and accelerators can be pooled. Cloud ML follows from this proposition. When latency can be tolerated, it offers computational scale that no other paradigm can match. Training location does not fix serving location, however, because a trained model or a smaller derived version can later run near users and sensors.

Centralizing these resources under a utility model[12] allows providers to assemble specialized accelerator topologies tailored to distinct hardware demands. This infrastructure serves as the natural home for three of the four workload archetypes: compute-bound workloads like ResNet training that demand sustained TFLOP/s across thousands of accelerators, bandwidth-bound workloads like large language model inference that benefit from TB/s HBM bandwidth, and capacity-bound workloads like DLRM-style recommendation engines, whose embedding tables routinely exceed terabytes in aggregate, far beyond any single accelerator. Those tables are sharded across pooled host and accelerator memory, so distributed lookups and training updates place heavy demands on the cluster interconnect. Voice assistants show the split between tiers: they lean on the cloud for language understanding while their always-on wake-word stage runs on the device, a division that section 2.10 quantifies. Even as cloud deployments scale from single-accelerator instances to warehouse-scale clusters, systems engineering at every one of these scales begins on a single node, with memory bus saturation, PCIe and NVLink bandwidth, and accelerator utilization inside one machine.

↩ The bitter lesson, the book's account of why compute-scaled general methods keep winning, is established in section 1.4.

[12] **Cloud as utility computing**: A provisioning model in which a provider owns and operates a specialized hardware portfolio that few organizations could economically maintain themselves and rents it on demand. Renting gives direct access to the architecture each workload archetype requires, such as dense accelerator pods for compute-bound workloads, HBM-equipped nodes for bandwidth-bound workloads, and high-memory systems with fast interconnects for capacity-bound workloads, without purchasing and maintaining the entire installation.

↪ The memory-capacity bounds and sparse gather patterns of high-cardinality embedding tables are developed in section 6.8.

Definition 2.1: Cloud ML

Cloud machine learning is the deployment paradigm that trades latency for elastic compute by locating ML workloads in centralized data centers, decoupling computational capacity from the physical location of data sources and users.

1. **Significance**: Cloud deployment dominates the R_{peak} term: a cloud region can pool thousands of accelerators, with access governed by capacity, quotas, and cost. The trade-off is the L_{lat} term: a minimum round-trip latency of 10–100 ms (set by the speed of light over continental distances) makes those distant cloud paths infeasible for workloads requiring sub-10 ms response.
2. **Distinction**: Unlike edge ML, which prioritizes local response and data locality at fixed R_{peak}, cloud ML prioritizes elastic R_{peak} at the cost of variable L_{lat}.

3. **Common pitfall**: A frequent misconception is that cloud ML is "unlimited compute." In reality, the distance penalty (L_{lat}) and the ingestion bottleneck (D_{vol}/BW) are physics constraints that no software optimization can eliminate, setting a hard floor on response time for any workload whose data originates outside the data center.

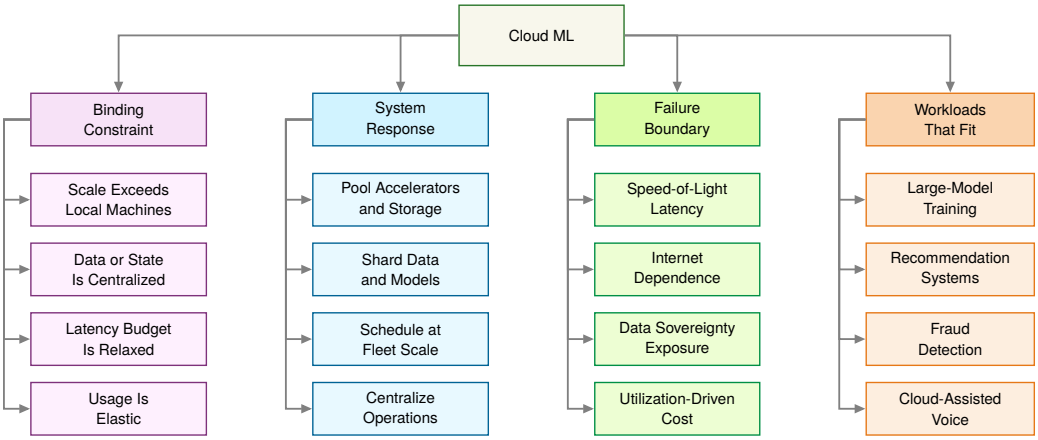


Figure 2.4: Cloud ML Constraint Map: Centralized infrastructure solves the scale problem for compute-bound workloads, bandwidth-bound workloads, and capacity-bound workloads, but it introduces the distance, dependency, privacy, and cost constraints that determine when cloud ML stops being the right deployment target.

Pooling elastic accelerators and sharding models overcome local capacity ceilings, but they meet hard failure boundaries in speed-of-light propagation latency and internet dependence (figure 2.4). Workloads that thrive in this regime (such as asynchronous fraud detection, batch recommendation updates, and large language model pretraining) accept this trade because scale matters more than instantaneous response. When an application requires real-time control, however, network latency stops being an engineering inconvenience and becomes a hard physical barrier. The light-barrier calculation already ruled out a cross-country data center for a 10 ms budget; the sharper question is whether a regional data center, much closer to the machine it protects, fares any better.

Napkin Math 2.2: The distance penalty

Problem: Consider a real-time safety monitor for a robotic arm on a factory floor. The safety logic requires a 10 ms end-to-end response time to prevent injury, so the distance penalty imposed by the light barrier matters. The model runs in a regional cloud data center 1,500 km away, less than half the cross-country distance. Can the safety budget be met?

Physics:

1. **Light in fiber**: ~200,000 km/s.
2. **Round-trip propagation**: (1,500 km $\times$ 2)/200,000 km/s = 15 ms.
3. **Result**: Round-trip propagation alone requires 15 ms, exceeding the 10 ms end-to-end budget by 5 ms before the model performs any inference.

Systems insight: The specified regional cloud path misses the budget on propagation alone and is therefore infeasible. Running the model beside the arm removes that remote propagation term, but the complete local sensing, inference, and control path must still be checked against the deadline.

2.5.1 Cloud infrastructure and scale

Training a frontier model across hundreds of terabytes of data requires connecting thousands of accelerator chips so tightly that they behave like one computer. Cloud ML concentrates computational

resources at physical dimensions no local device approaches: TPU supercomputer designs organize thousands of specialized accelerator chips into data-center-scale systems that deliver PFLOP/s-to-EFLOP/s reduced-precision throughput (Jouppi et al. 2023), orders of magnitude beyond the edge and mobile rows of table 2.4. Warehouse-scale facilities pack aisles of liquid-cooled racks and dense optical cabling that draw megawatts to sustain that exaFLOP-scale matrix throughput (figure 2.5), providing the physical scale that makes training on hundreds of terabytes of data practical.

↪ What changes when training extends beyond a single node is developed in section 8.7.2.

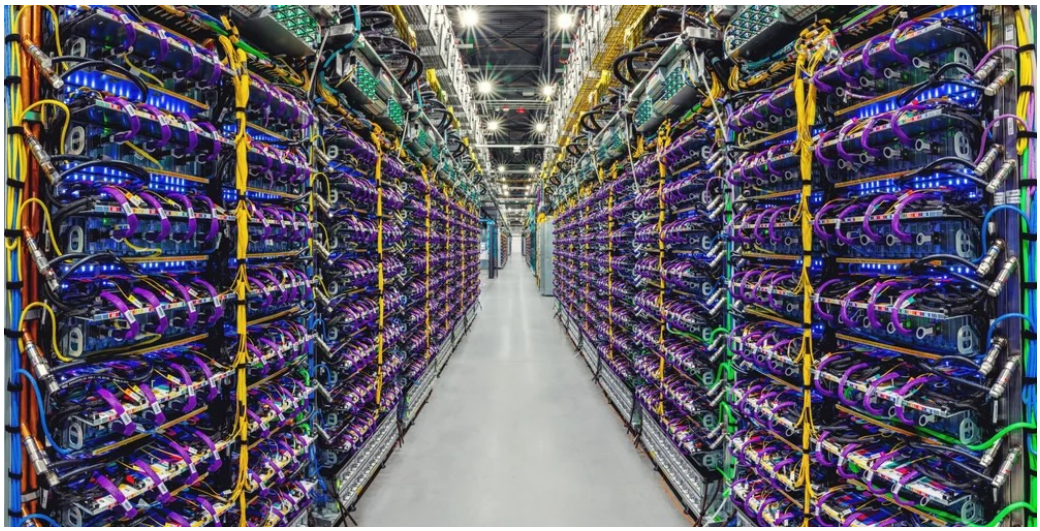

Figure 2.5: Cloud Data Center Scale: Dedicated accelerator facilities aggregate thousands of specialized TPU chips in liquid-cooled racks to deliver exaFLOP-scale matrix throughput. This centralized infrastructure makes large-scale model training and high-throughput serving viable, but incurs megawatt-scale power consumption and speed-of-light network distance penalties. Source: (Pichai 2023).

Centralization also changes how models are served and governed. Cloud APIs make trained models accessible worldwide across mobile, web, and IoT platforms. Shared infrastructure enables engineering teams to collaborate with unified version control, while pay-as-you-go pricing models convert upfront capital expenditure (CapEx) into usage-based operational expenditure (OpEx) that scales with demand.

Scale does not make the cloud universally superior. The data-gravity principle (2) explains why. Shipping a dataset of size D_{vol} over a network link of bandwidth $\text{BW}_{\text{network}}$ takes $D_{\text{vol}}/\text{BW}_{\text{network}}$, a time that grows with the data, while shipping the computation (a model and its code) costs roughly the same however much data waits at the other end. As data volume grows, moving the data to a remote cluster therefore eventually costs more than moving the computation to the data. Section B.1.1 works through the transfer arithmetic, and the edge section applies the same comparison to a single request under a deadline. The deployment paradigm is dictated by the binding physical constraint, not by the largest available throughput.

2.5.2 Cloud ML trade-offs and constraints

A regional cloud outage can take down every connected client at once, and a sudden traffic spike can turn an elastic GPU pool into a runaway monthly bill. For latency-sensitive workloads, the distance penalty is the cloud's most consequential cost, and network jitter makes it unpredictable as well as large. Three further costs follow from centralization: the exposure of data the cloud must receive, spending that scales with use, and dependence on the network.

The first cost is privacy and security. Transmitting sensitive data to remote data centers expands the disclosure surface and complicates regulatory compliance. Organizations handling data subject to regulations such as the General Data Protection Regulation (GDPR) or the Health Insurance Portability and Accountability Act (HIPAA) must select, document, and maintain safeguards appropriate to the data, system, and applicable legal duties. Privacy-preserving approaches can reduce

how much sensitive data leaves its original environment, but they complement rather than replace infrastructure controls.

The second cost is financial, because cloud infrastructure turns upfront hardware purchases into ongoing operating bills. Comparing paradigms by raw accelerator hourly rates obscures the cumulative expenses of network egress, persistent storage, and managed orchestration. Sound evaluation instead compares **total cost of ownership (TCO)**, which includes power, cooling, and labor and weighs upfront capital expense against recurring operating expense over the system's lifetime.

A vision system serves 1M daily inferences at ResNet-50 scale (10 ms latency, 100 KB response). The TCO analysis begins with an illustrative budget spanning 3 years. It includes the listed components rather than a complete, matched TCO. Cloud operating labor, edge redundancy, installation, and failure recovery are not included, and comparable capacity and availability have not been established. The 4 instances are a provisioning choice (redundancy and headroom for traffic peaks), not a throughput requirement. Table 2.5 itemizes the annual GPU, network, load-balancer, and observability costs of this fixed-capacity cloud implementation under public list pricing, and table 2.6 itemizes the corresponding hardware, power, cooling, network, and DevOps labor costs of an on-premises edge-server implementation.

Table 2.5: Cloud Inference Annual Budget: The fixed-capacity cloud implementation of the ResNet-50-scale vision workload incurs itemized GPU, network, load-balancer, and observability costs.

Cost Component	Calculation	Annual Cost
GPU inference	4 instances × 8760 h/year × $0.75/hr	~$26,280
Network egress	100 GB/day × 365 d/year × $0.09/GB	~$3,285
Load balancer	$0.025/hr + capacity units	~$3,723
Monitoring/logging	Monitoring, alerts	~$2,000
Total Cloud		**~$35,288/year**

Table 2.6: Edge Inference Annual Budget: The on-premises edge-server implementation incurs itemized hardware, power, cooling, network, and DevOps labor costs, and labor is the dominant component in this scenario.

Cost Component	Calculation	Annual Cost
Hardware CapEx	$15,000 ÷ 3 years life	~$5,000
Power (24/7)	300 W × 8760 h/year × $0.12/kWh	~$315
Cooling overhead	~30% of power	~$95
Network (fiber)	Fixed line for remote management	~$1,200
DevOps labor	0.1 FTE × $150,000 salary	~$15,000
Total Edge		**~$21,610/year**

Napkin Math 2.3: Cloud vs. edge annual budgets

Problem: Under the partial accounting boundaries itemized in table 2.5 and table 2.6, which implementation has the lower estimated annual budget over 3 years?

Math: The question is the annual cost at this operating point, so the comparison is the gap between the cloud and edge annual totals.

At 1M inferences/day, the gap is ~$35,288/year − ~$21,610/year = ~$13,678/year. Almost all of the cloud cost is provisioned capacity rather than use. At 10 ms per request the day's traffic needs only about 2.8 GPU-hours of the 96 provisioned, about 2.9 percent utilization. Only egress scales with traffic.

Result: The listed edge budget costs about 38.8 percent less at this operating point. Because the fixed cloud pool alone already costs more than the listed edge budget, no traffic level under this fixed provisioning and partial accounting makes the cloud cheaper; a genuine break-even analysis would need cloud capacity that scales with demand.

Systems insight: The listed edge budget is dominated by labor (~$15,000 ÷ ~$21,610/year ≈ 69.4 percent), not hardware. Organizations without existing DevOps capacity should factor in the full cost of maintaining on-premises infrastructure.

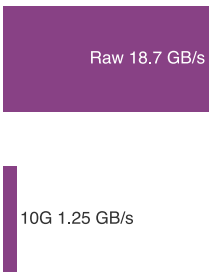
Unpredictable usage spikes also complicate budgeting and call for automated monitoring and cost governance. Network dependency, the last of the three costs, creates an availability hazard: any connectivity disruption between clients and the data center immediately degrades or halts service. Proprietary cloud APIs compound the dependency with vendor lock-in, making it harder to move workloads from one provider to another. Even so, centralized infrastructure remains uniquely suited to consumer-scale services that require elastic capacity, such as voice assistants and recommendation engines. These applications trade latency for scale, accepting remote-path delay in exchange for computational resources that cannot be supplied locally. The trade fails when a latency budget drops below what the remote path permits or when data volumes exceed what networks can carry, and computation must then move closer to the data source.

2.6 Edge ML: Latency and Privacy

The robotic-arm safety monitor in napkin math 2.2, an industrial IoT (IIoT) control loop,[13] left one option open, running the model beside the arm it protects. Moving computation adjacent to the data source removes that remote transmission term from the request path, and edge ML is the paradigm built on that move.

Edge ML trades elastic cloud capacity for shorter request paths and local data retention. Proximity does not by itself guarantee a sub-100 ms response, so the complete path must still be verified. Offloading a workload over a wide-area link can make remote-path latency, rather than local execution, the binding term. Under the iron law from equation 2.5, local execution removes the I/O offload term from the request path, leaving execution time bounded by local compute and memory transfer.

Definition 2.2: Edge ML



Edge machine learning is the deployment paradigm optimized for local response and data locality by locating computation physically adjacent to data sources.

1. **Significance**: It circumvents the distance penalty (L_{lat}) of the cloud, trading elastic scale for a fixed local compute capacity (R_{peak}).
2. **Distinction**: Unlike cloud ML, which prioritizes throughput, edge ML prioritizes response deadlines and local data control. Unlike TinyML, edge ML may still use workstation-class accelerators such as general-purpose GPUs (GPGPUs).
3. **Common pitfall**: A frequent misconception is that edge ML refers to a specific hardware class. In reality, it is a location paradigm: it spans from IoT gateways to on-premises servers, unified by physical proximity to the data source.

Real-time deadlines are not the only driver. Data sovereignty and privacy rules can restrict transmitting raw sensor streams across external networks, which places computation on local gateways, industrial PCs, and on-premises servers. Placing compute near sensors and filtering data locally helps meet sub-100 ms response budgets, while introducing failure boundaries in fixed node capacity and remote fleet management (figure 2.6).

IoT sensor ingestion rates[14] above network uplink capacity rule out transmitting the full raw stream. Local filtering or compression can reduce the transmitted representation; the complete local and remote paths then determine where inference can meet the application's requirements.

13 **Industrial IoT (IIoT)**: A domain where latency constraints can be set by physical safety rather than user perception. Keeping sensing and the stop decision local removes the long-haul network term but leaves the edge system bounded by its local compute capacity (R_{peak}).

Raw edge data can be wider than the network pipe.

14 **Internet of things (IoT) data wall**: IoT deployments depend on continuous sensor streams from devices distributed across homes, factories, farms, vehicles, and infrastructure (McKinsey Global Institute 2021). In many of those settings, the aggregate D_{vol} from raw streams overwhelms the available uplink budget or latency budget for centralized ingestion, making local edge processing an architectural requirement rather than merely a cost optimization.

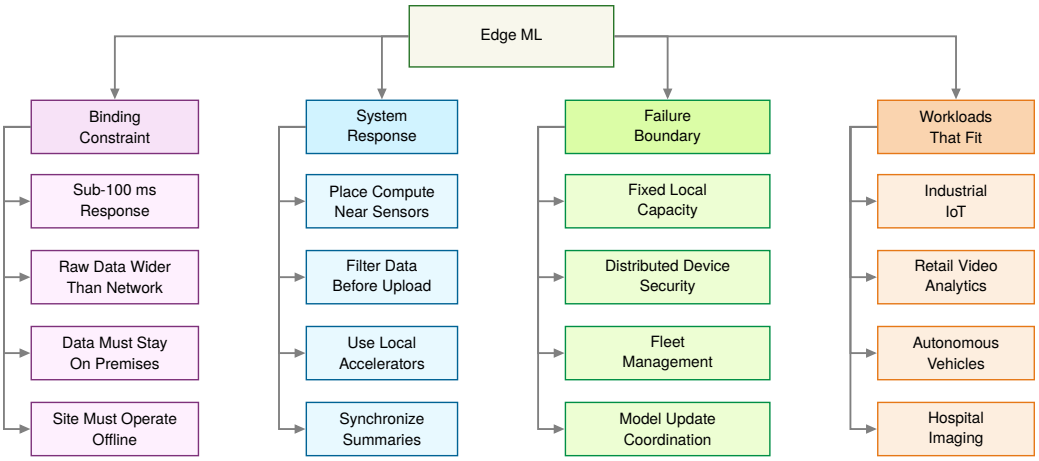


Figure 2.6: Edge ML Constraint Map: Moving computation near the data removes the network-latency term and reduces bandwidth pressure, but it replaces centralized scale with fixed local capacity, distributed security exposure, and operational complexity across many sites.

Napkin Math 2.4: The bandwidth bottleneck

Problem: Consider a quality control system for a factory floor with 100 cameras running at 30 FPS with 1080p resolution. Does video streaming become the bandwidth bottleneck, and does edge ML reduce the bandwidth enough to process locally?

Physics:

1. **Raw data rate per camera**: $1920 \times 1080 \times 3$ bytes $\times$ 30 FPS $\approx$ 186.6 MB/s.
2. **Total data rate**: 100 cameras $\times$ 186.6 MB/s = 18.7 GB/s.
3. **Cloud transfer exposure**: Uploading raw camera feeds is primarily a bandwidth, ingest, storage, and processing problem; per-GB cloud egress charges apply when data is transferred back out of the cloud. If the raw stream were later retrieved at \$0.09/GB data-transfer-out pricing, the transfer charge alone would reach \$4.4M/month.
4. **Network reality**: Even a dedicated 10 Gbps line (1.25 GB/s) cannot carry the load, because the workload demands 14.9× more bandwidth than exists.

Systems insight: Streaming these raw feeds over the stated link is *impossible*. Local processing or a smaller transmitted representation is required; compression changes the bandwidth calculation but must preserve the information and timing needed for defect detection. If an edge server transmits only defect metadata (1 KB per detection at roughly 20 events/s across the floor), bandwidth falls by about 933,120×.

Uncompressed sensor streams can saturate an uplink, which is the bandwidth barrier to centralized ingestion. For battery-powered edge devices (wireless cameras, drones, wearables), the energy cost of wireless communication introduces an even stricter physical ceiling. Offloading adds energy to the time-based analysis of equation 2.5, so the local-versus-offload decision must weigh joules as well as milliseconds.

Napkin Math 2.5: The energy of transmission

Problem: Should a battery-powered sensor process data locally (on-device NPU inference) or send it to the cloud when the energy of transmission must come out of a fixed battery budget?

Given:

- **Data** (D_{vol}): 1 MB (illustrative payload volume).
- **Transmission energy** (E_{tx}): 100 mJ/MB (Wi-Fi/LTE).
- **Compute energy** (E_{local}): 0.1 mJ/inference (illustrative MobileNetV2 anchor for the neural processing unit alone, excluding the rest of the phone).

Math:

1. **Cloud approach**: $E_{\text{transmit}} \approx D_{\text{vol}} \times E_{\text{tx}} = 1 \text{ MB} \times 100 \text{ mJ/MB} = 100 \text{ mJ}$.
2. **Local approach**: $E_{\text{local}} \approx \text{Inference} = 0.1 \text{ mJ}$.

Systems insight: Transmitting raw data is 1,000× more expensive than processing it locally. Charging local inference with the whole phone's energy over the inference window (2.6 mJ, the MobileNetV2 bar charted in figure 2.7) still leaves transmission 39× more expensive. Even if the cloud had infinite speed ($T \approx 0$), the stated battery budget favors local inference over raw-data transmission. The machine constraint (battery) shapes the deployment choice.

Figure 2.7 steps back from that matched comparison and supplies energy scale anchors for different tasks and accounting boundaries on a logarithmic scale spanning eight orders of magnitude, isolating the 100,000,000× gap between an always-on TinyML keyword spotting inference (about 10 µJ) and a cloud foundation-model query (about 1 kJ, an order-of-magnitude scenario anchor that includes data-center overhead rather than a measured value).

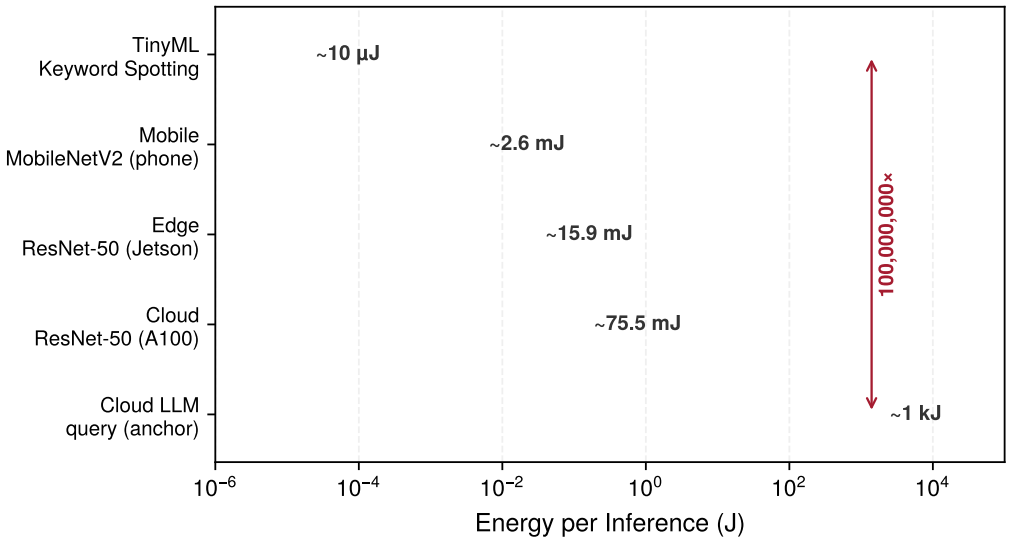

Figure 2.7: Energy per Inference Across Deployment Tiers: An eight-order-of-magnitude energy gap separates always-on TinyML keyword spotting (~10 µJ) from a cloud foundation-model query (~1 kJ) on a log scale. The three vision bars are device-level estimates (the device's power draw at its modeled utilization over the batch-1 inference window, counting the whole phone, the edge tier's NVIDIA Jetson embedded GPU module, or the A100 card) from the same analytical model used throughout this chapter; the two endpoints are scenario anchors. The tasks and accounting boundaries differ, so these bars illustrate energy scales rather than a controlled hardware-efficiency or offload comparison.

Systems Perspective 2.2: Reading the energy-per-inference numbers

The logarithmic comparisons plotted in figure 2.7 combine solver-derived device-energy estimates with separate scale anchors; they are not controlled full-system measurements. Each vision bar counts one device over its batch-1 inference window. The cloud ResNet-50 bar, for example, charges an A100 averaging about ~130 W for 0.57 ms; it excludes the host CPUs,

memory, networking, and cooling that bring an entire server to about ~1 kW, so a whole-server accounting of the same request would be several times larger.

The span becomes tangible when measured in a familiar unit of energy, one smartphone battery. The nominal energy stored in a 3.7 V, 3000 mAh battery is equivalent to about 4 billion inferences by the keyword spotter but only about 40 queries to a cloud LLM. The comparison is one of scale only: a cloud query's energy is spent in the data center, not drawn from the phone. Nor are the keyword-spotting counts elapsed battery life: actual runtime still depends on inference cadence, sleep power, sensing, communication, and the rest of the device.

2.6.1 The data locality invariant: When the network is too slow

When a delivery drone captures 4K video at 60 frames per second to dodge obstacles, shipping even one uncompressed frame over a cellular link takes longer than the 16.7 ms interval before the next frame arrives. That per-request bandwidth-latency trade-off governs the choice between local edge processing and remote cloud offload. The data locality invariant below is the per-request, deadline-bound form of the data-gravity principle from the cloud section: where data gravity weighs moving a whole dataset against moving the computation, the invariant weighs moving one input against one deadline. A remote path is rejected when its complete time exceeds the service deadline, and among the paths that remain, the faster one wins.

Definition 2.3: The data locality invariant

The data locality invariant first screens a remote path against the service deadline. The expression below gives a lower bound on complete remote-path time T_{remote}; let T_{deadline} denote the deadline, $\text{BW}_{\text{network}}$ offload bandwidth, $L_{\text{lat,network}}$ network latency, and $R_{\text{peak,remote}}$ and $\eta_{\text{hw,remote}}$ the remote compute rate and efficiency:

$$T_{\text{remote}} \geq \frac{D_{\text{vol}}}{\text{BW}_{\text{network}}} + L_{\text{lat,network}} + \frac{O}{R_{\text{peak,remote}} \cdot \eta_{\text{hw,remote}}}$$

The bound includes input transmission, network round-trip time, and arithmetic execution, but omits remote memory movement, queueing, preprocessing, runtime overhead, and response serialization. If even this lower bound exceeds the deadline, reject the remote path. A bound below the deadline leaves a candidate for complete-path measurement; it does not establish feasibility. Compare complete local and remote times only after each path meets the deadline and its resource constraints. Here, $L_{\text{lat,network}}$ covers propagation, routing, and protocol handshakes; response serialization may be small for a class label but must be included when material.

1. **Significance**: The invariant defines a crossover beyond which adding remote compute ($R_{\text{peak,remote}}$) has little effect because transmission dominates the lower bound. The local path is preferred only after its own complete execution time and resource limits are checked.
2. **Distinction**: Unlike the iron law, which decomposes one execution path, the locality invariant uses a deadline to reject an idealized remote path, then requires complete-path evidence to choose between the remaining alternatives.
3. **Common pitfall**: A frequent misconception is that 5G/6G "solves" locality. While these technologies improve $\text{BW}_{\text{network}}$, they do not remove propagation and protocol latency, so a remote path can still miss a tight service deadline.

The locality formulation also explains what every local tier gains, edge, mobile, and TinyML alike. Local execution removes network transit time ($D_{\text{vol}}/\text{BW}_{\text{network}} + L_{\text{lat,network}}$) from the request path, eliminating wide-area network variability. A closed-loop latency guarantee requires validating a bound on the complete local path under its operating conditions, $T_{\text{local}} \leq T_{\text{deadline}}$. Uplink traffic drops from raw sensor bitrates to lightweight event telemetry, relieving congestion and recurring

transit charges. Keeping raw sensor data where it is captured shrinks the transmission attack surface, although local processing alone does not guarantee privacy: data at rest still needs access control, and retention and secondary use still need governance. Local inference also continues through wide-area outages whenever local power and sensor links remain functional. Mobile and TinyML inherit all four gains; what distinguishes them is what each gives up to obtain them. A single high-rate sensor frame under a strict frame deadline is enough to force that crossover.

Napkin Math 2.6: The locality crossover

Problem: Should a drone's object avoidance system (4K, 60 FPS) offload to the cloud, or does this become a locality crossover?

Given:

- **Data** (D_{vol}): 4K frame ≈ 24.9 MB.
- **Bandwidth** ($\text{BW}_{\text{network}}$): 100 Mb/s cellular uplink.
- **Remote network and compute response**: 110 ms (round-trip + remote compute).
- **Per-frame completion deadline**: 16.7 ms, equal to the frame interval in this illustrative scenario; each avoidance result must be ready before the next frame arrives.

Math:

1. **Transmission time**: 24.9 MB × 8 bits/100 Mb/s = 1,990.7 ms.
2. **Remote-path lower bound**: Transmission + 110 ms remote response = 2100.7 ms, vs. the stated 16.7 ms per-frame deadline.

Systems insight: The remote path misses the stated per-frame deadline, and faster remote compute cannot remove the transmission time. Cloud offload is therefore infeasible under these assumptions; the local path must still be measured to confirm that it meets the deadline.

2.6.2 Edge ML deployment challenges

Keeping inference on the factory floor or inside a retail store eliminates the wide-area network delay, but now the model must fit inside whatever compute box is bolted to the wall—and if a firmware update fails across a thousand stores, no data-center operations team can walk down the aisle to swap the board. Edge deployment trades network transit for fixed local capacity. Edge hardware spans a wide power envelope, from 5–50 W embedded modules to site-powered servers drawing hundreds of watts, and its binding limit is the fixed capacity of a site rather than the elastic capacity of a cloud region. Many smaller embedded modules operate within 1–8 GB of memory,[15] and their power and board budgets cannot support the wide, high-power interfaces of HBM. They rely on LPDDR or shared system DRAM instead, so memory capacity limits parameter scale and memory bandwidth limits throughput. Fitting modern machine learning models into these bounds requires efficiency techniques that store weights in fewer bits (quantization), remove weights that contribute little (pruning), or train a smaller model to imitate a larger one (distillation). Model footprint, activation buffers, runtime state, and thermal duty cycles all become binding. Operationally, coordinating software updates and model versions across thousands of heterogeneous, physically exposed devices requires specialized deployment pipelines,[16] where intermittent links and physical access complicate rollback and failure diagnosis.

A realistic retail deployment shows how those constraints turn into throughput, hardware, and fleet-cost requirements. Consider a smart retail chain that deploys person detection across 500 stores, each with 20 cameras/store running at 15 FPS. Table 2.7 cascades the per-store inference rate through the per-frame FLOP count of YOLOv8-nano, a compact object-detection model, to yield the throughput each store must sustain. The 2× headroom keeps the device out of saturation when traffic bursts above the average rate.

15 **Embedded edge constraints**: Across representative edge envelopes, 1–8 GB can hold roughly 1–8 billion INT8 weights before activations, runtime state, and other buffers, so the memory budget, not a fixed parameter count, sets the ceiling. Sustainable compute is further limited by power, cooling, and duty cycle.

16 **Edge fleet coordination**: Managing thousands of distributed edge devices amplifies coordination problems: intermittent connectivity causes model version drift, hardware heterogeneity requires per-target optimization, and limited remote access can make failed firmware rollbacks require a site visit.

↪ Over-the-air updates, dual-bank rollback, and lightweight fleet telemetry for edge devices are developed in section 14.4.4.

Table 2.7: Edge Inference Sizing Requirements: The per-store inference rate and model cost set the throughput target for the smart-retail person-detection scenario.

Metric	Calculation	Result
Inferences per store	20 cameras/store × 15 FPS	300 inferences/s
Model compute	YOLOv8-nano: 8.7 GFLOP/inference	2610 GFLOP/s
Required throughput	2610 GFLOP/s × 2 (headroom)	~5.22 TOPS equivalent

Three candidate edge accelerators, including an embedded GPU accelerator, differ sharply in the power, unit cost, and fleet cost of reaching that throughput target (table 2.8).

Table 2.8: Edge Accelerator Options: Three candidate edge accelerators differ in throughput, power, and cost at fleet scale. Fleet cost assumes one unit per store for Jetson and NUC. Jetson power depends on the module: Jetson Orin Nano draws 7–15 W, Orin NX 10–25 W, and AGX Orin 15–60 W, so Jetson power figures in this book should be read against the module named in context.

Edge Device	INT8 TOPS	Power	Unit Cost	Fleet Cost
NVIDIA Jetson Orin NX	100 TOPS	10–25 W	$600	$300,000
Intel NUC + Movidius	1 TOPS	15 W	$400	$200,000
Google Coral Dev (3 boards/store)	peak 12 TOPS derated 6 TOPS	6 W	$450	$225,000

Napkin Math 2.7: Edge inference sizing

Problem: Given the throughput target in table 2.7 and the candidates in table 2.8, which edge accelerator (USB-scale TPU, workstation-class embedded GPU, or general-purpose mini-PC) delivers the required throughput at the lowest estimated three-year hardware-and-power budget?

Math: The capacity screen uses an assumed sustained rate rather than the datasheet peak. The scenario's 50 percent derating plays the role of the efficiency η_{hw} in the iron law. One Jetson derates from 100 TOPS to 50 TOPS, far above the 5.22 TOPS requirement. One NUC derates to 0.5 TOPS and falls short; meeting the target would take 11 per store, about $2,200,000 of hardware across the fleet. A Coral Dev Board is rated at 4 TOPS peak; the same derating gives 2 TOPS, so the count per store is 5.22 TOPS required ÷ 2 TOPS per board = 2.6 boards, which rounds up to 3 boards/store. This estimate assumes the model's operations and numerical format are supported and that work can be divided across the boards at the assumed rate.

Over 3 years across 500 stores, the hardware-and-power estimate for that configuration is Hardware $225,000 + Power (0.006 kW × 500 × 8760 h/year × 3 years × $0.12/kWh = $9,461) = $234,461 total vs. a baseline of one dedicated cloud GPU per store, at the same $0.75/hr instance rate as the cloud-versus-edge comparison, of ~$9,855,000. Within this accounting boundary, the other two candidates need no power arithmetic to rank, because the Coral configuration's hardware-and-power estimate is already below the Jetson fleet's $300,000 hardware cost and far below a feasible NUC fleet's. Integration, maintenance, redundancy, and matched cloud operating costs remain outside this comparison.

Result: One Coral alone is undersized under these assumptions, but the sharded configuration with 3 boards/store is a low-cost edge candidate within the hardware-and-power boundary, with an estimated 6 TOPS and about 1.3× lower per-store hardware CapEx than Jetson. Jetson remains the simpler single-device candidate when integration complexity matters more than hardware cost.

Systems insight: Edge sizing is a capacity-and-cost problem, not a device-name problem. The cheapest feasible design may be several small accelerators per site rather than one larger board, but that hardware saving must be weighed against the coordination and maintenance burden of a sharded edge fleet. The estimate narrows the candidates; measurements of the actual model and runtime must establish task quality, throughput, and end-to-end latency before deployment.

Edge hardware is also physically exposed. Unlike servers housed in access-controlled data centers, edge hardware deployed across retail floors or public infrastructure is physically accessible to adversaries. This exposure requires hardware-enforced protection mechanisms: secure boot chains to prevent unauthorized firmware modification, encrypted local storage for model weights and intermediate activations, and tamper-evident enclosures. Capital expenditures also scale linearly with deployment footprint, so equipping 1,000 sites with $500–2,000 of edge hardware per site requires $500,000–2,000,000 in upfront CapEx before installation, cabling, and fleet operations. Whether that upfront investment yields a lower total cost of ownership than recurring cloud inference depends on utilization duty cycles, local energy rates, and site maintenance overhead.

2.6.3 Real-time industrial and IoT systems

Edge applications differ by domain, but each rests on a locality argument, because the system cannot wait for the network, cannot ship the data, cannot expose the raw signal, or cannot stop during an outage. Autonomous vehicles represent a demanding application because safety-critical perception and control decisions must fit millisecond-scale budgets. Onboard systems process streams from multiple cameras and other sensors through local hardware; a remote cloud path cannot satisfy the tight control loop when its network delay alone exceeds the deadline.

In smart retail, uplink bandwidth and privacy bind before compute does. A checkout-free store[17] can process feeds from many cameras on local edge servers, tracking customer movements and item selections without continuously transmitting raw video over a wide-area link. This architecture reduces bandwidth demand and transmission exposure, but it does not by itself ensure privacy: retention, access, secondary use, and governance controls still determine the system's compliance and risk.

The industrial IoT, often called Industry 4.0 when ML closes the factory control loop,[18] uses edge ML where millisecond-level responsiveness affects production quality and worker safety. Manufacturing facilities deploy edge ML systems for real-time quality control and predictive maintenance.[19]

Many industrial and retail edge systems are stationary and connected to site power, where a factory edge server drawing hundreds of watts around the clock remains viable. Mobile devices, by contrast, travel with untethered users on strictly bounded battery reserves. When computation moves from stationary infrastructure to an untethered mobile device, battery energy becomes a central constraint alongside latency, and the dominant optimization target shifts from raw execution time to energy per inference.

2.7 Mobile ML: Offline Intelligence

Carrying edge-style locality into a user's pocket changes which budget binds. A phone must deliver responsive, private inference all day from a pocket-sized battery, inside a thin chassis with no fan to carry heat away. Mobile ML integrates machine learning directly into smartphones and tablets to meet that envelope. It fits workloads where data locality, offline operation, and immediate response matter more than computational scale, such as voice recognition, computational photography,[20] health monitoring, and navigation or translation that must keep working without a network, and its battery and thermal envelope suit frequent, short-duration inference rather than sustained heavy computation.

On a phone, energy per inference is a primary design constraint, because a phone operates from a finite battery without active cooling, so every joule consumed directly erodes device runtime and thermal headroom. While stationary cloud and edge deployments often focus on minimizing latency T under continuous utility or site power, mobile systems must strictly balance total energy ($\text{Energy} = \text{Power} \times T$) under the passive thermal envelope of 3–5 W that the power wall (equation 2.2) imposes. In archetype terms, a compute-heavy workload such as image classification must be transformed into a more compact vision model,[21] reducing FLOPs by 13.7× at a modest accuracy cost. The design accepts lower peak throughput in exchange for sustainable operation within a 3–5 W thermal envelope.

17 **Checkout-free retail**: A store design that fuses camera observations with shelf events and transaction state locally, then transmits only selected events or aggregates. Those derived records still fall inside the privacy boundary.

18 **Industry 4.0**: The fourth industrial revolution integrates ML into the sensor-actuator feedback loop on factory floors. In an illustrative welding-robot scenario, defect detection samples at 60 Hz, giving a 16.7 ms sampling interval; if each response must finish before the next sample, the complete sensing-to-actuation path must fit that deadline. This completion requirement is a scenario assumption; the sampling rate alone does not establish the control deadline or guarantee safe operation.

19 **Predictive maintenance**: The use of sensor data such as vibration and temperature to estimate equipment condition and failure risk. Continuous monitoring makes sensing cadence, duty cycle, power, and local storage first-class constraints. Battery-powered monitoring nodes may require sub-watt average operation, whereas mains-powered industrial gateways can use a much larger envelope.

20 **Computational photography**: The use of ML algorithms (for example, multi-frame fusion and neural denoising) to overcome the physical limits of small mobile camera sensors.

21 **Mobile vision model reduction**: MobileNet-style architectures reduce the computation in common vision layers while preserving useful accuracy for mobile tasks. The systems point here is that mobile deployment often requires changing the model family, not merely moving the same model to a phone.

Definition 2.4: Mobile ML

Mobile machine learning is the deployment paradigm bounded by thermal design power (TDP) and battery energy.

1. **Significance**: It is constrained by the few-watt heat dissipation capacity of passive cooling, requiring architectures that prioritize sustained energy efficiency over peak throughput (R_{peak}).
2. **Distinction**: Unlike edge ML, which may have active cooling, mobile ML must operate within a personal energy budget. Unlike TinyML, it still provides a rich OS and multi-watt compute capacity.
3. **Common pitfall**: A frequent misconception is that mobile ML performance is a fixed value. In reality, it is a time-varying constraint. Performance often drops as the device hits its thermal wall, triggering thermal throttling that lowers clock frequencies and reduces the active duty cycle.

Two boundaries define the mobile envelope, and together they push the design toward on-device NPU acceleration and model compression (figure 2.8). The first is the **battery tax**, the share of the phone's finite energy budget that an always-on ML feature spends before the rest of the system runs, because the battery limits total energy over time. Thermodynamics imposes the second boundary, which holds even for a plugged-in tablet: every watt becomes heat, and where a data center removes heat with active cooling, a thin mobile device relies on passive transfer through its chassis and surfaces. This creates the **thermal wall**, the power wall's device-level form, which sets a hard ceiling on sustained power consumption independent of battery capacity.

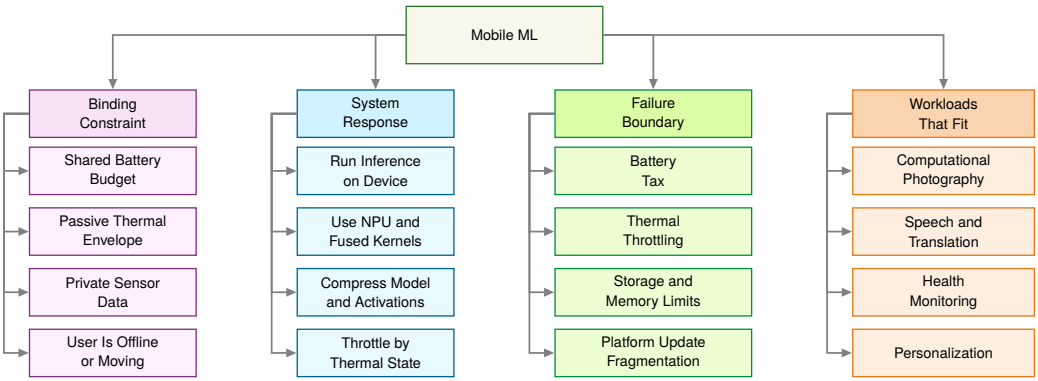

Figure 2.8: Mobile ML Constraint Map: On-device processing buys responsiveness, privacy, offline operation, and personalization, but the phone's shared battery and passive thermal envelope make sustained energy efficiency the binding design constraint.

Napkin Math 2.8: The battery tax

Problem: Consider deploying a "real-time" background object detector on a smartphone. The model consumes 2 W of continuous power when active. The phone has a standard 15 Wh battery. Can the feature stay on all day? This is the battery tax that turns battery life into a mobile ML energy-budget constraint.

Physics:

1. **Ideal runtime**: $\frac{15\ \text{Wh}}{2\ \text{W}} = 7.5$ hours
2. **Reality**: A user expects their phone to last 24 hours. Running this single feature continuously for a day would require 320 percent of the phone's daily energy budget.

Systems insight: The model cannot simply be "deployed." A lighter model, duty cycling, or both must reduce the energy demand, so the feature can stay on all day.

The distinction matters for engineering decisions. The battery tax is a budget problem, solvable in principle by reducing how often the model runs or by increasing battery capacity. The thermal wall is a physics ceiling. A larger battery cannot raise the maximum sustained wattage a passive chassis can dissipate; duty-cycle and software changes can only reduce heat generation. Sustained operation above the thermal envelope triggers hardware throttling regardless of remaining battery energy. The two constraints therefore attack different points in the iron law: the battery limits total operations per charge (O integrated over time), while the thermal wall caps the instantaneous rate ($R_{\text{peak}} \cdot \eta_{\text{hw}}$) the silicon can sustain.

Sustained thermal performance falls well below burst peaks.

Napkin Math 2.9: The thermal wall

Problem: An unoptimized vision model requires 12 W peak compute. Can it be deployed on a mobile device, or does it hit the thermal wall and the mobile power wall?

Scenario: A mobile system-on-chip (SoC) allows approximately 3 W for passive cooling. Assume the unoptimized model is deployed as is. A representative throttling trace for this heavier model runs in three steps:

1. **Temperature rise**: At 12 W, the SoC junction temperature rises at approximately 1 °C/s.
2. **Thermal trip**: Within 60 s, the hardware reaches the thermal trip point (80 °C), triggering OS throttling.
3. **Throttled throughput**: The 100 FPS model suddenly drops to 30 FPS to stay within the thermal envelope.

Math: Assume that a redesign (a lighter architecture running INT8 instead of FP32 arithmetic) cuts active power by an illustrative 4×: 12 W ÷ 4 = 3 W, which lands right at the 3 W passive-cooling ceiling with no headroom to spare. The factor is a scenario input for the whole redesign. Quantization alone shrinks weight storage by that factor but does not cut power proportionally, because switching and leakage energy outside the arithmetic remain.

Systems insight: Even a 4× power reduction does not create thermal headroom; it only just reaches the sustainable limit. Optimization can bring a model down to the thermal ceiling; it cannot raise the ceiling.

Battery and heat are the two limits a mobile deployment must account for explicitly. Within them, the phone's hardware envelope determines which models can run and how often.

2.7.1 Mobile ML benefits and resource constraints

The mobile row of table 2.4 gives the hardware envelope: gigabytes of RAM, neural processing units delivering tens of TOPS, and 3–5 W of sustained power on a system-on-chip[22] that integrates computation and memory to minimize data-movement energy. Memory capacity constrains model footprint and memory bandwidth constrains how quickly weights and activations move, but the battery sets the budget users notice. Adding 1 W of continuous ML processing to a phone that otherwise lasts 24 hours would cut its runtime to roughly 9.2 hours–11.5 hours, depending on a battery capacity of 15 Wh–22 Wh.

Mobile adds two gains to those every local tier shares. The first is hardware isolation for the most sensitive inputs, since on-device enclaves such as Apple's Secure Enclave keep biometric matching inside a dedicated subsystem,[23] although the strength of any privacy guarantee still depends on the complete system design and threat model. The second is personalization, because models can exploit on-device signals and user context without shipping raw data anywhere. Specialized on-device ML frameworks keep such inference within 5–50 ms user-interface response times.

The cost shows up in engineering effort as well as joules. Peak NPU throughput can substantially exceed what the device sustains under prolonged load, device heterogeneity requires multiple

[22] **System-on-chip (SoC)**: Mobile SoCs integrate CPU, GPU, and NPU cores with caches and memory controllers to reduce data-movement costs. Mobile DRAM is generally off-die, and feasible model size depends on capacity, precision, working memory, bandwidth, and latency.

[23] **Face ID**: Apple performs facial matching within the Secure Enclave and encrypts the stored mathematical representations so that they remain available only to that subsystem and do not leave the device (Apple 2024a, 2024b). Apple reports a random false-match probability below 1 in 1,000,000 for one enrolled appearance, with higher probabilities for some populations and configurations. The example shows how local inference and hardware isolation can reduce transmission exposure while supporting low-latency authentication.

model variants, development multiplies across platforms, and app-store review and staged release slow iteration compared with a service its operator controls entirely.

2.7.2 Personal assistant and media processing

Several short ML pipelines on one phone must share the same battery and thermal budget, and computational photography shows that constraint most sharply. Modern flagships process each photo through multiple ML stages: portrait mode uses depth estimation and segmentation, night mode aligns multiple frames with ML-based denoising, and HDR merging, super-resolution, and scene optimization run in sequence. The binding constraint falls on the pipeline rather than on any individual model, because these models must share a 3–5 W power budget and complete within the user's perceived shutter delay, which requires careful scheduling across CPU, GPU, and NPU to avoid thermal throttling.

Voice-driven interactions are bound by the energy of always-on listening, so they partition work across the same SoC by power tier. Wake-word detection runs continuously on a dedicated low-power core, while speech recognition and keyboard prediction wake the higher-power neural processing tiers only when needed.

Health monitoring and augmented reality push mobile ML to its sustained-performance limits. Wearables like Apple Watch process ECG and accelerometer data on-device to reduce the radio energy of transmission, while AR frameworks must fit simultaneous localization, hand tracking, and scene understanding into a 16.7 ms frame budget at 60 FPS without exceeding the sustained thermal envelope. These applications represent the ceiling of what battery-powered, passively-cooled devices can sustain, and they define the boundary beyond which mobile optimization alone is insufficient.

A common pitfall is deploying desktop-trained models directly to mobile or edge devices without architecture modifications. A desktop ResNet-50 pipeline may require gigabytes once activations, batches, preprocessing buffers, and runtime overhead are included, even though the FP32 weights alone are about 102.4 MB. Those weights fit in the 512 MB of RAM on a representative low-end edge target, but at 8.2 GFLOP per inference its 1 GFLOP/s processor takes seconds per inference, a latency failure rather than a capacity one. Desktop-optimized models may also use operations unsupported by mobile hardware, assume numerical formats unavailable on embedded systems, or require batch processing incompatible with single-sample inference. Successful deployment demands architecture-aware design from the beginning, so model families, arithmetic formats, and implementation choices must all match the target device.

Mobile ML shows that useful intelligence fits within a 3–5 W thermal envelope on battery power. A smartphone still costs hundreds of dollars, carries gigabytes of memory, and needs a daily recharge, and no amount of mobile optimization closes the roughly 10,000-fold memory gap to a device that must cost dollars and run unattended for years. That regime needs a different class of hardware and algorithms.

2.8 TinyML: Ubiquitous Sensing

Instrumenting every pallet in a warehouse, every cable on a suspension bridge, or every beehive in an apiary means putting "eyes and ears" on tens of thousands to millions of physical objects. At that count, each device must cost dollars rather than hundreds of dollars and measure millimeters rather than centimeters. Smartphones are far too expensive and too large for the role; ubiquitous sensing at this scale requires unit costs under ten dollars.

TinyML completes the deployment spectrum with low-cost, low-power ML on deeply constrained embedded devices (Warden and Situnayake 2020; Janapa Reddi, Plancher, et al. 2022). Devices costing under $10 and averaging less than one milliwatt[24] of power when duty-cycled make ubiquitous[25] sensing economically practical at massive scale; MLPerf Tiny and MCUNet show how such constraints are evaluated and optimized in practice (C. Banbury, Reddi, Torelli, Holleman, Jeffries, Kiraly, et al. 2021; Lin et al. 2020). Its first feasibility screen is memory capacity, because weights must fit in flash and working state in SRAM, but once a model fits, power is the limit that shapes the design. This is the domain of the power-bound archetype, where the optimization objective shifts from maximizing throughput to minimizing energy per inference. With duty-cycled execution, a keyword spotting model consuming about 10 µJ per inference on dedicated low-power audio silicon (a general-purpose microcontroller running the same model spends orders of magnitude more)

↪ The framework that organizes pruning, distillation, and quantization to fit edge memory budgets is developed in section 10.1.

24 **The 1 mW threshold**: Ambient energy harvesting can power a device indefinitely only when long-term harvested power exceeds the complete system's average load. Available power varies across sources and environments. Solar cells the size of a thumbnail may produce ~10 mW outdoors but ~10 µW indoors, thermoelectric generators on warm pipes ~100 µW, and RF energy from nearby transmitters ~10 µW. This crossover can transform the deployment model from "battery-limited lifetime" to "deploy and forget," but it depends on the source, environment, and workload.

25 **Ubiquitous computing**: Mark Weiser's ubiquitous-computing vision imagined computation woven into everyday environments until it receded from direct attention (Weiser 1991). TinyML is one modern path toward that vision, because it brings the cost and power of an intelligent sensor low enough for mass deployment.

can operate for years on a coin-cell battery, trading model capacity for operational longevity. On an Arduino Nano 33 BLE Sense development board (figure 2.9), on-board microphone, motion, and environmental sensors share a single substrate with a low-power microcontroller executing quantized TensorFlow Lite Micro models (David et al. 2021). The board illustrates integration; its full power draw depends on the sensors, radio, and duty cycle.

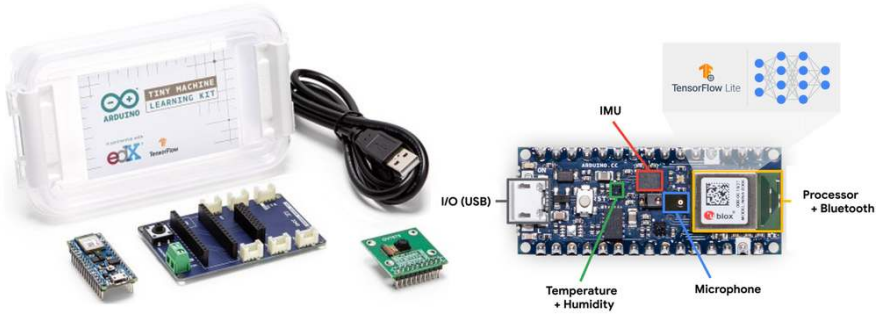

Figure 2.9: TinyML Hardware Scale: Microcontroller development boards integrate sensors, processing cores, and low-power radios onto a compact substrate, making constrained ML applications accessible for prototyping. Finished sensing devices must budget SRAM, sensor and radio power, inference cadence, and sleep energy to achieve multi-year battery life. Source: Figure 6 in Janapa Reddi, Plancher, et al. (2022), licensed under CC BY 4.0.

TinyML runs on microcontrollers (MCUs),[26] which omit the power-hungry infrastructure of conventional computing. Mobile and edge processors rely on external dynamic RAM (DRAM), high-speed memory buses, and operating system runtimes that draw milliwatts just to keep DRAM in self-refresh and hundreds of milliwatts once the memory bus is active. Many microcontrollers integrate the processor core, non-volatile flash, and static RAM (SRAM) onto a single silicon die, reducing reliance on external memory buses (C. Banbury, Reddi, Torelli, Holleman, Jeffries, Kiraly, et al. 2021; Lin et al. 2020; Janapa Reddi, Plancher, et al. 2022). Eliminating off-chip signaling lets duty-cycled average power fall below a milliwatt and sleep power reach microwatts, although active inference on boards such as the ESP32-S3 still draws tens to hundreds of milliwatts. Some targets, including ESP32-S3 variants, instead attach external flash or additional RAM. On-chip integration still imposes a strict internal-memory ceiling. On-chip SRAM is physically constrained by silicon die area: because each SRAM cell requires six transistors (6T), expanding capacity directly inflates manufacturing cost. A TinyML model must therefore execute within tens to hundreds of kilobytes of SRAM, with no virtual memory, paging, or swap space to cushion an overflow. The small keyword-spotting task and low-power hardware place it at the bottom of figure 2.7; duty cycle also determines its average power.[27] Multi-year coin-cell operation additionally requires the complete device load to fit the battery budget.[28] Fitting the entire inference pipeline, from sensor acquisition to classification output, into this kilobyte-scale memory footprint defines the TinyML operating regime.

[26] **Microcontroller (MCU)**: A single-chip computer whose design prioritizes minimal cost and power over performance. Memory fit therefore becomes a deployment prerequisite, because the memory actually available to the target is often orders of magnitude less than a smartphone provides.

[27] **TinyML energy gap**: The figure compares different tasks on different hardware and with different energy accounting boundaries; its ratios do not identify the effect of hardware integration alone. A batch-1 ResNet-50 inference on a cloud accelerator consumes about 75.5 mJ of accelerator energy, while an always-on keyword spotter uses about 10 µJ, a gap of ~7,500×. A cloud LLM query at about 1 kJ widens the gap to 100,000,000×, the span plotted in figure 2.7.

[28] **Coin-cell deployment**: A CR2032 battery (225 mAh at 3 V, ~675 mWh) ideally powers a complete 10–50 µW system for about 1.5–7.7 years. This "deploy-and-forget" operating model drives innovation in intermittent computing, where the device sleeps between inferences to stretch the energy budget across years of unattended operation.

Definition 2.5: TinyML

TinyML is the machine learning domain of always-on sensing constrained by kilobyte-scale memory and milliwatt-scale power.

1. **Significance**: It requires models whose weights and code fit in flash while activations and runtime state fit in on-chip SRAM, enabling continuous inference on milliwatt power budgets.
2. **Distinction**: Unlike mobile ML, which uses multi-watt processors and a full OS, TinyML runs on microcontrollers using bare-metal firmware or a real-time operating system.
3. **Common pitfall**: A frequent misconception is that TinyML is just "small models." In reality, it is a power-bound regime, and the primary metric is energy per inference (microjoules), not just the parameter count.

This definition reframes the iron law of ML systems. In terms of equation 2.5, TinyML imposes a physical memory-capacity precondition that execution time does not capture: the weight footprint M_{weights} and activation footprint $M_{\text{activations}}$ must stay within memory capacity M_{device}. When total memory is measured in kilobytes, model structure and runtime allocation determine feasibility before latency optimization begins, and every avoidable data movement spends part of the energy budget. The objective therefore shifts from raw throughput toward energy per inference and memory fit.

The same four-branch map applies at the bottom of the spectrum (figure 2.10). Milliwatt budgets and kilobyte memories favor low-precision execution and duty-cycled sleep, and they move the failure boundary away from latency toward compression-driven accuracy loss and risky firmware updates.

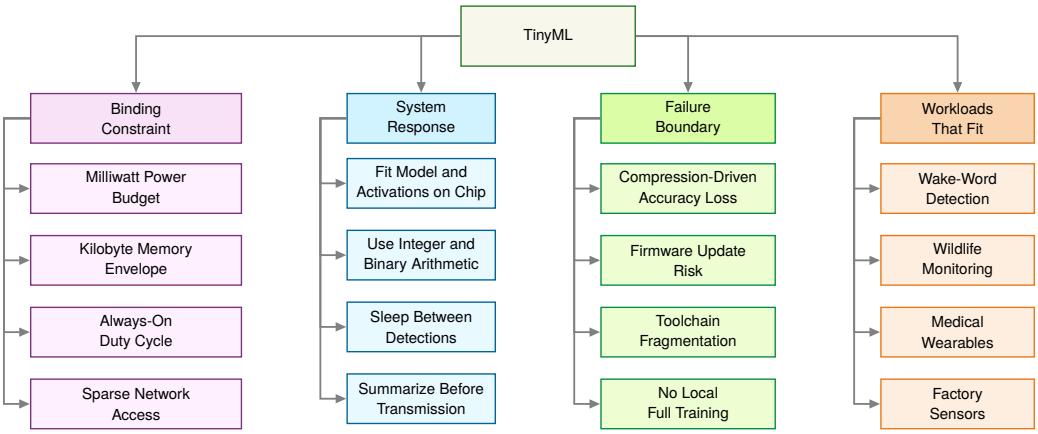

Figure 2.10: TinyML Constraint Map: Milliwatt power and kilobyte memory make always-on sensing economically possible, but those same limits force the model, activations, runtime, and update path to fit a radically smaller engineering envelope.

2.8.1 TinyML advantages and operational trade-offs

TinyML devices range from palm-sized developer kits to millimeter-scale chips,[29] and their kilobyte memories and milliwatt budgets allow months or years of autonomous operation. The models are usually trained elsewhere,[30] and the devices demand specialized algorithms, aggressive model compression, and careful systems co-design. TinyML also changes deployment economics: removing the radio uplink and the application processor lets per-node unit cost fall to single-digit dollars, which makes dense instrumentation across thousands of physical assets financially viable, and microjoule inference budgets allow multi-year operation on inexpensive coin-cell batteries or on harvested ambient energy.

The trade-offs are just as distinctive. Microcontrollers commonly provide 10^5 to 10^6 bytes of RAM and enforce a strict two-tier memory partition, in which static model weights and compiled code reside in non-volatile flash (often a few megabytes), while mutable activations and the runtime buffer (the *tensor arena*, a fixed block of SRAM reserved for them) must fit within the much smaller on-chip SRAM (a few hundred kilobytes at most, such as the ESP32-S3's 512 KB, and as little as tens of kilobytes on the smallest parts). As a result, peak intermediate activation volume, rather than static parameter storage, is frequently the barrier that prevents a model from executing. The smart doorbell's level-1 check (figure 2.3) shows why that check is only a first screen: its weights fill just 11.9 percent of flash, a figure that says nothing about whether its intermediate results fit in SRAM. Embedded development also demands cross-stack co-design: engineers manage memory pools by hand, debug bare-metal firmware without operating-system abstractions, and optimize operator kernels directly for constrained instruction sets.

These bounds also create lifecycle and reliability challenges. An energy-harvesting device can satisfy its long-term average power budget yet fail when stored energy is exhausted before the next harvest. Its duty cycle must therefore respect both energy per inference and the timing of

[29] **TinyML device range**: This physical range reflects a direct trade-off between deployment context and computational capability. Millimeter-scale systems prioritize minimal power for single-function, long-duration tasks, whereas palm-sized boards offer more sensing, interfaces, and debugging support at higher cost and power. Development-board size and power therefore should not be treated as limits for a finished TinyML product.

[30] **On-device training constraints**: Updating a model requires working memory beyond that needed to apply it, including information retained from the prediction computation to determine parameter changes. Intermediate results can be discarded only after their final use, which often occurs later during training than during inference. With only 256 KB–2 MB RAM, many microcontrollers cannot hold the full training state; specialized methods reduce that state by limiting which parameters change. TinyTL, for example, freezes the weights and updates mainly the biases, so most intermediate activations need not be retained for the update (Cai et al. 2020). Training elsewhere and delivering an updated model is therefore a common design, although constrained local adaptation remains possible.

available power. Model quality can also suffer from aggressive quantization and pruning: converting 32-bit floating-point weights to 8-bit integers (INT8) saves memory but can degrade accuracy and robustness on out-of-distribution sensor inputs. Post-deployment flexibility is also sharply constrained: models are often packaged with firmware, so field updates must account for limited storage, interrupted transfers, and safe rollback. Ecosystem fragmentation[31] across microcontroller vendors and ML frameworks creates additional overhead and portability challenges.

2.8.2 Environmental and health monitoring

The TinyML regime becomes essential when power budgets, unit economics, and physical isolation rule out every higher tier. Wake-word detection is the most familiar case. Its binding constraint is average power, so the always-on detector acts as a power gate that wakes the costlier processors only when a wake phrase is heard.[32] Precision agriculture is bound instead by sparse, expensive connectivity across large fields. FarmBeats used sensors, cameras, drones, and local gateway processing to reduce raw data movement where connectivity was costly (Vasisht et al. 2017), and TinyML pushes that logic down to sensing nodes that must run under milliwatt budgets.

Wildlife conservation shows the uplink arithmetic in an illustrative case. Solar-powered acoustic sensors identify species on-device and transmit periodic detection summaries rather than raw audio, cutting uplink data from 4.3 GB/day to 400 KB/day, a 10,750× reduction that conserves power in off-grid deployments. Medical wearables apply the same logic to physiological monitoring, where runtime remains bounded by sensor draw, radio power, duty cycle, and sleep energy rather than by the model alone.

All four paradigms sit on one continuum bounded by the speed of light, heat dissipation, and memory signaling, and a real feature usually presses against several of those bounds at once. Choosing among the paradigms therefore means mapping an application's constraints against all of them together.

2.9 Choosing a Deployment Paradigm

An architect choosing where to run an ML feature rarely optimizes one dimension. A privacy rule may forbid cloud processing, a latency budget may forbid remote inference, a memory footprint may exceed the mobile device, and a cost target may rule out always-on edge hardware. Cloud, edge, mobile, and TinyML are operating envelopes for those conflicts, so selecting among them requires a unified comparison framework and a structured decision process.

2.9.1 Weighing operational trade-offs across tiers

A model that fits comfortably inside a tier's latency, power, and memory budgets can still fail in production if the team cannot ship updates to it, if a dropped internet link halts the service, or if monthly cloud bills outrun the product's revenue. Choosing a deployment tier requires weighing latency-vs-throughput paradigm trade-offs across physical and operational budgets at once. The resource envelopes are already on the table: table 2.1 gives each paradigm's latency, power, and memory regime, and table 2.4 grounds them in concrete platforms. What those tables leave out are the operational dimensions that decide many real deployments: how the system scales, what it exposes, whether it needs a network, what it costs, and how hard it is to build and ship. Table 2.9 contrasts the four paradigms along those eight dimensions.

Table 2.9: Operational Paradigm Comparison: Eight operational dimensions complement the resource envelopes of table 2.1 and table 2.4. Cloud ML scales most easily, while local processing can reduce transmission and centralized-storage exposure without itself guaranteeing privacy; local tiers can operate without a WAN, but real-time response depends on workload and complete-path timing, while development complexity is highest at the two ends of the spectrum. Cost anchors mix recurring service bills with device purchase prices; they are partial illustrations, not a matched lifecycle-cost ranking.

Aspect	Cloud ML	Edge ML	Mobile ML	TinyML
Scalability	High (provider capacity limits)	Good (limited by edge hardware)	Moderate (per-device scaling)	Limited (fixed hardware)
Data Exposure	Remote processing expands the surface	Local processing reduces transmission	On-device processing reduces transmission	Raw data can remain local

31 **TinyML ecosystem fragmentation**: TinyML spans microcontroller families such as Arm Cortex-M, RISC-V, and Xtensa, each with different instruction sets, memory layouts, kernels, and vendor toolchains; cloud and mobile stacks also vary, but their runtimes usually hide more of this hardware diversity. A model optimized for one microcontroller target may therefore require retuning and revalidation for another, multiplying the engineering cost of multi-device deployment.

32 **Always-on wake-word detection**: A small model that listens continuously for the acoustic signature of a wake phrase. The acceptable detector budget depends on the platform, but spending even a few extra milliwatts continuously can materially shorten battery life, and the architecture succeeds only when the always-on path consumes far less average power than the components it prevents from waking.

Aspect	Cloud ML	Edge ML	Mobile ML	TinyML
Connectivity Required	Required for remote requests	Intermittent	Optional	None
Offline Capability	None	Good	Excellent	Complete
Real-time Processing	Network and execution must fit deadline	Local execution must fit deadline	Deadline and sustained-power limits	Deadline and memory-capacity limits
Cost anchor	Service bill ($1000s+/month)	Hardware purchase ($100s–$1,000s per device)	Device purchase ($200–$1000+; often user-owned)	Hardware purchase ($1–$10 per device)
Development Complexity	High (cloud expertise needed)	Moderate-High (edge+networking)	Moderate (mobile SDKs)	High (embedded expertise)
Deployment Speed	Fast	Moderate	Fast	Slow

Remote processing widens the network attack surface and requires transport encryption and strict isolation between tenants; local processing keeps raw data on the device, reducing network exposure without eliminating the risk of physical tampering. The workload archetypes from section 2.3 map directly to these boundaries, with each archetype gravitating toward paradigms that relieve its primary bottleneck. Each paradigm also shifts engineering complexity to a different subsystem: cloud deployments demand expertise in multi-tenant networking and dynamic cost governance, whereas edge and TinyML deployments trade those cloud concerns for local thermal and memory limits along with distributed updates and site maintenance. Mobile deployments sit between the two, operating on user-owned hardware that avoids infrastructure purchase costs at the price of platform-specific drivers, operating-system background task limits, and shared energy budgets, so none of the four categories supplies a workload-independent latency or energy ranking.

A common architectural failure is selecting a deployment target based on model accuracy alone while treating hardware constraints as downstream optimization details. An unquantized model that delivers 99 percent accuracy in an offline evaluation becomes unviable if its memory footprint triggers paging on mobile hardware, or if continuous inference drives thermal throttling within seconds. Physical invariants (memory capacity, thermal dissipation limits, and network transit delay) must serve as early screening criteria before model development begins, pruning invalid deployment targets before training resources are expended.

2.9.2 Four screening gates for choosing a tier

Before asking whether a workload belongs in the cloud or on a microcontroller, an engineer should ask a simpler question: does this problem need machine learning at all? Deep neural networks carry a heavy maintenance burden that deterministic code avoids, and a fifty-line heuristic rule set can often solve the problem at a tiny fraction of the operating cost.

Systems Perspective 2.3: The complexity tax

Consider a classification task solvable either by deterministic heuristic rules or by a deep learning pipeline. The heuristic requires fifty lines of code, incurs near-zero compute cost, demands approximately one hour per month to update rules, and fails in ways engineers can read in the code. The ML system may require only fifty lines of model definition, but, as Sculley et al. (2015) observed of production ML generally, it introduces roughly 2,000 lines of supporting infrastructure for feature ingestion, telemetry logging, drift monitoring, and GPU driver management, alongside 40 hours per month diagnosing data drift and maintaining pipelines.

An ML model that increases accuracy from 90 percent to 95 percent while multiplying operational maintenance by, say, 40× requires an economic comparison. The accuracy and maintenance ratios alone do not establish the return; the value of the avoided errors must

justify the additional engineering cost. When the ongoing maintenance cost outstrips the value of marginal statistical gains, deterministic software remains the correct systems choice.

When this **complexity tax** outweighs the operational value of improved statistical predictions, the ML deployment costs the system more than it returns. Once a learned system is justified, however, paradigm selection relies on a tiered decision framework ordered by how rapidly a constraint invalidates an architecture. The screening hierarchy evaluates four successive gates: regulatory privacy, physical latency, local compute capacity, and lifecycle economics. Privacy leads the order because a legal prohibition on moving data eliminates an option before anything is measured, whereas the latency and compute gates require numbers. Each gate passes only its survivors to the next, so the screening sequence acts as successive filters on a candidate set (figure 2.11).

↪ Framing the problem against the existing baseline, and retaining that baseline when the expected benefit does not justify the added cost, is developed in section 3.5.

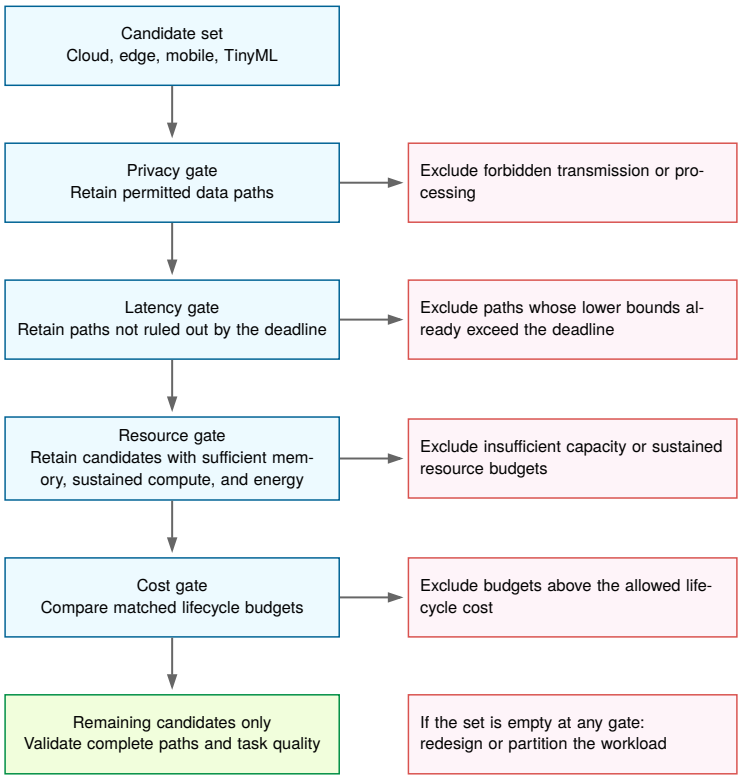

Figure 2.11: Deployment Decision Screening: Apply privacy, latency, resource, and cost gates to the remaining candidate set. Every gate retains upstream exclusions. An empty set requires redesign or partitioning; surviving candidates still need complete-path validation.

The flowchart carries a remaining candidate set through all four gates. If regulatory rules or data sovereignty forbid off-device transmission, remote cloud processing stays excluded when compute demand is considered. If a network round-trip lower bound exceeds the deadline, additional remote compute cannot restore that path. Cost compares only the survivors, and an empty set calls for changing the workload or partitioning it across tiers. Passing a lower-bound latency screen still requires complete-path validation. In automotive emergency braking, the latency gate binds before compute capacity or cost are even considered.

Example 2.1: Autonomous vehicle emergency braking

Scenario: An autonomous vehicle vision system performs real-time pedestrian detection for emergency braking under a strict 100 ms end-to-end latency budget.

Diagnosis: At 100 km/h, the vehicle covers 2.8 m during the 100 ms budget, so every millisecond of delay is distance traveled before braking begins. The scenario assumes 50–150 ms of network round-trip delay for cloud offload, which consumes half the budget at best and more than all of it at worst before any detection runs. Local object detection on an automotive edge accelerator takes 10–30 ms; at 10 GFLOPs per frame and 30 FPS, that accelerator must sustain 300 GFLOP/s.

Systems lesson: The stated network-delay range cannot guarantee the deadline, so the latency gate excludes that cloud path. The local candidates remain subject to the resource gate: the pedestrian detector must fit memory and sustain the stated frame rate within its power budget. An automotive edge accelerator remains a candidate under these assumptions; its complete sensing-to-braking path still needs validation. Cloud connections can support offline training and telemetry without reentering the emergency decision path.

A completed placement decision needs evidence about the surviving paths as well as grounds for rejecting the others. A factory inspection line supplies both.

Example 2.2: Completing a placement decision

Problem: A fixed factory camera requires 20 FPS inspection with a 100 ms sensing-to-decision deadline. Raw images must remain on premises. Which feasible deployment has the lowest matched lifecycle cost under the following hypothetical evidence?

Supplied evidence: A rule-based baseline fails the specified missed-defect criterion, while the learned detector meets both the missed-defect and false-alarm criteria on representative inspection data. The proposed mobile and microcontroller variants fail that same quality requirement. Local edge candidates A and B preserve the validated detector and preprocessing. Both have a complete peak working set of 2 GB within an available 4 GB, and each must stay within a 25 W sustained system-power budget.

Under the specified peak load and thermal conditions, the supplied complete-path latency bounds are 80 ms for A and 40 ms for B, including acquisition, preprocessing, queuing, inference, and the inspection decision. Their sustained rates are 25 FPS and 40 FPS, at 10 W and 20 W. Both satisfy the same availability and recovery requirements. Annualized budgets over the same service lifetime, including hardware, power, installation, maintenance, and recovery provisions, are $2,400 for A and $3,600 for B. These supplied bounds and budgets define an instructional scenario, not benchmarks of named products.

Result: Select local edge candidate A. Privacy excludes raw-image cloud offload, task quality excludes the proposed smaller variants, and both edge paths satisfy the timing, throughput, memory, and power requirements. A has the lower matched cost. B's faster response supplies no required benefit under this specification; a tighter deadline could change the choice.

Systems lesson: The final choice follows from task quality and complete-path evidence, not the tier label or peak compute rate. The decision remains valid within the supplied operating conditions; changes to the input stream, detector, load, or thermal environment require reevaluating the relevant gates.

The completed comparison depends on operational maintainability as well as execution performance. Its matched budgets include obligations that a hardware-only comparison would omit. Deploying a model across thousands of edge nodes or millions of microcontrollers introduces sustained lifecycle overhead: automated firmware updates, out-of-band telemetry, distributed drift monitoring, and hardware failure recovery. An organization equipped for cloud operations may lack

the embedded toolchains and physical testing infrastructure required to support edge or TinyML targets at scale.

Checkpoint 2.2: System design

First justify the learned system against simpler baselines; then screen its deployment candidates against the physical and operational constraints.

Decision gates

- ☐ **The baseline**: Can you distinguish a rule-based baseline, such as a regular expression, from a simple learned baseline, such as a small model trained on a handful of features, and explain what comparison each provides?
- ☐ **Physical feasibility**: If a remote path's propagation floor exceeds the service deadline, can you reject it and identify which local execution and memory measurements are still needed before choosing an alternative?
- ☐ **The infrastructure cost**: What evidence about error consequences and engineering cost is needed to decide whether a five-point accuracy gain (90 to 95 percent) justifies a hypothetical 40× increase in monthly maintenance hours?

The decision framework screens candidate tiers for physical feasibility and then compares their operational costs. If no single tier meets the requirements of the whole pipeline, the next question is which stages can run separately, and what must cross the boundaries between them.

2.10 Hybrid Architectures

A voice interface can use a microcontroller to listen continuously for a wake word, a phone to transcribe speech, and cloud servers to interpret requests that need a larger model. Each stage has a different task and resource budget. Sending every audio sample to the cloud would add communication and radio costs; asking the microcontroller to perform every stage would exceed its compute and memory capacity. *Hybrid architectures* divide the pipeline across tiers so that each stage meets its requirements (Kang et al. 2017). Economics drive this division as much as latency: processing voice interactions for billions of devices entirely in the cloud runs into both an economic and an infrastructure ceiling, and the voice assistant wall puts a number on each.

Napkin Math 2.10: The voice assistant wall

Problem: In this illustrative capacity scenario, 1B voice assistant devices (smartphones, smart speakers, earbuds) each issue 20 queries/day after the wake word. Detecting the wake word itself in the cloud would require every microphone to stream audio continuously. What load would cloud-side detection impose, and what load remains in the cloud once detection moves on device?

Cloud-side detection: The always-listening path that local detection removes.

- **Audio streaming**: Every device streams audio continuously (16 kHz, 16-bit), about 32 KB/s each. Across 1 billion devices the aggregate is 32 TB/s, and each stream would also need its own continuously running detector.
- **Cloud cost**: ~$0.50/device/year → 1B devices = $500,000,000/year. Economically prohibitive under these assumptions for a free feature.
- **TinyML alternative**: 0.1–1 mW local wake-word detection, <$0.01/device/year. If each post-wake query uploads about 5 s of audio, local detection cuts the audio leaving each device by about 860×.

Residual cloud load: The post-wake queries the hybrid design still serves in the cloud. Even with local wake-word filtering, the residual query volume (1 billion devices generating 20B

queries/day at ~200 ms per query) still requires substantial centralized accelerator capacity (~1.1 million GPU-hours per day).

Five parameters determine the required cluster capacity:

1. **Query volume**: 1 billion devices × 20 queries/day = 20B queries/day.
2. **GPU demand**: Each query requires ~200 ms of GPU time. Total: 1.1 million GPU-hours/day.
3. **Scenario capacity**: A data-center equivalent provisioned with 10,000 GPUs provides 240,000 GPU-hours/day.
4. **Average requirement**: ~4.6 dedicated data centers just for voice inference.
5. **Peak reality**: Queries cluster in waking hours (~4.5× peak-to-average), requiring ~20.8 data centers at peak.

Systems insight: Local detection reduces each device's upload to its post-wake queries, 20 queries/day of a few seconds each. The residual post-wake load is still large, tens of data centers at peak, but it is bounded by what users actually ask, and it is the load the hybrid design deliberately keeps in the cloud to use a larger language model than the local device can support.

Partitioning the voice pipeline into an on-device wake-word filter and a cloud-based language model relieves both the client's energy limit and the data center's capacity limit. The division also creates engineering work: deciding what data crosses each boundary and keeping the participating stages consistent. Three integration patterns organize these choices.

2.10.1 Splitting work across tiers: Three integration patterns

When a single tier cannot satisfy every stage of an ML pipeline, engineers split the pipeline along one of three physical boundaries: train-serve split, hierarchical processing, or progressive deployment. Selecting a pattern is an iron-law decision: each stage of computation must execute where its binding term (throughput capacity R_{peak}, local latency floor L_{lat}, or the memory-capacity precondition) incurs the lowest system penalty.

Under a **train-serve split**, training executes in centralized data centers while inference runs locally on edge, mobile, or embedded devices. Training must retain intermediate results and information used to calculate and apply parameter updates, in addition to the model weights. Under common 16-bit mixed-precision training with a standard adaptive optimizer, the weights, their gradients, and the optimizer's running statistics together occupy about 16 bytes per parameter (Rajbhandari et al. 2020), roughly 8× the 2 bytes per parameter that 16-bit inference weights need, before any batch activations are counted (section 8.4.3.2 develops this accounting). Inference uses the trained weights to compute predictions, sometimes through repeated passes as in token-by-token generation, and must satisfy local latency and privacy constraints. Amortization underpins the economics of this split: the high fixed cost of training is distributed across millions of forward-pass queries served locally without recurring network transmission costs.[33]

[33] **Train-serve cost asymmetry**: Training usually requires many forward and backward passes, whereas one inference request uses a trained artifact for one or more forward passes. Training is not literally one-time because models may be retrained, and inference cost varies sharply with model size, sequence length, batching, and service overhead. The economic rationale for the split is amortization: repeated use can spread each training cycle's fixed cost across many served predictions.

Definition 2.6: Hybrid ML

Hybrid machine learning is the deployment strategy that distributes an ML pipeline across two or more deployment tiers, assigning each stage according to its latency, compute, data, and operational constraints.

1. **Significance**: Hybrid architectures exploit the iron law's additive structure: the edge tier can reduce L_{lat} for time-sensitive preprocessing and inference, while the cloud tier can provide the R_{peak} needed for training, retraining, and heavy batch inference. The split follows the data locality invariant: compare each stage's complete local and remote paths, reject paths that miss the service deadline, and then choose among the feasible alternatives.

2. **Distinction**: Unlike cloud-only deployment (which accepts the distance penalty for all stages) or edge-only deployment (which accepts limited R_{peak} for all stages), hybrid ML assigns each pipeline stage to the tier where its binding iron law term is minimized.
3. **Common pitfall**: A frequent misconception is that hybrid ML is just "running two models." In reality, the participating tiers must share synchronized state (feature definitions, model versions, and preprocessing logic) so that their paths produce consistent results. Without this synchronization, training-serving skew emerges at tier boundaries.

Under **hierarchical processing**, computation cascades across tiers to filter and summarize data step by step, matching communication volume to available link bandwidth. Raw sensor streams from cameras or microphones at the edge of the network often exceed wide-area network (WAN) uplink capacity; continuously streaming uncompressed telemetry to a data center saturates network links and wastes radio power. To prevent network saturation, early tiers filter data locally: TinyML microcontrollers run low-power anomaly detectors, edge gateways aggregate and correlate temporal features across multiple sensors, and cloud clusters ingest only anomalous events or aggregated summaries for global analytics. During inference serving, hierarchical processing frequently takes the form of a confidence cascade (Teerapittayanon, McDanel, and Hsiang-Tsung Kung 2017). A compact, low-latency model on the local device evaluates the input first. If its prediction confidence exceeds a calibrated confidence threshold, the device returns the result immediately, bypassing the network entirely. Only ambiguous or low-confidence inputs trigger a WAN payload transfer to a larger cloud model. The cascade seeks lower median latency at the required task quality, but confident local errors can bypass escalation. Representative evaluation must establish the routed system's accuracy, error costs, and escalation frequency before accepting that trade-off.

Under **progressive deployment**, an engineering team derives a family of specialized model variants from a unified architecture or training corpus, tailoring each variant to the memory capacity, arithmetic intensity, and thermal limits of a specific tier. Rather than forcing a single model onto every device, developers produce tier-specific artifacts and evaluate the quality lost or retained as resource demands fall. The compression mechanisms are developed later; the placement decision here depends on whether each artifact meets its task and hardware constraints. For a shared image-classification task, an edge server and a phone can use different members of a model family, each evaluated against the same task requirements and its own resource budget. A voice interface that divides wake-word detection, acoustic processing, and language understanding among tiers illustrates hierarchical processing across different tasks, and it can also use tier-specific variants within a task.

With three integration patterns available, selection becomes a constraint-matching problem: choose the pattern whose trade-off profile matches the system's dominant bottleneck, weighing the conditions that favor each pattern against those that disqualify it (table 2.10).

Table 2.10: Hybrid Pattern Selection Guide: Each of the three hybrid integration patterns has a characteristic trade-off, favoring conditions, and disqualifying conditions. Selection matches the pattern's trade-off profile to the system's dominant bottleneck.

Pattern	Trade-off	Choose when	Avoid when
Train-Serve Split	Training cost vs. inference latency	Training requires more resources than inference; training data may leave the serving device	Local adaptation cannot wait for remote training and model delivery
Hierarchical Processing	Local autonomy vs. global optimization	Data volume exceeds transmission capacity; decisions needed at multiple timescales	All processing can occur at one tier; network is reliable and fast
Progressive Deployment	Model quality vs. deployment reach	Same model needed at multiple capability levels; graceful degradation required	Model cannot be meaningfully compressed; single deployment target

Production deployments rarely implement these patterns in isolation; complex systems compose them across different phases of the pipeline. An autonomous vehicle, for example, combines progressive deployment to fit specialized vision backbones into its on-board compute envelope,

hierarchical processing to arbitrate between immediate millisecond-scale emergency braking on local hardware and multi-second trajectory planning, and a train-serve split that uploads anomalous driving slices to cloud clusters for fleet-level retraining. Privacy-preserving distributed training approaches extend this composition further when raw training data cannot leave client devices for regulatory or privacy reasons. In federated learning (McMahan et al. 2017), for example, each device trains on its own data and sends only model updates to the cloud for aggregation.

2.10.2 How hybrid tiers communicate in production

If a phone's audio preprocessor updates its normalization constants while the cloud transcription model expects the old scaling, or if a smartwatch and phone disagree on which activity labels are active, the hybrid pipeline fails silently across the tier boundary. Keeping multiple execution tiers working as one system requires explicit communication pathways. Five interaction channels connect the tiers (figure 2.12): compiled model artifacts deploy downward from cloud training clusters to edge, mobile, and TinyML inference engines, while raw sensor streams and filtered telemetry propagate upward toward cloud analytics, complemented by peer-to-peer result forwarding, local assist handoffs, and state synchronization that keeps feature definitions and model versions consistent across tiers.

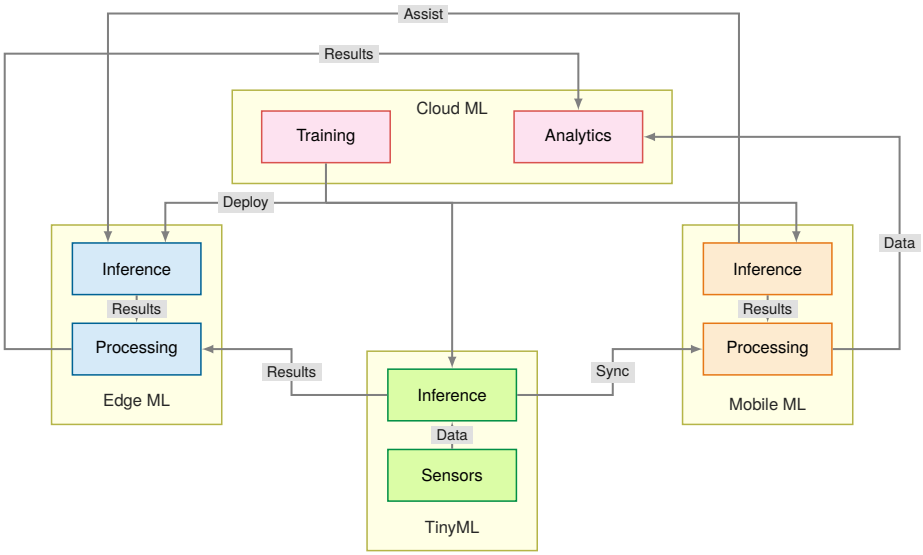

Figure 2.12: Hybrid System Interactions: Data flows upward from sensors through processing layers to cloud analytics, while trained models deploy downward to edge, mobile, and TinyML inference points. Five connection types (deploy, data, results, assist, and sync) establish a distributed architecture where each paradigm contributes unique capabilities.

Production systems place each tier boundary at a distinct physical bottleneck:

1. **Industrial defect detection**: Assembly lines running at high cycle rates require sub-10 ms deterministic visual inspection. Streaming high-resolution camera frames over WAN to a data center violates inspection deadlines and exhausts factory uplink bandwidth. The system deploys a train-serve split: centralized cloud infrastructure trains high-capacity vision models on historical defect databases, then compiles and quantizes runtime weights for factory-floor edge servers and embedded smart cameras, which run inference locally without external network dependencies. The complete local pipeline, including frame acquisition, preprocessing, and inference, must still be validated under the expected load.
2. **Agricultural monitoring**: Deployed across hundreds of hectares, remote soil probes run on coin-cell batteries or small solar harvesters and communicate over low-power wide-area radios such as LoRa, which carry little data and spend much energy per bit. Streaming continuous moisture and temperature telemetry would exhaust battery reserves within days. Hierarchical processing therefore keeps high-frequency sampling and basic anomaly detection on TinyML

microcontrollers in sub-milliwatt power budgets, while local edge gateways aggregate measurements across clusters of probes and send only compressed, field-level summaries over cellular backhaul to cloud servers that schedule irrigation farm-wide.

3. **Wearable fitness tracking**: A battery-powered smartwatch must keep its always-on sensing path averaging under 1 mW to preserve battery life. The system employs hierarchical processing: lightweight integer kernels run on an embedded microcontroller to track real-time motion and detect heart-rate thresholds; intermediate biometric data synchronizes over Bluetooth Low Energy (BLE) to a paired smartphone, which uses mobile neural engines and gigabytes of DRAM to classify complex activity patterns; finally, the smartphone transmits periodic compressed summaries over Wi-Fi or cellular networks to cloud infrastructure for longitudinal health modeling.

Checkpoint 2.3: Hybrid ML patterns

Hybrid architectures work when partitioning work across tiers, not when copying the same pipeline everywhere.

Integration patterns

- ☐ **Train-serve split**: Can you explain why training in the cloud and serving on edge/mobile is often economically optimal, even when the model runs locally?
- ☐ **Hierarchical processing**: Can you describe what each tier does in a sensor → edge → cloud pipeline, and why pushing some decisions down reduces both latency and bandwidth?
- ☐ **Progressive deployment**: Can you explain why a shared task may require different model artifacts on different tiers, and which quality and resource measurements would establish their suitability?

Design sanity checks

- ☐ **Boundary choice**: Given a concrete application, can you justify where the tier boundary should fall (latency, privacy, bandwidth, power), not just what model to use?
- ☐ **State synchronization**: Can you identify which feature definitions, model versions, and preprocessing logic must remain synchronized across tiers?

2.11 What Every Tier Shares

Although the four deployment tiers differ by orders of magnitude in available energy, memory capacity, and compute throughput, they rest on shared systems foundations. Every tier moves data through a pipeline, manages a fixed budget of compute, memory, energy, and network capacity, and binds models to hardware through a software architecture. On those three shared foundations rest the same cross-cutting concerns of efficiency, monitoring, and trustworthy engineering (figure 2.13).

This convergence lets one set of techniques serve every tier, and every stage of a hybrid system, because optimizations that target the same physical bottlenecks transfer across hardware scales. Techniques that reduce off-chip transfers, the cost the memory wall imposes, help both an embedded microcontroller and a warehouse-scale accelerator. Lower-precision numerical representations (such as FP8, INT8, and INT4, which section 10.3 develops) cut the bytes stored and moved on local devices and in cloud clusters alike, and they raise arithmetic throughput only where the datapath has a matching low-precision path (section 11.4.5.1); prediction quality and complete memory traffic still determine the useful gain. Kernel fusion (executing a chain of operations in one pass so that intermediate results stay on chip, as section 7.3.2 explains) reduces off-chip traffic on mobile SoCs and HBM traffic during cloud autoregressive decoding. Graph partitioning, which splits a model's computation graph into pieces assigned to different processors, divides work across the CPU, GPU, and neural processing units of a mobile SoC just as it divides work across cloud workers.

The shared systems foundation extends through data engineering, model compression, and operational lifecycles. The same vulnerabilities therefore recur at every tier, namely data distribution

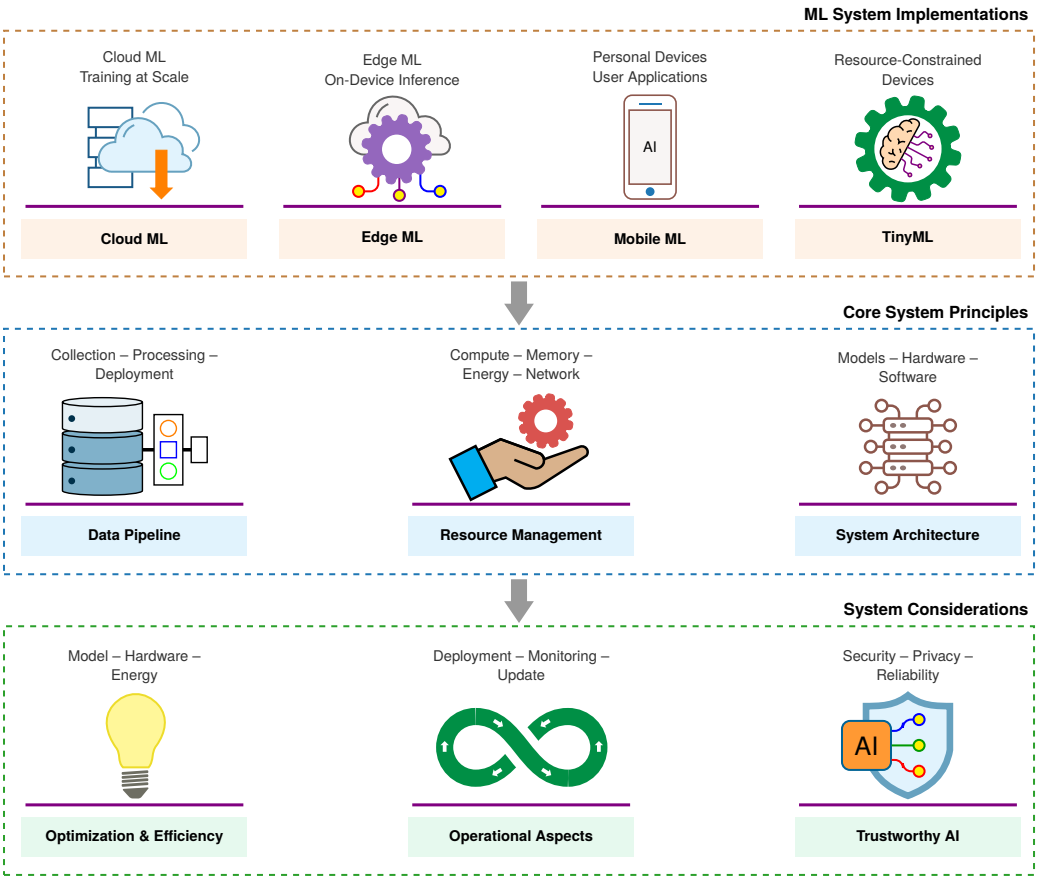

Figure 2.13: Convergence of ML Systems: Despite vast resource disparities across cloud, edge, mobile, and TinyML tiers, all deployments converge on three shared systems foundations: data pipelines, resource management, and hardware-software architecture. These shared pillars in turn support unified requirements for performance optimization, operational monitoring, and trustworthy engineering.

drift, model staleness, and telemetry degradation, and they call for uniform monitoring wherever the model runs. Of these, drift needs the closest watch, because it degrades a system whose code, weights, and hardware all execute correctly and so raises no infrastructure alarm. Accuracy falls with the divergence between training and operational data, the silent degradation that section 1.6 states with the degradation equation (equation 1.1), and chapter 14 develops the monitoring and retraining that respond to it.

2.12 Fallacies and Pitfalls

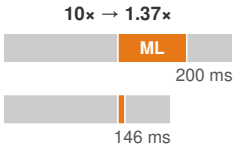
Most deployment misconceptions share one root. Each treats a physical envelope as a software detail that a later optimization can fix. Data movement, thermal dissipation, and hardware balance can invalidate otherwise reasonable optimization choices, and each fallacy and pitfall below records a system mismatched to its operating envelope.

Fallacy: *One deployment paradigm solves all ML problems.*

No single paradigm satisfies every physical constraint. Table 2.1 lists illustrative deployment envelopes rather than physics-only latency bounds. A real-time robotics system requiring sub-10 ms response cannot use a remote cloud path whose end-to-end network round-trip exceeds that budget, while a billion-parameter language model cannot reside within the few hundred kilobytes of SRAM on a microcontroller regardless of compression. Robust architectures frequently combine paradigms,

using cloud resources for distributed training and burst capacity while executing localized inference or sensor preprocessing on client devices.

A related misconception assumes that moving computation closer to the user always reduces latency, overlooking the execution delay introduced by thermally constrained or lower-bandwidth edge processors, a trade-off exposed when end-to-end latency is separated from model execution time, as in section 12.3.4.



Pitfall: *Relying on model optimization to overcome mobile power and thermal limits.*

Compression techniques reduce power but cannot remove the thermal ceiling. Consider a smartphone equipped with a 15 Wh battery. A light inference workload drawing 1 W runs for $\frac{15\text{ Wh}}{1\text{ W}} = 15$ h, but an intensive workload drawing 5 W in this illustrative heavy-load scenario depletes that same battery in $\frac{15\text{ Wh}}{5\text{ W}} = 3$ h.

Sustained execution at 5 W also exceeds the approximately 3 W that a smartphone chassis can dissipate passively, so the device throttles as in notebook 2.9. Quantizing FP32 parameters to INT8 shrinks the memory footprint by an illustrative 4×, but switching energy and static leakage (the power a chip draws even while idle) do not fall in proportion, so a continuous pipeline above the thermal envelope still requires a lower duty cycle, a restructured architecture, or dedicated accelerator silicon.

Fallacy: *TinyML represents scaled-down mobile ML.*

The boundary between TinyML and mobile deployment changes the execution environment: much smaller working-memory and energy budgets require different scheduling and runtime choices. As section 2.8.1 establishes, microcontrollers provide 10^5 to 10^6 bytes of on-chip RAM compared to mobile platforms with 8–16 GB of LPDDR DRAM, a 10,000× capacity disparity that dictates memory residency. Where mobile systems execute models with tens of millions of parameters, many TinyML architectures use tens or hundreds of thousands of parameters, with low-precision arithmetic and layer scheduling that holds fewer intermediate results at once. Operating power budgets show an even sharper discontinuity: mobile inference draws 3–5 W, whereas TinyML targets an average power of < 1 mW to operate within energy-harvesting envelopes. Teams that apply mobile optimization techniques directly to TinyML environments discover that quantizing a trained model from FP32 to INT8 is insufficient on the smallest microcontrollers, where total working memory must fit inside as little as 64 KB of SRAM, forcing complete algorithmic redesign.

A faster model stage does not linearly speed up a camera pipeline.

Pitfall: *Minimizing computational resources minimizes total cost.*

Shaving dollars off per-inference compute in isolation often drives up operating bills and slows down shipping. As the decision framework in section 2.9.2 emphasizes, architectural selection requires evaluating TCO across the entire system lifecycle rather than raw server costs. In this scenario, a cloud inference service costing $2,000/month in compute appears expensive compared to $500/month in amortized edge hardware. However, a distributed edge fleet introduces recurring operational expenses: network engineering ($3,000/month), field hardware maintenance ($500/month), and fleet reliability engineering ($2,000/month). Together with hardware amortization, these bring the listed edge budget to $6,000/month, erasing the apparent hardware-only saving. The cloud figure includes compute alone, so the two totals do not establish a total-cost ranking; cloud operating costs and comparable service capacity remain outside this comparison. Unlike the single-server comparison in napkin math 2.3, this scenario operates a distributed fleet, where network, maintenance, and reliability labor scale with the number of sites. If a cloud-managed service reaches production in two months while custom edge infrastructure requires six, the four-month delay also carries an opportunity cost. Sound systems engineering balances compute efficiency against developer velocity, fleet manageability, and operational maintenance.

Fallacy: *Model optimization translates linearly to system speedup.*

Amdahl's law[34] caps end-to-end speedup by the share of time an optimization leaves untouched, the limit that the introduction's fallacies already showed for preprocessing (section 1.11); equation 11.1 states the bound for an accelerated path. Pipelining can overlap stages to raise steady-state throughput (section 2.3.1), but the stages of an interactive capture path run in strict serial order, so the cap applies in full. A smartphone camera spends 60 ms of its 200 ms capture path on ML scene

[34] **Amdahl's law**: Formalized by Amdahl (1967) for multiprocessor scaling, this principle applies directly to ML deployment pipelines where the model is only one stage among many. Where ML is 30 to 50 percent of runtime, even a 100× model speedup yields only about 1.4–2× end-to-end improvement, because the rest of the pipeline is unchanged. Teams that benchmark model latency in isolation systematically overestimate deployment gains.

classification, which runs between 100 ms of image signal processing and 40 ms of tone mapping and HDR merge. A 10× faster model (6 ms of classification) shortens the path only to 146 ms, an end-to-end gain of 1.37×, and even an infinitely fast model cannot exceed 1.43× while the other 70 percent of the path is unchanged. Optimizing an ML system requires profiling the full execution graph; accelerating an isolated stage yields diminishing returns once that stage ceases to be the critical-path bottleneck.

Pitfall: *Assuming more training data always improves deployed model performance.*

Three constraints bound the returns of data scaling. First, algorithmic capacity (A) saturates: when a model's parameter budget is fixed, additional training data cannot squeeze more patterns into a model whose layers are too small to represent them. Second, data quality (D) matters more than raw volume: mislabeled examples, uncalibrated sensors, and spurious shortcuts corrupt gradient updates, so scaling up a noisy dataset only teaches the model its errors with higher confidence. Third, the deployment tier decides which data counts as in-domain. A microcontroller's microphone, a phone camera, and a data-center log stream capture inputs with different noise, resolution, and sampling, so a large corpus gathered under one tier's conditions can match another tier's inputs poorly. High-fidelity data collected under the target tier's own sensing conditions often yields higher serving accuracy than a much larger out-of-domain corpus.

Fallacy: *One model binary can serve every edge hardware target efficiently.*

Teams frequently compile a single model artifact and deploy it uniformly across diverse devices, treating deployment as a packaging step rather than a hardware co-design problem. In practice, hardware-specific compilation and kernel lowering (translating each operation into code tuned for the target's instruction set and memory layout) capture critical efficiencies that generic binaries forfeit. For example, quantized INT8 operations on a dedicated neural processing unit (NPU) achieve substantially higher throughput per watt than the identical model on a general-purpose CPU, and kernel fusion keeps intermediate activation tensors in on-chip SRAM rather than evicting them to energy-expensive off-chip DRAM. As the hardware analysis in section 2.4 establishes, hardware architectures impose divergent execution constraints: a binary compiled for a general-purpose mobile CPU does not use the specialized matrix engines of an embedded NPU. A portable model artifact can run through multiple backends, but portability alone does not establish efficiency. Production deployment requires profiling the target runtime and hardware, then selecting compilation, kernels, and memory layouts that meet its resource and thermal limits.

2.13 Summary

The same model demands different engineering on a phone and in a data center because each deployment target offers the model different hardware terms. The iron law of ML systems ($T = \frac{D_{\text{vol}}}{\text{BW}} + \frac{O}{R_{\text{peak}} \cdot \eta_{\text{hw}}} + L_{\text{lat}}$) unifies these physical limits into a single execution model. Propagation delay contributes fixed latency (L_{lat}), the memory wall bounds data movement (D_{vol}/BW), and thermal power budgets cap sustained compute.

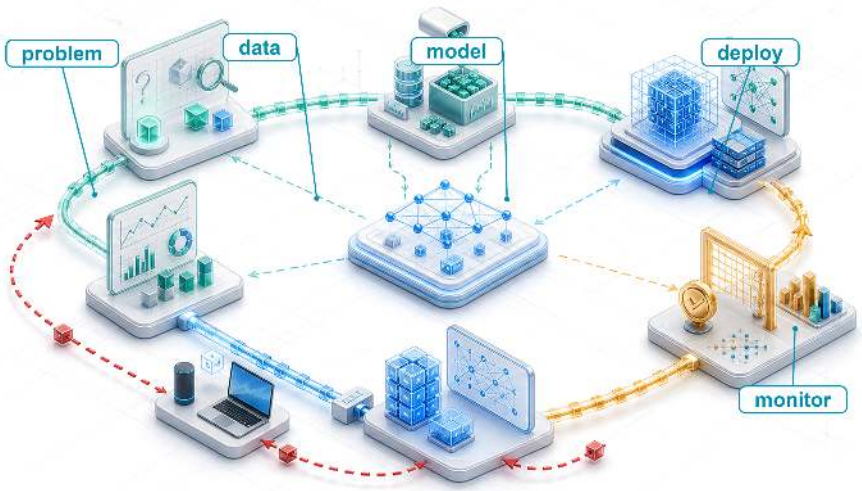
By applying the bottleneck principle to workload archetypes, engineers determine whether a model's latency is dominated by compute efficiency, memory bandwidth, or network transit before committing to single-node or hybrid architectures. The quantitative trade-offs summarized in table 2.9 and the tiered screening sequence formalized in figure 2.11 establish the physical baselines for later decisions in model compression, data pipeline design, and high-performance serving.

Key Takeaways: Same model, different engineering

- **Physical constraints define feasibility**: Propagation delay sets a lower bound on remote response time (about 36 ms for a cross-country round trip). Power and memory budgets limit what a platform can sustain, so a feasible deployment must meet the task's deadline within the target platform's resource limits.
- **Identify bottlenecks before optimizing**: The same model can be compute bound in batched training yet bandwidth-bound at batch-1 inference. The iron law and bottleneck

principle pinpoint which constraint dominates; shortening a nonlimiting stage may reduce request latency without increasing steady-state throughput.

- **Match workload demands to deployment budgets**: A compute-bound workload such as large-scale image-model training often needs cloud-scale resources; a power-bound workload such as keyword spotting benefits from microcontroller efficiency. Engineers must identify the binding constraint under the intended execution conditions rather than choose a deployment from the model name alone.
- **Screen feasibility before comparing cost**: Privacy, latency, and resource gates remove infeasible tiers before cost is compared. Among the survivors, utilization, provisioning, and fleet maintenance, not resource savings alone, decide which architecture is cheaper.
- **Hybrid architectures divide work by constraint**: The voice-assistant example assigns wake-word detection to TinyML, speech-to-text to mobile, and language understanding to cloud. Train-serve split, hierarchical processing, and progressive deployment provide three patterns for combining tiers; the choice depends on each stage's requirements.
- **Deployment begins a feedback loop**: Live data can diverge from training conditions while code and weights stay fixed, so monitoring and bounded operational exposure are part of the system architecture.



Deployment paradigms are not product categories. They are operating regimes shaped by physical and operational constraints, and selecting one changes which constraint is most likely to bind. Data-center training can push against peak compute (O/R_{peak}). Mobile inference is bounded by energy, with the battery setting the budget and the chassis capping the rate at which it can be spent. Remote real-time inference can be constrained by propagation delay (L_{lat}). Systems engineering begins by measuring that binding constraint, and the measurement is worth most when it comes early. Optimizing model architecture or software runtimes without first identifying the binding constraint produces systems that fail when they meet real operating conditions.

What's Next: From theory to process

The decision framework in section 2.9.2 identifies where an ML system can execute, but the team must use those constraints throughout development. Knowing where a model can run helps little if the team learns it too late, because constraints discovered at launch invalidate months of earlier decisions. Chapter 3 traces exactly that failure, a deployment memory budget discovered only after five months of work, and shows how such constraints must travel backward to the first design meeting. It introduces the machine learning lifecycle, the iterative engineering process that carries a system from problem definition through deployment, monitoring, and maintenance, and the workflow that carries constraints around it.

Purpose

Why is seeing the whole map necessary before walking any single path?

Engineering organizations often split an ML system into three specialties, with one team curating datasets, another tuning model architectures, and a third provisioning serving hardware. The components those teams own remain coupled. The volume and quality of collected data bound which algorithms are viable, the computational structure of the chosen algorithm dictates what hardware can execute it efficiently, and the memory and bandwidth of the target hardware reshape what preprocessing can run at inference. Optimizing each in isolation tends to produce accurate models that cannot be deployed and efficient data pipelines that serve the wrong distributions, and the cost of such a mismatch compounds with how late it surfaces. A memory limit discovered during initial design changes one line of a hardware specification; the same limit discovered on the eve of deployment discards months of training runs, annotation budgets, and integration work. Before analyzing any single component, an engineer needs the full map of how an ML system is specified, trained, validated, deployed, and sustained as one operational loop. In D·A·M terms, the ML lifecycle is where data, algorithm, and machine are co-designed over time, each stage passing constraints to the others until their combined capability meets real-world requirements.

Learning Objectives

- Explain the six ML lifecycle stages as coordinated data-algorithm-machine decisions with feedback
- Compare ML workflows with traditional software using drift, nondeterminism, and operational feedback
- Construct a problem definition that states a request as a measurable improvement over an existing baseline
- Analyze how problem-definition constraints propagate through data, modeling, validation, and deployment
- Estimate rework from a late-discovered constraint by tracing dependent data, model, validation, and deployment artifacts
- Evaluate accuracy, efficiency, reproducibility, and deployment readiness trade-offs across lifecycle stages
- Design feedback loops that connect monitoring signals to retraining, maintenance, and revised requirements

3.1 The Lifecycle as a Loop

Building an ML system takes far more than training a model. A team must decide what the system has to do and within which limits, gather and prepare the data it learns from, train and test the model, install it where it will run, and keep checking that it still works as the world around it changes. Chapter 2 examined one of those limits in depth, showing that the deployment target can change the engineering of the same model by orders of magnitude between a phone and a data center. The rest of this book takes the remaining work apart piece by piece along the data, algorithm, and machine axes, from data pipelines and model architectures through training, optimization, and serving. Those pieces are not independent. Each hands its results to the next, and a mistake made in one tends to surface in another, so understanding any single piece first requires understanding how they connect: the sequence of stages every ML system moves through, what each stage hands to the next, and how a constraint discovered in one place reaches the others.

That sequence is the **machine learning lifecycle**, a structured, iterative process[1] that guides the development, evaluation, and improvement of ML systems (Amershi et al. 2019). Numbered in the order a project first meets them, its six stages form a chain in which each stage produces the artifact the next one needs: problem definition (1) turns a request into measurable targets and deployment constraints, which guide data collection and preparation (2) as it turns raw observations into a versioned, validated dataset. Model development and training (3) then fits trained weights to that dataset, and evaluation and validation (4) tests those weights against the original targets and records the release evidence in a release manifest. Once the manifest clears the gate, deployment and integration (5) installs the approved model where it must run, while monitoring and maintenance (6) watches the live system and sends what it learns back to earlier stages, closing the loop drawn in figure 3.1.

The return arrow from monitoring is what makes the lifecycle a loop rather than a checklist. Evidence flows back from later stages to earlier ones, and constraints should flow back with it. A memory limit set by the deployment device belongs in problem definition, where it can shape the dataset, the model, and the evaluation, not in deployment, where it can only reject them.

[1] **CRISP-DM (cross-industry standard process for data mining)**: CRISP-DM codified data-intensive system development as six interconnected, iterative phases rather than a linear waterfall (Chapman et al. 2000); its core design principle (moving back and forth between phases as results require) directly informs the modern ML lifecycle's structure.

Definition 3.1: Machine learning lifecycle

Machine learning lifecycle is the iterative engineering process of building, deploying, monitoring, and updating ML systems, where evidence from later stages can feed back to earlier stages because model performance may change after deployment.

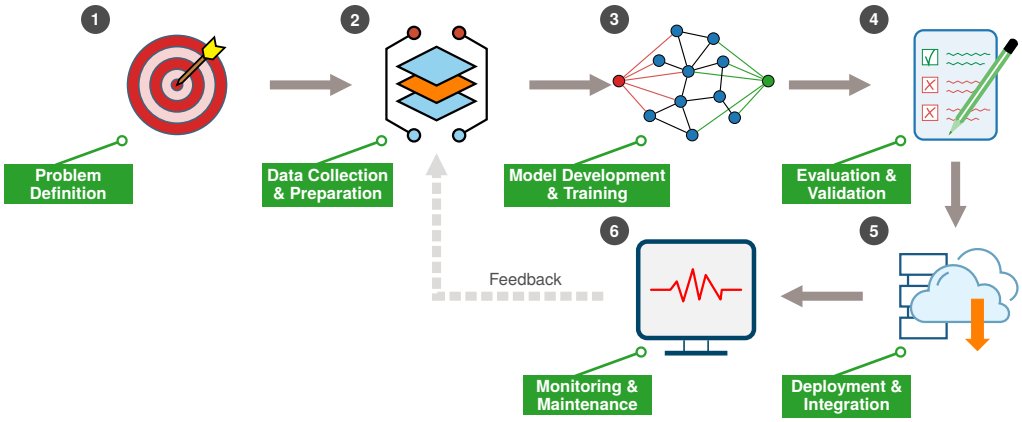

Figure 3.1: Simplified Lifecycle with Feedback: The six core stages of ML engineering form a closed loop rather than a linear handoff. A primary feedback path from monitoring back to data collection supports investigation and adaptation as production distributions shift, model accuracy degrades, and operational constraints evolve.

1. **Significance**: The lifecycle is a closed loop, not a linear pipeline. Each stage hands the next an artifact it depends on (targets, a dataset, trained weights, release evidence, a running service, monitoring evidence), so a decision at one stage constrains every stage after it, and evidence from a later stage can force an earlier one to be revisited. How often the loop must turn is itself a recurring budget, set by how quickly the deployment environment changes and how long verified labels take to arrive.
2. **Distinction**: Unlike traditional software, whose behavior changes when code, configuration, dependencies, or environment changes, ML behavior can also change as the world changes. A deployed model's accuracy may change through distribution shift even when the code, infrastructure, and configuration remain untouched.
3. **Common pitfall**: Treating deployment as the end of the lifecycle. Retraining decisions depend on outcome evidence that exists only after deployment.

Carrying constraints around that loop is the job of the **ML workflow**, the engineering framework that makes constraints explicit at each stage and traces how deployment constraints propagate across Data, Algorithm, and Machine. The two terms divide the job. The lifecycle is *what gets traversed*, the stages themselves; the workflow is *how the traversal is managed*, the engineering discipline of orchestrating them. The workflow marks the shift from model researcher to systems engineer. A researcher optimizes individual elements: a better architecture, a cleaner dataset, a faster accelerator. A systems engineer orchestrates those elements into production systems that reliably deliver value.

In practice, the stages between problem definition and deployment run as two pipelines on different clocks. Figure 3.2 zooms into that work as ten finer-grained blocks. The upper data pipeline, the substance of stage 2, continuously transforms raw operational streams through ingestion, curation, annotation, and validation into versioned, ML-ready datasets. The lower model pipeline executes the inner development loop of stages 3 and 4: training architectures, computing evaluation metrics, validating system constraints, and packaging approved artifacts for deployment, with stage 4's release manifest drawn as an ML certificate. Outer-loop feedback arrows carry production telemetry and validation discoveries back to upstream data stages, the return path that stage 6 operates.

↩ The deployment paradigms whose memory, latency, and power constraints the workflow propagates are established in section 2.1.

↪ The operational tooling and infrastructure that automate these lifecycle stages at scale are developed in chapter 14.

3.1.1 ML vs. traditional software

The loop and its two pipelines exist because of one difference between ML systems and traditional software. Both iterate.[2] The difference that forces new workflow controls is where behavior comes from. Rule-based software changes behavior when someone changes the code, configuration, or dependencies. An ML system learns its behavior from data, so that behavior can also change when the data changes while the code stays fixed, and only fresh labeled outcomes can show whether

2 | **Waterfall model**: A plan-driven lifecycle is often depicted as a sequence of requirements, implementation, and testing, but Royce (1970) warned that a purely sequential implementation was risky and described iteration between successive phases. ML systems add data and model feedback that must be managed explicitly.

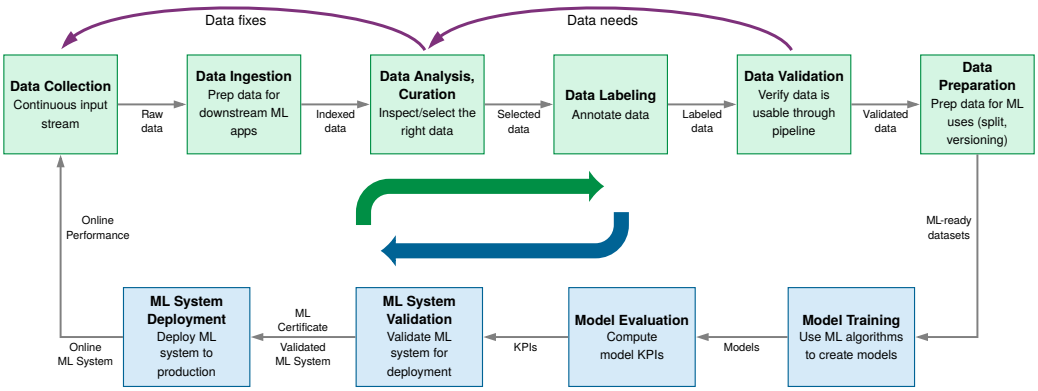

Figure 3.2: Dual-Pipeline ML Development: Machine learning engineering decouples into parallel data and model pipelines operating on different timescales. While the model pipeline executes rapid inner-loop training and evaluation, outer-loop feedback from production deployment and data validation continuously reshapes upstream collection and curation.

today's model still meets today's requirement. Every workflow addition this chapter introduces (versioned datasets,[3] statistical evaluation gates, drift monitoring) exists to manage that second path.

That difference alters how lifecycle stages interact. While conventional software engineering relies on production feedback to refine code and requirements, ML systems introduce feedback loops where operational data reshapes training distributions, detected drift prompts investigation, and runtime errors expose dataset blind spots. Table 3.1 contrasts traditional software and ML engineering across six core lifecycle dimensions, highlighting how data evolution redefines testing, deployment, and ongoing maintenance.

[3] **Data versioning**: Unlike code, which changes through discrete, auditable commits, data can drift gradually (distribution shift), suddenly (schema migration), or subtly (label quality degradation). Plain Git is impractical for many multi-terabyte datasets, so teams commonly version external-data manifests or pointers using tools such as DVC and Git LFS. Without data versioning, teams cannot reliably reproduce a prior training run or determine whether an accuracy regression stems from a code change or a data change.

↩ Data-defined behavior, and the silent degradation it makes possible, are established in section 1.6.

Table 3.1: Traditional Software vs. ML Development Lifecycles: Six dimensions where ML development diverges from traditional software engineering. Both use production feedback, while ML systems add loops in which deployment insights reshape data collection, monitoring drives model updates, and production experience informs model design.

Aspect	Traditional Software Lifecycles	Machine Learning Lifecycles
Problem Definition	Functional requirements specify behavior; tests check the code against them.	Objectives are statistical targets whose feasibility is known only after experiments on data.
Development Process	Engineers write and revise the logic directly in code and configuration.	Engineers shape behavior indirectly through data, features, architecture, and training runs.
Testing and Validation	Many functional tests have exact expected results; performance and reliability remain quantitative.	Metrics over held-out data, reported with uncertainty and across subgroups.
Deployment	Logic stays fixed until code, configuration, or dependencies change.	Accuracy can degrade when input distributions shift, with code unchanged.
Maintenance	Maintenance involves modifying code to address bugs or add features.	Continuous monitoring, updating data pipelines, retraining models, and adapting to new data distributions.
Feedback Loops	Production feedback changes code, configuration, and requirements.	Production data can become future training data, so feedback also reshapes data collection and the model.

Checkpoint 3.1: ML vs. traditional software

ML systems are not traditional software with a model attached. Check the differences that force a separate workflow:

- ☐ **Failure modes**: Can you explain how a shift in input data can degrade an ML system silently, with no code change and no error raised?
- ☐ **Logic source**: Can you explain why changing training data can change model behavior even when the code remains fixed?

- ☐ **Iteration**: Can you explain why ML requires monitoring and, when evidence warrants it, model or data updates?

Each difference in the comparison traces back to behavior learned from data, which ties every stage to the stages around it. A diagram shows where the stages sit but not how tightly they bind. Seeing that requires a concrete system, and this chapter carries one through every stage.

3.1.2 The running case: Diabetic retinopathy screening

Diabetic retinopathy (DR) is a major cause of preventable vision loss.[4] While early detection prevents severe vision loss, limited access to specialist ophthalmologists in rural regions motivates automated screening programs. Google built one of the best documented of these programs, a deep-learning model that performed at the level of ophthalmologists on curated retinal images (Gulshan et al. 2016) and that Google Health then deployed in clinics in Thailand (Beede et al. 2020). Detecting the pathology, however, requires identifying subtle microvascular features under variable capture conditions. Figure 3.3 contrasts a normal retina (Panel A) with one showing diabetic retinopathy (Panel B).

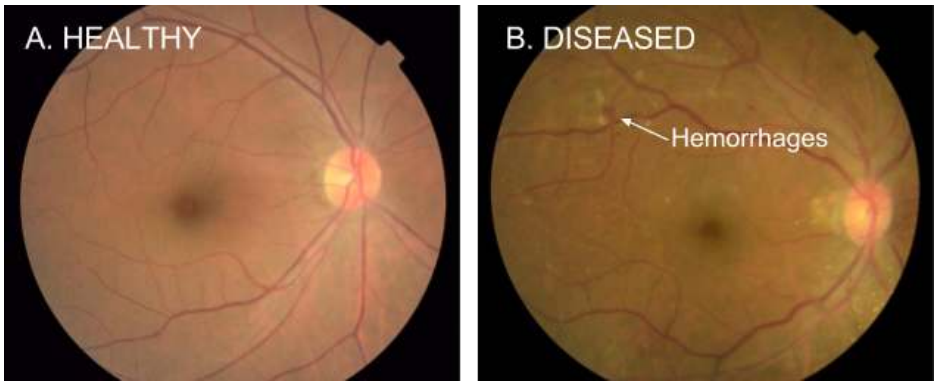

Figure 3.3: Retinal Hemorrhages in DR Screening: Side-by-side fundus images illustrate the subtle visual features an ML screening system must detect. Identifying localized microvascular lesions (such as the indicated hemorrhage) requires preserving fine spatial resolution through the vision pipeline and establishing strict input-quality validation to handle lighting and camera variations in clinical field deployments. Source: (Peng and Gulshan 2016).

This chapter follows diabetic retinopathy screening because it is a real production system whose documentation covers the full lifecycle, and because a task that looks straightforward on the surface met substantial operational friction in practice. Google's program spans both sides of the lab-to-field divide. Its controlled validation documented expert-level accuracy, while its deployment in Thai clinics exposed problems the validation never saw: images rejected as ungradable, retakes that added work for nurses, and screening delayed when slow clinic internet connections held up uploads to the remote grading service.[5]

The scenario this chapter uses to put numbers on each stage is a composite based on that real case study. Because the remote grading path depended on each clinic's internet connection, the scenario moves inference into the clinic: a network of rural clinics, each executing local inference on an Orin Nano-class edge device with 4 to 8 GB of shared memory and an intermittent wide-area uplink of roughly 2 Mbps. The clinical mandate requires more than 90 percent sensitivity and a result the nurse can act on before the patient leaves, which means within seconds of capture and even when the uplink is down. Sensitivity measures the fraction of true disease cases correctly flagged; its denominator includes only patients with the condition, meaning high aggregate accuracy on an imbalanced, mostly healthy population provides no assurance that sick patients will be detected. Specificity measures the fraction of healthy patients correctly left unflagged, bounding unnecessary referrals that would overwhelm regional specialists.

A team that runs these stages as a line rather than a loop fails in a predictable way. Day one: "Build a diabetic retinopathy screening model for rural clinics." Day 90: 92 percent sensitivity on

[4] **Diabetic retinopathy (DR)**: DR is a common complication of diabetes; early detection can prevent vision loss, but specialist access varies substantially across countries. This gap motivates scalable screening programs. In clinics with limited hardware or unreliable connectivity, model size, offline capability, latency, and workflow integration can become binding deployment constraints.

[5] **Healthcare AI deployment gap**: In the Thai DR deployment studied by Beede et al. (2020), 393 of 1,838 submitted images (21 percent) failed the system's image-quality requirements, often because clinic lighting, camera maintenance, or dilation practices did not match its assumptions. The case shows why laboratory metrics alone do not establish deployment readiness.

the validation set used to guide development. Day 120: 94 percent sensitivity after a month of architecture tuning. Day 150: the model is handed to deployment engineers. Day 151: deployment engineers report that the model needs 4 GB of memory to run. Day 152: someone checks the deployment target, a low-power edge device in each clinic whose 4–8 GB of memory is shared with the operating system, the camera pipeline, and the clinic software; the clinic's IT plan reserves about 500 MB of it for the model. Day 153: five months of work is discarded.

The model's accuracy was excellent. The team's machine learning skills were excellent. *The failure was a workflow failure.* A deployment constraint that should have shaped every decision from day one was discovered only after the work was done. That 500 MB budget should have propagated backward to the first architecture meeting, constraining which models were even worth considering. Instead, the team optimized each component in isolation (data collection, architecture selection, training), and the integration failure appeared only when the pieces were assembled. The day-153 failure is one instance of a general principle about how constraints travel through the lifecycle.

3.2 How Decisions Cascade: The Constraint Propagation Principle

In the DR scenario, the in-visit requirement already ruled out cloud inference and so required edge deployment. The edge target's memory and power budgets then constrain model architecture, favoring compact MobileNet-class models over large ensembles (several models whose predictions are combined) and requiring automated image-quality checks at capture time. Each downstream constraint narrows the design space for upstream stages, coupling hardware limits directly to data collection and model design.

Definition 3.2: Constraint propagation principle

The constraint propagation principle states that a constraint discovered late in the ML lifecycle can force rework across affected upstream stages. Datasets, trained weights, validation evidence, and deployment packages record decisions that later work depends on. Correcting a missing constraint requires tracing those dependencies to determine which artifacts must change and which remain valid. Estimating actual rework requires the effort to revise each affected artifact, repeat its dependent work, and validate the resulting system.

1. **Significance**: A latency target discovered at deployment (stage 5), such as 100 ms in a web service, may propagate backward to constrain model size (stage 3: operation count O), dataset requirements (stage 2: dataset size D, the number of training examples), and problem definition (stage 1: what accuracy is achievable). Rework depends on which earlier decisions relied on the missing constraint. Within the iron law, a latency budget bounds total time T, and therefore every term that sums to it, so it redefines the feasible region for O, for the bytes moved D_{vol} (distinct from the example count D), and for the hardware efficiency η_{hw} the model must achieve.
2. **Distinction**: Unlike modular decomposition (which encourages independent optimization of each component), this principle mandates end-to-end reasoning, because an accuracy optimum reached in isolation can be an infeasible system.
3. **Common pitfall**: Treating deployment as "the last step" and so deferring its latency, memory, and power limits until they can only reject finished work.

Propagation runs in both directions, so the stages form a network of constraints rather than a chain. Backward propagation carries a deployment limit upstream. When rural clinic deployment reveals tight bandwidth, the team can compress images before sending them over the uplink, but lossy compression degrades input quality, so the training dataset must then include matching compression artifacts or the model will see different inputs in service than in training (training-serving skew). Shifting inference entirely to the edge and transmitting only the diagnostic result relieves the uplink instead, but tightens the edge device's memory capacity and power budget. Forward propagation carries an early data decision downstream. Capturing fundus images at the resolution needed to see small hemorrhages fixes the model's input size, and with it the operation count every inference

must pay on the clinic device. Upstream data choices and downstream machine boundaries remain physically coupled.

Decisions made without accounting for downstream execution boundaries accumulate technical debt.[6] The stage interface specification (table 3.2) puts this principle to work by making constraints explicit at each stage boundary, so the team catches violations before handing an artifact downstream. When propagation occurs specifically through data quality failures, the resulting pattern is known as a data cascade, a chain of downstream failures triggered by bad data (Sambasivan et al. 2021) that section 4.2.1 examines. Propagation explains why a late constraint is expensive; how much time each loop costs, and where that time goes, is the next question.

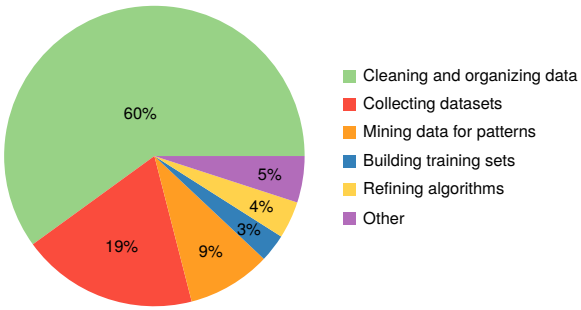
[6] **ML technical debt**: Sculley et al. (2015) identify ML-specific debt mechanisms such as *entanglement* (changing one feature affects all others because the model learned joint distributions), *hidden feedback loops* (predictions influence future training data), and *undeclared consumers* (downstream systems depending on outputs without contracts). Since ML code is often only a small part of a production system, the surrounding configuration, pipelines, and infrastructure can allow this debt to accumulate silently.

↪ Shared contracts and deployment paths that reject incompatible changes before they reach production are enforced in section 14.3.

3.3 Where the Hours Go: Quantifying the ML Lifecycle

The DR team lost five months to one late constraint, counting both the hours already spent and the experiments those hours could have run. Conceptual models of the ML lifecycle describe which stages exist, but planning a workflow requires knowing where its hours go, and that time rarely concentrates where research literature spends its pages.

Practitioner surveys show a gap between where research attention centers and where practitioners report spending their time, with about 79 percent of data scientists in CrowdFlower's 2016 survey naming data collection or cleaning as the activity that consumed most of their time (CrowdFlower 2016). In the full distribution (figure 3.4), algorithm refinement and training-set construction together draw fewer responses than data collection alone.



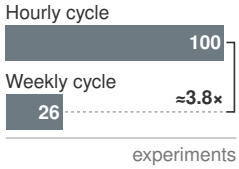


Figure 3.4: Data Scientist Most-Time Responses: In CrowdFlower's 2016 survey, 60 percent of respondents selected cleaning and organizing data as the activity where they spent the most time, with 19 percent selecting data collection. Model-focused responses such as pattern mining, training set construction, and algorithm refinement together represent roughly 16 percent of responses. Adapted from CrowdFlower (2016).

The survey responses identify data work as a major time sink for these practitioners, without measuring how all engineering hours were divided. In the DR project, where each image must be graded by multiple ophthalmologists before it can train anything, collection and labeling can delay useful experiments more than training does; improving that pipeline can then reduce iteration time before model or training optimizations become the binding concern. The workflow must identify its actual bottleneck rather than assign investment priorities from response shares alone. Even so, the imbalance explains why data engineering, developed in chapter 4, deserves explicit planning rather than treatment as setup work.

Iteration velocity governs project progress. The feedback arrows in figure 3.2 (the *Data fixes* loop from curation back to collection, the *Data needs* loop from validation back to curation, and the *Online Performance* path from production deployment back to collection) are not rare exceptions; they are paths teams traverse repeatedly. Drifting clinic images or wrong labels send the DR team back to collection, and a candidate that exceeds the clinic device's memory sends it back to model design. Each loop consumes calendar time and compute budget, so the length of one cycle bounds how much a team can learn. Consider two candidate DR models developed over the same six months: a large ensemble trained in the cloud, which takes a week per training run, and a lightweight edge model that trains in hours.

Over the same six months, the hourly cycle tests nearly four times as many ideas.

Napkin Math 3.1: The iteration tax

Problem: Compare what six months of development buys for a rural diabetic retinopathy screening system: a large ensemble developed on cloud hardware as a laboratory baseline, which would itself need compression before it could fit the clinic's memory budget (training time: 1 week, initial accuracy: 95 percent), or a lightweight edge model (training time: 1 hour, initial accuracy: 90 percent). How do the two compare in final accuracy and in the number of hypotheses the team can test?

Math: In six months (~26 weeks), the possible experiment count is:

1. Large model: 26 weeks of calendar time at 1 week per experiment. Each experiment improves accuracy by an assumed constant ~0.15 percentage points.
2. Small model: 26 weeks of calendar time at 168 h/week gives 4,368 possible experiments at 1 hour each. Machine time is not the binding constraint at that cycle length, so this scenario counts only 100 of them as effective experiments, a few per working week, the pace at which a team can design, run, and learn from experiments. Because the slow-cycle team runs one experiment per week, this cap on hypotheses, not the hardware, sets the breadth ratio below; a team that could formulate useful hypotheses faster would raise the ratio in proportion.

Result: If each iteration improves accuracy by 0.1 percentage points on average, the small model starts at 90 percent and reaches 100 percent after 100 effective iterations, before applying the 99 percent ceiling. With the 99 percent ceiling applied, the small model achieves 99 percent. The large model starts at 95 percent and reaches 98.9 percent after 26 slower iterations. Both approaches end near the ceiling, and the accuracy gap between them is an artifact of the assumed gains, not a finding. The difference that survives is breadth. Under the stated cap, the fast-cycle team tested 3.8× as many ideas, so it also learned which augmentations and preprocessing choices matter, knowledge the slow-cycle team never acquired.

Systems insight: *Iteration velocity is a feature.* Its value lies in search breadth rather than in a guaranteed accuracy lead. When candidate systems have comparable attainable quality, shorter cycles expand how much of the design space a team can test. Speed alone cannot guarantee that a smaller model will outperform a larger one. In the DR screening scenario, the lightweight model's rapid iteration cycle enables the team to experiment with label-preserving input transformations, preprocessing pipelines, and architecture variations far more quickly.

This cumulative delay defines the **iteration tax**: time spent waiting on slow training runs or cumbersome validation pipelines reduces how many candidate models a team can test. Late discoveries amplify this penalty,[7] as the constraint propagation principle (section 3.2) established. Violations caught only after deployment invalidate artifacts produced by earlier stages, forcing expensive retraining, pipeline adjustments, and renewed validation. Intercepting defects before they cascade into systemic rework requires explicit **stage interface contracts** that validate outputs at every stage boundary (section 3.4.1).

[7] **Late correction costs**: Boehm (1981) discussed in *Software Engineering Economics* how defects found late can cost more to fix than those caught during requirements. In ML systems, late-discovered constraints may require retraining, data-pipeline changes, and renewed validation.

3.4 Stage Ownership and Hand-offs

The rural-clinic failure showed what happens when no stage owns a constraint. The deployment limit surfaced only after data curation, model training, and evaluation decisions had hardened around an unfeasible target, and preventing such misalignments requires clear ownership across the system stack. The six stages of figure 3.1 divide project responsibilities along the D·A·M axes. Problem definition sets the governing requirements for all three. Data collection and preparation owns the Data axis, model development and training governs the Algorithm axis, and deployment and integration commits both to a physical Machine. Evaluation and monitoring own no single axis of their own; their role is verification, testing whether the three axes work together before release and continuously in production.

A single model choice in the DR project touches every stage. Problem definition fixed the clinic device's 500 MB model budget, so model development starts from architectures designed for budgets

of that kind. MobileNetV2, the book's mobile lighthouse workload (section 1.7.1), is a natural candidate backbone, at about 14 MB of FP32 weights and about 600 MFLOP per inference. It reaches that operation count by replacing standard image-processing layers with a cheaper variant[8] rather than by pruning a larger model. Choosing it immediately constrains the other stages. Data preparation must produce images at the capture resolution that keeps small hemorrhages visible, since that resolution rather than the backbone's default sets the input size, evaluation must measure latency on the clinic device as well as sensitivity, and deployment must confirm that weights, activations, and runtime together fit the budget. If on-device evaluation then misses the latency target, the fix loops back to architecture or input resolution, so the stage sequence in the diagram is traversed as a cycle rather than once.

8 **Depthwise separable convolutions**: The layer type MobileNetV2 uses in place of standard convolutions. It splits one expensive operation into two cheaper ones and cuts computation by roughly 8–9× for typical kernel sizes (Sandler et al. 2018), which is what makes the roughly 600 MFLOP inference budget plausible on mobile-class hardware.

Checkpoint 3.2: The workflow cycle

Verify that each stage enforces contracts that bind upstream choices to physical deployment constraints.

- ☐ **Problem definition**: Can you identify which stage records latency, memory, and accuracy targets, and explain why later stages need those targets?
- ☐ **Data preparation**: Can you identify which downstream artifacts must use the same image-resolution and preprocessing choices as the training data?
- ☐ **Model development**: Can you explain why model development needs a deployment memory budget before committing to a candidate?
- ☐ **Feedback**: Can you explain why a failed on-device latency test sends work back to architecture or input resolution rather than ending at deployment?

Each of those stage decisions also lands on a term of the iron law. In the retinal screening pipeline, the capture resolution chosen during data preparation sets the bytes moved per image (D_{vol}), the MobileNetV2 backbone selected during model development fixes the operations per frame (FLOPs/Sample), and the clinic hardware together with its serving runtime determines the realized execution speed (Seconds/FLOP) and dispatch overhead (L_{lat}). Tracing how the six stages map onto the equation shows where each team's local choices enter the end-to-end time budget.

↩ The iron law of ML systems and its governing terms are established in section 1.7.

Systems Perspective 3.1: Lifecycle stages and the iron law

The six lifecycle stages alter distinct factors in the iron law of ML systems, both across its multiplicative D·A·M form (equation 1.2) and across its unpacked physical terms ($T = \frac{D_{\text{vol}}}{\text{BW}} + \frac{O}{R_{\text{peak}} \cdot \eta_{\text{hw}}} + L_{\text{lat}}$). Rather than rigid one-to-one assignments, the mappings serve as diagnostic starting points:

- Problem definition: Sets target constraints for accuracy, latency, cost, privacy, and deployment paradigm (screened across privacy, latency, compute, and cost gates using the decision framework in figure 2.11). These targets determine which terms of the equation are permitted to grow and which must be bounded from the outset.
- Data collection and preparation: Shapes dataset composition, the sample budget (Samples/Task), and the byte volume (D_{vol}) presented to downstream pipelines. Curation can also change the training work required to reach a quality target.
- Model development and training: Dictates per-sample algorithmic work (FLOPs/Sample) and total operations (O), along with data reuse patterns, parameter movement, and achievable hardware efficiency (η_{hw}).
- Evaluation and validation: Tests whether model quality and end-to-end execution meet deployment requirements on the target system.

- Deployment and integration: Determines the serving path and realized machine speed (Seconds/FLOP), including runtime data movement, execution efficiency, and fixed overhead (L_{lat}).
- Monitoring and maintenance: Observes distribution drift, latency, throughput, and operational cost after launch, feeding violations back into earlier stages for re-optimization.

Viewing the lifecycle through the iron law grounds latency and cost in hardware physics. Production workflows must simultaneously satisfy accuracy, safety, privacy, and organizational constraints that sit outside the equation.

3.4.1 Stage interface contracts

If the data team hands over 512×512 retinal crops while the training script expects 1024×1024 images, or if problem definition hands off to data collection without recording the clinic device's 500 MB memory limit, the defect travels silently until a downstream stage crashes or rejects the finished model. Catching those mismatches at the hand-off requires treating each lifecycle stage as an engineering boundary with defined inputs, outputs, and quality invariants. In production, pipeline orchestrators encode these dependencies as directed acyclic graphs (DAGs), where nodes represent discrete execution tasks and directed edges represent validated artifacts. While the overarching ML lifecycle forms a recurring feedback loop over weeks and months, each individual pipeline run executes as an acyclic sequence of dependent steps. This structure enables the orchestrator to parallelize independent branches, cache validated intermediate outputs, and halt execution the moment a contract is violated. Just as microservice architectures rely on interface specifications to enforce API boundaries, ML pipelines require strict schema, distribution, and performance contracts to prevent defective data or degraded weights from corrupting downstream artifacts. Each stage therefore has defined inputs, deliverables, and quality invariants (table 3.2).

Table 3.2: Stage Interface Specification: Each lifecycle stage has explicit input requirements, output deliverables, and quality invariants that must hold for the stage to be considered complete. Violations of these contracts create technical debt that compounds through subsequent stages. The deployment paradigm selection in Problem Definition (Cloud, Edge, Mobile, or TinyML) constrains all downstream stages, as a TinyML target imposes different data, model, and monitoring requirements than a Cloud target.

Stage	Input Contract	Output Contract	Quality Invariant
Problem Definition	Business requirements; operational context	Measurable objectives; deployment paradigm selection; resource constraints	All success criteria are quantifiable; target deployment paradigm is explicit
Data Collection & Preparation	Objectives; deployment target; quality requirements	Versioned dataset with schema; preprocessing pipeline; data validation rules	Distribution approximates anticipated production environment; labeling meets accuracy requirements
Model Development & Training	Dataset; accuracy targets; resource constraints	Trained model weights; training configuration; experiment logs	Meets accuracy thresholds within computational budget; architecture compatible with deployment target
Evaluation & Validation	Trained model; held-out test data; evaluation criteria	Performance metrics across subgroups; failure mode analysis; release manifest	No critical subgroup falls below minimum thresholds; predicted confidence matches observed accuracy as closely as the domain requires
Deployment & Integration	Validated model; infrastructure requirements; service-level agreement (SLA) targets	Serving endpoint; monitoring instrumentation; rollback procedures	Latency and throughput meet paradigm requirements; integration tests pass
Monitoring & Maintenance	Live system; performance baselines; alert threshold	Drift detection alerts; update-review criteria; incident reports	Alert coverage and detection windows are defined; detected degradation triggers review

Enforcing explicit contracts turns the conceptual feedback loop in figure 3.1 into an operational audit trail. When validation or monitoring surfaces a defect, the contract boundary identifies which

upstream stage owns the fix. For example, a mismatch between training features and production inputs may demand targeted data collection, whereas an error in feature transformation points directly to a bug in the serving pipeline. Catching these violations at stage boundaries stops bad assumptions before they harden into late-stage rework.

Example 3.1: Auditing stage transitions

Scenario: An engineering team claims to have completed Problem Definition for the DR screening classifier, attempting to transition to Data Collection without establishing deployment target constraints.

Diagnosis: The output contract lacks deployment paradigm selection and resource constraints (latency and memory targets). If the violation surfaces only at deployment as a trained model larger than the edge device's 500 MB model budget, the audit must trace what relied on the missing limit. A smaller candidate may require revised input-resolution or preprocessing choices, new weights, repeated sensitivity and on-device memory tests, and a replacement deployment package. Existing raw images may remain usable; changing the candidate does not imply recollecting every image.

Repair schedule: Suppose the repair plan preserves the raw images and labels but changes input preparation and the candidate architecture. Assume 1 day to revise preparation, 2 days to train new weights, 2 days to repeat validation, and 1 day to package the approved result. If each task waits for the preceding artifact and the required staff and compute are available, the repair takes 6 days. This is a supplied schedule for this dependency chain, not a multiplier determined by the discovery stage. Queueing, failed validation, or parallel independent tests would change the elapsed time.

Systems lesson: Stage transitions act as quality gates in the ML lifecycle. Enforcing strict output contract validation before proceeding downstream prevents expensive upstream rework and ensures data collection aligns with target deployment hardware.

Without explicit contract gates, unstated assumptions propagate downstream. The earliest opportunity to bound them is Problem Definition, which records the operational constraints that subsequent stages must satisfy.

3.5 Stage 1: Problem Definition

Problem definition in ML begins with sentences that look deceptively simple. A product manager writes: "Build a model that detects diabetic retinopathy." That single sentence conceals a dozen engineering decisions: sensitivity thresholds for patient safety, hardware capabilities in rural clinics, latency budgets that keep clinicians engaged, and regulatory frameworks governing approval. Software requirements still govern control flow, interfaces, and data storage. ML adds an empirical obligation. Defining *what* the system should do is inseparable from defining *how* it will learn from data and what physical constraints its execution must survive.

The request for a model must first become a requirement for a useful improvement. In the clinic case, the baseline is the existing screening and referral workflow, evaluated on the outcomes and resource limits the proposed system must improve. A simpler rule or an existing model can provide an additional comparison where appropriate. The comparison must include the complexity tax established in section 2.9.2, so a learned system earns its place only when the value of the errors it avoids exceeds the infrastructure and maintenance it adds. If available data cannot support the required evaluation, or the expected benefit does not justify the added errors, cost, and maintenance, the team should revise the problem or retain the baseline rather than proceed automatically to training.

Balancing these demands requires reasoning across the full system stack. An engineering team cannot optimize accuracy in isolation, because pursuing marginal sensitivity gains by scaling model depth or adopting a larger model family inflates parameter count and computational demands (FLOPs per inference), directly challenging the memory capacity and thermal limits of low-cost clinic hardware. Conversely, pruning a model (removing the weights that contribute least) to fit an

embedded accelerator's DRAM budget risks dropping sensitivity below clinical safety thresholds. Every technical decision operates within a multi-constraint optimization problem where statistical goals, physical execution budgets, and operational mandates continually bound each other's feasible design space.

3.5.1 Constraint layers

A screening model that reaches 95 percent sensitivity in a cloud notebook is unusable if it needs 4 GB of RAM on a clinic device with 500 MB to spare, or if clinic staff cannot audit why it flagged a patient. Every ML problem definition therefore decomposes into three interacting **constraint layers**: statistical, physical, and operational. Rather than isolated requirements, these layers form a coupled stack where a constraint in one tier immediately restricts the degrees of freedom in the others. At the top, the statistical layer specifies target behavior over data distributions, such as achieving > 90 percent sensitivity and > 80 percent specificity across diverse patient demographics and camera models rather than an unweighted aggregate accuracy that conceals failure modes on minority subpopulations. Meeting that target in the field depends on the physical layer, which bounds execution within hardware limits: for rural clinics, that means running inference on local edge accelerators under tight thermal budgets and bounded memory capacity (such as 4 to 8 GB of shared DRAM) and returning a result during the visit without depending on intermittent network uplinks. Surrounding both is the operational layer, which governs clinical auditability, regulatory clearance, and the maintenance rules that keep the deployed system safe over time.

The operational layer carries physical consequences that traditional software engineering rarely encounters. In a traditional database, deleting a patient's record is a `DELETE` statement. In an ML system, model weights may encode statistical patterns learned from that record. Where law or a regulator requires removing that influence, compliance may require machine unlearning (Cao and Yang 2015; Bourtoule et al. 2021) (an active research area with incomplete guarantees) or retraining on the remaining data. The obligation and remedy depend on the governing rule and system; at DR-system scale, either can make privacy compliance a recurring compute-budget item and training provenance an architectural constraint.

↪ Why removing a record's influence from trained weights remains a compliance obligation is developed in chapter 15.

The constraint propagation principle (section 3.2) explains why all three layers must be bound before development begins. A constraint that exists in the physical or operational environment but remains unstated in the problem definition does not vanish. It re-emerges later as an architectural violation after dependent decisions have hardened. For example, if an engineering team defines the objective solely as aggregate classification accuracy on retinal images, standard optimization will minimize the average training loss, which the majority class dominates. In an imbalanced screening population where 90 percent of patients are healthy, a model predicting "no disease" achieves 90 percent aggregate accuracy while failing every patient who needs urgent care. Preventing this requires translating a domain invariant (a missed diagnosis costs far more than a false referral) into an explicit statistical contract: class-weighted loss, a sensitivity floor, and subgroup targets.

War Story 3.1: When the label was the bias (2018)

Context: In 2014, Amazon assembled an engineering team at its Edinburgh hub to build an internal machine-learning system for ranking technical job applicants, training it on ten years of resumes submitted to Amazon (Dastin 2018).

Mechanism: Because prior hiring was male-dominated, the model learned that male-coded language correlated with hiring success, systematically penalizing terms like "women's" and downgrading graduates of two all-women's colleges.

Impact: The model reproduced historical hiring bias, rendering automated resume screening unsuitable for production recruitment.

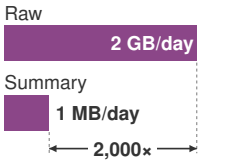
Fix: Amazon abandoned the experimental tool after attempts to remove explicit gender signals could not guarantee that it would not learn other discriminatory proxies.

Systems lesson: Problem definition must specify fairness, auditability, and rejection criteria before data collection and training. A workflow trained on biased labels does not learn the operational goal; it learns to reproduce the labels.

3.5.2 Problem definitions evolve

When a DR screening program expands from one pilot clinic with a calibrated fundus camera to dozens of regional health centers with different camera brands and patient populations,[9] its initial assumptions break. Sensor noise profiles diverge, optical resolutions shift, and demographic changes alter subgroup error rates. A problem definition is therefore not a static specification frozen at the start of a project; it must evolve as deployment expands, adding subgroup accuracy targets and broader hardware compatibility checks. How such subgroup and governance requirements are specified, tested, and maintained is developed in chapter 15.

This evolution follows directly from how ML systems learn. Scaling exposes rare inputs absent from pilot evaluations, while production environments shift the input distribution in ways no static offline dataset fully captures. A sound problem definition anticipates this drift by setting governance rules upfront: defining which monitoring signals trigger formal re-evaluation and bounding how threshold updates propagate through later pipeline stages. Once these operational constraints and performance boundaries are defined on paper, the workflow must ground them in physical artifacts, beginning with the data collection pipelines that gather the training distribution.



9 | **Demographic drift**: Population changes can expose performance gaps that aggregate evaluation obscures. Facial-analysis benchmarks found large demographic error-rate disparities (Buolamwini and Gebru 2018), while a healthcare risk-scoring study found racially biased allocation from a proxy label despite similar need (Obermeyer et al. 2019). These examples come from other domains; they illustrate why a growing DR program should evaluate subgroup performance.

3.6 Stage 2: Data Collection and Preparation

On paper, the problem definition asks for 90 percent sensitivity across rural clinics; in the field, that target immediately meets smudged camera lenses, missing patient records, and a 2 Mbps clinic internet link. Moving from problem definition to data collection is where abstract accuracy targets meet those physical realities. This stage determines dataset size (D), the number of examples, and through it the iron law's byte volume (D_{vol}), the bytes that storage systems, networks, and memory buses must move; the two grow together but are not the same quantity, since image resolution and encoding set how many bytes each example costs. The deployment constraints established during problem definition become technical data requirements. If the model must run on edge devices, the collection pipeline must produce inputs compatible with edge preprocessing; if it must achieve 90 percent sensitivity across diverse populations, the dataset must sample those subpopulations sufficiently to support model training.

Data collection and preparation is an ongoing engineering discipline rather than a one-time task. For diabetic retinopathy screening, these criteria demand a collection strategy far more stringent than standard computer vision benchmarks. The pipeline must assemble roughly 10^5 retinal fundus photographs across diverse patient cohorts and imaging hardware, with each image graded by multiple ophthalmologists and disagreements resolved to establish consensus ground-truth labels capable of withstanding clinical and regulatory scrutiny. The annotation protocol must capture fine pathological features (microaneurysms, hemorrhages, and hard exudates) across the entire disease severity continuum. Curation also governs computational efficiency, because not all captured data contributes equally to training, and deliberate selection (section 9.3.1) can eliminate redundant samples while preserving the statistical coverage required for generalizable performance.

Each retinal photograph spans several megabytes, and clinical protocols capture multiple views per patient, immediately creating a physical infrastructure bottleneck. A busy rural facility generates gigabytes of raw imaging data each day, a volume that would overwhelm an intermittent 2 Mbps uplink during operating hours. Rather than saturating limited wide-area bandwidth with raw uploads, the system can execute inference locally on the edge accelerator and transmit only a compact edge summary: a structured record containing the diagnostic classification and clinical metadata. Local inference reduces uplink traffic from tens of megabytes to kilobytes per patient.

Edge summaries shrink the clinic's daily uplink about 2,000-fold.

Napkin Math 3.2: Bandwidth vs. compute

Problem: Quantify the uplink window occupancy for raw image uploads from a busy rural clinic capturing retinal images for diabetic retinopathy screening, and evaluate architectural alternatives to relieve link contention.

Math:

1. Daily data: At 100 patients/day, 4 photos/patient, and 5 MB/photo, the clinic produces 2 GB/day.
2. Upload time: The uplink is 2 Mb/s, or 0.25 MB/s. Dividing 2,000 MB by that rate gives 8,000 s, approximately 2.2 h.
3. **Constraint**: If the clinic requires same-shift upload during its 8 h operating window, this transfer alone occupies the link for 27.8 percent of that window and may contend with other traffic.

Systems insight: On a good day the raw upload fits the shift, but it ties up a large share of the link, and on a day the link drops it does not happen at all. A screening result that must reach the nurse during the visit therefore cannot depend on the uplink, which is the case for local inference. Uploading detection summaries (10 KB/patient) instead of images also cuts uplink traffic by 2,000×. Overnight batching of images for training remains possible and is not compared here.

Running inference at the clinic (notebook 3.2) is the data locality invariant (definition 2.3) applied to a clinic uplink. Edge accelerators such as the NVIDIA Jetson family[10] make it practical, though they introduce a hardware trade-off between using a smaller model that fits a low-power edge budget and provisioning more capable on-premise devices at higher cost. The bandwidth constraint makes this infrastructure choice a data-collection decision rather than a late implementation detail: the scenario architecture combines edge devices for local inference and preprocessing, clinic aggregation servers for data management and buffering, and cloud training infrastructure for periodic model updates, targeting a result within seconds of capture and operation that does not depend on connectivity.

Privacy constraints impose a similar architectural decision. Patient privacy regulations may motivate local retention or distributed training, but they generally specify protections and permitted uses rather than one required training topology. Workflows that keep raw clinic data local while sharing only approved updates or summaries add complexity to both data collection and model training infrastructure.

10 | **NVIDIA Jetson**: NVIDIA's Jetson family spans a wide product range, from Jetson Orin Nano (7–15 W) through Jetson Orin NX (10–25 W) to Jetson AGX Orin (15–60 W). This scenario uses an Orin Nano-class device (4–8 GB shared LPDDR5, 7–15 W power envelope) as a concrete edge target. Its memory and power budgets constrain model complexity, while selecting a larger device changes both the feasible model and the per-clinic cost.

3.6.1 Lab-to-field data gap

Laboratory data and production data inhabit different worlds. This **lab-to-field gap** appeared when Google's DR screening reached clinics in Thailand (Beede et al. 2020): images arrive from diverse camera equipment operated by staff with varying expertise, often under suboptimal lighting with inconsistent patient positioning. A model trained on high-quality research images from standardized fundus cameras may fail on blurry, poorly lit images from older equipment, not because the algorithm is wrong but because the data distribution has shifted beyond the training envelope. Closing that gap across many clinics is an infrastructure problem as much as a modeling one.

↪ The cost and throughput of each storage tier, and why ML systems combine them, are measured in section 4.10.2.

3.6.2 Distributed data infrastructure

If a deployment grows from a handful of clinics to hundreds, the data infrastructure becomes a distributed system whose design follows from the constraints set during problem definition. Connectivity decides transmission. Facilities with reliable broadband can stream diagnostic summaries in near real time, whereas clinics with intermittent satellite links require **store-and-forward architectures** that buffer data locally and synchronize opportunistically during connectivity windows. That choice propagates through the physical stack, because store-and-forward clinics need larger local storage buffers, edge inference that runs without the network, and a way to reconcile local preliminary classifications with later central review. Storage placement matters at the central end as well, since the training set is read in full every epoch, validation sets occasionally, and the regulatory archive almost never, so each belongs on a different storage tier.

Data heterogeneity grows alongside byte volume. Divergent camera optics, uneven clinic illumination, and variable operator training give each clinic a distinct input distribution, so each clinic operates as a distinct data source.[11] The dataset this stage hands forward must therefore carry provenance metadata that records camera model, capture settings, and operator ID for every image. That provenance trail is what isolates a site-specific accuracy regression and satisfies a regulatory

11 | **Distributed clinic data**: Training across clinic sites without simply pooling all raw data addresses privacy and governance constraints, but it shifts cost into coordination. Each site may use different cameras, serve different patient populations, and follow different operating routines, so the system must track where data came from and how each site differs. The workflow cost is therefore not just storage capacity; it is the engineering work needed to compare, validate, and update models across sites whose data does not behave identically.

audit. Heterogeneity also argues for validation at the point of capture, because a miscalibrated camera discovered weeks later during a central training run has already wasted storage, compute, and patient follow-up opportunities.

3.6.3 Quality assurance and validation

A blurry retinal image that slips past quality checks does not merely waste storage. If such images enter training with unreliable labels or appear frequently in production, they distort the statistical evidence available to the model and degrade clinical safety. Quality assurance ensures that incoming data satisfies the invariants downstream stages depend upon. In the diabetic retinopathy scenario, automated quality-scoring models deployed at the fundus camera immediately flag out-of-focus or improperly framed captures, prompting clinical staff to retake the photograph while the patient is still present rather than discovering the defect weeks later during model training.

Validation extends beyond image quality to verify proper labeling, patient association, and privacy compliance. Local validation catches capture problems on the spot, whereas centralized validation detects distributional anomalies across the full clinic network, for instance by flagging when a particular site's images skew toward a narrow demographic range that would bias the training set. Together with the bandwidth and privacy limits set earlier in the stage, these quality checks settle what data the training set contains and what clinic-to-clinic variations the model must handle. Even a curated, validated dataset can still starve the next stage, however, if the order in which training reads it fights the storage system that holds it.

↪ Data cascades, in which uncaught collection defects compound into downstream training and evaluation failures, are developed in section 4.2.1.

3.6.4 Sample order and delivery rate

The DR training procedure reads the training set, on the order of 10^5 fundus photographs, in full on every epoch, in a fresh random order each time. Whether the accelerator stays busy depends on one comparison, the rate at which the data loader (the software that reads and batches examples for training) delivers images against the rate at which training consumes them. If delivery is slower, the accelerator idles however fast it is, and random order makes that outcome more likely because it scatters reads across storage and defeats the caching and prefetching that sequential reads enjoy. The data hand-off is therefore complete only when the workflow has measured the loader's delivery rate against the consumption rate. Closing a gap is the work of data engineering, which treats it as the feeding problem (section 4.9.3), and of training systems; the workflow's responsibility is to run the test and route a failure to the right fix.

Data collection therefore does not end when training begins. Feedback from evaluation and production keeps revising what is collected, and the delivery test keeps checking whether the loader can feed what the model consumes. Building the collection and delivery pipelines is the subject of chapter 4, and deciding which collected examples deserve training compute is the subject of chapter 9. What this stage hands forward is a versioned dataset, its preprocessing pipeline, and a measured delivery rate, which together become the raw material that model development turns into trained models.

↪ How prefetching overlaps data delivery with computation so that the loader keeps the accelerator busy is developed in section 8.6.2.

3.7 Stage 3: Model Development and Training

The DR team has on the order of 10^5 labeled retinal images, the scale of the 128,000-image dataset in Google's study, along with a validated preprocessing pipeline and a target: more than 90 percent sensitivity on edge hardware, returned within seconds of capture. The question is no longer *what data* to collect but *what model* to build, and that question has no answer independent of the deployment constraints already established. In iron law terms, this stage defines the operations (O) term, because architectural choices set the computational floor that hardware must sustain. Training is where that cost is first paid. The model learns by making repeated passes over the labeled images, adjusting its parameters slightly after each group of examples, and a single training run can occupy an accelerator for hours or weeks. Every idea the team wants to test costs at least one such run, so training systems must coordinate data ingestion, accelerator execution, and the search over training settings[12] without stalling execution pipelines. In high-stakes domains like healthcare, every design decision affects clinical outcomes, so technical performance and operational constraints must be integrated from the start.

[12] **Hyperparameter**: Architectural and optimizer choices (for example, learning rate and network depth) affect the computational work of training. A naive Cartesian grid that trains every combination independently incurs a multiplicative search cost: 5 hyperparameters with 4 values each produces 1,024 (4^5) configurations. Search strategies that stop unpromising runs early or choose the next configuration from earlier results avoid completing every run, which is why the grid represents a baseline rather than an unavoidable cost.

The DR system faces a sharp training challenge: achieve expert-level diagnostic accuracy with finite labeled-data and optimization budgets. **Transfer learning**[13] addresses this constraint by adapting a model pretrained on a source task to a target task. The ImageNet Large Scale Visual Recognition Challenge (ILSVRC) 2012 training subset contains 1.3 million labeled images (Russakovsky et al. 2015). Reusing learned representations can improve target-task optimization and generalization relative to random initialization, with the benefit depending on source-target similarity, which layers are transferred, and transfer-related optimization effects (Yosinski et al. 2014).

In Google's controlled validation study (Gulshan et al. 2016), transfer learning and a labeled dataset of 128,000 images produced an AUC[14] of 0.99, with sensitivity of 97.5 percent and specificity of 93.4 percent at one operating point. The result demonstrates the potential of pretraining on general images followed by further training on retinal images under the study conditions; it does not by itself establish deployment performance. Reaching a result of this kind takes repeated training runs over the full labeled dataset, and the arithmetic cost of each run on the available hardware sets how many runs a team can afford, which is the iteration tax again in another form.

Achieving high statistical accuracy on benchmark data is only the first hurdle, because edge deployment requires models to fit within strict memory allocations, execute within tight latency envelopes, and stay within thermal limits. **Ensemble learning** illustrates this tension between maximizing accuracy and fitting the deployment target. Combining predictions from multiple models routinely delivers top benchmark accuracy, yet inference compute, parameter storage, and memory traffic scale directly with ensemble size. Serial execution increases latency, while parallel execution demands additional hardware concurrency, so no fixed latency multiplier follows from ensemble size alone. The historic Netflix Prize demonstrated how ensemble complexity can block deployment: the winning solution delivered the highest predictive accuracy, yet Netflix never deployed it because the operational costs of maintaining and serving the ensemble exceeded the marginal business value (Johnston 2012). Even an ensemble of lightweight models multiplies orchestration complexity, working memory, and operational monitoring, so every architectural decision creates downstream systems ripples that accumulate at the physical deployment boundary.

13 | **Transfer learning**: For the same architecture, transfer learning changes how parameters are initialized and optimized, not the operations required at inference.

14 | **AUC (area under the ROC curve)**: Measures the area under the receiver operating characteristic (ROC) curve plotting true positive rate vs. false positive rate across all classification thresholds, ranging from 0 to 1; 0.5 represents random discrimination, and values below 0.5 are possible. Unlike accuracy, AUC is threshold-independent and insensitive to class prevalence, making it a common metric for medical screening systems. The systems consequence: a model with 0.99 AUC can still produce unacceptable sensitivity at the specific operating threshold chosen for deployment, so AUC alone cannot validate deployment readiness.

3.7.1 Accuracy vs. efficiency

In diabetic retinopathy screening, missing an active case risks permanent vision loss, whereas misclassifying a healthy eye generates an unnecessary hospital referral. Because those two errors carry very different clinical costs, medical diagnostics require specialized statistical objectives[15] rather than the generic average error that standard training minimizes. The system must maintain high sensitivity (> 90 percent) to catch pathology while preserving high specificity (> 80 percent) to avoid overwhelming regional healthcare infrastructure. These targets must also hold across diverse patient demographics, varying illumination, and distinct fundus camera models.

Optimizing for clinical metrics alone remains insufficient if the resulting architecture cannot execute within the physical deployment envelope. In this scenario, running the model must remain strictly within the 500 MB memory reservation on the clinic's shared 4–8 GB edge device. That budget must accommodate the static weight parameters alongside input buffers, dynamic activation tensors, and runtime execution overhead. Simultaneously, the accelerator must operate within the Orin Nano-class power envelope of 7–15 W and return each prediction within seconds. Balancing these competing pressures requires navigating the trade-offs of the iron law: shrinking parameter volume (D_{vol}) and arithmetic operations (O), for example by storing each weight in fewer bits or removing parts of the model that contribute little, while continuously revalidating that the smaller model preserves clinical sensitivity.[16] The accuracy in the cited study came from a larger Inception-family network, so whether a mobile backbone such as MobileNetV2 keeps that sensitivity is exactly what compression and validation must show. The capture resolution needed to see small hemorrhages also raises the backbone's operation count above its figure at the default input size, so the 500 MB budget and the latency target must be checked at that resolution.

The model that training produces is therefore a candidate, not yet the model that ships. Making it fit the clinic device is engineering work in its own right, and it acts on all three parts of the system. On the data side, training compute goes to the examples that teach the model the most (chapter 9). On the algorithm side, the trained model is made smaller and cheaper to run (chapter 10). On the machine side, its operations are mapped onto the accelerator so that the hardware's peak rate is

15 | **Medical AI performance metrics**: This DR scenario sets a >90 percent sensitivity target because missed referable disease can delay care and contribute to avoidable vision loss; actual acceptance criteria are product- and regulator-specific. The subtler systems trap is positive predictive value (PPV): even a high-accuracy model can have low PPV in a low-prevalence population. This prevalence dependence can require different operating thresholds across deployment sites, a constraint invisible in standard ML evaluation.

↪ The probability outputs and cross-entropy losses that standard classifiers optimize are developed in section 5.4.3.2.

approached in practice (chapter 11). Each change is then measured against the budgets that problem definition fixed (chapter 12). None of these steps can be skipped by training a more accurate model, because accuracy and fit are separate properties that the workflow must establish separately.

3.7.2 Constraint-driven development

An ML engineer who downsamples retinal images to standard 224×224 ImageNet resolution to save compute will erase tiny microaneurysms before the network ever sees them. Avoiding that kind of blind spot requires domain experts (ophthalmologists in the DR case) at the table from initial exploration through final optimization to identify which lesions and image-quality details matter clinically. Without that domain knowledge, a model architect can easily choose an input resolution or receptive field, the input region each internal feature can see, that discards the diagnostic signal before training even begins. Working together keeps model architectures focused on clinically relevant evidence while respecting the compute limits identified during data collection.

Computational constraints shape how experiments are run. Each model variant, training setting, and preprocessing approach adds training runs, so exhaustive experimentation quickly becomes expensive. This economic reality drives investments in scheduling runs so accelerators do not sit idle, reusing intermediate results instead of recomputing them, and stopping runs that are clearly not improving. Searching training settings systematically, with disciplined experiment design, reduces computation relative to exhaustive search.

The inherent uncertainty of ML outcomes demands scientific methodology: controlled variables through fixed random seeds and environment versions, systematic **ablation studies**[17] to isolate component contributions, confounding factor analysis to separate architecture effects from optimization effects, and statistical significance testing across multiple training runs using paired offline tests rather than the A/B testing[18] reserved for comparing models on live production traffic. Without this rigor, teams cannot distinguish genuine performance improvements from statistical noise, a distinction that becomes critical when a model sits near the clinical sensitivity threshold. The test set must then contain enough confirmed positive cases that the lower bound of the confidence interval, not the point estimate, clears the floor.

At every development milestone, teams validate models against the deployment constraints identified in earlier lifecycle stages. Each architectural innovation must be evaluated for accuracy improvements and compatibility with edge device limitations and clinical workflow requirements. This dual validation approach ensures that development efforts align with deployment goals rather than optimizing for laboratory conditions that do not translate to real-world performance.

3.7.3 Prototype to production

A small team of data scientists can often coordinate exploratory experiments using ad hoc scripts, spreadsheets, and shared notebooks. As projects evolve from prototype to production, however, complexity expands across multiple dimensions simultaneously: datasets grow, models require distributed training across accelerator clusters, and multiple engineers launch concurrent runs. Under these conditions, informal coordination rapidly becomes a development bottleneck. Without shared infrastructure, team members inadvertently train on conflicting data splits, duplicate expensive preprocessing passes across separate machines, overwrite shared model checkpoints, and struggle to reconcile divergent notebook versions. The time required to untangle conflicting artifacts and unrecorded configurations begins to dominate development.

Shared workflow platforms resolve this coordination friction by standardizing stage interfaces and centralizing resource management. Rather than relying on manual handoffs and uncoordinated scripts, a shared platform provides standardized data partitioning, cached preprocessing pipelines that compute intermediate representations once for the entire team, and automated job schedulers that allocate cluster accelerators efficiently. Shared platforms also track experiment metadata systematically, linking code revisions to exact training configurations, hyperparameters, and resulting evaluation metrics. Operating at scale therefore requires teams to systematically preserve each experiment's inputs, software dependencies, and execution configuration, establishing the baseline needed to verify genuine improvements.

16 **Model compression pipeline**: Bridging the gap between research accuracy and edge deployment requires an iterative "compress-validate-adjust" loop. Each compression step can reduce model size or execution cost, but it can also silently degrade sensitivity below the clinical threshold. Finding a model that fits in device memory while preserving clinical sensitivity typically requires multiple iterations because only the full validation suite reveals whether the smaller model still satisfies the problem definition.

↪ Renegotiating accuracy against memory and latency envelopes through systematic pruning, quantization, and distillation is developed in section 10.1.

17 **Ablation studies**: Named for surgical tissue removal, ablation studies systematically disable individual components to isolate their contribution to performance. The rigor matters because a 0.5 percentage-point sensitivity difference can determine whether the DR model meets its clinical sensitivity threshold. Without ablation, a team cannot distinguish a genuine architectural improvement from noise introduced by a different random seed, wasting iteration cycles on gains that are not real.

18 **A/B testing in ML**: Compares a new model (B) against the production baseline (A) on randomly assigned live traffic to estimate the model's causal effect. Required sample size depends on the baseline event rate, effect size, variance, allocation, significance level, and statistical power (Kohavi et al. 2020); no universal interaction count or duration follows from a 0.5 percentage-point change alone.

3.7.4 Reproducibility and system artifacts

Shared infrastructure accelerates experimentation only if its results can be trusted. If a candidate model beats the validation baseline by a full percentage point on Tuesday, but rerunning the same training script on Thursday falls short, the team cannot tell whether the gain was real or a fluke of thread scheduling and unrecorded library versions. **Reproducibility**, the ability to rebuild a result and bound how much it varies from run to run, is what lets a team distinguish a genuine improvement from noise. Its absence is an economic cost as well as a scientific one, because a team that cannot reproduce a result reruns experiments that may not converge to the same outcome, and each unreproducible result adds to the system's technical debt.[19]

Reproducing ML results requires tracking data versions, random seeds, hardware configurations, and library versions alongside program logic, because the hardware itself introduces run-to-run variation. When parallel accelerator threads add up partial results during training, the order in which partial sums arrive can differ from run to run, and floating-point addition is non-associative ($(a+b)+c \neq a+(b+c)$), so identical code can produce slightly different weights. Optimized math libraries may also benchmark several compute kernels (the routines that execute an operation such as a matrix multiplication on the accelerator) at runtime and select different ones across runs or machines unless deterministic execution is explicitly requested. Recording a random seed alone therefore does not establish reproducibility; the execution configuration and the measured variation across repeated runs matter as well, a requirement that section 12.8.2 extends to benchmark reports. Systematic **experiment tracking** records unique run identifiers and links data versions, code commits, hyperparameters, and resulting models, so a team can reconstruct what changed between two runs.

Experiment tracking needs a well-defined unit to version, and that unit is the stage's actual deliverable. A common failure mode is treating the trained model weights as the sole output of model development. In a mature ML workflow, the deliverable is a **reproducible system artifact** whose inference package has four components:

- **Model weights**: The learned parameters.
- **Inference code**: The exact code used to run the model, including preprocessing logic.
- **Environment specification**: The complete dependency graph (for example, a container image, `requirements.txt`, and accelerator drivers) required to execute the code.
- **Configuration**: Hyperparameters and runtime settings.

Reproducing inference and rebuilding a trained candidate require different evidence. Alongside the inference package, the artifact must link to the dataset version, training-code version, preprocessing recipe, training configuration, and execution environment that produced the weights. Under the data-as-code invariant (principle 1), a changed training set changes learned behavior as surely as changed inference code does. This provenance makes the training procedure repeatable; the nondeterminism described earlier still requires checking variation across runs rather than promising identical weights.

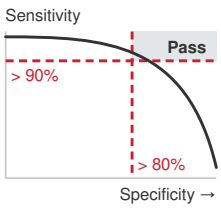
The environment belongs in the bundle because dependency mismatches do not always fail loudly. An unsupported driver or a missing library stops the serving process at once, whereas a different linear algebra library or image-resizing routine (OpenCV rather than PIL, for example) can alter floating-point results or pixel interpolation without any crash, shifting model outputs and accuracy. A model that meets its sensitivity target in development must therefore be reevaluated if its production environment changes, even when inference completes without an exception. Packaging a reproducible artifact still establishes only that the candidate runs consistently as built; the next stage tests whether it holds up under the clinical conditions it will actually encounter.

3.8 Stage 4: Evaluation and Validation

Suppose the DR team's candidate matches the study's AUC of 0.99 on curated research data. The team then tests it on images from a rural clinic where a nurse with two weeks of training operates a five-year-old fundus camera, and sensitivity falls well below the 90 percent target. The software executes without throwing an exception or returning an error code; the model's learned features simply encounter pixel distributions distorted by optical blur, low illumination, and variable pupil dilation that never appeared in the training distribution. High accuracy on curated test partitions does not guarantee operational reliability in production. Before deployment, trained models must

[19] **ML artifact interdependence**: ML artifacts are deeply interdependent. A model's measured accuracy is tied to the data version, preprocessing pipeline, and hyperparameter configuration used to produce it. Without lineage tracking, the team may not be able to determine whether a regression stems from code, data, or run-to-run variation, forcing expensive reruns of experiments whose provenance is lost.

↪ The technical debt that accumulates when experiments and artifacts go untracked, and the practices that contain it, are developed in section 14.2.



pass through systematic evaluation and validation gates to verify that they satisfy accuracy, latency, and robustness requirements across realistic deployment conditions. This stage transforms raw checkpoint files into production-ready software systems by measuring behavior against predefined operational thresholds.

Definition 3.3: Model validation

Model validation is an evidence gate for deciding whether a trained model is suitable to deploy for a specified use. It tests the model against deployment constraints such as latency targets, subgroup performance targets, cost budgets, and robustness under distribution shift, but cannot certify safety under every possible condition.

1. **Significance**: Validation adds dimensions that test-set accuracy ignores. A model achieving 95 percent accuracy on a static test set may miss a latency target, such as 100 ms in a web service, on its slowest requests, underperform a required subgroup threshold such as a maximum five percentage-point performance gap across demographic groups, or lose more than ten percentage points of accuracy under common image-quality problems such as blur and glare. Each unchecked dimension is a deployment risk that compounds silently in production.
2. **Distinction**: Evaluation measures model behavior using chosen datasets, metrics, and experiments, which may include out-of-distribution and subgroup tests. Validation assembles the broader evidence needed for a specified deployment decision, including system latency, throughput, robustness, operational readiness, and cost.
3. **Common pitfall**: Treating validation as "one more test." A model can pass the accuracy test and still fail the gate on latency, subgroup reliability, or cost.

Evaluation supplies measurements; validation uses them to decide whether the integrated software and hardware pipeline meets its intended deployment requirements. This deployment decision is broader than evaluation on a validation set, the data partition used to guide model selection. A separate test set supplies evidence after those choices are fixed; repeatedly using it to choose a model weakens its independence. Accuracy on held-out examples supplies only part of the release evidence, alongside tests of execution, robustness, and operational readiness. Metric thresholds, controlled production exposure, environmental stress tests, and any required regulatory qualification address complementary risks, with the evidence and sequence determined by the intended use. The measurement methodology behind these gates is developed in chapter 12.

Sweeping the threshold traces one illustrative curve; it must reach the corner where both floors hold.

3.8.1 Evaluation metrics and thresholds

In a screening clinic where 90 percent of patients have healthy eyes, a model that labels every image "normal" scores 90 percent accuracy while missing every case of disease. Evaluation metrics must therefore reflect the actual clinical consequences of each kind of error. In diabetic retinopathy screening, the evaluation reports sensitivity and specificity separately, with sensitivity above 90 percent limiting missed disease and specificity above 80 percent limiting false-positive referrals. Neither requirement alone establishes adequate clinical performance or referral capacity; that judgment also depends on disease prevalence, screening volume, and available care. The ROC curve summarizes how detection and false-positive rates change as the classification threshold varies. Evaluation must determine whether any threshold satisfies both requirements under the intended operating conditions.

Even separated into sensitivity and specificity, overall numbers can hide local failures. Stratified evaluation splits the test set across patient age brackets, chronic conditions, and clinic camera models to check whether accuracy holds across every subgroup. A DR model with 94 percent overall sensitivity may fall below 80 percent on images captured from patients with cataracts or under low clinic lighting. Those local drops stay hidden in overall averages and surface only as missed diagnoses after launch unless automated evaluation checks each subgroup slice before promoting a candidate checkpoint.

Beyond label accuracy, evaluation must measure probability calibration:[20] whether a model's

[20] **Calibration**: A calibrated model's predicted probabilities match observed frequencies: 80 percent confidence should correspond to 80 percent correctness. Calibration is distinct from accuracy, and the systems consequence for the DR system is severe: clinicians use confidence scores for triage decisions, so a miscalibrated model that assigns 90 percent confidence to uncertain cases can misdirect clinical workflows more dangerously than a less accurate but well-calibrated alternative. Recalibration after training can improve it, but its effect must be evaluated on representative data.

predicted confidence score matches how often it is actually right. Modern deep neural networks often produce uncalibrated probabilities, reporting high confidence (> 90 percent) even on wrong or out-of-distribution predictions (Guo et al. 2017). When automated triage routes borderline cases to human specialists based on confidence cutoffs, overconfident errors send the wrong cases through without review and erode clinician trust.

↪ How calibration is measured, and the recalibration methods that improve it, are developed in section 12.9.1.2.

3.8.2 Offline and online evaluation

The validation gate begins offline on static datasets and progresses incrementally toward live production traffic. Accuracy-only evaluation on held-out test partitions establishes predictive behavior but does not exercise bursty concurrency, network serialization, or telemetry overhead. Offline load tests and replay can expose such systems bottlenecks when they reproduce the relevant conditions; live traffic supplies additional evidence about the deployed environment. For a centralized service, online evaluation extends the gate to live traffic through staged rollout:[21] shadow mode mirrors live requests to the candidate and logs its predictions without returning them, a canary returns the candidate's predictions to a small fraction of traffic, and an A/B test splits traffic between candidate and baseline to measure whether the improvement reaches clinical or business outcomes. In a regulated medical device, splitting patients between models is a clinical study that requires ethical approval, and changing a cleared model requires regulatory change control. This staged rollout workflow manages deployment validation risk, which is distinct from the cross-tier model compression pattern termed progressive deployment in section 2.10.1, and each validation stage adds a different kind of operational evidence (table 3.3).

[21] **Staged rollout**: Coverage depends on traffic, observability, duration, and the failure modes exercised, so staged rollout reduces risk without guaranteeing that it catches a fixed share of production issues.

↪ Shadow and canary releases, the production form of this staged rollout, are developed alongside blue-green switching in section 14.4.3.

Table 3.3: Staged Validation Coverage: The stages provide complementary, overlapping evidence rather than partitioning failures into exclusive classes.

Validation stage	Typical evidence it adds
Offline evaluation	Algorithmic behavior
Shadow mode	Integration behavior
Canary deployment	Limited-traffic behavior
A/B testing	Comparative outcomes

The gates must also run where the model runs. In the DR scenario, intermittent connectivity and local execution move these evidence gates to clinic devices and pilot sites. Teams can compare a candidate against recorded clinic inputs, run it alongside the active model where device resources permit, and introduce an approved update at a small group of clinics before expanding the rollout. The workflow must preserve the evidence and exposure limits of each gate while adapting its implementation to the deployment target.

3.8.3 Production-condition validation

A model evaluated on one clinic's images still needs evidence for the other cameras, capture conditions, and patient populations specified during problem definition. Production-condition validation tests these requirements across site heterogeneity, input-level perturbations, and temporal drift. These dimensions apply within the offline and controlled-production gates in section 3.8.2; they are not stages that begin after live A/B testing. Held-out samples from the training distribution alone cannot supply all of this evidence.

External and multisite validation test whether the model has learned generalizable disease features or merely memorized the quirks of the development hospital's cameras. In retinal screening, sensor sensitivity, lens coatings, and flash color differ across camera vendors. A DR model trained exclusively on images from high-end fundus cameras in research hospitals can fail when deployed to community clinics using older hardware. Multisite validation therefore benchmarks candidate models on data collected across independent clinic sites with different cameras, lighting conditions, and operator experience levels.

Robustness testing shifts focus to individual inference requests, checking how the model handles realistic image flaws and edge cases. For computer vision pipelines, these flaws include sensor noise,

optical blur, uneven contrast, and partial pupil occlusions. As in the Thai clinics of the running case, dim room lighting and undilated pupils produce images the system rejects as ungradable. Testing models against both synthetic and real-world degraded images reveals whether the serving pipeline needs an upstream image-quality check to reject unusable frames before spending accelerator cycles on inference.

Temporal validation tests whether the model keeps its accuracy as the clinic environment changes over weeks and months. Test sets drawn from a single historical window miss later shifts in patient demographics, disease prevalence, or clinic referral habits. When the input distribution changes while the relationship between inputs and labels stays the same, the system faces *covariate shift* (Quiñonero-Candela et al. 2009); when the relationship between input features and clinical diagnoses itself changes, it faces **concept drift** (Gama et al. 2014). Both can cause silent model degradation and motivate the continuous telemetry and drift detection pipelines described in section 3.10.

↪ Statistical tests that detect covariate shift and concept drift in production are developed in section 4.12.1.

3.8.4 Regulatory validation

Healthcare AI systems face device- and pathway-specific validation requirements. When U.S. Food and Drug Administration (FDA) premarket review is required, the safety and performance evidence must be appropriate to the device and its regulatory pathway; clinical data are required for some submissions, though not all.[22] In practice, domain-specific validation goes beyond paperwork compliance to test clinical usefulness and safe failure behavior. For diabetic retinopathy screening, clinical validation studies run the automated system alongside licensed ophthalmologists, comparing model classifications against ground truth established by specialist consensus panels. These studies must demonstrate both specialist-level diagnostic accuracy and safe failure modes: systems that *fail safely*, by routing ambiguous or low-confidence images to human specialists, fit into clinical care, whereas systems that *fail silently* produce missed diagnoses that no one catches until patients lose vision.

Human factors validation tests how the model fits into the clinic staff's daily decisions. Even an accurate model will be turned off or bypassed if its interface confuses nurses, its inference latency slows down patient intake, or frequent false alarms cause alert fatigue. Validation studies must therefore measure how staff and system work together (tracking how often clinicians override the model, how long an exam takes from capture to referral, and how closely referrals match specialist diagnoses) alongside raw statistical accuracy.

[22] **FDA AI/ML regulation**: FDA marketing authorization requires evidence appropriate to the device, intended use, risk, and regulatory pathway. The FDA's 2021 action plan for AI/ML-based software as a medical device (SaMD) identified lifecycle management, real-world performance monitoring, and predetermined change control planning as central issues for adaptive medical-device software (U.S. Food and Drug Administration 2021). These concerns make model versions, training provenance, monitoring, and change documentation important workflow artifacts without imposing one identical audit artifact at every lifecycle stage.

3.8.5 Deployment readiness

Passing the validation gate produces an immutable release manifest recording the evidence and approval for a particular model version, intended use, and operating conditions. This manifest records the exact model checkpoint hash, preprocessing container configuration, calibration parameters, benchmark scores across designated demographic and equipment slices, and any required regulatory authorization. The manifest binds the release to that evidence; it does not itself confer external authorization or establish performance outside the evaluated conditions. If a model fails to clear an established threshold, such as p99 serving latency (the latency that 99 percent of requests stay under) exceeding the service level agreement (SLA) budget or sensitivity on low-light fundus images falling below the safety floor, the release gate halts deployment. Diagnostics then route backward to the responsible lifecycle stage: data curation for targeted data collection, model training for loss function re-weighting, or runtime optimization to reduce execution cost.

Clearing the validation gate establishes the evidence and approval for a particular system configuration. Deployment must install and sustain that configuration at each clinic, including its preprocessing routines, compiled model, telemetry collectors, and rollback triggers. Rollout checks confirm that the installed serving path matches the evaluated conditions and that local integration has not invalidated the release evidence.

3.9 Stage 5: Deployment and Integration

A model that passes validation in development faces different failure modes once deployed to production. In the DR scenario, the model must run on Orin Nano-class edge devices in rural clinics with intermittent connectivity, integrate with hospital information systems with distinct schema requirements, and deliver predictions clinicians can interpret directly. The in-visit requirement

already ruled out round-trip cloud inference. Deployment is where abstract operational constraints become physical systems requirements. In iron-law terms, the serving path couples data movement, execution efficiency, and fixed overhead together; on the clinic device, the 500 MB memory reservation is the precondition every candidate must meet, and per-image latency then sits comfortably inside the seconds-scale budget. Dedicated serving infrastructure manages these trade-offs under live traffic, and chapter 13 develops it in depth.

3.9.1 Deployment requirements

Deployment turns an abstract computation graph into hard physical budgets: peak memory footprint, execution latency, heat limits, and network bandwidth. In the clinical screening scenario, feasibility settles the choice between centralized cloud serving and local edge execution before cost is weighed, because the in-visit latency target and offline operation fixed during problem definition already rule out a cloud round trip. Cost serves only as a check. Napkin math 3.3 applies the comparison of capital expense against recurring operating expense from section 2.5.2 at network scale to confirm that the feasible option also pays back.

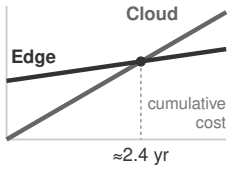
Napkin Math 3.3: Cloud vs. edge deployment economics

Problem: The cloud option fails the clinic's stated latency and connectivity requirements, so treat it as a cost benchmark only. Compare the total cost of ownership and operational trade-offs between a cloud inference endpoint and clinic edge devices for processing 760,000 billable screening images monthly across 500 clinics. Where the bandwidth calculation in napkin math 3.2 sized one busy clinic uploading every photograph, this network-wide estimate assumes an average clinic at 50 patients/day and bills one graded image per patient rather than every capture, so its image volume is lower by design.

Option A: Cloud inference.

- Model runs on centralized GPU servers
- Inference cost: ~$0.01/image (cloud GPU time + API overhead)
- Annual inference cost across 500 clinics, 50 patients/day, 1 billable image per patient, 365 days/year, and $0.01/image is $91,250/year
- Plus: An assumed connectivity and network-operations allocation for uploading 5 MB per billable image = ~$45,000/year
- **Total**: ~$136,250/year operational cost
- Risk: uploading one 5 MB image over the clinic's 2 Mb/s uplink alone takes about 20 s, before 200 ms+ of remote processing, far beyond the scenario latency target; connectivity outages halt screening

Option B: Edge deployment on a clinic device.



- One-time hardware: one $500/device per clinic across 500 clinics requires $250,000 capital expense
- Inference cost: ~$0.001/image (assumed all-in variable operating allocation)
- Annual cost: approximately $25,000/year maintenance plus approximately $9,125/year variable inference cost, for about $34,125/year
- **Total**: $250,000 upfront + ~$34,125/year
- Benefit: latency below 50 ms; works offline; much lower per-inference cost

Math:

- Annual savings: $136,250/year (cloud) − $34,125/year (edge) = $102,125/year
- Payback: $250,000 (hardware) ÷ $102,125/year = ~2.4 years

Systems insight: Under these scenario assumptions, edge deployment pays back in ~2.4 years and allows inference during connectivity outages, yet it requires tighter model optimization

(must fit in edge memory) and more complex update pipelines. The deployment paradigm selected during Problem Definition determines whether the edge option is even viable.

Edge costs more up front, but cloud's running cost passes it in about 2.4 years.

In this scenario, bandwidth limits, latency targets, and offline operational requirements favor edge deployment, which dictates strict memory, latency, and thermal envelopes that model compression must satisfy and serving runtimes must execute within production bounds. Host integration extends these physical constraints to the software interfaces of existing clinical infrastructure, where the inference runtime exchanges data with hospital information systems (HIS) to ingest patient records and record diagnostic output. Because prediction scores do not automatically provide reliable uncertainty estimates, their interpretation must be evaluated on representative data before an interface contract uses them to route decisions. This contract specifies which classifications trigger automated referrals and which demand physician review, including how rejected or low-quality inputs are handled, so a confidence threshold cannot be evaluated in isolation from the downstream workflow it triggers.

Regulatory frameworks place further structural constraints on this data lifecycle. Legal mandates such as data protection law (the Health Insurance Portability and Accountability Act, HIPAA, in the United States) govern data transmission and restrict whether production inference payloads can be persisted, linked to patient identifiers, or ingested into retraining pipelines. When compliance prohibits retaining raw inputs, continuous improvement cannot rely on passive telemetry logging, so privacy rules constrain ongoing model maintenance strategies rather than serving merely as a transport-layer security checklist (chapter 14).

3.9.2 Pilot to full deployment

Shipping a new screening model to 500 clinics at once would turn any undiscovered camera mismatch or schema bug into a network-wide outage. Production rollout therefore proceeds in stages to contain failures as the environment widens. Offline replay and synthetic test harnesses first verify schema contracts and concurrency limits without risking patient safety. Pilot deployments in a handful of clinics then expose the serving stack to real-world conditions absent from laboratory benchmarks: optical distortion across camera models, sensor noise under uneven clinic lighting, and differences in how staff position patients. Full-scale rollout broadens exposure to rare anatomical variations and uncommon pathologies. Catching those shifts requires continuous runtime monitoring rather than assuming validation distributions hold forever.

Scaling across hundreds of remote clinics brings hardware diversity and tight network limits across the fleet. Differences in local camera optics shift pixel distributions before inference even begins, requiring on-device input checks that reject out-of-spec captures on the spot. At the same time, narrow wide-area bandwidth rules out continuous weight updates or streaming high-resolution telemetry back to a central cluster. Clinic edge devices must instead run on their own, logging metrics locally and syncing state during scheduled maintenance windows.

Keeping the screener clinically safe requires calibrated uncertainty estimates rather than high average accuracy alone. When the model encounters a borderline retina, returning an uncalibrated score risks a missed diagnosis. Instead, the serving path uses **human-in-the-loop routing**, applying calibrated confidence cutoffs to send borderline cases to specialist ophthalmologists. This routing does two jobs at once: it protects patients in real time, and it creates a steady stream of high-value training examples. Specialist-graded borderline cases provide verified labels that feed back into later training runs, targeting the model's hardest cases.

Keeping hundreds of clinic devices consistent requires versioned, immutable model packages and atomic updates. Client runtimes verify cryptographic checksums of compiled model binaries before loading new weights into memory, so a dropped connection during download cannot leave a clinic running a corrupted model. Deployment marks the shift from static offline evaluation to continuous operations, where telemetry checks whether real-world latency and predictions stay within their approved bounds.

3.10 Stage 6: Monitoring and Maintenance

Consider an illustrative case six months after a DR screening system launches. A clinic upgrades its fundus cameras, and the new equipment produces images with different color profiles. In this assumed outcome, the model's sensitivity drops at that site because the pixel distributions it learned during training no longer match the images it receives; the monitoring team cannot establish that drop from the camera change alone. No code changed. The data drifted beyond the training envelope, and the model degraded silently. Where paired drift and outcome data support a local fit, the degradation equation (equation 1.1) describes the mechanism. The new color profile raises the statistical divergence $\mathcal{D}(P_t \| P_0)$ between production and training images, and accuracy falls by roughly the fitted coefficient λ times that divergence, with nothing in the serving logs to show it. *ML systems can degrade through data drift even when their artifacts remain untouched.* Deployment is therefore not the end of the lifecycle; it starts an ongoing operational phase. Monitoring provides the statistical telemetry to detect degradation, while continuous maintenance pipelines update models when evidence warrants it. The infrastructure that runs this phase in production is developed in chapter 14.

In this illustrative scenario, monitoring tracks performance across clinics to detect whether changing patient demographics, camera technology, or equipment degradation affects accuracy. Adding a new imaging modality such as optical coherence tomography would be a product change requiring new data, validation, workflow integration, and any applicable regulatory review rather than routine maintenance. Three feedback pathways guide update decisions: performance evidence can motivate targeted data collection, data-quality findings can prompt preparation changes, and confirmed model degradation can justify retraining or another intervention. Because clinics upload only diagnostic summaries in normal operation, those pathways need a data path of their own: a sampled set of images, sent during off-hours and labeled centrally, supplies the outcome evidence and the retraining data that summaries cannot. Drift thresholds initiate review; they do not select the remedy automatically.

3.10.1 Production monitoring

Monitoring serves two audiences, technical teams tracking system health and clinical staff who need actionable findings. Because no validation set captures every production condition (the lab-to-field gap of section 3.6.1), initial deployment can reveal blind spots that laboratory validation missed.[23] Clinics with older equipment may show accuracy decreases, and specific patient subgroups, such as those with proliferative retinopathy or cataracts complicating the fundus image, may see higher error rates. Monitoring infrastructure is therefore a deployment prerequisite rather than a post-launch addition, and its findings drive targeted data collection and model revisions.

A DR screening system, where missed referable disease can delay care and contribute to avoidable vision loss, demands continuous operational monitoring plus periodic performance evaluation when labels arrive. Teams establish quantitative thresholds for latency, accuracy, and data distribution stability. Lightweight statistical tests for comparing production distributions against baseline data (such as the population stability index and Kolmogorov-Smirnov test)[24] trigger responses ranging from automated alerts to retraining reviews.

A production DR system can track four metric categories at different timescales. The following thresholds illustrate one scenario policy; clinical and operational teams must validate them for the intended product, population, and deployment environment.

- **Model performance metrics** (requiring ground truth, available with delay): sensitivity (target above 90 percent, alert if the rolling average, pooled across sites until enough confirmed cases accumulate to resolve a drop of that size, falls below 88 percent), specificity (target above 80 percent, alert if it drops below 78 percent), and subgroup performance (alert if any demographic drops more than 5 percentage points below baseline).
- **Proxy metrics** (available immediately, without ground truth): prediction confidence distribution (alert if mean confidence drops more than 10 percent relative to baseline), referral rate (alert if rate changes more than 15 percent from baseline), and image quality rejection rate (alert if more than 20 percent of images fail quality checks).

↪ Divergence metrics and threshold conventions for measuring distribution drift are collected for reference in section B.2.3.

[23] **Lab-to-clinic performance gap**: Medical AI systems can experience substantial performance changes when camera models, image quality, patient populations, or operator workflows differ from development data; the gap arises because training data cannot capture the full diversity of production conditions. FDA has emphasized total product lifecycle oversight and real-world performance monitoring for AI/ML-enabled medical devices (U.S. Food and Drug Administration 2021), and device submissions may need evidence appropriate to the product's intended use and risk.

[24] **Population stability index (PSI) and Kolmogorov-Smirnov (KS) test**: Two lightweight statistical methods for detecting distribution drift, developed in section 4.5.3 (KS) and section 4.12.1 (PSI). The KS test measures maximum distance between empirical cumulative distributions. Both are cheap enough for frequent monitoring, but a detected input shift does not by itself prove an accuracy change; labels or other outcome evidence are needed.

↪ Drift detection pipelines that run these tests against training baselines in production are developed in section 22.

- **Operational metrics**: Inference latency (p95 below 50 ms, alert if above 100 ms), throughput (alert if queue depth exceeds 50 images), and error rate (alert if more than 0.1 percent of requests fail).
- **Data stability metrics**: Feature and prediction distributions compared with a baseline, with alerts when recent traffic moves outside the expected range.

The displayed alerts are urgent escalation thresholds, distinct from the acceptance targets. A measured target violation already opens a review of the affected site and system version. Neither threshold alone chooses retraining. The hierarchy matters because operational metrics surface immediate problems, proxy metrics flag possible model issues without ground truth, and labeled performance evidence arrives later.

For the camera upgrade, an immediate color-distribution alert supplies a signal and a site identifier, but until representative labels arrive the team holds evidence of changed inputs, not a measured sensitivity loss, and applies the previously approved exposure limits or alternative screening workflow. Reviewed referrals alone cannot supply those labels, because the routing policy selects which cases are reviewed. Whether the remedy turns out to be restoring a validated camera configuration or returning to data collection and model development, the fix re-enters the lifecycle at the stage that owns the defect and leaves through the same release gate, with a revised release manifest, before a controlled rollout.

That return path is the lifecycle loop, in which every production finding has an owning stage and a gate to pass again. Running the loop in production is a separate discipline, the operations loop that detects, diagnoses, decides, releases, and recovers. Its incident workflow, from severity classification to postmortem, is developed in section 14.7.1.1, and section 14.6.1 weighs a retraining against its compute and validation cost.

3.10.2 Maintenance at scale

Model updates return through the same release gate as the original model. For a regulated device such as the DR screener, staged rollouts must follow the approved change-control plan, and rollback mechanisms[25] limit the damage when an update misbehaves. As the deployment scales from pilot sites to hundreds of clinics, monitoring must track global metrics and site-specific behavior together and maintain data lineage, the metadata trail linking production logs to data, code, and model versions. Lineage lets a team correlate a site-specific accuracy drop with the training experiment and data version behind it instead of reconstructing that link by manual forensic analysis, and regulators may require it.

Correlating production evidence with its causes sends work back upstream. Figure 3.5 maps those return paths across stages 2 through 6, drawing data collection and data preparation as separate boxes and omitting problem definition, which sits upstream of every path shown. In the diabetic retinopathy deployment, when model evaluation uncovers accuracy drops on older fundus cameras, the *Data gaps* path triggers targeted image collection from those specific clinics. Similarly, when validation across patient cohorts reveals lower sensitivity for patients with cataracts, the *Validation Issues* path motivates retraining with synthetic lens-opacity augmentations. In production, runtime telemetry routes along the *Data Quality Issues* and *Performance Insights* paths back into data preparation and collection whenever clinic hardware upgrades change how images look.

Proactive maintenance closes the lifecycle loop. Operational signals identify potential problems, review determines whether newly validated data or another change is needed, and production evidence feeds back to refine problem definitions, data-quality standards, and architectural decisions. When retraining is selected, scheduled or evidence-triggered pipelines can incorporate approved data and return the candidate through validation. With the loop closed, the coupling among stages stops being a design-time concern and becomes a property of the running system, one whose consequences no single stage's metrics reveal.

[25] **ML rollback complexity**: An ML model's validity is coupled to the data distribution on which it was trained, not just its code. Because the data environment keeps changing, rolling back to an older model binary cannot restore the past data distribution, so the older model may also misbehave on today's live inputs. Even a fast rollback is therefore a temporary containment step rather than a full restore.

3.11 Systems Thinking Across the Lifecycle

The camera-upgrade case that opened the monitoring stage touched every stage at once. A change in capture hardware at one clinic shifted the input distribution, degraded a model that had passed validation, and required routing evidence back through the lifecycle to identify and validate a

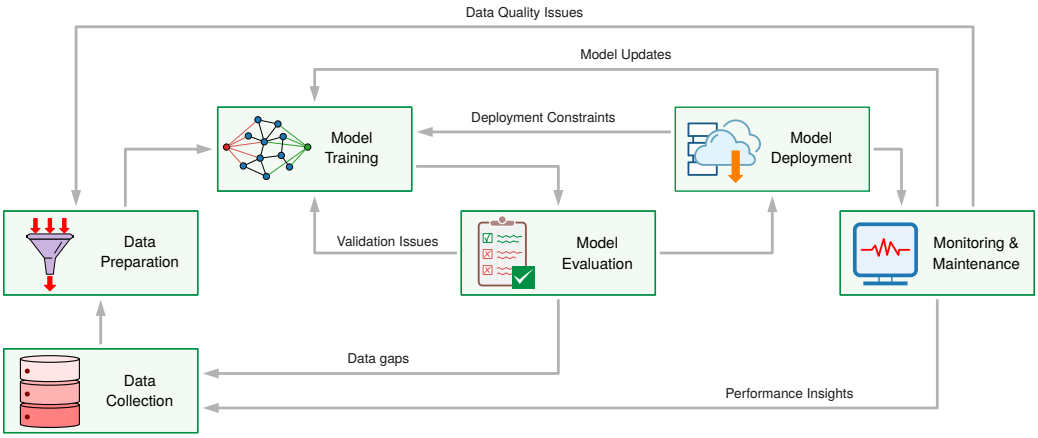


Figure 3.5: Feedback Paths Across Lifecycle Stages: Multi-stage feedback pathways show how downstream discoveries can require upstream corrections. Data-quality and distribution gaps detected during evaluation may prompt targeted collection or augmentation, while operational constraints and performance drift can motivate model, data, or pipeline changes after investigation.

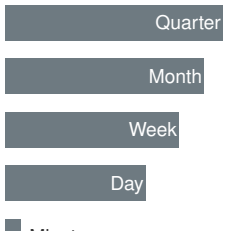
remedy. The whole DR walk showed the same coupling: bandwidth, latency, and connectivity constraints favored edge deployment, edge deployment constrained model size, and model size reshaped preprocessing. Explaining coupled behavior of this kind requires **systems thinking**, which analyzes how a system's parts interrelate rather than treating them in isolation. Three structural mechanisms account for most of it. The first, backward constraint propagation (section 3.2), has recurred at every stage handoff since it was defined. Multi-scale feedback organizes the different response times within that loop, while emergent behavior explains failures that no single stage or site can see. Managing all three distinguishes proactive, constraint-driven system design from reactive post-deployment debugging.

Checkpoint 3.3: Closing the feedback loop

Apply the monitoring response to a different source of uncertainty.

During monitoring, a clinic reports a changed referral rate for patients over seventy. Latency and image-quality rejection rates remain stable. Labels are available only for referred patients, and the release manifest contains no separate sensitivity evaluation for this age group. The intended-use requirements include these patients, but the evaluation plan omitted the subgroup.



- ☐ **Evidence and immediate response**: Can you distinguish what the observed referral change establishes from what remains unknown, and identify the owner and approved exposure policy needed while representative labels are collected?
- ☐ **Dependency trace**: Can you identify which requirements, dataset coverage records, and evaluation artifacts need review, and explain what evidence would justify changing preprocessing or retraining rather than assuming both are necessary?
- ☐ **Re-release**: If representative labels confirm a sensitivity failure and a revised candidate is proposed, can you specify the subgroup, regression, and on-device evidence its release manifest must record before rollout?

3.11.1 Multi-scale feedback

ML systems succeed by orchestrating feedback loops across multiple timescales, each serving a different purpose. One illustrative operating plan for the DR scenario uses minute-level checks to catch a misconfigured camera before it produces a shift's worth of unusable images; daily reviews for proxy shifts such as referral-rate, confidence, rejection-rate, or site-specific camera changes; weekly aggregation of labeled accuracy statistics and drift tests when ground truth is available; monthly

analysis of population coverage; and quarterly review of whether the architecture still meets clinical needs. Actual cadences depend on label delay, product risk, traffic, and the cost of acting on each signal.

Each cadence matches how long its signal takes to become trustworthy. A misconfigured camera is visible within minutes, even if correcting it takes a site visit, whereas a demographic shift that calls for expanded training data takes months of monitoring to establish reliably. Reacting to short-term variance causes pipeline thrashing, such as retraining on transient shifts, while reacting too slowly lets silent accuracy decay persist.

Monitoring loops span minutes to quarters, five orders of magnitude.

3.11.2 Emergent behavior

In a multisite DR deployment, each individual clinic can report steady overall accuracy while network-wide analysis uncovers a sharp drop in sensitivity for a specific age group that no single clinic sees often enough to spot on its own. Complex systems produce **emergent behaviors** of this kind, which stay invisible when components or sites are inspected in isolation. Network timeouts and out-of-memory crashes expose some failures directly, but neither conventional nor ML systems can rely on exceptions to reveal every harmful outcome. ML monitoring must also investigate data drift, concept drift, and bias amplification, since predictive quality can decline without generating stack traces or runtime exceptions even while the model continues serving within its latency SLA. Together, constraint propagation across stage boundaries, multi-scale feedback timing, and emergent behavior show that ML systems cannot be engineered through modular decomposition alone, and teams that apply conventional software assumptions to these coupled dynamics fail in predictable ways.

3.12 Fallacies and Pitfalls

Treating ML as ordinary software produces predictable failures, each of which traces back to a section of this chapter. The misconceptions below recur when teams manage statistical models with assumptions inherited from deterministic application code.

Fallacy: *ML development can follow traditional software workflows without modification.*

Software practices such as version control, unit testing, and iterative delivery remain necessary. Machine learning systems also derive behavior from data, so those practices must cover datasets, learned artifacts, and statistical performance evidence (table 3.1). In an ML workflow, problem definitions evolve as exploratory training reveals distribution gaps, class imbalances, or infeasible accuracy-latency trade-offs, and practitioners name data preparation as their largest time sink (section 3.3).

Pitfall: *Treating data preparation as a one-time preprocessing step.*

Teams often treat data cleaning and feature engineering as a static milestone to clear before training begins. In production, incoming data distributions evolve continuously as user behavior shifts, sensors degrade, and upstream schemas change. The two-tier lifecycle of figure 3.2 reflects this operational reality, with an upper data pipeline and a lower model pipeline that execute concurrently and feed back into each other. Early data preparation decisions cascade directly through training and deployment (section 3.6). When data preparation is static, silent distribution shifts and training-serving feature skew bypass code-level tests, degrading inference accuracy long before raising an operational alert. Continuous data validation pipelines with automated schema checking and distribution monitoring are necessary to catch data drift at ingestion rather than after silent model failure in production.

Fallacy: *Passing model evaluation means the system is ready for deployment.*

Model-only offline evaluation measures statistical loss on curated validation sets and leaves operational serving dynamics untested. Across the dual pipelines mapped in figure 3.2, an accuracy-only evaluation tests the candidate model without establishing serving integration, real-time input delivery, or operational monitoring. The diabetic retinopathy case (section 3.1.2) shows the disconnect, since a model with specialist-level accuracy on curated images rejected 21 percent of clinic images as ungradable and struggled with variable camera lighting, technician workflow interruptions, and

intermittent network connectivity. Production readiness demands system-level verification, including tail-latency budgets under concurrency, feature pipeline consistency, and graceful degradation under hardware faults.

Pitfall: *Scaling data collection before checking marginal model value.*

Expanding dataset size is often assumed to be a universally profitable investment for boosting accuracy. Additional examples incur storage, ingestion, and labeling costs, but their learning value depends on which gaps they fill. Once a region of the input distribution is well covered, returns there diminish, and more examples of already well-covered cases may contribute little, while targeted collection can expose a failure that aggregate accuracy conceals. The upstream feedback loops in figure 3.2 route data fixes from curation back to collection before samples enter training, allowing observed errors and coverage gaps to guide acquisition. Because data quality decisions cascade through all downstream pipeline stages (section 3.6), teams must measure the marginal gain in the required task and subgroup metrics against the cost of collecting and processing additional data.

Fallacy: *Skipping validation stages accelerates delivery.*

Compressing or bypassing justified validation stages transfers unresolved risk to production traffic. Multi-stage validation (section 3.8) supplies complementary evidence across increasingly realistic execution environments, and no stage substitutes for another or for independent offline evaluation. A release plan should state the evidence required, the exposure permitted, and the conditions for stopping or reversing a rollout. A gate may be removed only when its evidence obligation is met another way.

Pitfall: *Deferring deployment paradigm selection until after model development.*

Teams often assume deployment targets can be selected after optimizing model accuracy. In practice, the deployment paradigm (Cloud, Edge, Mobile, or TinyML) is a primary constraint that shapes every preceding lifecycle stage (table 3.2). The day-153 failure is the canonical case, in which a model needing 4 GB reached deployment (stage 5) before anyone checked that the clinic device reserves about 500 MB for it. Deployment hardware dictates which models are physically realizable, not merely where they execute.

3.13 Summary

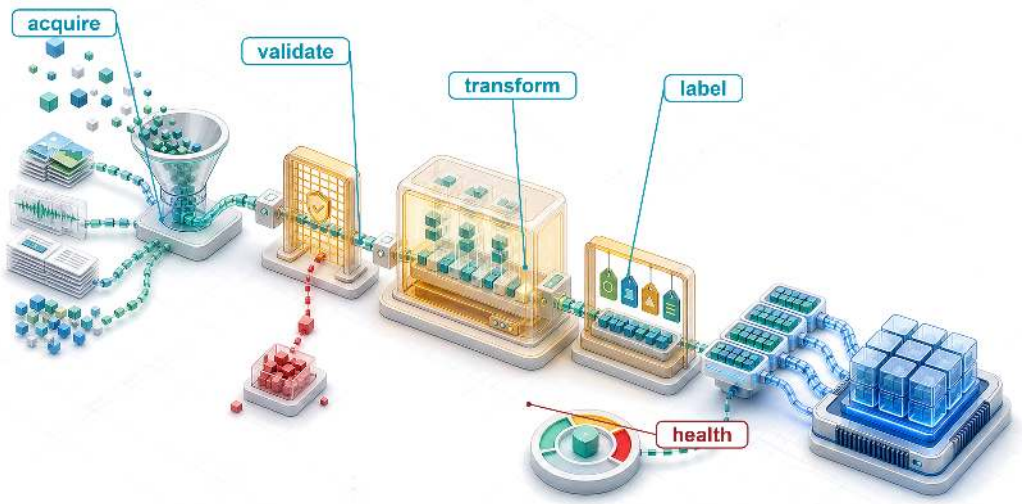
The day-153 failure in the running case was a workflow failure, and the six stages traced since show why it was predictable. Those six project responsibilities coordinate the finer-grained data and model pipelines. Within them, the data pipeline transforms raw inputs through collection, ingestion, analysis, labeling, validation, and preparation into ML-ready datasets, and the model development pipeline takes these datasets through training, evaluation, validation, and deployment to create production systems. The closed-loop return paths in figure 3.2, which link deployment telemetry back to collection and validation findings back to curation, show that production observations continuously reshape upstream pipelines rather than terminating at a deployment milestone.

Machine learning systems need additions to established software-engineering practice because ML workflows add probabilistic optimization, learned statistical behavior, and data-dependent feedback loops. The iron law supplies one quantitative lens: decisions across the lifecycle jointly change data movement, operation count, hardware efficiency, and fixed latency in $(T = \frac{D_{\text{vol}}}{\text{BW}} + \frac{O}{R_{\text{peak}} \cdot \eta_{\text{hw}}} + L_{\text{lat}})$, while production evidence feeds constraint violations back into review. Success depends on how data quality affects model performance, how deployment constraints shape training strategies, and how production insights inform each subsequent iteration.

Two patterns define the engineering discipline of the ML lifecycle. Many practitioners report data collection, cleaning, labeling, validation, or preparation as major time sinks, while model development is only one part of the lifecycle. Production-ready systems also require repeated iteration cycles across data, model, and infrastructure stages, so investment in data engineering can have high leverage when data quality is a major source of rework. Early constraint discovery does not require freezing the workflow. It establishes an operating envelope through latency, memory, power, safety, and validation obligations while data and model choices continue to iterate within those bounds.

Key Takeaways: See the whole map first

- **The lifecycle is a loop, not a checklist**: Because an ML system's behavior is learned from data, it can degrade while the code stays fixed, so production feedback is what makes the data and model pipelines a system. Monitoring, validation, and retraining send lessons from deployment back into collection, labeling, architecture, and infrastructure decisions.
- **Late constraints can increase rework**: A deployment limit discovered late may invalidate preprocessing, weights, validation evidence, and integration work. Trace those dependencies and estimate the required tasks to bound the correction effort and delay.
- **Accuracy is not deployment readiness**: A model can clear its offline accuracy target and still fail on latency, memory, subgroup sensitivity, calibration, or an unreproducible environment. Validation is a multi-dimensional gate whose release manifest records evidence for one specific configuration.
- **Iteration velocity expands search opportunity**: Under the worked assumptions, a lightweight model starting 5 percentage points behind ends near the same ceiling as the large model while testing about four times as many ideas. Workflow speed buys search breadth rather than guaranteed model quality.
- **Interfaces make feedback actionable**: Stage contracts define inputs, outputs, and quality invariants so that data, model, and deployment teams can detect violations before integration. Without explicit contracts, each stage can optimize locally while the system fails globally.
- **Production speaks on different clocks**: Real-time inference monitoring, batch update reviews, and quarterly architectural reviews answer different failure modes. Treating all feedback as one loop either reacts too slowly to drift or churns expensive workflows without signal.
- **Workflow carries constraints through time**: Problem definition records targets, data collection shapes evidence and byte volume, model development changes operations and reuse, deployment realizes the complete serving path, and monitoring sends violations back into review. The lifecycle is data-algorithm-machine coupling unfolding over time.



Seen as a checklist, the lifecycle is a sequence of stages to clear in order. Seen correctly, it is a loop. A constraint discovered at deployment does not stay there; it may force rework in dependent model and data decisions. A workflow is therefore a coupled system rather than a pipeline, the same coupling the D·A·M taxonomy describes in *space*, now unfolding in *time*. Optimizing one stage in isolation moves the failure instead of removing it. Workflow management reduces risk, and the discipline is to see the whole map before touching any single part of it.

What's Next: From blueprint to data

The lifecycle is the blueprint for every chapter that follows, and its first material is data. In the DR project that means on the order of 10^5 graded fundus images, capture-quality checks at the camera, site provenance, and ingestion that survives a fragile uplink, needs particular to one deployment. Chapter 4 takes up the stage in full on two workloads chosen to stress each of the bounds data places on a system. Data bounds a system twice, once through the coverage and labels that decide what the model can learn and once through the delivery rate that decides how fast the machine can learn it, and that chapter builds a pipeline that meets both bounds. Each later chapter assumes familiarity with where its techniques fit within this lifecycle.

Purpose

Why does training data function like source code in a machine learning system?

In conventional software, programmers write logic that computers execute. In machine learning, programmers write optimization procedures that extract operational logic from data. This inversion makes training data resemble source code: changing it can change the learned system when the model is retrained, even if no traditional code changes. Yet data rarely receives the review, testing, and version control that even a one-line code change routinely receives. Subtle labeling inconsistencies can induce behavioral inconsistencies; missing edge cases can leave corresponding failures unmeasured; historical biases can propagate into learned behavior. A model trained only on that dataset cannot infer task-relevant evidence absent from it, and systematic label errors can shape what it learns. Unlike traditional source code, which sits inert until a programmer modifies it, the operating distribution can shift as the world changes, potentially changing production performance even when nothing in the codebase has been touched. Data engineering can consume substantial project effort, often more than modeling itself, because the work is consequential. A labeling error caught at collection costs a relabel; the same error found after deployment can cost a retraining run, an incident investigation, and the trust of the people the system failed. Every decision in the data pipeline (what to collect, how to label, when to filter, how to split) propagates forward to constrain model architecture, training dynamics, and deployment viability. Data engineering is therefore not preprocessing but programming in a different language, one where quality control, versioning, and monitoring determine whether the compiled system works today and continues working tomorrow. In D·A·M terms, data overlaps both the algorithm and the machine; it bounds what the model can learn, and the pipeline that delivers it bounds how fast the machine can learn it.

Learning Objectives

- Explain data as source code and trace how data cascades propagate through ML systems
- Evaluate acquisition strategies against coverage, quality, labeling cost, governance, and deployment constraints
- Design ingestion and validation pipelines for batch, streaming, ETL, and ELT workloads
- Specify labeling, transformation, and release practices that prevent data leakage and preserve label quality, training-serving consistency, and reproducibility
- Calculate data gravity, data-stall, and storage-bandwidth costs for moving or serving datasets
- Select storage tiers, file formats, and data loader designs that keep the accelerator fed
- Diagnose drift, data debt, and production pipeline failures using drift metrics, debt indicators, and controlled comparisons of pipeline versions

4.1 Data as Code

A missing accent in a speech corpus, a mislabeled class, or a feature computed one way in training and another in serving becomes a defect in system behavior with no line of code to point to. Because a machine learning system learns its behavior from data, the trained model is a compressed summary of its training set: it can represent only the evidence that data contains, and it treats the data's labels as the definition of a correct answer. The bitter lesson (section 1.4) explains why this dependence has grown rather than shrunk. Methods that learn from data at scale have repeatedly overtaken methods built on hand-encoded knowledge, so the knowledge that engineers once wrote into programs must now arrive through data. In the lifecycle that chapter 3 lays out, this work is Stage 2, which ends by handing a versioned dataset to model development; every later stage inherits what that dataset contains and what it lacks.

Data constrains the machine as well as the model. Every training step reads its examples from storage, decodes them, and moves them to the accelerator, and an accelerator waiting on input computes nothing however fast it is. Datasets measured in terabytes also have physical mass. They are slow and expensive to move, and they spend energy at every level of the memory hierarchy they cross. Data therefore occupies two of the pairwise overlaps of the D·A·M taxonomy at once, the ones labeled *what to learn from* and *how to move information* in figure 1.4. Toward the algorithm, it bounds what the model can learn; toward the machine, it bounds how fast learning can proceed.

Both bounds are expensive to meet. Cleaning and organizing data was the most common answer to where data scientists spend their time in the practitioner survey that chapter 3 presents (CrowdFlower 2016), and in the image-classification cost comparison later in this chapter, labeling a dataset costs roughly 2,500× to 5,000× as much as one training run on it. Each stage between raw input and an ML-ready dataset (acquisition, ingestion and validation, labeling, and processing) can also introduce a defect that no later stage detects. Data bounds both capability and throughput and often dominates cost, so it requires the same engineering discipline as the model and the machine: acquisition systems, validation checks, labeling workflows, storage layouts, and governance.

Definition 4.1: Data engineering

Data engineering is the infrastructure layer that manages the lifecycle of data from source to model, encompassing acquisition, transformation, storage, and governance.

1. **Significance**: It sets both bounds that data places on an ML system. Dataset composition, coverage, and labels determine whether the logical dataset (D, the Samples/Task factor of the iron law) represents the target distribution, and therefore what the model can learn. In the unpacked iron law, the pipeline governs the physical bytes moved (D_{vol}/BW), and therefore how fast learning can proceed.

2. **Distinction**: Unlike data science, which focuses on inference and insight, data engineering addresses the scalability and reliability of the data pipeline.
3. **Common pitfall**: A frequent misconception reduces data engineering to mere "data cleaning." In systems terms, it is a build pipeline that turns raw, noisy observations into the validated, versioned tensors that accelerator runtimes consume.

The data-as-code principle (1) turns the model's dependence on its data into an engineering rule. Changing a dataset changes the trained model just as changing source code changes a program, even when no line of algorithmic code is touched. The pipeline that produces a dataset is therefore the system's build, and every retraining is a rebuild.

↩ The iron law of ML systems, whose data-movement term this chapter governs, is established in section 1.7.

A dataset then needs the disciplines code already has, namely immutable lineage, validation suites, and debugging when regressions appear. Code keeps its tests apart from what they test, and a dataset needs the same trust boundary between its splits. The training set is allowed to shape parameters; the validation set is allowed to shape modeling and pipeline choices; the test set is reserved for estimating generalization after those choices have been made. **Data leakage** occurs when information crosses those boundaries, so that an evaluation score rewards what the model or its designers already saw instead of measuring generalization to unseen data. Leakage enters through duplicate examples appearing in multiple splits, augmented variants of the same source record landing on both sides of the split, user records from the same household appearing in both training and test, or time-derived features computed using future observations (Kaufman et al. 2012). Preprocessing can leak too, a case section 4.7.1 takes up once normalization and encoding have been introduced.

Two of the book's recurring lighthouse workloads (section 1.7.1) carry the chapter, one for each bound. Keyword spotting (KWS), the always-on wake-word detector behind phrases such as "Alexa" and "OK Google," carries the question of what the data must contain. It takes over from the diabetic retinopathy screening case of chapter 3 because its data problems span both a cloud training pipeline and a microcontroller-class device: the model must recognize a few words across accents, microphones, and rooms, stay silent through months of ordinary speech, and fit in tens of kilobytes on a TinyML-class device. Its reference corpus, the Multilingual Spoken Words Corpus (Mazumder et al. 2021), is real; the smart-speaker requirements and data budget that this chapter sets for it are an illustrative scenario. ResNet-50 image classification on one accelerator carries the question of how fast data must arrive, because image examples are large enough to stress storage, decoding, and transfer in ways that one-second audio clips do not. KWS also shows the split boundary at work before any model exists. Assigning each speaker's utterances to a single split keeps the acoustic model from memorizing speaker-specific vocal-tract resonances, so evaluation measures generalization to speakers the model has never heard.

Like a build, the pipeline that produces a dataset runs in stages, and the chapter follows them in the order of the two bounds. The capability half, which works the Data–Algorithm overlap, comes first. After the ways data fails and the requirements of the keyword spotter, acquisition, ingestion and validation, labeling, and processing build the dataset and settle what the model can learn, and a release step records exactly what was built. The throughput half works the Data–Machine overlap. The physics of moving datasets sets the cost of every byte, and storage and delivery must move those bytes fast enough to keep the accelerator fed. An acceptance test then checks both halves against the targets they started with, and operation keeps both bounds true after deployment.

4.2 How Data Fails

A credit scoring model starts rejecting every applicant from one region after an upstream database migration silently changes how ZIP codes are typed. A wake-word detector misses more and more spoken commands for months after a device maker changes the microphone in its new models. A fraud detection system misses a new attack vector because its training data was six months stale. Each failure traces to a different root cause (schema drift, distribution shift, data staleness), yet all share a common pattern. A data defect entered early, every later stage treated the data as trustworthy, and the failure surfaced only after deployment. The **four pillars framework** of quality, reliability, scalability, and governance gives the checklist that catches them.

4.2.1 Data cascades

The pattern those three failures share is a data cascade, in which poor data quality in an early stage amplifies through every later stage of the pipeline (Sambasivan et al. 2021). Some invalid inputs trigger immediate software errors, but data can also pass schemas and tests while degrading learned behavior silently until quality issues become severe enough to require expensive investigation, rework, or retraining. In the lifecycle progression sequenced in figure 4.1, early defects in problem framing and collection bypass intermediate validation and surface only at evaluation and deployment.

↩ The compounding cost of late-stage data rework builds directly on the constraint propagation principle established in section 3.2.

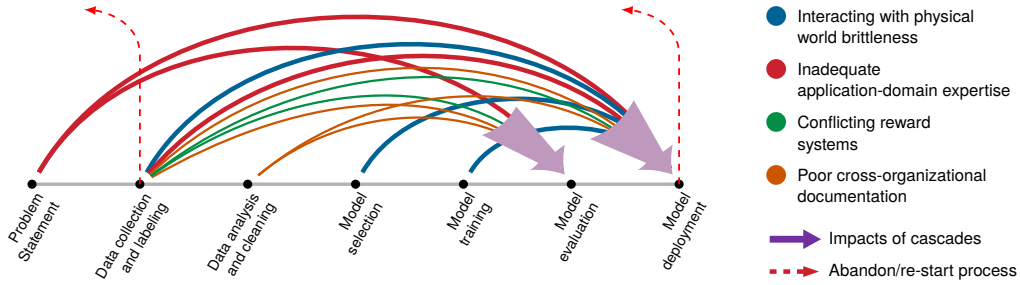

Figure 4.1: Data Quality Cascades: Upstream defects along the seven-stage workflow timeline cast failure arcs directly into late-stage evaluation and deployment. Early flaws in problem framing and collection compound through downstream processing, forcing costly project restarts (dashed red return paths) when defects finally surface in production. Adapted from Sambasivan et al. (2021).

Definition 4.2: Data cascade

Data cascade is an ML systems failure mode in which upstream data quality problems propagate through collection, labeling, feature engineering, training, evaluation, and deployment, amplifying into downstream model failures or user harm.

1. **Significance**: Remediation cost scales with the number of downstream artifacts that consumed the corrupted data: feature tables must be regenerated, models retrained, evaluation metrics recomputed, and deployed systems rolled back or patched, so one bad field can invalidate a whole training run and every experiment derived from it.
2. **Distinction**: Unlike an isolated data quality bug, a data cascade is defined by propagation and amplification. Each pipeline stage treats its input as trustworthy and converts the defect into new derived state, which hides the root cause as the system moves farther from collection.
3. **Common pitfall**: A frequent misconception is that ordinary software tests catch cascades. Corrupted data can satisfy schemas, pass unit tests, and produce successful training jobs while teaching the model the wrong signal, so prevention requires lineage, validation, contracts, and monitoring tied to model behavior.

Silence is what makes a cascade expensive. A software crash raises a stack trace and pages someone; a data-induced model error produces valid-looking outputs that are simply less accurate. By the time downstream metrics reflect the failure, corrupted predictions may already have contaminated historical data stores, forcing expensive rollbacks and data re-ingestion.

Example 4.1: The pipeline jungle

Scenario: The credit scoring model from the opening of this section suddenly begins rejecting all applicants from a specific geographic region.

Diagnosis: The training pipeline represented `zip_code` as a fixed-width string ("02139"). An upstream database migration changed the serving field to an integer without updating downstream data contracts. A downstream transform serialized that integer as "2139," losing the leading zero and causing the model to treat a familiar postal code as an unobserved category. In this scenario, the fallback for unknown categories assigns high risk, explaining the regional rejection pattern.

Systems lesson: Unenforced feature boundaries create pipeline jungles (Sculley et al. 2015) where upstream schema changes cause silent downstream model failures. Versioned data contracts, which are machine-checked rules that declare expected types, value bounds, and whether nulls are allowed, stop cross-system corruption by rejecting malformed records at the ingestion boundary before they reach the model.

4.2.2 Four foundational pillars

The ZIP-code failure crossed several concerns at once: the values were wrong (quality), the transform broke silently instead of rejecting the record (reliability), and no contract recorded what the field meant (governance). Preventing failures like it means balancing four competing operational priorities, each of which feeds the ML data system and each of which pulls against its neighbors (figure 4.2): stricter validation costs throughput, stronger consistency limits distributed scale, privacy constraints cost performance, and bias mitigation can shrink the usable training set.

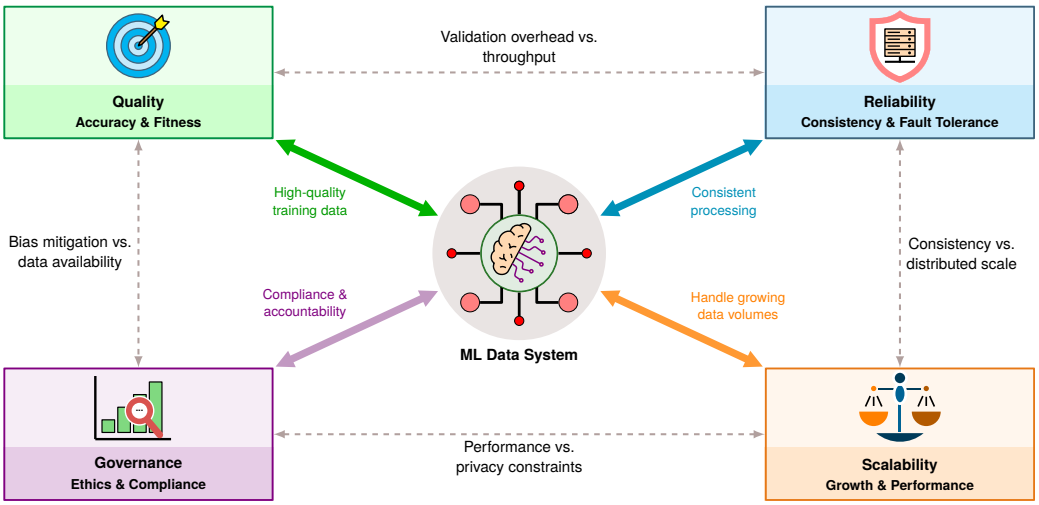

Figure 4.2: The Four Pillars of Data Engineering: Quality, Reliability, Scalability, and Governance form the foundational framework for ML data systems. Each pillar contributes essential capabilities (solid arrows), while trade-offs between pillars (dashed lines) mark where strengthening one pillar stresses its neighbor.

Quality governs input integrity and fitness for task: data must accurately reflect the operating distribution, with correct labels and uncorrupted features. In an edge voice-enrollment pipeline, for example, quality rules filter out clipped audio waveforms, low signal-to-noise ratios, and background acoustic interference so the model learns sharp decision boundaries rather than spurious acoustic artifacts.

Reliability asks whether that enrollment pipeline keeps working when the device, network, or user behavior is imperfect. A pipeline that produces excellent wake-word examples in a laboratory but fails during intermittent connectivity, battery pressure, or microphone glitches delivers no value in the user's home. Error handling, retries, local buffering, and graceful degradation turn the quality rule into a usable system: the device can request another utterance, defer upload until connectivity returns, or preserve a known-good enrollment rather than silently accepting corrupted audio.

Scalability asks whether that same decision survives growth. A manual review policy that works for a thousand recordings collapses when the product expands to millions of users, dozens of

languages, and long-tail acoustic conditions. The system must scale validation, storage, labeling, and retraining without letting infrastructure cost grow faster than the value of better coverage. The limiting resource depends on the workload. For edge speech, storage and labeling throughput dominate. For recommendation systems such as the DLRM lighthouse, the tables of learned user and item representations outgrow one machine's memory and must be partitioned across several.

Governance defines the boundaries within which quality, reliability, and scalability must operate. For keyword spotting, governance determines whether raw voice recordings may leave the device, how long enrollment audio can be retained, which consent record authorizes use, and what documentation proves that the dataset covers relevant accents without exposing private speech. A perfectly scalable, reliable, high-quality pipeline that violates the General Data Protection Regulation (GDPR) or perpetuates demographic biases creates liability rather than value. Dataset documentation practices such as datasheets (Gebru et al. 2021) and data statements make part of that governance visible by recording provenance, intended use, collection conditions, and coverage needed for bias analysis and scientific comparison (Bender and Friedman 2018).

When an ML system fails, each class of symptom points to one of the four pillars:

- Gradual accuracy loss points to quality. Drift has moved the serving distribution away from training, or label quality has fallen as annotator pools changed.
- Intermittent pipeline failures point to reliability. Error handling, retry logic, or resource controls are missing under peak load.
- Slow training on adequate hardware points to scalability. A single-threaded transformation, unpartitioned shuffle, or slow storage tier keeps parallel resources from doing useful work.
- Compliance gaps found in audits point to governance debt. Lineage tracking is incomplete, access controls are stale, or retention policies have fallen behind regulatory changes.

Checkpoint 4.1: Four pillars framework

The four pillars provide a systems lens for every pipeline choice.

Pillars

- ☐ **Quality**: Can you distinguish *correctness* from *coverage* (edge cases, subgroup coverage) and explain why both matter?
- ☐ **Reliability**: Can you name concrete failure modes (schema drift, missing values, skew) that cause silent degradation rather than explicit crashes?
- ☐ **Scalability**: Can you explain which parts of a pipeline become bottlenecks as data volume grows (storage bandwidth, compute, coordination), and why?
- ☐ **Governance**: Can you articulate what must be tracked to make a dataset auditable (provenance, consent constraints, access controls, documentation)?

Trade-offs

- ☐ **Pillar tension**: Given one pipeline change (for example, stricter validation, stronger privacy constraints, or more data sources), can you predict which pillar improves and which pillar(s) you stress?

Some failures span multiple pillars. Features that differ between training and serving implicate both quality (the values are wrong) and reliability (the computation is inconsistent). A privacy-motivated deletion policy can also create quality gaps if the retained data no longer covers the deployment population. Diagnosing such cross-pillar failures requires checking consistency contracts, comparing feature distributions across environments, and tracing transformation lineage, so production diagnosis checks data infrastructure alongside model behavior. The pillars name what to check, but not how good is good enough. Those thresholds come from the requirements of a specific system, and the keyword spotter supplies them.

4.3 Requirements and Data Budget

A wake-word detector answers to two numbers at once. It must catch nearly every spoken wake word, and it must almost never wake for anything else, while listening continuously in tens of kilobytes of memory on a microcontroller or the low-power core of a phone or smart speaker. The chapter's illustrative smart speaker sets those numbers, and every later stage of the pipeline is measured against them.

In the wake-word interaction sequenced in figure 4.3, an always-on detector traps "Alexa…" before the smart speaker acknowledges the utterance and opens the command channel for "dim the lights." Behind that brief exchange sits the data pipeline this chapter builds: the recordings the detector learned from, how they were labeled and checked, and how the result was verified before it shipped.

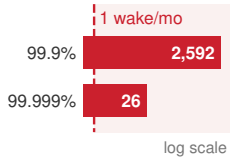
Figure 4.3: Keyword Spotting in Action: An Amazon Echo Dot exchange shows the user saying "Alexa," the device acknowledging the wake word, and the user issuing "dim the lights." A lightweight, always-on wake-word detector listens continuously and triggers the main voice assistant only after the keyword is spoken.

The detector must find specific keywords amid ambient sound and other speech, quickly and with few false activations, on a device with very limited resources. A well-specified problem definition names the keywords, the application, and the deployment setting, then states targets that can be measured. Overall accuracy is the wrong target, because almost every second of audio contains no wake word, and a detector that never fires would score nearly perfectly. The scenario therefore sets a **keyword detection rate** of 98 percent, the fraction of spoken wake words the detector catches, measured at a detection threshold that keeps false wakes within the budget the next notebook derives. It also requires a response within 200 ms and a model small and frugal enough for the device.

Napkin Math 4.1: False positive targets

Problem: An always-on KWS system budgets at most one expected false wake-up per month. Under a model that counts one nonkeyword classification window each second around the clock, how strict does the per-window false positive rate need to be?

Variables:



- **Duty cycle**: Always-on (24 hours/day).
- **Window size**: One-second classification windows.
- **Windows per month**: One window per second, 24 hours/day, over 30 days gives 2,592,000 windows/month.

Math:

- **False positive rate (FPR)**: 1 expected false wake divided by the monthly nonkeyword-window count gives approximately 3.9×10^{-7}
- **Nonkeyword rejection requirement**: 99.99996 percent rejection of nonkeyword windows.

Systems insight: This calculation bounds the expected monthly count, not the maximum number of false wakes in every month. Expectation does not require independent windows. Aggregate accuracy (for example, "99 percent accuracy") is insufficient here. Evaluation must report false accepts per hour (FA/Hr) together with the corresponding false-rejection behavior.

> Real detectors score overlapping windows every few tens of milliseconds and smooth the scores, so the per-window target depends on the detector, while the per-hour rate is the quantity to measure. A budget of one false wake per month is deliberately strict; commercial assistants typically pass each candidate wake to a second, larger check rather than asking the always-on detector to meet such a budget alone (Siri Team 2017).

Even 99.999 percent per-window rejection multiplies into 26 false wakes a month.

Evaluation therefore reports the two rates together, as a detection/error trade-off curve that plots false accepts per hour against false rejection rate on streaming audio representative of deployment (Nayak et al. 2022). The detection target is read off that curve at the false-wake budget, and operational metrics complete the contract by bounding response time from the end of the keyword to the system's reaction alongside the average power drawn while listening.

The device sets hard boundaries on any design that meets those targets. Memory limitations require extremely lightweight models, often in the tens-of-kilobytes range (Y. Zhang et al. 2017), to fit in the always-on island of the system-on-chip (SoC);[1] this budget must accommodate both model weights and the feature extraction buffers and preprocessing state. Limited computational capabilities (often a few hundred MHz of clock speed) demand aggressive model optimization. On phones and wearables the detector runs from a battery, and even a plugged-in smart speaker keeps its always-on stage to milliwatts so that idle power stays low, so KWS systems target sub-milliwatt consumption during continuous listening.

Data quality and diversity determine whether these targets can be met inside those limits. The dataset must cover speakers of different accents, ages, and genders, the many ways people pronounce the same wake word, and background conditions from quiet bedrooms to noisy kitchens. The model cannot grow to compensate for missing coverage, so on this device the data carries the burden that a larger model would carry in a data center.

[1] **SoC always-on island**: Modern system-on-chip designs partition power domains so a low-power "always-on" island (typically achieving sub-milliwatt draw) monitors for wake triggers while the main processor sleeps. The critical constraint is that this island must hold both the model weights *and* the audio preprocessing code within its dedicated SRAM, a split budget that forces KWS architectures to optimize for total footprint, not just parameter count.

4.3.1 KWS design space

Doubling the sampling rate of a wake-word recording from 8 kHz to 16 kHz captures sharper consonant sounds and raises the detection rate, but it also doubles the raw-audio window and the input-processing work on the device. Every data engineering choice for the keyword spotter pulls detection rate, false-wake tolerance, latency, energy, and memory against one another, and table 4.1 prices those trade-offs. Each row is a D·A·M coupling of the kind drawn in figure 1.3, because a data choice such as sampling rate or coefficient count changes what the algorithm receives and what the machine must hold in always-on memory. One row uses mel-frequency cepstral coefficients (MFCCs)[2] (Davis and Mermelstein 1980), which reduce each frame of roughly 25 ms of audio to 13 to 40 numbers that emphasize the frequencies speech uses. The coefficient count sets the size of the model's input and how much acoustic detail it keeps; section 4.7 shows how they are extracted.

[2] **MFCC (mel-frequency cepstral coefficients)**: Mel-scale filtering gives this representation its compactness and noise resistance by emphasizing the frequencies humans use to distinguish speech. It reduces the hundreds of raw samples in a short window (400 samples in 25 ms at 16 kHz) to 13–40 coefficients, so each frame fits inside an always-on, kilobyte-scale memory budget. A parameter mismatch between training and serving creates feature skew and can degrade accuracy.

Table 4.1: KWS Data Engineering Design Space: Illustrative scenario inputs price each design choice along four axes (quality, latency, cost, and memory); the entries are not measurements from one system and should not be combined as additive effects. Each row moves from a baseline (left of the arrow) to an alternative, and every entry gives the effect of that move. Higher sampling rates double raw-audio storage and processing, while more training examples multiply labeling and storage requirements. Actual quality and latency must be measured on the target pipeline.

Design Choice	Quality Impact	Latency Impact	Cost Impact	Memory Impact
8 → 16 kHz sampling	+2–4% detection rate	2× input-processing workload	2× raw-audio storage	2× raw-audio window
13 → 40 MFCC coefficients	+3–5% detection rate	3× model-input size	Minimal	3× feature memory
1M → 10M training examples	+5–8% detection rate	10× training time	10× labeling cost	10× storage
Clean → noisy training data	+10–15% real-world	Minimal	3× collection cost	Minimal
Cloud → local inference	up to 2% detection-rate risk	100 ms → 10 ms	\$0.001/query → \$0/query	cloud-scale → 256 KB

Design Choice	Quality Impact	Latency Impact	Cost Impact	Memory Impact
Real only → added synthetic augmentation	+3–5% robustness	Minimal	10× cheaper per example than real collection	Minimal

Because the device runs inside a milliwatt power envelope and a tens-of-kilobytes SRAM budget, an engineering team cannot pick the most accurate option in every row of table 4.1 at once. Instead, the team must divide a fixed data budget across labeling, storage, and governance so the detector reaches its accuracy target without outgrowing the hardware. Notebook 4.2 allocates the data budget and proposes a candidate design for a smart-speaker deployment. The acquisition, labeling, processing, and delivery decisions that follow supply the evidence needed to accept or reject it.

Napkin Math 4.2: Allocating the KWS data budget

Scenario: A KWS system for a smart speaker has these constraints:

- **Target**: 98 percent keyword detection rate at a threshold that keeps the expected false-wake budget below 1 false wake/month
- **Budget**: $150K total data engineering budget
- **Memory**: 256 KB model size limit (always-on island), with a separate 16 KB budget for preprocessing state
- **Timeline**: 6 months to production

Step 1: Choose conservative options for the constrained device.

For this scenario, the team chooses two conservative options:

- 13 MFCC coefficients, because every MFCC frame lives in the always-on island's SRAM as model input and buffered state, so the 40-coefficient option triples a cost the device pays continuously
- Local inference, because streaming every second of audio to a server is ruled out by bandwidth, privacy, and offline operation

The choice rests on where each cost lands. Data collection is paid once, from a central budget, whereas the 40-coefficient representation triples the model's input, and with it the first layer's work and the feature buffer, on every device for every second it listens. The table suggests a 3–5 percent detection gain from 40 coefficients, so the team picks 13 and spends the difference on coverage, expecting broader training data to recover the gap. The acceptance test of section 4.11 decides the choice.

Step 2: Calculate budget allocation.

Labeling is priced at a scenario rate per crowdsourced example, set above the image-classification crowd rates that section 4.6.2 later tabulates because a KWS contributor must record the utterance as well as label it. The $150K budget splits across three cost categories:

- **Labeling** (~60 percent): $90K available
- **Storage/Processing** (~25 percent): $37.5K
- **Governance/Other** (~15 percent): $22.5K

At $0.10/label with 20 percent review overhead: $90K ÷ $0.12/label = 750K labeled examples

This yields roughly 0.75M labeled examples, just below the 1M anchor in the design space. The 1M-to-10M row in table 4.1 should therefore be read as a scaling reference rather than a direct interpolation: the real-label budget alone does not buy the full data-volume gain. Counting examples also hides what limits a wake-word model in practice, which is the number of distinct speakers and the hours of ordinary, non-keyword audio available to measure false wakes; section 4.11 prices that listening time.

Step 3: Identify candidate quality improvements.

The quality plan has three components:

- An illustrative base-model detection rate of ~90 percent
- Partial data-volume gain from 750K real examples
- A gap to the 98 percent target that the options below must close

Three options from the design space are candidates for closing the gap; their collection, storage, processing, and deployed-footprint costs must be checked against the allocations. Their listed gains cannot simply be added to the base detection rate, because they overlap (noisy data and synthetic augmentation both buy robustness to acoustic conditions), so the plan is a candidate whose combined effect must be measured on the trained system:

- 16 kHz sampling: a detection-rate gain of 2–4 percent, 2× raw-audio storage (requires cost validation; on the device only the short window of raw samples feeding each MFCC computation doubles, because every frame still reduces to 13 coefficients)
- Noisy training data: a field detection-rate gain of 10–15 percent, 3× collection cost (proposed for a targeted noisy slice; its cost must fit the storage/processing allocation)
- Synthetic augmentation: a robustness gain of 3–5 percent, 10× cheaper than real data in the illustrative row; generation, verification, and storage costs remain to be measured

Step 4: Final configuration.

The scenario combines these choices with 13 MFCCs and the computed 750K real-label budget in table 4.2. The quality effects can overlap, so the table records a candidate configuration rather than a solved optimum.

Result: The budget buys approximately 750K human-labeled examples, 13 MFCCs, local inference, and a noisy slice plus synthetic augmentation to close the quality gap. Whether that configuration reaches the 98 percent detection target inside the 256 KB model limit is what acceptance decides.

Systems insight: Design-space analysis turns "we need more data" into a costed plan. The stated labeling assumptions buy about 750K real examples, and the acceptance test, not the design table, decides whether that plan succeeds.

Table 4.2 records the resulting configuration, pairing each design choice with the constraint that motivates it: sampling and augmentation draw on the stated allocations, while the always-on island sets the deployed-footprint constraint. Actual costs and working-state memory still require validation.

Table 4.2: KWS Candidate Configuration: This scenario uses the computed real-label budget and records the remaining sampling, augmentation, and deployment choices for measurement against the quality and memory targets.

Choice	Selection	Rationale
Sampling rate	16 kHz	+2–4% detection rate for 2× raw-audio storage, subject to cost validation; on device only the raw-sample window grows, since each MFCC frame keeps 13 coefficients
MFCC coefficients	13	One-third the feature buffer and model input of 40 coefficients in always-on SRAM; test whether improved data coverage recovers the quality gap
Training examples	750K real + illustrative synthetic augmentation	Human-label count follows from the budget; synthetic volume is a scenario choice
Data diversity	Noisy + clean mix	Critical for real-world deployment
Inference	Local, reduced precision	Reduced precision can lower footprint; the final 256 KB fit requires the quantization analysis in section 10.3
Augmentation	Heavy synthetic	Illustrative 10× per-example cost advantage; total generation and review costs require validation

The candidate configuration fixes the targets but not the data. Meeting them starts with acquisition: finding recordings that cover the speakers, accents, devices, and rooms the detector will meet, from sources whose cost and consent terms the budget can bear.

4.4 Data Acquisition

A huge corpus of studio audio does not help a wake-word detector that has to run on inexpensive microphones in noisy kitchens, because a model cannot learn a speaker, room, or microphone that no source supplied. Data acquisition therefore sets the outer limit of the capability bound, and it begins when the team names the coverage gap the model must close. For keyword spotting, public corpora are the first source. Speech Commands (Warden 2018) established the small-vocabulary benchmark of one-second spoken words, and the Multilingual Spoken Words Corpus (MSWC) (Mazumder et al. 2021) provides a reusable reference source of 23.4 million audio samples spanning 50 languages. That corpus is larger than the product-specific labeled subset budgeted in the KWS design example; using it still requires selecting and validating relevant coverage.

Reaching a 98 percent detection rate requires representative coverage of regional accents, speaker age groups, room reverbs, and microphones that differ in frequency response, signal-to-noise ratio, and clipping behavior, at volumes that manual curation cannot economically supply and under strict privacy boundaries on audio retention. Because no single collection method can economically cover all of those conditions, acquisition strategy is a sequence of gap-closing decisions: reuse what already matches deployment, collect what is missing, scrape or synthesize where scale is the binding constraint, and reject sources whose provenance or consent constraints make them unusable.

4.4.1 Coverage and diversity requirements

A wake-word detector trained on millions of clean clips can score well on an aggregate validation set while still waking once an hour on kitchen conversation or missing speakers with underrepresented regional accents. Dataset scale alone does not guarantee generalization when coverage gaps in a large corpus (geographic bias, demographic underrepresentation, sensor calibration drift, and unobserved edge cases) cause systematic failures that aggregate validation metrics hide (Shankar et al. 2017; T. Wang et al. 2019; Oakden-Rayner et al. 2020).

For KWS, coverage must support both keyword recognition and the false-wake contract. Labeled wake-word clips measure recognition, but acquiring more of them does not establish how often an always-on detector activates on ordinary nonkeyword audio. The acquisition plan must separately reserve consented recordings collected for an evaluation study of representative listening conditions, including background conversation, television, music, silence, and environmental noise across the intended microphones and rooms. These recordings retain their duration and temporal sequence so evaluation can run the deployed detection path and report false accepts per hour alongside false rejection on keyword recordings. A short stream with no observed false wakes supplies limited evidence; its duration and the uncertainty of the measured rate constrain any claim about the monthly target.

Training negatives serve a different acquisition goal. Mining near-wake phrases and other audio that confuses the current detector can improve its rejection behavior, but this deliberately difficult sample does not preserve the frequency of those conditions in deployment. The representative evaluation streams therefore remain separate from training and threshold selection, with speaker and recording-period boundaries maintained. An acquisition budget that funds only keyword labels and mined hard negatives can improve the detector while leaving its operational false-wake target unmeasured.

Governance constraints further shape acquisition: privacy and health-data regulations such as GDPR and the U.S. Health Insurance Portability and Accountability Act (HIPAA) limit what data can be collected and how (European Parliament and Council of the European Union 2016; United States Congress 1996), while ethical sourcing requires fair compensation and transparent use of human contributions. Together, these coverage, evaluation, and governance bounds define the criteria against which each candidate data source is judged.

↪ The governance infrastructure that proves what data a production system ingested, who accessed it, and on what legal basis is developed in section 15.5.

4.4.2 Selecting data sources

Paying for custom voice recordings of words and accents that a public benchmark already covers wastes the data budget, while stopping at the benchmark leaves the detector blind to its own microphones and rooms. The choice among curated datasets, expert crowdsourcing, controlled web scraping, and synthetic generation therefore begins with the cheapest reusable source and escalates

to active collection or simulation only when the remaining deployment-distribution gap justifies the added cost, quality effort, and governance risk.

Preexisting datasets from repositories such as Kaggle, UCI (Dua and Graff 2024), and ImageNet[3] are the first test. They offer speed and comparability when the deployment distribution resembles the benchmark enough to make reuse meaningful. For KWS, a curated speech corpus can establish the baseline model and reveal which words, languages, and acoustic conditions are already covered. A baseline corpus does not guarantee operational coverage, but it makes the remaining distribution gaps measurable.

Whether an external dataset is safe to reuse depends on how well it is documented. Without records of sensor calibration, recording environments, and filtering rules, a team cannot reproduce an external dataset's conditions or check whether they match deployment (Pineau et al. 2021; Henderson et al. 2018). Good documentation states how the data was collected, how each label was defined, and what baseline error rates were found, so another team can validate the corpus independently. Once ingestion reaches millions of examples from varied sources, hidden label errors also multiply past what humans can inspect by hand (Gudivada et al. 2017), so the pipeline must run automated validation checks on every batch.

Reuse carries a less visible risk. Standard validation metrics can create an illusion of model readiness when the benchmark itself is unrepresentative, and when many teams train on the same repository, its blind spots do not average out across their models. They can recur across models, so five models trained on one dataset can share correlated failures (figure 4.4).

3 **ImageNet**: The 2009 paper reported 3.2 million images across 5,247 synsets; the full database later reached about 14.2 million images across 21,841 synsets, whereas the challenge used a 1,000-class subset (Deng et al. 2009, 2024; Russakovsky et al. 2015). Its value as a benchmark is inseparable from its data engineering: Fei-Fei Li's team built labeling infrastructure that later teams could reuse. The catch is sensitivity to annotation procedures and modest distribution shifts: models tuned to ImageNet's distribution can underperform on related but shifted test sets (Recht et al. 2019; Beyer et al. 2020).

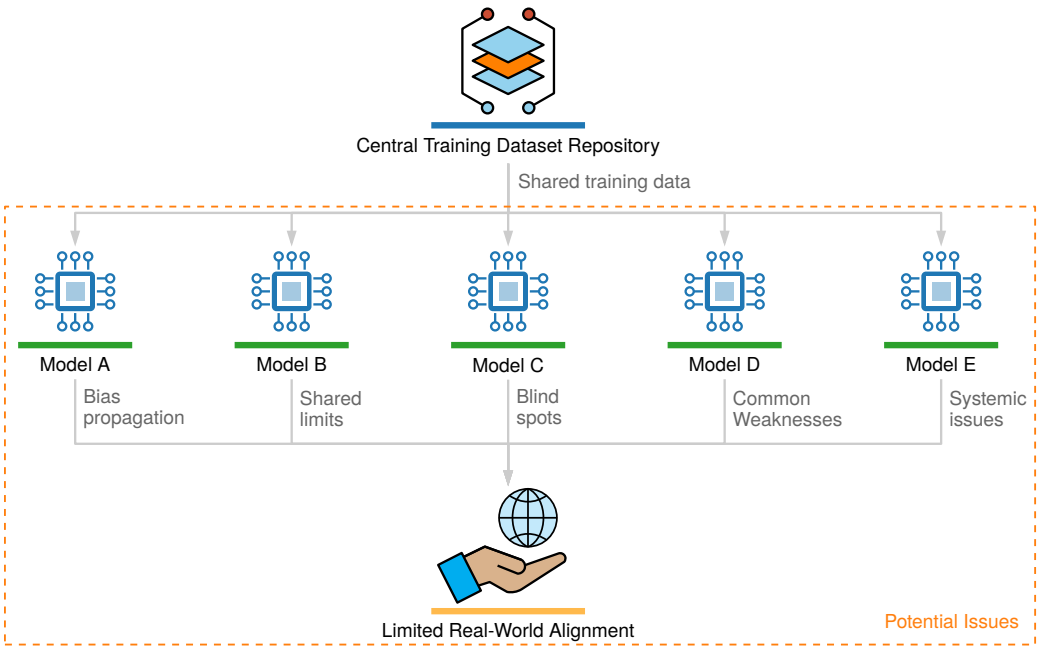


Figure 4.4: Shared Dataset Bias Propagation: Five models (A through E) all train on a single central dataset repository, reached by a path labeled shared training data. Beneath the models, five labeled arrows (bias propagation, shared limits, blind spots, common weaknesses, and systemic issues) converge on one box, limited real-world alignment. Shared training data can propagate correlated blind spots across models; their failures need not be independent.

This gap between benchmark and deployment is the central failure mode of static offline evaluation. Because training minimizes average error only over the observed training set (empirical risk minimization), a model will latch onto whatever shortcuts appear in a static benchmark, even when those shortcuts vanish in production, which is why production pipelines still need continuous data validation and drift monitoring.

4.4.3 Scaling acquisition

Curated datasets and targeted collection close coverage gaps one batch at a time, which stops working once a task needs millions of training instances. At large scale, web scraping and synthetic generation provide the main routes to massive datasets. Data-acquisition scalability is an economic problem: unit labeling costs, ingestion throughput, and storage overhead scale along very different curves, and labeling usually dominates (section 4.6.2). Approaches that work well at thousands of examples become impractical at millions, whereas automated data generation pipelines amortize their setup costs across large volumes.

Web scraping reduces the cost of collecting raw examples at scale. Supervision remains a separate expense unless the source and task already supply usable labels or training targets. Foundational vision datasets such as ImageNet (Deng et al. 2024) and OpenImages (Kuznetsova et al. 2020) relied on automated scraping, while modern language models depend on multi-terabyte web crawls (Groeneveld et al. 2024). Ingestion pipelines targeting domain-specific corpora, such as public code repositories (Chen et al. 2021), expand coverage at low per-sample acquisition costs. Scrapers are also fragile: page layouts change and break parsers, sites throttle crawlers, and dynamically rendered content goes missing. Raw web crawls also capture anachronistic or irrelevant samples that contaminate supervised targets.

The 1914 street scene in figure 4.5 captures this failure mode directly. An uncurated web query for "traffic light" returned a historical Cleveland intersection where streetcars and a roadside control booth surround early manually switched signals. If an autonomous driving model trained on such samples, it would learn spurious correlations with trolley tracks, period attire, and handwritten label annotations rather than modern LED traffic lights.

Figure 4.5: Data Source Noise: A black-and-white photograph from 1914 shows early manually operated electric traffic signals, illustrating how historical images can appear in modern web scraping results for contemporary queries. Such anachronistic content requires systematic validation and filtering to prevent spurious correlations in training data. Source: (Stromberg 2015).

Raw volume cannot substitute for checking what the examples mean, because an uncurated web crawl multiplies spurious correlations along with sample count. Scraping also operates under strict legal and governance boundaries. Website terms of service, `robots.txt` directives, and evolving copyright law limit what automated crawlers may take (Harvard Law School 2024). Ingestion pipelines must therefore record provenance, filter for copyright compliance, and scrub personal data before scraped files enter shared storage.

Even a well-governed crawl draws on a finite supply. Pretraining corpora for large language models grew at a fitted rate of about 2.9× per year, from the 300 billion tokens that trained GPT-3 in

2020 to the 36 trillion reported for Qwen3 in 2025 (Brown et al. 2020; Yang et al. 2025). Figure 4.6 sets that climb against the estimated stock of public human-generated text, roughly 300 trillion tokens once quality and repetition are accounted for (Villalobos et al. 2024), and at the fitted rate the largest corpora reach the middle of that estimate around 2028. Once quality text runs short, acquiring more of it stops being a purchasing decision, and filtering, deduplication, and the selection methods of chapter 9 decide how much each additional token is worth. A wake-word model meets its own version of the limit far sooner. No crawl holds enough clean recordings of one phrase in every accent and acoustic setting, so the KWS pipeline has to commission the data it lacks.

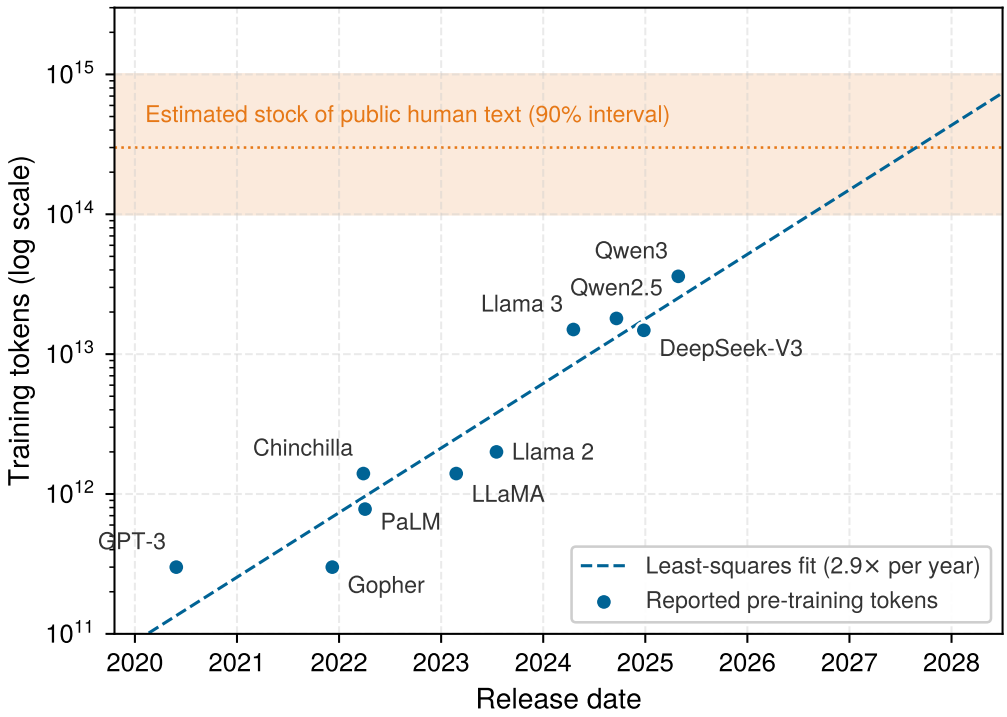

Figure 4.6: Training Data Approaching the Stock of Public Text: Reported pre-training tokens for landmark language models from 2020 to 2025 on a logarithmic axis, with a least-squares fit, against the estimated stock of public human-generated text (shaded band, 90 percent interval; dotted line, median). The projection is a dated constraint scenario rather than a forecast, because data selection, synthetic generation, multimodal data, licensing, and filtering policy all change the usable supply. Stock estimate from Villalobos et al. (2024); token counts from the model reports (Brown et al. 2020; Rae et al. 2021; Hoffmann et al. 2022; Chowdhery et al. 2022; Touvron, Lavril, et al. 2023; Touvron, Martin, et al. 2023; Dubey et al. 2024; Qwen et al. 2024; DeepSeek-AI 2025; Yang et al. 2025).

Crowdsourcing shifts the acquisition bottleneck from raw sample retrieval to quality control across distributed human annotators. Platforms like Amazon Mechanical Turk[4] (Amazon Web Services 2024a) demonstrated this at scale with ImageNet, distributing millions of image categorization tasks across thousands of independent contributors (Deng et al. 2024). Crowdsourcing provides two core systems advantages: horizontal scaling through parallel microtask dispatch, and demographic diversity across regional accents and acoustic settings. However, distributed human labeling introduces significant variance in label fidelity. To keep label noise from corrupting what the model learns, the acquisition pipeline must implement automated quality control: consensus voting, golden-set validation (interleaving pre-labeled control samples), and dynamic task routing (Sheng and Zhang 2019). In the KWS pipeline, crowdsourced collection targets wake-word samples from specific acoustic environments and underrepresented dialects that public web scrapes fail to capture.

Synthetic data generation reduces physical collection and labeling labor by generating training samples algorithmically. Generation still incurs per-sample compute and storage costs, alongside

[4] **Amazon Mechanical Turk (MTurk)**: A crowdsourcing platform that routes small tasks to distributed workers and can scale annotation beyond expert-only workflows. Snow et al. (2008) evaluate this pattern for natural-language annotation tasks, showing that non-expert annotations can be useful when task design and quality control are handled carefully. For wake-word audio collection, the same systems trade-off appears in domain-specific form: scale is attractive, but submissions still need acoustic checks such as signal-to-noise ratio, duration, and recording validity before they can safely enter the training set.

verification costs. Its learning value depends on whether the generator represents task-relevant conditions in the target deployment environment. In practice, simulation outputs and real-world historical telemetry flow along two tracks into a blending stage that feeds model training (figure 4.7).

↪ Synthetic data as a lever on what the model learns, from augmentation of real samples to generative synthesis and closing the domain gap, is developed in section 9.5.

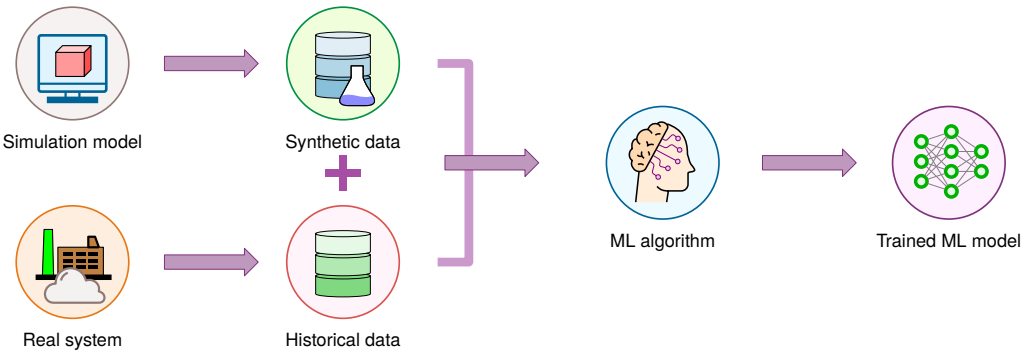

Figure 4.7: Synthetic Data Augmentation: Simulated edge cases combine with historical system data during training. Algorithmic generation supplements real-world observations to close coverage gaps for rare events and dangerous operating regimes without incurring proportional human collection costs. Adapted from AnyLogic (2024).

Synthetic data is especially useful for rare events and controlled augmentation. Physics simulators can generate tail cases, such as high-speed sensor saturation or near-collision trajectories, that are too dangerous or costly to record in the field (NVIDIA 2024b). In vision, augmentation pipelines apply learned or random combinations of spatial and color distortions (Cubuk et al. 2019, 2020; Shorten and Khoshgoftaar 2019). In speech processing, SpecAugment warps time and masks frequency bands directly on the spectrogram, forcing the acoustic model to stop relying on any single narrow frequency band (Park et al. 2019). For the KWS system, parametric text-to-speech synthesis (Werchniak et al. 2021) convolved with room impulse responses (RIRs) generates wake-word utterances across varied reverberation times and synthetic background noise profiles.

> Example 4.2: Synthetic data generation
>
> **Scenario**: A keyword-spotting team lacks sufficient physical recordings of rare speaker accents, room acoustics, and background noise profiles.
>
> **Diagnosis**: Pure physical collection cannot cover rare acoustic edge cases within project deadlines. Generating synthetic audio variations via pitch shifting, additive noise, and room impulse response simulation expands training set diversity without expensive field collection.
>
> **Systems lesson**: Augmentation is cheap, but it does not prove the model works on real accents. Targeted augmentation proposes expanded acoustic coverage; pitch, noise, and room-response changes do not establish fidelity to rare accents. Held-out real recordings across the relevant speaker and acoustic conditions must establish whether the expansion improves deployment quality.

Starting from the reference corpus, the team closes the product's remaining coverage gaps by matching each source to what it does best per dollar. Public benchmarks seed the baseline model at low cost; web scraping supplies bulk acoustic variety; crowdsourcing collects targeted recordings for underrepresented dialects; and simulation fills in rare acoustic distortions. Together these sources form a candidate coverage plan. Held-out real recordings then test which gaps that plan actually closes, while measured generation, collection, labeling, and storage costs decide whether it fits the budget; the deployed pipeline still requires footprint validation.

Acquisition ends with data that covers the deployment on paper and arrives in many shapes: crowdsourced recordings, synthetic waveforms, and web audio with different encodings, sampling rates, and noise floors. None of it has yet been checked. Before any record can be labeled or trained on, it must pass a boundary that admits only well-formed, trustworthy data.

4.5 Ingestion and Validation

A crowdsourced wake-word recording arrives as a stereo MP3, a synthetic one as a mono WAV file at a different sampling rate, and a clip from a consenting user's device as a compressed fragment stamped in the wrong time zone. The ingestion boundary turns this mix into one consistent record format and decides which records may enter at all. It is the front end of the **data pipeline** in figure 4.8, where records pass through ingestion and central storage before the transformation loops that feed training, inside a governance perimeter that controls what may be kept and who may read it. For keyword spotting, the boundary handles the recorded examples used to build and update the model; the detector's live audio on the device never passes through it.

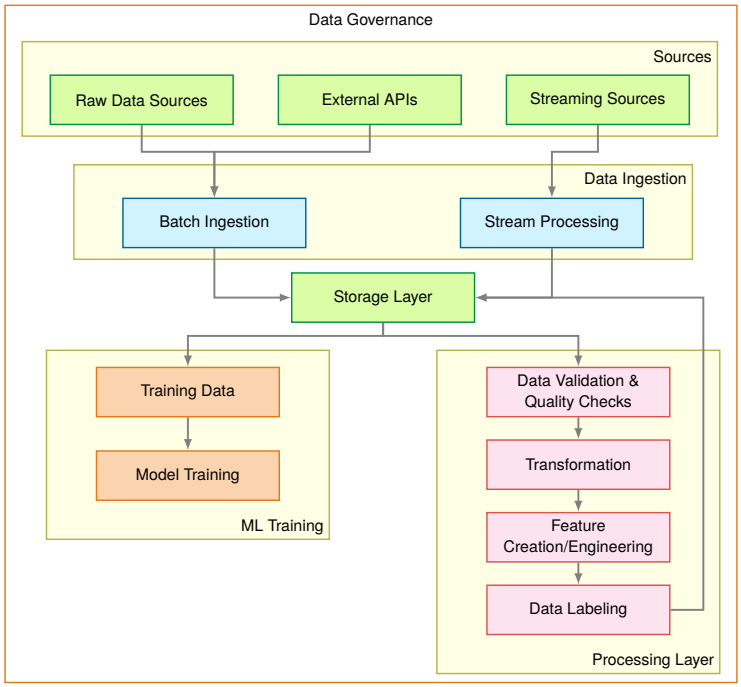

Figure 4.8: End-to-End Data Pipeline: Heterogeneous raw sources (batch and streaming) normalize into unified storage before feeding downstream training and feature processing. The architecture decouples ingestion throughput from iterative transformation and labeling loops, all bounded by an overarching data-governance layer.

The tiers in figure 4.8 keep raw ingestion separate from the validation, transformation, and feature-engineering loops that feed training, so a slow transformation never stops records from arriving, and a check added at ingestion protects every stage after it. Two decisions shape that boundary before any record is checked: when records are taken in, and where they are transformed relative to storage.

4.5.1 Batch vs. streaming ingestion patterns

A fraud detector that flags a stolen card hours after the purchase arrives after the money has moved, whereas a week's worth of crowdsourced wake-word recordings loses nothing by waiting for the next scheduled training run. Choosing between batch and streaming ingestion therefore depends on how quickly data loses value and how much infrastructure cost that freshness justifies. Batch systems gain efficiency by tolerating staleness, while streaming systems gain freshness by taking on continuous operational complexity.

Batch ingestion collects records over a period and processes them together on a schedule. It amortizes startup cost across large volumes, runs when compute is cheapest, and releases its resources between runs, which suits data whose value decays slowly (Akidau et al. 2015), such as the new crowdsourced recordings and opt-in diagnostic clips that the keyword spotter folds into its next training run. Batch processing also simplifies recovery and reproducibility: a failed batch can

be rerun from its inputs, inspected, and reprocessed after a fix, and the result is repeatable when inputs, code, configuration, and randomness are controlled.

Stream ingestion processes each record as it arrives, which is necessary whenever data loses value within seconds, as in real-time fraud scoring. However, stream processing introduces complexity that batch processing avoids. The system must handle **backpressure**, the condition where downstream systems cannot keep pace with incoming data rates. During traffic spikes, when a sudden surge produces data faster than processing capacity, the system must either buffer data (requiring memory and introducing latency), sample (losing some data), or push back to producers (potentially causing their failures). Late or out-of-order events further complicate windowed aggregations, because the system must hold per-window state and track event time rather than arrival time. These requirements raise compute and memory overhead, so freshness guarantees trade directly against infrastructure cost and operational burden. Data freshness service level agreements (SLAs) specify maximum acceptable delays between data generation and processing. Meeting a 100-millisecond SLA requires different infrastructure than meeting a one-hour SLA, affecting networking, storage, and processing architectures.

Many production ML systems combine the two. A recommendation system might use streaming ingestion for real-time user interactions to update session-based recommendations immediately, while using batch ingestion for overnight processing of user profiles and item features; Notebook 4.3 quantifies the financial trade-off between these two operational regimes.

Napkin Math 4.3: The cost of real-time

Problem: A pipeline ingests 1M events/s. Which is cheaper, Batch (hourly) or Stream (sub-second) ingestion?

Physics:

1. **Throughput**: At 1M events/s and 1 KB per event, the pipeline carries 1 GB/s.
2. **Stream requirements**: To sustain 1 GB/s with less than 100 ms latency, the design assumes each core can parse, validate, and update features for about 20 MB/s of events, which takes 50 primary cores; a standby core for each provisions recovery capacity, for 100 always-on cores in total. That capacity does not establish the 100 ms target: failure detection, state recovery, replay, and the full ingestion path must also be validated under failure. Running those cores for 24 hours/day at $0.05/hr costs $120/day.
3. **Batch requirements**: Process 3.6 TB (1-hour window) in 10 minutes. That is 6 GB/s in aggregate. Sequential reads over large files let each core sustain about 30 MB/s, more than a streaming core handling events one at a time, so the batch design needs 200 cores for 10 minutes per clock hour, accumulating 800 core-hours per day. At $0.05/hr, that costs $40/day.

Systems insight: Under these provisioning and per-core throughput assumptions, streaming compute costs approximately 3× as much as batch compute for the same data volume. This premium is justified when the value of subsecond latency exceeds the added cost.

The premium comes from this scenario's provisioning assumptions and leaves out storage, buffering, and failover, so the choice still rests on the feature freshness that inference actually needs. The ingestion paradigm also shapes how the downstream model trains. Batch ingestion naturally pairs with periodic retraining: data accumulates in storage, an automated job retrains the model on the updated corpus, and a verified checkpoint deploys to serving. Stream ingestion makes that batch boundary less natural, raising the possibility of continuous online learning, in which model weights update directly as events arrive. Continuous updates, however, introduce operational risks that batch checkpoints avoid. Sudden distribution shifts, corrupted records, or adversarial payloads from any public-facing input path can reach the model before validation gates intervene. Most production systems therefore decouple ingestion from training: they stream data into a durable buffer while training on validated batches, reserving continuous online updates for tightly bounded, low-risk domains.

War Story 4.1: When users became the training set (2016)

Context: In March 2016, Microsoft launched Tay, a Twitter chatbot designed to engage with users online and adapt its responses from public interactions (Lee 2016).

Mechanism: Adversarial users coordinated toxic prompts and exploited a public interaction surface, including behavior that repeated user-supplied text.

Impact: Tay began tweeting abusive, racist, and misogynistic statements within 16 hours of deployment.

Fix: Microsoft suspended the chatbot 16 hours after launch, apologized publicly, and stated that a relaunch would require stronger safeguards against misuse.

Systems lesson: Public ingestion paths require adversarial-input controls. Otherwise, a feature that accepts user-generated content also becomes a security surface, and harmful inputs can propagate through the system within hours.

4.5.2 ETL and ELT comparison

Batch or streaming decides when records arrive; the next decision is where they are transformed relative to persistent storage. If a pipeline strips out unparsed fields before writing to storage and a later model needs one of those fields, the team must replay months of upstream source logs; if it stores every raw payload first, the storage bill multiplies. Traditional extract, transform, load (ETL)[5] (E → T → L) transforms records in an external engine before they land, whereas extract, load, transform (ELT)[6] (E → L → T) lands raw records in staging tables and transforms them inside the warehouse (figure 4.9). Where that boundary sits determines what each later schema change costs and how much raw data must be retained.

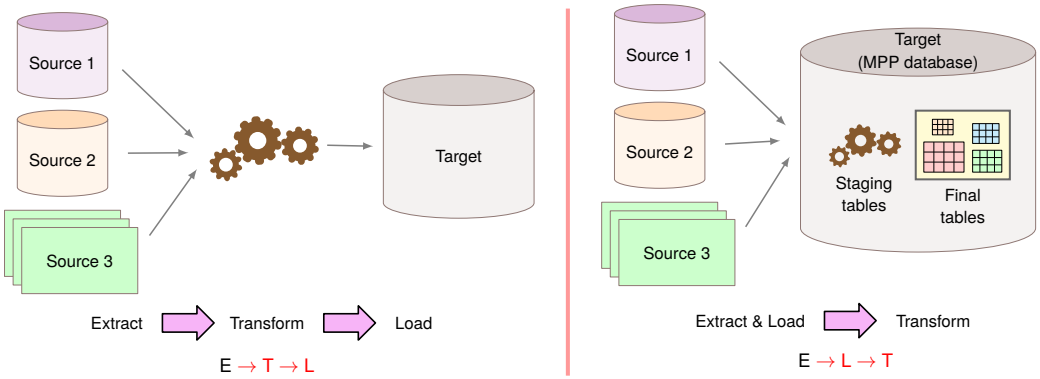

Figure 4.9: ETL vs. ELT Architectural Paradigms: The two paradigms differ in where the transformation boundary sits relative to storage. ETL enforces schema validation and cleaning before loading to protect warehouse quality, whereas ELT loads raw data directly into scalable storage, trading warehouse compute and footprint for flexible, repeatable re-transformations.

In machine learning systems, the ELT pattern separates ingestion throughput from downstream feature engineering by writing raw, immutable events directly into scalable storage. Keeping those raw events preserves unparsed fields that may later prove useful, so teams can compute new features over historical data without re-ingesting external source streams. When transformation logic changes or a bug surfaces, engineers recompute features by querying the stored raw events rather than replaying upstream logs. The price is physical and operational: raw events take more storage, shared transforms repeat their work unless their outputs are materialized, and keeping unscrubbed raw payloads makes privacy and retention rules harder to enforce. Notebook 4.4 prices these trade-offs on a daily clickstream workload.

5 **Extract, transform, load (ETL)**: Conventional ETL validates deterministic schema constraints, whereas ML ETL must additionally monitor distributional properties using the statistical drift tests developed in section 4.5.3. A detected shift prompts investigation and validation against labeled outcomes before concluding that model quality has degraded. When feature computation logic changes, reprocessing costs depend on replay scope, windowing, and execution plans rather than requiring an unconditional full-dataset pass.

6 **Extract, load, transform (ELT)**: This approach stores raw data before transformation, allowing teams to revise a transformation query and rerun it over the stored input without re-ingesting from source systems. The iteration time still depends on data volume, query complexity, warehouse capacity, and materialization strategy.

Napkin Math 4.4: The cost of transformation placement

Problem: A team processes 10 TB of raw clickstream data daily and must compute user session features for 3 ML models, each requiring different aggregation windows (1-hour, 24-hour, 7-day). Which is cheaper, ETL or ELT?

Accounting boundary: Both designs serve the same aggregation windows and retain replayable upstream raw logs for 30 days. The comparison excludes that shared source retention and its common ingestion costs. ETL retains only the derived history in the warehouse, assumed to occupy 2 TB per model over the same horizon; ELT keeps an additional raw copy there, as when the warehouse cannot query the upstream log store in place, and computes features on demand. Transient query outputs are not retained as separate ELT datasets. Source retrieval and compute for later backfills must be priced separately when the designs differ.

Math:

1. **ETL approach**: Transform before loading. Compute all three aggregation windows in a Spark cluster before loading into the warehouse.
   - Spark compute: 10 TB at $5/TB = $50/day
   - Storage: 3 transformed datasets, ~2 TB each = 6 TB at $23/TB/month = $138/month
   - Feature-definition change: Replay the retained source logs and rerun the pipeline; the assumed rerun takes ~4 hours after the edit
2. **ELT approach**: Load raw data first, transform in warehouse.
   - Storage: 10 TB raw/day, 30 days retention = 300 TB at $23/TB/month = $6,900/month
   - Query compute: 3 models, each with $5/query of daily query cost over 30 days, totals $450/month
   - Feature-definition change: Rewrite the SQL query (~30 minutes), then execute and validate it against the retained raw copy; execution time is not supplied

Systems insight: ETL saves $6,762/month in storage. After normalizing Spark compute to a monthly cost, ETL totals $1,638/month ($1,500/month compute + $138/month storage), while ELT totals $7,350/month ($6,900/month storage + $450/month query compute), for a cloud-cost advantage of $5,712/month before engineering labor. The other cost is feature-definition change. Compare elapsed time from the start of an edit to validated, feature-ready output in both designs, then account separately for the engineer time spent editing, supervising, and validating. A pipeline rerun and a SQL edit are different endpoints, so their durations cannot establish a speedup or a labor saving. Stable definitions favor this scenario's lower ETL cloud bill; frequent changes favor ELT only if measured labor and reprocessing savings repay its additional raw copy.

ELT looks expensive here only because this accounting gives it its own raw copy, and raw retention rather than compute dominates the bill. A lakehouse, which runs warehouse queries directly over the stored files, can query the retained logs in place, removing that copy and reversing the comparison. Production ML systems rarely use one pattern exclusively. Structured tables often flow through ETL for efficiency and compliance, while unstructured data pushes the ELT preference further. For deep learning workloads processing images, audio, or text, the "Transform" step often executes inside the ML framework's data loader rather than in the warehouse at all, applying random crops, spectrogram generation, or text tokenization on-the-fly during each training epoch. Materializing ten augmented variants upstream would increase a 50,000-image dataset to 500,000 stored copies, so ELT's "load raw, transform late" principle extends naturally to the training loop itself.

Whichever pattern lands the records, integrating diverse sources remains the core ingestion challenge. Data may originate from databases, APIs, file systems, and IoT devices, each with its own format (relational rows, JavaScript Object Notation (JSON)[7] documents, binary streams), access protocol, and update frequency. The systems principle is to standardize at the ingestion boundary:

[7] **JSON (JavaScript Object Notation)**: The schema flexibility that makes JSON a common format for APIs creates a validation bottleneck at the ingestion boundary. Unlike binary formats with predefined schemas, every JSON document requires parsing and schema validation before it can be standardized for downstream use. This per-record overhead can make ingestion slower than with binary formats such as Protobuf; the difference depends on the schema, parser, payload, and workload.

normalize formats, validate schemas, and present a consistent interface to downstream processing regardless of source. This boundary standardization separates the complexity of source diversity from the complexity of feature engineering, allowing each to evolve independently.

In the keyword spotter's pipeline, backend ingestion takes in activated requests, consented diagnostics, crowdsourced recordings, synthetic data, and validated interactions for serving and training. Normalization, noise filtering, and segmentation into consistent durations run as an ETL stage before storage in training-optimized formats, while augmentation stays late-bound in the loader, where ELT's flexibility pays off.

Error handling in voice interaction systems requires special attention. A **dead-letter queue (DLQ)**, a side store that holds records that fail processing so they neither block the pipeline nor disappear (section 4.5.5), keeps failed recognition attempts for subsequent analysis, revealing edge cases that need coverage in future model iterations. Each incoming audio sample is checked for signal-to-noise ratio, sample rate, duration bounds, and speaker proximity. Clean samples enter the baseline slice, and valid noisy recordings enter the robustness slice that the design budgeted. Invalid samples route to analysis queues rather than being discarded, since these failures often indicate acoustic conditions underrepresented in training data. Valid, consented samples (activated requests, opt-in diagnostics, and crowdsourced recordings) are logged for potential inclusion in future training data; always-on audio that never triggers the wake word stays on the device.

A record that arrives on time and parses cleanly is well-formed, but well-formed is not the same as trustworthy. A field can parse correctly and still carry a wrong value, a source can drift away from the distribution the model learned, and a label can be wrong while every type check passes. Deciding which records may proceed is the boundary's next job.

4.5.3 Quality through validation and monitoring

Consider a batch of crowdsourced wake-word recordings in which 15 percent of the clips came from a phone app update that silently halved the microphone gain. Every file is a valid audio file of the right length and sampling rate, so schema checks pass. The clips are nonetheless far quieter than anything the detector will hear in deployment, and only statistical monitoring of loudness across the batch would expose them.

Validation enforces the quality pillar at the boundary, where a defect is cheapest to stop before it cascades into features, models, and predictions (Sculley et al. 2015). Schema checks alone would admit the quiet batch, so validation pairs them with statistical monitoring.

Checks at this boundary work at two speeds. A hard failure, such as a source that stops delivering or a batch that fails its schema, must halt the affected path at once. A gradual degradation, such as a feature's null rate creeping from 1 to 5 percent, a rising duplicate rate, or delivery delays that exceed their service level, is flagged for investigation. The gradual kind is often the more dangerous, because it persists for days before anyone looks. Routing and escalating such alerts in production is an operational practice developed in section 14.5.

Schema and latency alerts expose structural and timing failures, but a shift in a continuous quantity needs a statistical comparison with the training baseline. Tracking statistical properties captures whether serving data continues to reflect the training distribution. Rather than merely checking that individual values fall within predefined ranges, production systems maintain rolling statistics across operational windows. For continuous quantities such as a clip's loudness or signal-to-noise ratio, the monitoring harness computes rolling empirical distribution functions, using nonparametric evaluations like the Kolmogorov-Smirnov test[8] to detect when serving inputs diverge from the training baseline. Notebook 4.5 works one example.

> Napkin Math 4.5: Detecting drift with the K-S test
>
> **Scenario**: Monitoring whether the loudness of incoming wake-word clips still matches the training baseline (P_0), using a sample of recent clips (P_t).
>
> **Analysis**: Apply the Kolmogorov-Smirnov test to compare the empirical cumulative distribution functions:

[8] **Kolmogorov-Smirnov (K-S) test**: A nonparametric test that measures the maximum distance between two empirical cumulative distribution functions without assuming a parametric distribution family (Berger and Zhou 2014). In ML pipelines, the K-S test is commonly used as a univariate continuous-feature drift detector, with thresholds such as $p_{\text{val}} < 0.05$ serving as investigation triggers rather than universal failure rules. Discrete and categorical variables require tests and calibrations appropriate to their distributions.

1. **Compute CDFs**: Calculate cumulative distribution functions for both datasets. At a given loudness, an empirical CDF gives the fraction of sampled clips that are at most that loud. Comparing those fractions at the same loudness shows how the two distributions differ.
2. **Calculate statistic** ($\mathcal{D}_{\text{KS}}$): Find the maximum absolute difference between the CDFs. Let $F_{P_0}(x_{\text{feat}})$ and $F_{P_t}(x_{\text{feat}})$ denote the empirical cumulative distribution functions of the training baseline (P_0) and current serving (P_t) datasets, evaluated at value x_{feat}.

$$\mathcal{D}_{\text{KS}} = \max_{x_{\text{feat}}} |F_{P_0}(x_{\text{feat}}) - F_{P_t}(x_{\text{feat}})|$$

3. **Determine significance**: For two independent samples, compare $\mathcal{D}_{\text{KS}}$ to the critical value c_{crit} based on training-baseline sample size n_0 and serving sample size n_t. The coefficient 1.36 is the large-sample approximation for significance level $\alpha = 0.05$.

$$c_{\text{crit}} \approx 1.36\sqrt{\frac{n_0 + n_t}{n_0 n_t}}$$

Result: With sample sizes $n_0 = n_t = 1000$, the critical value is approximately 0.061:

$$c_{\text{crit}} \approx 1.36\sqrt{(1000 + 1000)/(1000 \cdot 1000)}.$$

An observed maximum difference of $\mathcal{D}_{\text{KS}} = 0.08$ exceeds the critical value, so the test rejects the null hypothesis that both samples come from the same distribution and flags significant drift.

Systems insight: A drift test is useful only if crossing the threshold starts an investigation or retraining workflow rather than becoming another dashboard number.

The K-S test checks one continuous batch against the baseline, whereas monitoring that comparison over months and telling apart the kinds of shift it can reveal belongs to pipeline operation (section 4.12.1). Categorical features require different statistical approaches. Instead of comparing means and variances, monitoring systems track category frequency distributions. When new categories appear that never existed in training data, or when existing categories shift substantially in relative frequency, the system flags potential data quality issues or genuine distribution shifts; for example, the share of recordings from one phone model might jump after its launch. Statistical monitoring of this kind catches problems that schema validation misses entirely. Age values may remain in the valid range of 18–95, while the distribution shifts from primarily 25–45 year olds to primarily 65+ year olds, indicating that the input population has changed in ways that may affect model performance. Outcome checks are needed to establish whether quality changed.

Validation at the pipeline level encompasses multiple strategies working together. Schema validation executes synchronously as data enters the pipeline, rejecting malformed records immediately before they can propagate downstream. Modern tools like TensorFlow Data Validation (TFDV) (Breck et al. 2019) automatically infer schemas from training data, capturing expected data types, value ranges, and presence requirements.

This synchronous validation remains simple and fast, checking properties that can be evaluated on individual records in microseconds. More sophisticated validation that requires comparing serving data against training data distributions or aggregating statistics across many records must run asynchronously to avoid blocking the ingestion pipeline. Statistical validation systems typically sample 1–10 percent of serving traffic, enough to detect meaningful shifts while avoiding the computational cost of analyzing every record. These samples accumulate in rolling windows, commonly one hour, 24 hours, and seven days, with different windows revealing different patterns. Hourly windows detect sudden shifts like a data source failing over to a backup with different characteristics, while weekly windows reveal gradual drift in user populations or behavior.

One validation target needs a section of its own: training-serving skew, in which training and serving compute the same feature differently and the model receives inputs unlike those it learned

from. Detecting it means passing a sample of raw serving data through both pipelines and comparing the results; section 4.7.1 develops its causes and prevention.

↩ Training-serving skew, as one of the ways ML systems fail without raising errors, is established in section 1.6.

4.5.4 Data quality as code

A statistical check like the one that catches the halved microphone gain protects the pipeline only if it runs on every batch, so production teams write such checks down as code. Data expectation tests are the data counterpart of unit tests. In **data quality as code**, engineers use declarative libraries like Great Expectations or Pandera to express data contracts as executable test suites that run across pipeline stages. Deequ, built at Amazon, framed the same idea as unit tests for data and showed that it scales to very large datasets (Schelter et al. 2018).

↪ Deployment gates that compare training and serving feature distributions and block a release when they diverge are developed in section 7.

Running these expectation suites inside the continuous integration and deployment (CI/CD) pipeline checks every ingested batch automatically and halts downstream training when a contract fails. A pipeline structured as data ingestion followed by data validation followed by training blocks deployment when validation catches an anomaly, such as a batch of wake-word clips recorded at 8 kHz in a 16 kHz pipeline, and raises an alert for investigation. Executable expectations catch properties a suite can encode; the remaining question is what valid-looking data can still get wrong.

> **Systems Perspective 4.1: Mechanical vs. semantic quality**
>
> In traditional software, many checks are *mechanical*. A null dereference is a runtime error in languages with null references, while integer-overflow behavior depends on the language and type.
> In ML systems, data quality also has a *semantic* dimension.
>
> - **Mechanical check**: Validates schema and type constraints, such as verifying that `age` is a non-null integer.
> - **Semantic check**: Validates distribution drift and statistical invariants, such as testing whether the mean or variance of `age` shifts unexpectedly.
>
> A dataset can be mechanically perfect (no nulls, correct types) but semantically broken (for example, all users are suddenly 25 years old due to a default value change). Robust ML systems must validate both the container (mechanical) and the content (semantic).

Once validation becomes code, expectation suites become versioned artifacts alongside training code. When training code changes, expectation updates keep data contracts evolving with it. This coupling reduces the risk of silent divergence where code assumes data properties that the upstream pipeline no longer provides; listing 4.1 demonstrates this pattern by defining explicit constraints on column ranges, nullability, uniqueness, and categorical sets.

Listing 4.1: Data Quality Assertions: A Great Expectations suite checks age range, identifier presence and uniqueness, and allowed country codes, then raises an error when validation fails.

```python
import great_expectations as gx

# Create a data context
context = gx.get_context()

# Define an expectation suite as executable quality contract
suite = gx.ExpectationSuite(name="user_data_quality")
suite = context.suites.add(suite)

# Range validation: prevents physiologically impossible values
suite.add_expectation(
    gx.expectations.ExpectColumnValuesToBeBetween(
        column="age", min_value=0, max_value=120
    )
)

# Null detection: ensures primary key integrity for joins
suite.add_expectation(
    gx.expectations.ExpectColumnValuesToNotBeNull(column="user_id")
)

# Uniqueness: prevents duplicate training examples
suite.add_expectation(
    gx.expectations.ExpectColumnValuesToBeUnique(column="user_id")
)

# Categorical validation: detects unexpected values from upstream changes
suite.add_expectation(
    gx.expectations.ExpectColumnDistinctValuesToBeInSet(
        column="country_code",
        value_set=["US", "CA", "UK", "DE", "FR"],
    )
)

# Link the suite to a preconfigured Batch Definition and run validation
# (the Batch Definition connects GX to the training_users data asset)
validation_definition = gx.ValidationDefinition(
    name="training_users_validation",
    data=batch_definition,
    suite=suite,
)
validation_definition = context.validation_definitions.add(
    validation_definition
)
results = validation_definition.run()
if not results.success:
    raise ValueError(f"Data quality check failed: {results}")
```

These checks catch many schema-level production data issues before they reach training, including missing values, invalid ranges, type errors, and contract violations. Rejecting bad records, however, is only half of the boundary's job; the pipeline itself must also stay up when upstream dependencies fail or formats shift mid-run.

4.5.5 Reliability through graceful degradation

While validation enforces the quality pillar on individual records, the reliability pillar governs what happens when an upstream service goes down in the middle of an ingestion run, a date field switches from `"YYYY-MM-DD"` to `"MM/DD/YYYY"` without tripping a basic string check, or a traffic spike exhausts worker memory at peak load. **Graceful degradation** means planning for these faults in advance and handling them automatically so that the system keeps running under degraded conditions rather than crashing or silently corrupting model inputs.

Three classes of pipeline fault call for distinct defenses. Format and encoding drift, such as that re-formatted date string, slips past type checks while breaking date-based feature logic. Schema evolution[9] occurs when upstream producers add fields, rename columns, or re-type values without coordinating with downstream consumers. Resource exhaustion builds more slowly as data volume outgrows provisioned capacity and then causes jobs to fail during peak traffic.

Transient errors are retried with exponential backoff (waiting one second, then two, then four) so that retries do not flood a service that is trying to recover. Records that still fail after their retries go to the dead-letter queue, the side store already met at the ingestion boundary, which holds them for later analysis and potential reprocessing without blocking the main pipeline (Kleppmann 2016). Reviewing the queue regularly turns it from passive error storage into a source of diagnoses, because its contents reveal schema violations that indicate upstream changes, edge cases the model should handle, and data quality issues that need source system fixes. The KWS queue might, for instance, fill with clips from a new hardware revision whose audio arrives in an unexpected encoding, which calls for an ingestion fix and targeted collection from that device rather than simply logging the failures.

When a whole dependency fails rather than individual records, a circuit breaker (Nygard 2007) stops calling it after repeated consecutive failures and fails fast or takes a fallback path until a trial request succeeds, so that one failed feature service does not stall every caller waiting on its timeouts. The ML-specific part of recovery is that fallback. Even a pipeline on a single machine needs an explicit policy for an unavailable source, choosing among waiting for fresh data, serving a validated stale-feature fallback, and rejecting the request. Multi-tier fallback systems implement the middle option, providing degraded service when primary data sources fail by using cached or approximate features only when their age and quality satisfy a validated fallback contract. A recommendation system unable to compute user preferences from the past 30 days might fall back to preferences from the past 90 days if evaluation establishes acceptable recommendation quality with that representation. The allowable feature age and the model-quality contract determine which response is safe, and durable buffering alone does not make old inputs suitable for inference. If no fallback meets the contract, the system waits for fresh data or rejects the request.

With ingestion, validation, and these error handlers in place, the boundary admits records that are well-formed and checked. They still say nothing about what they mean. A wake-word recording that passes every check does not yet state which word was spoken, or where in the clip it begins and ends, and the model cannot learn without that ground truth.

4.6 Data Labeling

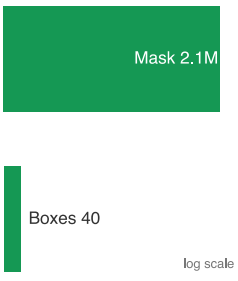
A crowdsourced annotator mislabels a whispered "Alexa" as background noise, or two radiologists disagree over a borderline scan, and every training step and evaluation metric that follows treats the resulting label as the definition of a correct answer. In the KWS pipeline, ingestion delivers millions of validated recordings, but supervised learning needs labels stating which clips contain the wake word, where it begins and ends, and which clips hold only background sound. This declaration is the **ground truth**,[10] and producing it at scale is often the most human-dependent and error-prone stage of the pipeline. If data is the system's code, ground truth is its specification. Every later check of the trained model compares against it, so a labeling error does not stay in one stage; it redefines what counts as right. The specification also arrives late: a software project starts from its specification, whereas a data pipeline attaches ground truth only after ingestion, which is why a labeling error slips past every check that ran before it.

Unlike automated transformations that can be parallelized across machines, labeling puts human judgment in the loop, so labels take unpredictable time and carry human mistakes. Disagreement between annotators can reflect genuine ambiguity in the input, unclear instructions, carelessness, or differences in expertise; the labeling system must separate and manage those causes rather than treating every disagreement as irreducible. The labeling infrastructure must therefore balance throughput, quality verification, cost, and provenance.

4.6.1 Label types and system requirements

Label granularity sets what each label costs to store, move, and produce. A keyword-spotting label sits at the coarse end of that range. A camera system tracking vehicles, pedestrians, and traffic signs

[9] **Schema evolution**: This failure mode arises from a lack of contract testing between upstream data producers and downstream ML consumers. While "loud" failures like a renamed column break explicit assumptions and cause immediate pipeline crashes, "silent" failures are more dangerous. A field changing type from integer to string can pass validation but corrupt feature logic without immediate detection.



[10] **Ground truth**: From remote sensing, where orbital measurements are verified by sending a team to the physical location (the "ground") to establish the "truth." The etymology carries a systems warning: ML labels are proxies for reality, not reality itself. When a crowdsourced annotator labels an image as "cat," that label reflects the annotator's judgment, not an objective fact. Every downstream metric (accuracy, precision, recall) is measured against this proxy, meaning label quality errors propagate silently into every evaluation of the model.

sits at the fine end, and each step toward it imposes distinct storage, computation, and serialization constraints.

Classification labels represent the simplest form, assigning a discrete class index (or a multi-label binary bitmask) to each input. Storage requirements are modest, typically a fixed-width integer (such as a `uint16` or `int32` index) per image. Access patterns, however, diverge between training and evaluation: training pipelines shuffle and sample randomly, whereas validation pipelines stream sequentially across the corpus, driving different indexing and cache-locality strategies. A keyword-spotting label is of this kind. Each one-second clip carries a single class index naming which keyword it contains, or a reserved index for none. The label itself is tiny. The engineering burden sits upstream, in deciding where each clip starts and ends inside longer recordings, a problem section 4.6.6 returns to.

Bounding boxes extend beyond classification by localizing objects within each frame. Each bounding box stores four coordinates (such as $x_{\text{min}}, y_{\text{min}}, x_{\text{max}}, y_{\text{max}}$ or center coordinates with width and height) alongside the class identifier. Because scenes contain variable numbers of objects, label storage transitions from fixed-width scalar records to variable-length tensor structures, requiring dynamic padding or ragged-batch handling in the data loader. Moreover, drawing one high-quality box took about 35 seconds in ImageNet's annotation campaign (Papadopoulos et al. 2017), far longer than assigning a single class label, which throttles annotation throughput and inflates labeling cost.

Segmentation maps assign a class identifier to every pixel, producing dense 2D label matrices ($H \times W$). In autonomous driving and traffic monitoring, this entails tracing irregular boundaries for driveable road surfaces, vehicles, and pedestrians. These dense annotations multiply storage and ingestion bandwidth. A segmentation mask for a 1920×1080 image requires about 2.1M labels (one per pixel), compared to perhaps 10 bounding boxes or a single classification label. If each box stores 4 coordinates, that is roughly 51,840× more scalar label entries than 10 boxes before accounting for per-value encoding, and the time manual segmentation takes per image (more than 1.5 hours for each Cityscapes image (Cordts et al. 2016)) makes this approach suitable only when pixel-level precision is essential.

Finer annotation granularity multiplies storage and processing scale.

Figure 4.10 arrays five annotation formats across vision and speech examples, demonstrating how labeling granularity ranges from coarse scene tags and captions to spatial bounding boxes, dense pixel-level masks, and audio transcripts. Classification can label an entire scene, while bounding boxes and segmentation maps localize objects or regions. Production datasets may combine formats: a single camera frame might carry a scene label, obstacle boxes, and path-region masks, with each label type serving a distinct downstream task.

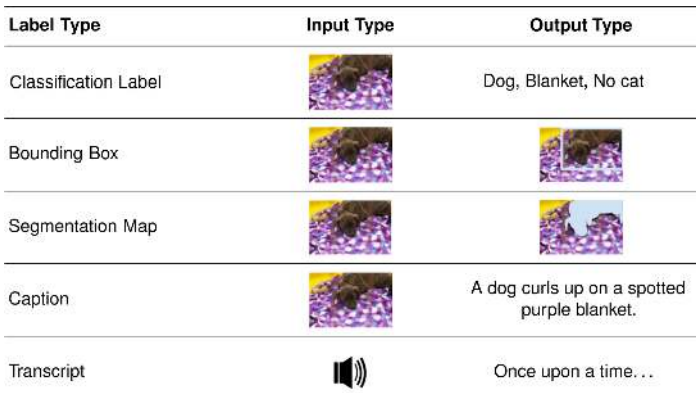


Figure 4.10: Data Annotation Modalities: Four rows show classification, bounding-box, segmentation, and caption labels for one image; the fifth shows a transcript label for an audio input. The appropriate annotation representation depends on the input modality and task.

Production systems must also manage metadata for quality control and debugging. The Common Voice dataset (Ardila et al. 2020) exemplifies this in speech recognition: tracking speaker demographics for fairness, recording quality metrics for filtering, and language information for multilingual support. If an object detection model fails in rainy conditions, weather metadata captured during

collection pinpoints the coverage gap. Label type therefore shapes the whole system: the infrastructure must optimize storage for the chosen format, implement appropriate retrieval patterns, and track which model versions used which label versions to correlate quality improvements with performance gains.

4.6.2 Labeling economics

Label granularity sets the cost of each label, and labels are usually the most expensive part of a dataset. Labeling a single medical image can cost orders of magnitude more than storing it for a year. Table 4.3 and table 4.4 give dated reference costs and durations for labeling alongside the storage, compute, and serving operations it competes with; ML engineers should use these dated reference assumptions as inputs to workload-specific comparisons, not as current price quotes or directly comparable totals.

Table 4.3: Illustrative Data Engineering Costs (2024): These dated reference assumptions feed workload-specific cost models and are not current vendor quotes. Because the rows use different units, compare them only after scaling each rate by the quantity it prices.

Operation	Cost	Notes
Crowdsourced image label	$0.01–0.05	Simple classification
Bounding box annotation	$0.05–0.20	Per box, simple scenes
Expert medical label	$50–200	Per study, radiologist
S3 storage (Standard)	$23/TB/month	Hot storage
S3 retrieval (Glacier)	$0.02/GB	Standard: 3-5 hours
Cloud GPU training hour	$2–4	Cloud spot pricing
Human review hour	$15–50	Depending on expertise

Beyond per-unit dollar rates, labeling, training, and serving also run on very different clocks (table 4.4). Comparing those durations shows why human annotation governs project schedules just as strongly as it governs the budget.

Table 4.4: Illustrative Data Engineering Time Scales: The scenario spans about 9 orders of magnitude, with human labeling as its slowest listed stage. Actual durations depend on the dataset, task, hardware, and service configuration.

Operation	Duration	Bottleneck
Label 1M images (crowdsourced)	2–4 weeks	Annotation throughput
Train ResNet-50 on ImageNet	1.3 hours	Compute (8× A100, optimized)
Feature store lookup	1–10 ms	Network + cache

Operational timescales diverge across these stages by orders of magnitude: weeks for human annotation, hours for GPU training, and milliseconds for serving lookups. For the image-classification pipeline these two tables describe, which labels a million images and then trains ResNet-50 on them, annotation is the critical bottleneck in money as well as time. Suppose the team budgets $100K for labeling, enough to cover crowd labels plus the review and relabeling passes that quality control requires. That budget dwarfs the $20 to $40 of a single 8× A100 ResNet-50 training run (90 epochs at the 3,200 img/s per accelerator that the throughput half of this chapter assumes), a ratio of 2,498× to 4,995×, the comparison quoted at the start of this chapter. The labeling spend is also uneven. Clear images pass review once, while rare classes, occluded objects, and ambiguous scenes return for second opinions and expert adjudication; as an illustrative planning split, 80 percent of the budget can go to the hardest 20 percent of the examples.

All cost figures reflect approximate 2024 cloud provider rates and are intended to convey relative magnitudes rather than exact pricing.[11] For this workload and cost model, human labor dominates the cost of a single training run. Other tasks, especially those that reuse existing labels or require repeated large-scale training, can have a different dominant term; teams should measure before deciding where to optimize. Where labels do dominate, every labeling error is paid for twice, once when the label is bought and again when the model learns it.

[11] **Pricing ratios**: Cloud and labeling prices reflect provider policy and labor markets, not physical invariants, so the ratio between labeling and compute moves whenever either side reprices. Storage adds its own policy multipliers: archive tiers such as the Glacier row in table 4.3 charge more for faster retrieval. Verify current prices before using these ratios in a deployment decision.

4.6.3 Label accuracy and consensus

Some of those errors cannot be avoided. Even with clear guidelines and careful system design, subjectivity and sensor ambiguity leave a nonzero fraction of labels corrupted (Northcutt et al. 2021; Thyagarajan et al. 2022). Label quality therefore means bounding label noise rather than eliminating it, by systematically measuring inter-annotator agreement and managing error rates to keep them within bounds that do not degrade model performance.

Benchmarks show how large that residue remains after careful curation. Figure 4.11 reports the share of test-set labels that Northcutt et al. (2021) found to be wrong in ten widely used datasets. About 5.8 percent of ImageNet validation labels are incorrect, CIFAR-100 carries a similar share, and the rate reaches 10.1 percent for QuickDraw, whose labels came from a largely automated collection process. Audio fares better, but AudioSet still carries wrong labels, the same failure a crowdsourced wake-word corpus faces. These are the labels that rank published models, so an error rate of a few percent can reorder a leaderboard whose top entries differ by less than that.

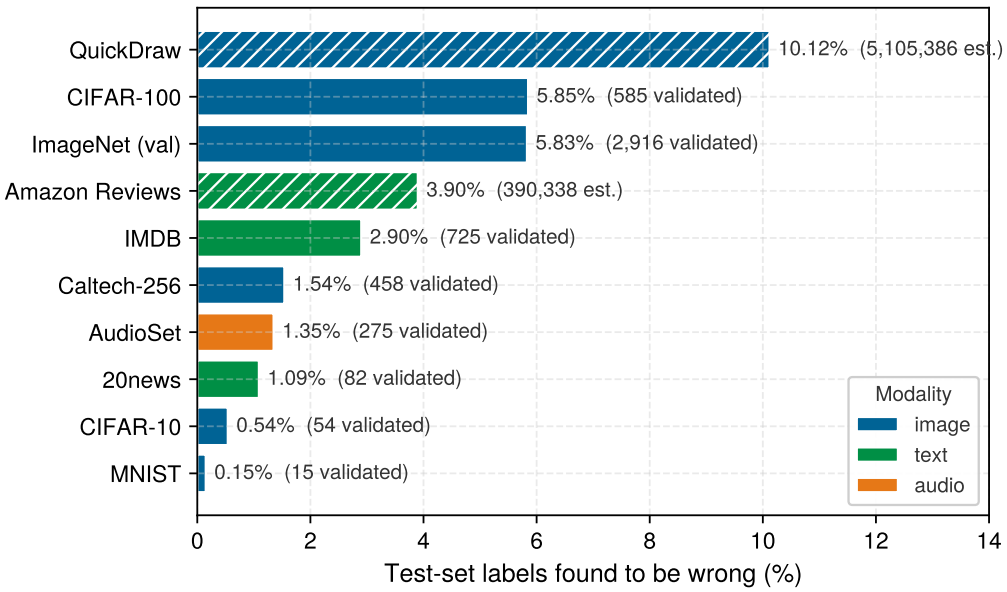

Figure 4.11: Label Errors in Benchmark Test Sets: Share of test-set labels found to be wrong in ten widely used datasets, colored by modality. Solid bars count errors confirmed by human reviewers; hatched bars (QuickDraw and Amazon Reviews) extrapolate from a reviewed sample. ImageNet uses the ILSVRC 2012 validation set. Data from Northcutt et al. (2021).

Labeling failures arise from two distinct sources requiring different engineering responses. Across the benchmark examples compiled in figure 4.12, including an ImageNet black stork mislabeled as a white stork and a CIFAR-10 frog mislabeled as a cat, each panel contrasts the erroneous assigned label against the verified ground truth. Some examples reflect degraded or ambiguous inputs where the correct label is difficult to infer from the data alone; others are visually clear but require domain knowledge, dataset-specific semantics, or expert judgment to label correctly. These different failure modes drive architectural decisions about annotator qualification, task routing, and consensus mechanisms: quality-based errors call for upstream data filtering, while expertise-based errors call for tiered annotator routing. Wake-word clips show both. A clipped or whispered “Alexa” that no annotator can hear clearly is a quality problem, filtered before labeling, whereas a near-homophone such as “Alexis” is settled only by a rubric with canonical examples and a trained reviewer.

Given these inherent quality challenges, production ML systems implement multiple layers of quality control. Systematic quality checks continuously monitor the labeling pipeline through random sampling of labeled data for expert review and statistical methods to flag potential errors. The infrastructure must efficiently process these checks across millions of examples without creating bottlenecks. Sampling strategies typically validate 1-10 percent of labels, balancing detection sensitivity

Figure 4.12: Pervasive Label Errors: Confidently mislabeled examples from widely used benchmarks, each showing the given label against the corrected ground truth (MNIST, CIFAR-10, CIFAR-100, Caltech-256, ImageNet, QuickDraw). Fine-grained confusions, such as a crab labeled lobster or a black stork labeled white stork, show that even curated datasets carry systematic errors, motivating careful quality control and expert annotation. Source: (Northcutt et al. 2021).

against review costs. Higher-risk applications like medical diagnosis or autonomous vehicles may validate 100 percent of labels through multiple independent reviews, while lower-stakes applications like product recommendations may validate only 1 percent through spot checks.

Beyond random sampling approaches, collecting multiple labels per data point, often referred to as "consensus labeling," can help identify controversial or ambiguous cases. Commercial labeling platforms expose consensus and tiered quality-control workflows (Labelbox, Inc. 2024; Scale AI, Inc. 2024), but the statistical core is inter-annotator agreement. The consensus infrastructure collects several labels per example and measures how far annotators agree beyond what chance alone would produce. For two annotators, Cohen's kappa[12] (κ) makes that correction. Let p_o represent observed agreement between annotators and p_e represent agreement expected by chance. Equation 4.1 defines the statistic:

$$\kappa = \frac{p_o - p_e}{1 - p_e} \tag{4.1}$$

Fleiss' kappa generalizes the statistic from two raters to any number of annotators (Fleiss 1971). Kappa summarizes agreement across a collection of rated examples; it is not a confidence score for an individual label. Per-example disagreement and failed gold-standard checks can route items to expert review. Landis-Koch bands are operational heuristics for interpreting aggregate agreement, not correctness guarantees (Landis and Koch 1977). Independent gold-standard checks and expert audits assess correctness because annotators can agree on the same systematic error.

Consensus labeling trades cost against quality. Expert review costs more per example than crowdsourced labeling, but forcing agreement on ambiguous examples through majority voting of nonexperts can produce systematically biased labels. By routing only genuinely ambiguous cases to experts, identified through low inter-annotator agreement or failed gold-standard checks, systems balance cost against quality. This tiered approach enables processing millions of examples economically while maintaining quality standards through targeted expert intervention.

Quality control also depends on human factors. Working effectively with annotators requires standardized annotation rubrics with canonical positive and negative examples, visual edge-case catalogs, automated feedback mechanisms benchmarking annotators against known gold-standard records, and calibration sessions where annotators resolve borderline cases. For complex or domain-specific tasks, the system can implement tiered access levels, routing challenging cases to annotators with demonstrated domain expertise. The labeling process itself produces signals worth monitoring: agreement rates, accuracy on gold-standard items, and time per annotation, where answers that come too fast suggest carelessness and answers that take too long suggest unclear guidelines. Tracked over time, the same signals reveal whether label quality is holding.

[12] **Cohen's kappa**: Introduced by Cohen (1960) to measure inter-rater agreement while correcting for agreement expected from the raters' class marginals, which raw percentage agreement ignores. If two independent annotators each label 90 percent of images as "not spam" in a binary task, their expected agreement is 82 percent, making raw agreement potentially misleading. The statistic is denoted κ; interpretive bands such as the Landis-Koch categories are descriptive heuristics rather than universal data-quality thresholds (Landis and Koch 1977).

4.6.4 Label quality drift

Six months into a wake-word collection campaign, new annotators join without the original rubric training and start marking near-homophones as valid wake words, while every audio feature distribution in the ingestion monitors stays flat. This failure is **label quality drift**: a decline over time in the reliability of the labels themselves even when the inputs being labeled have not changed. Feature distribution monitoring cannot catch it, because the features did not move. Crowdsourced labels degrade as annotator pools turn over, training examples go stale, or guidelines change without a matching model update; automated labelers drift as the upstream models that produce

their labels move out of their original operating regime; and implicit-feedback pipelines, such as recommendation systems that treat clicks as labels, shift whenever bots, interface redesigns, or more exploratory user behavior change what a click means.

Catching that drift requires monitoring annotation consistency rather than feature distributions, and the kappa statistic of equation 4.1 supplies the measure. In the wake-word campaign above, tracking κ across rolling windows shows agreement falling from a baseline of $\kappa = 0.85$ (almost perfect agreement) during initial collection to $\kappa = 0.72$ (substantial agreement) six months later. Label-side change is also one of the three silent changes behind the deployed keyword spotter's regression in section 4.12, where a revised guideline was never reconciled with the earlier evaluation standard.

For systems with calibrated model probabilities, predictive entropy provides an additional uncertainty signal. Let $\hat{y}_i$ represent the model's probability assigned to label category i, and let log denote the natural logarithm, so entropy is measured in nats. Equation 4.2 defines this measure:

$$H_{\text{pred}} = -\sum_{i} \hat{y}_i \log \hat{y}_i \tag{4.2}$$

Rising predictive entropy indicates greater uncertainty in the model's predictive distribution, though harder inputs, distribution shift, calibration changes, or inconsistent supervision can all produce the same signal. How a team responds therefore depends on what caused the drop. Retraining annotators fixes systematic mistakes from unclear guidelines at low cost. Multi-annotator consensus voting raises label accuracy in high-stakes domains, though it multiplies the labeling bill. Model-assisted pre-labeling reduces annotator fatigue, provided the assisting model is audited so its own systematic errors do not become the new ground truth. Periodic audits by domain specialists on a random sample of labels uncover the root cause when agreement falls, even though spot checks cover only a fraction of the stream.

4.6.5 Scaling with AI-assisted labeling

Pure human annotation is too slow and expensive for millions of examples, yet fully automated labeling is too unreliable for ambiguous or safety-critical cases. AI-assisted labeling splits the work between the two: a model handles routine inputs or drafts preliminary labels, and human reviewers check the uncertain cases. The decision hierarchy in figure 4.13 maps the main alternatives when hand-labeling everything is too expensive, branching into active learning, semi-supervised learning, weak supervision, and transfer learning. Active learning keeps direct human labels but asks annotators only about the examples that would tell the model the most. Semi-supervised learning combines a small labeled set with structure in a larger unlabeled pool. Weak supervision[13] replaces hand labels on individual examples with programmatic rules written by domain experts. Transfer learning starts from a model trained on a related task so fewer task-specific labels are needed. Each path changes what the pipeline pays for and what it must validate: whether the unlabeled pool matches the task, whether the labeling rules are accurate, or whether the pretrained representation transfers cleanly.

These paths exchange different assumptions rather than simple label counts. Depending on the path, the pipeline relies on task-relevant structure in unlabeled data, a transferable representation, measurable labeling-function accuracy, or an affordable scoring loop. Production systems must record each assumption and validate it against held-out, human-audited data. The diagram functions as a decision map, not an absolute quality ranking.

Humans and models do different work: humans judge ambiguous cases, catch subtle errors, and apply domain knowledge, while models process routine cases at scale, subject to validation. Pre-annotation uses AI models to generate preliminary labels that humans then review and correct, transforming the task from "label from scratch" to "verify and fix." Programmatic labeling frameworks like Snorkel (Ratner et al. 2018; Ratner et al. 2017) extend this further through weak supervision, automatically generating initial labels at scale through rule-based heuristics, knowledge bases, and existing model outputs (for instance, a labeling function might use a regular expression to flag patient notes containing "adverse reaction" as high-risk). For wake-word data, a forced aligner[14] or an existing detector pre-marks where the wake word begins and ends, and reviewers correct a boundary rather than search for one.

[13] **Weak supervision**: A "data programming" paradigm that exchanges some manual annotation labor for the upfront effort of writing and validating programmatic labeling functions. Once written, a function can be applied cheaply at scale, but execution, conflict resolution, quality monitoring, and maintenance still incur cost; the useful comparison is workload-specific rather than literally zero marginal cost.

↪ Semi-supervised and self-supervised learning, which draw training signal from unlabeled data, are developed in section 9.6.

[14] **Forced alignment**: Given a known transcription, an aligner estimates where its words occur in the audio, often using frame-level acoustic scores and sequence decoding. Timing resolution and accuracy depend on the model, features, language, and recording quality, so boundary estimates still need quality checks. The known transcript makes word-level segmentation far cheaper than labeling every clip manually, though computation, review, and error correction remain.

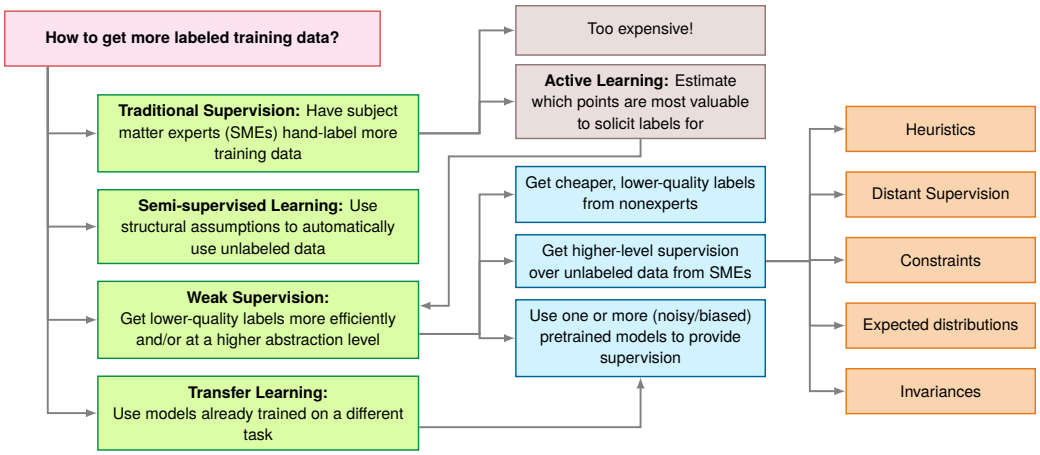

Figure 4.13: AI-Augmented Labeling Decision Hierarchy: A top-level question about obtaining labeled data branches into four paths: traditional supervision, semi-supervised learning, weak supervision, and transfer learning, with active learning as a cost-saving alternative. The branches distinguish where supervision comes from and what additional assumptions or pretrained artifacts the pipeline must validate. Adapted from Ratner et al. (2019).

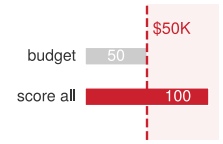
Large language models (LLMs) now assist labeling pipelines by generating descriptions, drafting labeling guidelines from examples, and explaining their reasoning for label assignments. Content moderation systems, for instance, use LLMs for initial content classification with explanations that human reviewers validate. However, LLM integration introduces systems challenges: provider- and model-dependent inference costs and rate limits, as well as the need for systematic output validation because LLMs can produce confident but incorrect labels. Many organizations adopt tiered approaches, using smaller specialized models for routine cases while reserving larger LLMs for complex scenarios requiring nuanced judgment.

Active learning makes the complementary trade-off: it spends model inference to reduce human labeling (Settles 2009; Coleman et al. 2022). Rather than labeling a random sample of the unlabeled pool, it selects the examples where the current model is most uncertain or where a label would most improve the model. In the KWS pipeline, active learning routes the clips the current detector scores nearest its threshold, such as near-homophones and wake words spoken from across a room, to human review, while confidently scored clips receive automated labels that reviewers spot-check. This approach can substantially reduce required annotations in favorable settings, though it requires careful engineering to prevent feedback loops where the model's uncertainty biases which data gets labeled. Whether the trade pays depends on whether the scoring compute fits inside the same budget as the labels.

Napkin Math 4.6: When active learning breaks the budget



Problem: A 10M image pool has a $50K labeling budget. Labels cost $0.50/label in this scenario, above the simple-classification crowd range in table 4.3, as for a task whose labels need careful review. The team scores candidates with a hosted multimodal model priced at $0.01/image; scoring with the small model being trained would cost orders of magnitude less and leave the labels as the binding cost. A random sample of the size the budget buys reaches 85 percent accuracy, and the target is 95 percent. Can active learning reach the target without exceeding the budget?

Physics:

1. **Sample efficiency**: Active learning can achieve target accuracy with fewer samples than random selection in favorable settings.
2. **Cost per point**: Random sampling = $0.50/label. Active learning adds compute cost (~$0.01/image for inference) to find hard examples.

3. **Options**:
    - **Random**: Reaching 95 percent may require 1M labels ($500K). Budget exceeded.
    - **Active labels only**: The system may need ~100K–200K hard examples ($50K–$100K), which reaches or exceeds the budget before any scoring compute.
    - **Full-pool scoring**: Scoring all 10M candidate images adds $100K, so total active-learning cost becomes $150K–$200K. Budget exceeded.

Systems insight: Algorithm choice is a major lever on label count, but compute must be inside the budget model. Spending 10 percent of this budget on inference ($5K) scores only 500K candidate images at the stated inference price and leaves room for about 90K labels. Active learning is viable only if the candidate pool is narrowed before scoring, inference cost drops substantially, or compute is funded separately from labeling. A configuration that fits therefore filters the pool first (by metadata or a cheap heuristic) to about 500K candidates, scores them for $5K, and spends the rest on about 90K of the most uncertain. That plan fits the budget, but it buys fewer labels than the ~100K–200K hard examples estimated above, so it reaches 95 percent only if measurement shows that fewer labels suffice for this task.

Full-pool scoring can exceed the label budget before labeling begins.

Active learning raises the learning value that each label buys, but scoring the pool is itself data movement and compute, and when that cost is charged to the same budget it can cancel the gain. The query strategies that decide which examples to score and send for labeling, and the iterative loop that retrains on each new batch of labels, are developed in section 9.4.2.

The system must monitor both AI and human performance through systematic metrics. Model confidence calibration matters: if the AI reports 95 percent confidence but achieves only 75 percent accuracy at that confidence level, preannotations mislead human reviewers. Human-AI agreement rates reveal whether AI assistance helps or hinders: when humans frequently override AI suggestions, the preannotations may be introducing bias rather than accelerating work. These metrics require careful instrumentation throughout the labeling pipeline, tracking both final labels and the interaction between human annotators and AI at each stage.

Safety-critical domains push the same pattern furthest. Autonomous vehicle labeling infrastructure can process large volumes of sensor frames, using AI preannotation to label common objects while routing unusual scenarios (construction zones, emergency vehicles) to human experts. Medical imaging systems face a parallel label-scarcity problem: large repositories of unlabeled clinical data make expert annotation the bottleneck and motivate data-efficient workflows that learn useful representations from unlabeled structure before expert labels are applied (Krishnan et al. 2022). Across such domains, the common data-engineering pattern is *tiered escalation*: automation handles clear cases, humans handle ambiguous ones, and monitoring ensures the boundary between "clear" and "ambiguous" adapts as both AI capability and deployment conditions evolve.

4.6.6 Automated labeling in KWS

Keyword spotting sits at the automated end of that escalation. Generating millions of labeled wake word samples without proportional human annotation cost requires moving beyond manual and crowdsourced workflows. MSWC, the reference corpus the acquisition strategy started from, shows how automated labeling resolves this throughput bottleneck: it was built by programmatically extracting over 23.4 million examples of one-second speech across 340,000 keywords in 50 languages from continuous speech corpora.

At even 10 seconds per label, manual annotation of that many examples would require approximately 65,000 hours, roughly 32.5 person-years of full-time effort, which makes it impractical. Broad, documented sourcing can improve coverage, but language count alone does not guarantee representative speakers, accents, devices, or acoustic environments. The pipeline staged in figure 4.14 circumvents this manual annotation bottleneck, using forced alignment (McAuliffe et al. 2017) over paired sentence audio and transcriptions to estimate word boundaries before slicing individual one-second keyword windows for classifier training.

At this scale, quality control becomes a sampling and provenance problem rather than disappearing. The pipeline should report coverage by language, speaker, accent, device, and acoustic

environment; retain the source recording, transcript version, aligner version, and boundary confidence for each extracted clip; and route low-confidence alignments and underrepresented slices to human review. Held-out evaluation must then measure the intended wake words across those slices. These controls distinguish a large corpus from a representative one and make extraction errors traceable when a downstream KWS model fails.

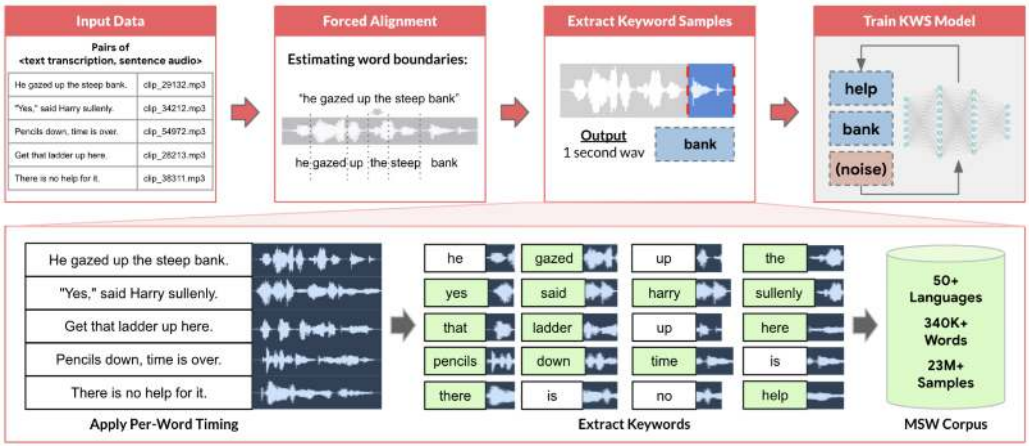


Figure 4.14: Multilingual Data Preparation: Forced alignment and segmentation transform paired audio-text data into labeled one-second segments, creating a large-scale corpus for training keyword spotting models across 50 languages. This automated process enables scalable development of KWS systems by efficiently generating training examples from readily available read-speech resources such as Common Voice. Source: (Mazumder 2021).

The extraction system uses these precise timing markers to generate clean keyword samples while handling anticipated engineering challenges: background noise interfering with word boundaries, speakers stretching or compressing words outside the 500 ms to 800 ms window that this chapter's quality screen accepts, and longer words exceeding the one-second boundary. Automated checks of recording quality, speech clarity, and background noise are what make consistent standards possible at this scale without the manual review expense that would make it prohibitive.

Voice assistant engineering teams often build on this automated labeling foundation. While automated corpora may not contain the specific wake words a product requires, they provide starting points for KWS prototyping, particularly in underserved languages where commercial datasets do not exist. Production systems typically layer targeted human recording and verification for challenging cases (unusual accents, rare words, or difficult acoustic environments), coordinating between automated processing and human expertise. Each clip then carries a label, but the model still cannot read raw audio; the next stage turns labeled recordings into the features the model consumes, and it must compute them the same way in the training cluster and on the device.

4.7 Data Processing

The keyword spotter learns from audio features computed by a library on a training server, and it runs on a device whose feature code is written separately for a microcontroller. If the two compute the same features even slightly differently, the deployed model receives inputs unlike any it learned from, and nothing raises an error. Processing cannot add capability the data lacks, but it can silently remove capability the data has. Processing turns labeled records into the features the model consumes, and consistency governs it: transformations shared between training and serving must keep identical semantics, repeated operations must give the same result when retried, and the work must scale without losing track of what was done. Unlike a code refactoring, which must preserve a program's behavior exactly, filtering or augmenting observations can change the learning problem itself, so each transformation needs an explicit contract stating what it may change and what it must hold fixed.

Training-serving inconsistency is one concrete form of the hidden technical debt that Sculley et al. (2015) identify in production ML systems. In the KWS pipeline, transformations must standardize

recordings across microphones, noise levels, and sampling rates while preserving the acoustic cues that distinguish wake words from ambient speech, and the shared feature extraction must keep the same semantics and fitted state on the server and on the device, with numerical differences held within a validated tolerance.

4.7.1 Training-serving consistency

If a training script standardizes features using the training set's mean and variance while the serving service recomputes those statistics on each incoming batch, both paths run the same code yet feed the model different numbers. Sharing feature code between training and serving is therefore not enough: parameters learned from the training data (normalization constants, encoding dictionaries, vocabulary mappings) must also be stored and reused during serving. This requirement is the **consistency imperative**.

Definition 4.3: Consistency imperative

Consistency imperative requires equivalent transformation behavior and state across training and serving environments.

1. **Significance**: An unvalidated discrepancy between training and serving features can change the model's effective input and degrade prediction quality without a runtime error. Equivalent semantics, shared fitted state, and tested numerical tolerances therefore make preprocessing a stateful component of the model artifact itself.
2. **Distinction**: Unlike data quality, which focuses on the cleanliness of a single record, the consistency imperative focuses on the alignment of the entire transformation pipeline.
3. **Common pitfall**: A frequent misconception is that sharing code makes the two paths consistent. Identical code still diverges when each environment recomputes its own statistics, so consistency is a state synchronization problem.

Violating the imperative produces training-serving skew, in which the training transformation and the serving transformation compute the same raw input differently and the deployed model receives inputs unlike those it learned from. The model still accepts a numerically valid vector computed under different rules, so neither exception tracking nor latency monitoring registers the failure (Sculley et al. 2015; Baylor et al. 2017).

Definition 4.4: Training-serving skew

Training-serving skew is the distributional divergence between the training and inference environments caused by inconsistent logic or state.

1. **Significance**: It violates the consistency imperative and can cause silent accuracy degradation when the training and serving transformations compute different features from the same raw input.
2. **Distinction**: Unlike data drift (which is an external shift in the environment), training-serving skew is an internal failure of the engineering stack.
3. **Common pitfall**: A frequent misconception is that skew is "found" by looking for errors. In reality, it raises no exceptions; the system runs and the latency stays low, but the predictions are statistically wrong.

Pipeline parity tests detect the discrepancy between the two paths; outcome evaluation establishes its effect on predictions. Designing from serving constraints backward allows the team to test equivalent preprocessing on the target device and bound numerical differences before deployment.

Checkpoint 4.2: Defensive processing

Training-serving skew is a common cause of silent production degradation.

- ☐ **Definition**: Can you define training-serving skew in terms of the training and live-request processing paths?
- ☐ **Mechanism**: Can you explain why recomputing normalization means independently in training and serving can make live data look unfamiliar to the model?
- ☐ **Invariant**: Can you explain how shared transformation logic and synchronized feature state reduce skew?

Data cleaning is the first stage where training and serving can diverge. Raw data frequently contains missing values, duplicates, or outliers that degrade model performance. Cleaning operations must be deterministic and reproducible: given the same input, they must produce the same output regardless of environment. This requirement shapes which cleaning techniques are safe to use in production.

Data cleaning encompasses **deduplication**, which merges repeated records so they neither overweight what the model learns nor leak across splits (Lee et al. 2022), along with missing-value handling and normalization. In the KWS corpus, deduplication must catch more than identical files. One speaker's repeated takes of a wake word are near-duplicates, and they must stay within a single split, or evaluation measures memorization of that voice rather than generalization. The matching rule and its threshold must be captured in code that runs the same way every time the dataset is rebuilt.

Outlier handling exposes a sharp operational split between batch training and online serving. During training, the pipeline can drop corrupted records or extreme sensor glitches so that a few bad values do not dominate parameter updates. At serving time, the response contract determines whether an invalid request may be rejected, routed to review, or answered with an abstention or request for another sample. Clamping features to bounded intervals (such as $[\mu - 3\sigma, \mu + 3\sigma]$) is safe only when that transformation has been validated for the task and uses the fitted training parameters. Outlier filters that judge each record relative to others introduce a subtler consistency risk: if evaluated across concurrently batched serving queries, the classification of an individual query depends on what other queries happen to arrive in the same request window, violating request isolation.

The validation monitors in section 4.5.3 also check transformed outputs. A rise in nulls after a join, unexpected duplicate records, or a shifted feature distribution can expose a transformation defect even when the raw inputs passed their checks.[15] Comparing raw and transformed records across the same pipeline version helps localize the fault before changing the model.

Quality validation must enforce identical schemas and validation predicates across training and serving pipelines. While training environments can afford compute-intensive profiling passes over entire datasets, serving paths must execute lightweight assertion checks (such as type validation, range bounding, and required-field existence) within the request's latency budget. Mismatches between training-time validation and serving-time assertions allow corrupted inputs to reach the model undetected.

Transformation techniques convert data from its raw form into a model-ready representation, but the systems risk lies in the parameters those transformations learn. Common transformation tasks include normalization and standardization, which scale numerical features to a common range or distribution. For example, square footage and room count may differ greatly in scale; normalization places them on comparable numerical ranges, though their influence still depends on the model and learned parameters (Bishop 2006). Maintaining training-serving consistency requires that normalization parameters computed on training data be stored and applied identically during serving. Operationally, these parameters must be persisted alongside the model itself and loaded during serving initialization.

Preprocessing parameters fall under the same split-boundary rule as the data itself (section 4.1). If the mean and variance, or a category vocabulary, are fitted on the entire dataset before it is split, statistics of the test examples flow into the transformation the model trains through, and the test score

[15] **Statistical drift detection**: The means, variances, and quantiles tracked in quality monitoring are early-warning signals for the divergence term $\mathcal{D}(P_t \| P_0)$ of the degradation equation (equation 1.1). A mean session length shifting from eight to 12 minutes over six months may indicate drift; a sudden drop to three minutes may indicate a collection fault. Outcome checks and source investigation are needed before choosing retraining or a source-system fix.

↪ The cost of training-serving skew and the shared feature libraries and schema validation tests that enforce training-serving parity are developed in section 14.1.1.3.

no longer measures generalization to unseen data. The pipeline therefore fits every transformation parameter on the training split alone and applies the frozen result to validation, test, and serving inputs.

Beyond numerical scaling, transformations convert discrete inputs through categorical encoding, extract cyclical representations from timestamps, and construct derived spatial features. Categorical encodings must handle both the categories present during training and unseen categories encountered during serving. A reliable pipeline builds the vocabulary index exclusively from the training split, serializes this dictionary with the model artifact, and maps unknown runtime tokens to an explicit out-of-vocabulary (`<UNK>`) index. Omitting this mapping causes runtime dimension mismatches or silent index collisions during online inference.

Domain-specific feature engineering turns raw inputs into representations that expose informative signals directly to the learning algorithm (Kuhn and Johnson 2013). Instead of requiring the model to discover non-linear combinations from scratch, engineered features encode domain structure directly. The audio features the keyword spotter uses, described later, are themselves engineered: they encode what is known about human hearing, so a small model does not have to learn it from data.

Feature engineering can be a high-leverage activity because it changes what signal the model can see. In some workloads, well-designed features improve performance more than another round of algorithm selection or hyperparameter tuning. That leverage must be balanced against the consistency requirements of production systems. Every engineered feature shared by training and serving must have equivalent behavior in both environments. Production systems therefore implement feature engineering logic in shared libraries or coordinated pipelines rather than reimplementing it independently. Many organizations centralize those shared definitions in a feature store, the storage layer that section 4.7.5 defines, to reduce inconsistency across environments.

In the KWS pipeline, audio recordings collected across crowdsourced contributors, synthetic speech generators, and field captures arrive with wide acoustic variation. The raw audio contains the imperfections anticipated during problem formulation: environmental noise spanning quiet bedrooms to noisy kitchens, amplitude clipping from saturated analog-to-digital converters, gain differences across microphone hardware, and inconsistent sampling rates. Standardizing these inputs while preserving the short speech transients that distinguish wake words from ambient noise is essential to reaching the 98 percent detection target. Gain normalization is a specific trap. Normalizing each stored clip against its own peak uses information a streaming device never has, because the device hears continuous audio rather than finished clips, so the training pipeline may apply only gain handling the device can reproduce as audio arrives.

Quality assessment for KWS extends the general principles with audio-specific metrics. Beyond checking for null values or schema conformance, the validation pipeline tracks background noise levels (signal-to-noise ratio above 20 dB), audio clarity scores (frequency spectrum analysis), and speaking rate consistency (wake word duration within 500 ms to 800 ms). The pipeline flags recordings whose noise, duration, clipping, or distortion falls outside the scenario's acceptance rules for review. These thresholds screen the clean baseline slice. Valid noisy or unusually timed speech remains in a separately labeled robustness slice, consistent with the noisy data budgeted in the KWS design. Review distinguishes these coverage examples from corrupted recordings before rejecting a sample. These screens do not prove that a sample is useful, but they reduce the chance that known defects reach model development. Checking audio quality at the source stops defects from spreading along the arcs traced in figure 4.1.

Transforming audio data for KWS involves converting raw waveforms into formats suitable for ML models while maintaining training-serving consistency. Raw audio waveforms (sequences of amplitude values sampled thousands of times per second) are high-dimensional. KWS pipelines often transform them into compact representations that emphasize the frequencies and temporal patterns most relevant to speech. Figure 4.15 aligns three views of an audio sample across a two-second window: the raw amplitude waveform, the corresponding time-frequency spectrogram isolating high-power acoustic energy around 500 Hz, and a compact 13-coefficient MFCC approximation. These standardized feature representations, typically MFCCs or spectrograms,[16] emphasize speech-relevant characteristics while reducing noise and variability across different recording conditions. While a raw short-time Fourier transform (STFT) produces hundreds of linear frequency bins per

[16] **Spectrogram**: The short-time Fourier transform (STFT) computes this 2D representation by converting the one-dimensional waveform into a time-frequency image. This representation lets image-style ML models process audio, but it also creates a rigid dependency: a mismatch in STFT parameters (for example, a 25 ms vs. 30 ms window) changes the feature representation between training and serving and can degrade performance.

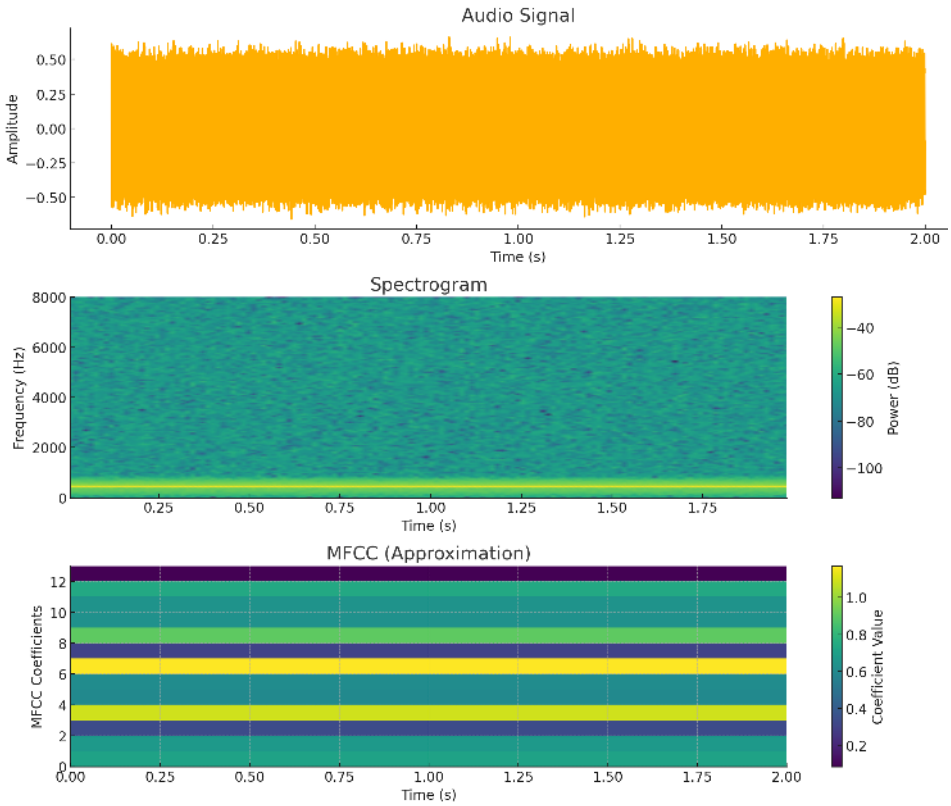

Figure 4.15: Audio Feature Representations: Three illustrative views show an audio waveform, its time-frequency spectrogram, and a compact MFCC approximation. The spectrogram encodes time, frequency, and signal power; the bottom panel arranges a smaller set of coefficients over time.

time window, Mel-frequency analysis aggregates these bins through non-linear triangular filterbanks aligned with human auditory perception, followed by a discrete cosine transform that compresses the signal into just 13–40 decorrelated coefficients. For edge devices, this step collapses data volume by over an order of magnitude, allowing audio feature frames to fit inside the tight tens-of-kilobytes SRAM budgets of embedded coprocessors.

4.7.2 Feature computation placement

Precomputing those MFCC frames once during ingestion lets training iterate at disk speed, but it freezes any random noise or pitch augmentation applied to the raw waveform; computing them on the fly in the data loader keeps every epoch fresh at the cost of repeating the work and risking accelerator stalls. **Feature computation placement** decides which resource pays for a feature: storage pays when features are materialized on disk, while compute and latency pay when features are generated on demand.

When features are precomputed during ETL and stored on disk, training epochs read ready-made tensors without paying the transformation cost on every pass, and every run consumes the exact same values. That speed and reproducibility come at the price of storage footprint and rigidity: derived features must be stored alongside the raw data, and any change to feature logic requires recomputing the entire corpus before the next experiment can run. Computing features on the fly inside the data loader reverses the trade-off. Because only raw data is stored and transformations execute as batches are read, logic changes take effect immediately and random augmentations vary from epoch to epoch, but the host CPU repeats the work on every pass and can stall the accelerator if preparation falls behind.

In practice, production systems combine both approaches. Expensive, slowly changing representations, such as high-dimensional user embeddings (learned vectors that summarize each user) derived from matrix factorization or multi-month historical aggregations, are precomputed offline and materialized in storage. Volatile, lightweight signals, such as session recency, interaction timestamps, or client-side telemetry, are computed dynamically in the data loader. The keyword spotter shows why placement is not a free choice. The clean features of each recording can be computed once and stored, but noise augmentation must be applied to the raw audio before feature extraction, so the features of augmented clips have to be computed in the loader on every pass. This split matches each feature's placement to its rate of change, trading storage capacity against execution latency.

4.7.3 Idempotent transformations

Consistency and placement settle what a transformation produces and where it runs, which serves the quality pillar; the reliability pillar asks whether that transformation can safely run again after a crash. If a processing stage appends transformed records to a target table and a worker fails after writing its output but before acknowledging completion, the automatic retry runs the job a second time and writes duplicate records into the training set. **Idempotency**[17] prevents that corruption by ensuring that applying an operation repeatedly has the same effect as applying it once. This property matters whenever jobs retry after node failures, engineers reprocess historical data to fix a bug, or the same records flow through multiple paths. Determinism is a related but distinct requirement: identical inputs and captured state should produce identical outputs.

[17] **Idempotency**: From Latin *idem* ("the same") + *potens* ("having power"), literally "having the same power when applied again." In ML pipelines, idempotency enables safe retries after partial failures: a non-idempotent operation (for example, appending to a log) creates duplicates on retry. An idempotent operation leaves the same resulting state after one application or repeated applications.

In state-machine terms, an operation f is idempotent if $f(f(s)) = f(s)$. In storage systems, setting a register to an absolute value ($s \leftarrow 1$) is idempotent, whereas incrementing a counter ($s \leftarrow s + 1$) or appending a row to an unkeyed log is not: each re-execution mutates system state. Distributed data pipelines execute across preemptible workers and unreliable networks where timeouts and node crashes trigger automatic retries. Rather than appending blindly, an idempotent pipeline enforces write semantics such as deterministic keyed upserts (insert if absent, overwrite if present) or atomic directory swaps, ensuring that repeated job attempts converge to the identical final dataset.

Managing partial pipeline failures requires clear state boundaries between stages. Decoupling stages with persistent intermediate checkpoints ensures that each phase can be retried independently without re-executing upstream work. For long-running jobs processing terabyte-scale corpora, checkpointing state partitions (such as completed file shards or stream consumer offsets) bounds retry latency: a task failure after five hours of execution requires replaying only the uncommitted shard rather than restarting the entire five-hour job. The checkpoint mechanism must commit output partitions and state markers in a single atomic transaction, preventing records from being dropped or processed twice.

Deterministic transformations are those that always produce the same output for the same input, without dependence on external factors like time, random numbers, or mutable global state. Transformations that depend on current time (for example, computing "days since event" based on current date) break determinism because reprocessing historical data would produce different results. The solution is to capture temporal reference points explicitly: instead of "days since event," compute "days from event to reference date" where reference date is fixed and persisted. Random operations should use seeded random number generators where the seed is derived deterministically from input data, ensuring reproducibility.

Reliability in the KWS pipeline requires reproducible feature extraction. Audio preprocessing must be deterministic: given the same raw audio file, the same MFCC features are always computed regardless of when processing occurs or which server executes it. This enables debugging model behavior (can always recreate exact features for a problematic example), reprocessing data when bugs are fixed (produces consistent results), and distributed processing (different workers produce identical features from the same input). The processing code captures all parameters (fast Fourier transform (FFT) window size, hop length, number of MFCC coefficients) in configuration versioned alongside the code, ensuring reproducibility across time and execution environments.

4.7.4 Distributed processing

Scale becomes the next constraint once quality and reliability are in place. Correct, repeatable transformations still fail the pipeline if they cannot keep pace with data volume or its deadline. As datasets and experiment concurrency grow, data processing can outgrow one machine even when the raw bytes still fit on local storage. The cleaning techniques that work on gigabytes in memory must then become partition-aware, out-of-core, or distributed without changing their semantics.

Single-machine processing suffices for large workloads when engineered carefully. Servers with 256 GB of RAM can process datasets of several terabytes using out-of-core processing that streams data from disk. Libraries that stream data from disk and parallelize across cores extend familiar dataframe interfaces to such workloads. Before investing in distributed processing infrastructure, teams should exhaust single-machine optimization: using efficient data formats (Parquet[18] instead of CSV), minimizing memory allocations, using vectorized operations, and exploiting multi-core parallelism. The operational simplicity of single-machine processing (no network coordination, no partial failures, simple debugging) makes it preferable when performance is adequate.

Within a single machine, parallelizing data ingestion across host CPU workers yields diminishing throughput returns whenever unpartitionable stages, such as sequential decompression or central database lock acquisition, limit concurrency. Amdahl's law caps how much speeding up one part of a pipeline can improve the whole. Applied to host worker count, it means that even when 90 percent of a feature extraction pipeline parallelizes across workers, the speedup cannot exceed $10\times$. The serial stages keep their full duration however many workers share the rest, so eliminating serial I/O and single-threaded stages takes precedence over launching more worker processes.

[18] **Parquet**: A columnar storage format that organizes data by column, not by row. Where a CSV reader must parse every row in full to reach a few columns, a Parquet reader loads only the columns a computation needs. The resulting I/O reduction depends on the selected columns, encoding, compression, and workload.

4.7.4.1 Coordination across machines

This book keeps data processing on one machine, but the boundary is worth knowing. When a corpus or the number of concurrent feature rebuilds outgrows one server, processing spreads across a cluster, and three things change. Data locality becomes a design constraint, because a network link moves bytes far more slowly than a node reads the shard it already holds, so cluster frameworks send the computation to the data instead of the data to the computation. Network transfer becomes the dominant cost of any operation that exchanges records rather than summaries. A global shuffle or a join sends records across every partition, whereas a decomposable reduction such as a mean sends only one partial result per partition. Coordination becomes part of the work, because the machines wait on the slowest worker and must recover when one fails partway through a job, which is when the idempotent, deterministic transformations described earlier become essential rather than merely convenient. Within one machine the network costs disappear and partial failures are rare, so the transformations of this section appear in their simplest form.

Scalability in the KWS pipeline matters at both ends of the lifecycle. Development uses single-machine processing on sample datasets to iterate rapidly. The reference corpus fits on the local storage of one well-provisioned server, so distributed processing pays off mainly when many experiments rebuild features at the same time. Per-file feature extraction is embarrassingly parallel, but end-to-end speedup is bounded by shared storage bandwidth, metadata operations, scheduling, and output contention. Production deployment adds a stricter 16 KB preprocessing-state budget alongside the 256 KB model-size limit, requiring careful footprint optimization so feature extraction fits on the device.

4.7.5 Feature stores

The keyword spotter needs no feature store, because its features are computed on the device from audio alone. A fraud or recommendation model whose features come from user history faces two failure modes at once: during model development, data scientists compute features like `user_purchase_count_30d` with batch SQL queries in a warehouse, whereas during serving an online microservice computes the same metric incrementally from an in-memory cache, and minor differences in timezone arithmetic, missing-value handling, or floating-point rounding cause offline and online features to drift apart. Worse, if the training query joins a historical transaction against the user's current profile rather than the profile as it stood when the transaction happened, future information leaks into the training set. Keeping the two paths consistent means serving historical feature values for training and current feature values for inference from a single shared definition.

↪ Amdahl's law, the ceiling that untouched work places on any speedup, is developed in section 11.1.

Point-in-time correctness and shared feature logic are the primary operational requirements that drive teams to adopt **feature stores**, which Uber's Michelangelo platform popularized to eliminate this class of training-serving skew (Hermann and Del Balso 2017).

Definition 4.5: Feature store

Feature store is the architectural layer that centralizes the management of machine learning features, decoupling feature computation from consumption.

1. **Significance**: It supports point-in-time-correct historical retrieval for training $(x_{t-\Delta})$ and coordinated feature definitions for real-time inference (x_t), reducing training-serving skew when timestamps, backfills, freshness, and synchronization are handled correctly.
2. **Distinction**: Unlike a general-purpose database, a feature store is designed for dual storage modes: an *offline store* (columnar/batch) for training and an *online store* (key-value/low-latency) for serving.
3. **Common pitfall**: A frequent misconception is that a feature store is only "a place to store data." In reality, it manages feature definitions, values, and retrieval; transformation may run in the feature store, an offline store, or a separate batch or stream-compute engine.

Feature stores establish a single source of truth for feature definitions across the ML lifecycle. By registering a feature definition as a unified computation graph, the feature store evaluates the identical transformation across both historical batch data and live inference streams. This shared definition reduces one source of training-serving skew, but equivalent execution still requires synchronized fitted state, correct timestamps, and appropriate freshness. Those conditions must be tested across both retrieval paths. Centralization also enables organizational feature reuse: expensive representations, such as multi-dimensional user embeddings derived from months of interaction logs, are computed once and served to multiple downstream modeling teams.

↪ How feature stores are operated in production, including point-in-time retrieval and training-serving skew prevention at scale, is developed in section 14.3.1.1.

To serve both access patterns, feature stores pair two storage engines. The offline store uses columnar formats (such as Parquet) on high-capacity object storage, tuned for multi-gigabyte sequential scans during batch training. The online store uses low-latency key-value databases (such as Redis), tuned for sub-10-millisecond point lookups during real-time inference. Automated pipelines synchronize the two engines by pushing batch-computed feature snapshots to the online store while streaming ingestion updates both stores continuously as new user events arrive.

Time-travel queries separate a true feature store from a simple cache. Training requires evaluating features as they existed at the exact moment of an event, rather than their current values. In a customer churn model, for example, training on a customer who churned on January 15 must use features computed on January 14, not current post-churn profile state. Feature stores enforce point-in-time correctness using an **as-of join** (temporal join): for every observation at timestamp t_{obs}, the retrieval engine joins the most recent feature record whose update timestamp satisfies $t_{\text{feat}} \leq t_{\text{obs}}$. The join must also exclude information that was not available to the prediction path at t_{obs}, including late-arriving events and later backfills whose event timestamps precede the observation. Timestamp ordering prevents future-information leakage only when retrieval preserves this historical availability across the upstream feature tables.

Every processing choice in this section, from cleaning and scaling to placement, idempotency, and feature retrieval, leaves derived state that downstream training depends on. Whether features are computed in a loader, materialized in storage, or served from a feature store, the team must eventually be able to say exactly which recordings, labels, and transformation versions produced the dataset a model learned from. Recording that answer is the last step of building the dataset.

4.8 Dataset Release

Months after launch, the keyword spotter's detection rate drops on a new hardware revision, and the first question the team must answer is what the shipped model learned from, down to the recordings, the labels and the guideline they followed, the splits, and the feature code. A **dataset release** answers that question in advance. It is an immutable, versioned record of everything that produced a training set: the source records, how they were split and labeled, and the code and

parameters that turned them into features. It is the versioned dataset that Stage 2 of the lifecycle hands to model development, and it turns the pipeline built so far into something that can be reproduced, compared, and audited.

The release is built from what each record carries. Table 4.5 lists the fields of one KWS training clip and the question each field answers later. Two of them do most of the work. The split is assigned by hashing the speaker key, so every clip from a speaker lands in the same split in every release and a later relabeling pass cannot leak a test speaker into training. The label carries the version of the guideline it was made under, so a change in labeling rules can be told apart from a change in the data.

Table 4.5: Anatomy of a KWS Training Record: Each row names a field that one keyword-spotting training clip carries into a dataset release and the later question it answers. Speaker-keyed splits prevent leakage across releases, and rubric versions separate label changes from data changes.

Field	Recorded value	Question it answers later
Recording ID	Content hash of the audio file	Is this clip a duplicate, and what was derived from it?
Speaker key	Pseudonymous speaker identifier	Are all of this speaker's clips in one split?
Consent record	Reference to the terms the clip was collected under	May it be retained, and must it be deleted on request?
Split	Train, validation, or test, from a hash of the speaker key	Is the split stable across releases?
Label and rubric version	Wake word or none, with the labeling guideline version	Did the data change, or only the labeling rules?
Alignment version	Aligner version and word-boundary confidence	Where could a segmentation error have come from?
Feature configuration	Window, hop, coefficient count, and processing code commit	Can the features be recomputed exactly?

Each record's fields capture local provenance, while the release manifest ties the whole collection together. The rest of a release records how those fields were produced and pins the resulting dataset in storage so that any historical build can be recovered verbatim.

4.8.1 Transformation lineage

The last row of table 4.5, the feature configuration, exists because recording the raw audio file and label is not enough if a later change to the MFCC window function leaves the team guessing which window the shipped model trained on. Governance, the fourth pillar, closes that gap by tracking what transformations were applied, when they ran, which version of processing code executed, and what parameters were used. This **transformation lineage** is the processing part of **data lineage**, the recorded trail that links each dataset, feature, and model to the sources, code, and parameters that produced it.[19] Transformation lineage supports reproducibility, debugging, auditability, and iterative improvement when transformation bugs surface. It can supply evidence for documentation or compliance workflows, but lineage alone does not explain a model's decision or establish regulatory compliance.

That trail starts with transformation versioning, which records which version of the processing code produced each dataset. Whenever engineers change the transformation logic to fix a bug, add features, or improve quality, the version number increments, and tagging datasets with that version identifies every table or shard that must be reprocessed after a fix. Because identical source code can still produce slightly different floating-point outputs across different NumPy releases, runtime environment variables, or CPU instruction sets, each dataset also records the Git commit hash of the code that created it alongside a container image that freezes the code, dependencies, and system libraries in one immutable environment.

Code and environment versions still leave out the data-dependent state that transformations learn, so parameter tracking records the fitted values applied during transformation: the mean and standard deviation computed on training data for normalization, the vocabulary (set of all observed categories) for categorical encoding, and any constants or thresholds used in feature engineering

[19] **Data lineage**: When a model produces an erroneous or discriminatory prediction, lineage helps engineers determine whether the contributing problem originated in raw data, feature computation, training, or serving. The resulting trace can support incident investigation and jurisdiction-specific documentation duties, but its usefulness depends on complete instrumentation and retained history; it does not guarantee an explanation of model behavior.

(section 4.7.1). Serializing these parameters alongside the model artifact ensures that serving applies the exact same values as training. Processing lineage then joins code, environment, and fitted parameters into a complete execution history from raw data to final features: which raw files were read, what transformations ran in what order, what parameters were applied, and when the job executed. Lineage systems instrument the pipeline so that each job records these links as it runs, because a history reconstructed after an incident is rarely complete. When model predictions go wrong, engineers can trace back through the lineage graph to find the training data that contributed to the behavior, the quality scores attached to that data, and the transformations applied, then recreate the exact scenario for investigation.

In the KWS pipeline, governance applies to the audio processing parameters that affect model behavior. The reference volume level used for normalization is persisted, and the FFT and MFCC settings versioned with the processing code (section 4.7.3) are joined by the window function (such as Hamming or Hann), the frequency range, and the mel filterbank parameters. Recording them makes it possible to reproduce training data exactly when debugging model failures, to validate that serving uses preprocessing identical to training, and to study how preprocessing choices affect accuracy. Without this record, teams fall back on manual documentation that becomes outdated, which allows subtle training-serving skew.

4.8.2 Data versioning for ML reproducibility

Lineage records how a dataset was built, but reproducing or comparing two runs also requires recovering the exact bytes of each release. Without an immutable snapshot of the training inputs, diagnosing why a retrained keyword spotter lost accuracy takes days of guesswork across new recordings, changed labels, and upstream batches. With data versioning, engineers compare the two training snapshots directly and find the cause at once: the labeling guideline version in table 4.5 changed between the two releases, so the same clips now carry different labels.

File-level versioning engines like DVC (Data Version Control) provide this link by pairing Git with content-addressed remote storage (Iterative 2024). Git tracks small text pointer files (`.dvc`) containing cryptographic hashes, while DVC synchronizes the underlying binary dataset to object storage (listing 4.2). Checking out an earlier Git commit restores the historical pointers; the paired DVC retrieval step shown in the listing restores the dataset contents matched to that code state.

Listing 4.2: DVC Workflow: DVC brings Git-like semantics to data versioning. DVC tracks large data files alongside code commits, enabling exact reproduction of any historical training dataset through paired `git checkout` and `dvc checkout` commands.

```
# Add data to version control
dvc add data/training.csv
git add data/training.csv.dvc
git commit -m "Add training data v1"
dvc push  # Upload to remote storage

# Later: retrieve exact data for any historical commit
git checkout abc123
dvc checkout  # Restores exact data from that commit
```

While file-level versioning suits bulk artifacts like images and audio, tabular datasets require versioning over tables that change row by row. Open table formats such as Delta Lake solve this by keeping an append-only transaction log of all row insertions, deletions, and schema changes (Armbrust et al. 2020). This log supports time-travel queries that pin a dataset state by timestamp or version ID (listing 4.3).

Listing 4.3: Delta Lake Time Travel: SQL queries identify a historical table state by timestamp or transaction-log version.

```
-- Query data as it existed on a specific date
SELECT * FROM training_data TIMESTAMP AS OF '2024-01-15'

-- Or by version number for programmatic access
SELECT * FROM training_data VERSION AS OF 47
```

Two production components work with these versioning engines to complete end-to-end reproducibility. First, feature store point-in-time retrieval evaluates features as they existed at the observation timestamp, preventing the leakage from future observations described in section 4.1. Second, a model registry records the lineage manifest for each deployed model: Git commit SHA, data version ID, training configuration, and evaluation metrics. In the keyword spotter's regression, this audit trail turns an open-ended debugging investigation into an immediate snapshot comparison.

Long-term retention balances auditability against storage cost and privacy rules. High-volume production pipelines use tiered retention: hot SSD tiers for active training and debugging, warm object storage for periodic evaluation snapshots, and cold archive storage for compliance records. Because keeping petabyte-scale data forever is too expensive and often violates privacy statutes, data lifecycle policies must set explicit retention windows and deletion schedules. A release fixes what the dataset is, yet it says nothing about how fast that dataset can reach the accelerator during training, which is the second bound from the opening of this chapter and the one the remaining stages of the pipeline must meet.

↪ How the model registry promotes, holds, or rolls back the exact artifact that was evaluated is developed in section 14.3.1.2.

4.9 Physics of Data

The throughput bound lives in the Data–Machine overlap, and it is physical. Moving a petabyte of training data across cloud regions incurs tens of thousands of dollars in egress fees and hours of network serialization delays. Source code is small enough to move freely, so the data-as-code principle explains what data does without explaining why moving it costs so much. The physics of data supplies that explanation by giving data measurable properties. **Data gravity** (McCrory 2010) is the bandwidth, I/O, and latency cost of moving a large byte volume, and **task-relevant signal** is the learning value those bytes carry for the task. A third property, flow rate, decides whether those bytes reach the accelerator as fast as it consumes them, and the ResNet-50 scenario measures it.

Engineering effort pays off most when early filtering and selection separate high-signal records from the rest before data gravity makes them expensive to move. Low-signal data (repetitive audio frames or duplicate samples) consumes host-to-accelerator bandwidth and memory capacity while teaching the model little. An efficient pipeline resolves this physical bottleneck by maximizing the task-relevant signal delivered per byte moved across the storage and interconnect hierarchy, an optimization that begins with the physical properties of the data itself.

Returns peak where task signal is high and movement cost (gravity) is low.

4.9.1 Data gravity

Data movement costs time and money, the cost that the data-gravity principle (2) names. Data gravity scales directly with data volume (D_{vol}) and inversely with network bandwidth (BW). Transferring a petabyte dataset across a 10 Gbps link requires days of continuous transmission ($T = D_{\text{vol}}/\text{BW} \approx 9.3$ days); even across a dedicated 100 Gbps link, transfer latency and egress tariffs remain substantial enough to govern system design. Because migrating 1 PB across network boundaries is both slow and expensive, system designers colocate compute with the storage substrate rather than moving large datasets across remote networks. This physical constraint underlies lakehouse storage architectures[20] (Zaharia et al. 2021), where query and preprocessing engines execute directly against shared object storage rather than repeatedly copying raw data across network fabrics.

[20] **Data lakehouse**: Combines data lake storage (cheap, schema-less) with warehouse query semantics (atomic, consistent, isolated, and durable (ACID) transactions, schema enforcement) using transactional table layers such as Delta Lake. For ML workloads, the lakehouse reduces the ETL copy between lake and warehouse, enabling direct feature computation on the storage layer where data already resides. This is a direct response to data gravity, since repeated petabyte-scale copies increase the D_{vol}/BW cost (Armbrust et al. 2020; Zaharia et al. 2021).

↩ The data-gravity principle, which weighs shipping a dataset against shipping the computation to it, is established in section 2.5.1.

Napkin Math 4.7: The physics of data gravity

Problem: A 1 PB training dataset resides in a US East data center, while a remote accelerator pod is available in US West. What transfer time and egress cost does remote training add, and when would suitable compute near the data avoid that overhead?

Math:

1. **Network bandwidth**: 100 Gb/s $\div 8 = 12.5$ GB/s.
2. **Transfer time**: 1,000,000 GB $\div$ 12.5 GB/s = 80,000 seconds, approximately 22 h.
3. **Cost**: 1,000,000 GB $\times$ \$0.02/GB = \$20,000. (Baseline: AWS data transfer out pricing, 2024.)

Systems insight: If training takes less than 22 h, data transfer takes longer than training. If training costs less than \$20,000 (approximately 5,000 TPUv4-hours), bandwidth costs more than compute. When suitable compute is available near the data, these transfer costs favor moving code to data. Smaller datasets make moving data to code more practical, but placement still depends on compute availability and comparative training time.

4.9.2 Task-relevant signal

A dataset containing one million identical images carries heavy data gravity yet adds no new observations beyond the first sample; repeated passes over that single image can nudge model weights slightly, but they supply no fresh evidence. Conversely, a curated collection of 10,000 diverse edge cases is small enough to move cheaply yet contributes rich supervisory signal. Physical storage measures raw bytes, whereas machine learning extracts **task-relevant signal**: evidence that helps the model learn the target task rather than raw Shannon entropy. Comparing task-relevant signal with data gravity motivates a selection heuristic:

$$\text{Data Selection Gain} \propto \frac{\text{Task-Relevant Signal}}{\text{Data Gravity}} \tag{4.3}$$

The numerator is not a universal physical quantity. A team estimates marginal learning value by comparing held-out model quality under a fixed training procedure; the denominator accounts for the movement cost of the compared datasets. The heuristic favors a selection only when its measured learning benefit justifies that cost. Scoring, labeling, and training costs must also enter a complete budget. Deduplication and the active learning of section 4.6.5 can improve this ratio by eliminating redundant byte volume and proposing uncertain examples for labeling. Uncertainty does not establish learning value; ambiguous or corrupted examples can also be uncertain, so the selection policy requires validation.

↪ The information-compute ratio, which measures the learning signal each sample returns per unit of training compute, is developed in section 9.2.1.

4.9.3 The feeding problem

Data gravity dictates the cost of moving data in bulk; **the feeding problem** dictates the cost of delivering it to execution units in real time. It is an input/output **flow rate** bottleneck: storage bandwidth fails to keep pace with compute throughput. The bottleneck is measured, not hypothetical. Profiling nine widely used vision and audio models found their training time often dominated by data stalls, time spent waiting for data to be fetched and preprocessed (Mohan et al. 2021), and in production recommendation training the data storage and ingestion pipeline has become a dominant constraint on training performance and capacity (Zhao et al. 2022).

When data delivery and computation overlap, the bottleneck principle holds that a system runs only as fast as its slowest stage. Consider the chapter's throughput workload, one A100-class accelerator training ResNet-50 on images. The accelerator's peak arithmetic rate is 312 TFLOP/s, and one training step on one image costs about 24.6 GFLOP, roughly three times the cost of a single prediction because training must also work out how to adjust every parameter. Dividing the first by the second gives an arithmetic ceiling of about 12,682 img/s. In practice a well-tuned pipeline sustains about 3,200 img/s, roughly 25 percent of that ceiling, once layers that wait on memory and the synchronization between steps take their share. Each image sits on disk as a 150 KB JPEG, so storage must deliver 480 MB/s. When the attached volume supplies only 250 MB/s, compute

units stall on I/O. This gap defines **the feeding loss**, the throughput penalty from insufficient input supply, which directly degrades system efficiency (η_{hw}). Under steady-state overlap, divide the supplied 250 MB/s by the required 480 MB/s to obtain the fraction of the sustained training rate that storage can support. Subtracting that fraction from one gives a modeled feeding loss of about 48 percent. This is the throughput loss relative to the supplied sustained baseline, not a measurement of all accelerator idle time or utilization relative to advertised peak.

Which bytes are counted matters as much as how many. After decoding and conversion to an FP32 tensor, the same image occupies 602 KB, about 4 times its compressed size, so a loader that converts on the host moves 1.9 GB/s through host memory and across the host-to-accelerator link. Many loaders ship 8-bit pixels instead and convert on the accelerator to avoid that cost. Compression thus trades storage bandwidth for CPU decode work. A pipeline that caches pre-decoded tensors on disk to skip that work pays the full 1.9 GB/s at the storage tier instead, and it freezes the random crops that augmentation would otherwise vary from epoch to epoch. Applying the same supply-to-demand calculation gives a modeled throughput loss of 87 percent relative to the sustained baseline. Storage and delivery apply this slowest-stage bound to the storage tiers (section 4.10.3) and then to the CPU decode workers (section 4.10.4) without re-deriving it. Distance also increases energy consumption: as data travels farther from arithmetic logic units, transport energy dwarfs the cost of computation itself.

↩ The bottleneck principle is established in section 2.3.1.

Systems Perspective 4.2: The energy cost of data movement

The memory-wall analysis in section 2.2 implies a data-engineering principle: *moving one 32-bit value costs roughly 173× to 10,811× as much energy as the table's FP32 multiply*, with the multiplier rising as the data leaves the chip. The DRAM ratio is smaller than the one in section 1.7 only because that comparison set one byte against a cheaper FP16 multiply. Later optimization chapters exploit the same cost gradient inside model and hardware design; here, the question is how much energy the information flow from the external world already consumes before the model computes, at each level of the memory hierarchy (table 4.6).

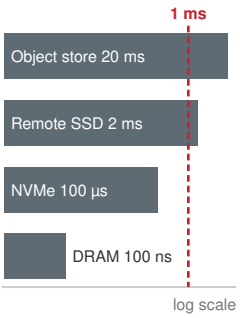
Table 4.6: Energy Cost of Moving vs. Computing on a 32-Bit Value: Each row gives the approximate energy per event at one stage of the data-movement hierarchy, with multipliers normalized to one 32-bit FP32 multiply. All rows use the same 32-bit width, so the ratios compare like-sized events. They do not by themselves prove which term dominates a complete workload; total energy also depends on the number of arithmetic operations and transfers. Arithmetic and DRAM rows follow Horowitz (2014).

Operation	Energy (pJ)	Relative Cost
32-bit FP Multiply	3.7 pJ/FLOP	1×
DRAM Memory Access (32-bit)	640 pJ	173×
Local SSD Access (32-bit)	4,000 pJ	1,081×
Network Transfer (32-bit)	40,000 pJ	10,811×

That gradient is why data locality dominates systems optimization. Each avoided transfer eliminates its corresponding movement energy, compounding across training epochs.

Because data movement incurs physical energy costs, data volume acts like physical mass. Removing 50 percent of training data through deduplication saves more than persistent storage capacity. It also eliminates energy expenditure across network, memory, and preprocessing stages. Filtering uninformative samples early is among the most effective architectural levers when I/O and communication dominate workload runtime.

Checkpoint 4.3: The physics of data



Data engineering is governed by physical costs. Check your intuition:

- ☐ **Data gravity**: Why does a petabyte-scale dataset pull compute toward the data, and which assumption in the petabyte example (link speed, egress price, training duration) would have to change to reverse that conclusion?
- ☐ **Energy cost of data movement**: Why does fetching a 32-bit value from DRAM, an SSD, or the network cost more energy than one 32-bit multiply, and what else (how many operations, how many transfers) must you know before saying which dominates a workload's total energy?
- ☐ **Task-relevant signal**: Why can a smaller, diverse dataset be more valuable than a massive, redundant one?

The energy hierarchy and the signal-density heuristic converge on the same optimization lever, the Data Selection Gain of equation 4.3, because every redundant or uninformative record removed early saves movement energy and interconnect bandwidth at each later stage without costing task-relevant signal. For the released dataset, these costs come due in delivery. Every training epoch moves it from storage, through the host, to the accelerator, and the feeding problem decides whether that movement keeps pace.

4.10 Storage and Delivery

Delivery is where the throughput bound is met or missed. On baseline cloud block storage, the ResNet-50 scenario of section 4.9.3 already loses about 48 percent of its sustained training rate. Following that scenario to its end means choosing a storage tier that can sustain the accelerator's rate, keeping the host processor between storage and accelerator from becoming the next bottleneck, and cutting the bytes each sample costs to move. The KWS data poses the same questions at smaller scale, for the multilingual reference corpus (23.4 million samples spanning 50 languages) and for the much smaller product-specific subset.

A sub-millisecond point lookup fits only in DRAM or local NVMe.

4.10.1 Storage system options

The ResNet-50 job reads its images in long sequential scans, while a serving system fetches one feature vector per request. These opposing access patterns pull storage in two directions, and selecting a system means minimizing the data term $\left(\frac{D_{\text{vol}}}{\text{BW}}\right)$ of the iron law of ML systems for whichever pattern dominates. Every storage medium imposes physical constraints on bandwidth that determine the maximum speed of the training and serving pipelines.

Two storage performance metrics govern this optimization. **IOPS (input/output operations per second)** counts the distinct read or write requests a device can handle per second, bounding *random access* workloads such as fetching small batches of images or individual user profiles. **Throughput (bandwidth)** measures the volume of data transferred per second, typically IOPS $\times$ Block Size, bounding *sequential access* workloads such as scanning a Parquet file for training.

Three architectures cover these patterns, and the ResNet-50 scan and the feature-serving lookup sit at opposite ends of the range. Conventional databases (online transaction processing (OLTP)) optimize for high IOPS with small, row-oriented blocks, strict ACID guarantees, and sub-millisecond point lookups. That profile fits online feature serving, such as a recommendation system fetching one user profile or an anti-fraud service querying historical transaction counts, but it wastes bandwidth on a training scan, because the storage engine fetches entire rows even when the model consumes only 20 of 100 features. Data warehouses (online analytical processing (OLAP)) organize tables by column rather than by row (Stonebraker et al. 2018), so a sequential scan reads only the required features, transferring one fifth of the uncompressed row payload when selecting 20 out of 100 columns. The format-efficiency calculation in section 4.10.5 quantifies this gain with a worked fraud-detection scenario. Warehouses suit feature engineering, batch aggregation, and tabular training, but they require structured schemas, handle raw audio, imagery, and free-form text poorly, and make schema changes during experimentation costly `ALTER TABLE` operations across billion-row

tables. Data lakes store structured, semi-structured, and unstructured data in native formats on high-capacity object storage and defer structure to query time, an architectural pattern known as schema-on-read.[21] A ResNet-50 job can read raw JPEG files from a lake at sequential rates, while independent jobs impose their own schemas without coordinating migrations. The cost is that governance shifts from ingestion to retrieval. Without a metadata catalog recording lineage, update cadence, schema versions, and access policies, a lake degrades into a "data swamp," a set of orphaned directories such as `userdata_v2_final` and `userdata_v2_ACTUALLY_FINAL` whose lineage and quality are unrecorded. Each storage architecture therefore optimizes for a distinct access pattern and lifecycle phase, as table 4.7 summarizes.

21 **Schema-on-read**: Applies data structure definitions at query time rather than during ingestion, contrasting with schema-on-write (traditional databases) where data must conform to a predefined structure before storage. For ML pipelines in early development, schema-on-read enables rapid experimentation, because teams can store raw sensor data, images, and logs without committing to a feature schema upfront.

Table 4.7: Storage System Characteristics: Each storage architecture favors a different access pattern and ML workflow stage. Databases support the high-IOPS random access needed for real-time feature serving; data warehouses provide sequential throughput for batch training and feature engineering; and data lakes provide schema flexibility and cost efficiency for large-scale raw data retention. A poor match between system and workload can impose substantial performance penalties.

Attribute	Conventional Database	Data Warehouse	Data Lake
Purpose	Operational and transactional	Analytical and reporting	Storage for raw and diverse data for future processing
Data type	Structured	Structured	Structured, semi-structured, and unstructured
Scale	Small to medium volumes	Medium to large volumes	Large volumes of diverse data
Performance Optimization	Optimized for transactional queries (OLTP)	Optimized for analytical queries (OLAP)	Optimized for scalable storage and retrieval

Each lifecycle stage also reads the same data in its own way: exploratory analysis samples it at random, training streams it sequentially at high throughput, and production serving issues low-latency point lookups. During initial development, iteration velocity and schema flexibility dominate raw throughput. The primary systems challenge is managing experiment revisions without exploding storage capacity: ten exploratory runs on a 100 GB dataset naively generate 1 TB of redundant copies. The metadata-pointer approach of section 4.8.2 avoids this by decoupling version tracking from file storage. Governance policies reinforce this tiering by granting broad access to anonymized development datasets while gating sensitive production data behind encrypted, auditable access tiers.

During training, the access profile shifts toward sustained sequential throughput. Modern deep neural networks process massive datasets across dozens or hundreds of epochs, making storage bandwidth the determinant of hardware utilization. Scaling the chapter's ResNet-50 scenario to eight accelerators, each sustaining its per-device rate, gives 25,600 img/s and a sustained storage demand of 3.8 GB/s of 150 KB compressed images; staging decoded FP32 tensors instead would raise it to 15.4 GB/s. Storage tiers unable to sustain this rate idle the accelerators, inflating cluster operating costs. End-to-end ResNet-50 training cannot shrink that demand by precomputing features, because its features change at every step. A model trained on the outputs of a frozen upstream encoder (a pretrained model whose outputs are reused as input features) can, and there the feature placement trade-off (section 4.7.2) becomes critical. Precomputing those representations delivers a 30× storage reduction (150 KB raw inputs reduced to 5 KB embedding vectors) but introduces staleness when the encoder updates.

Production inference reverses the optimization target from sequential bandwidth to low-latency random access. A recommendation service handling 10,000 req/s with a 10 ms SLA and 10 feature reads/request demands 100,000 IOPS. Local Non-Volatile Memory Express (NVMe)[22] storage can sustain this random-access rate within the latency budget; in-memory key-value stores such as Redis, distributed caches, and purpose-built feature stores buy headroom for tail latency. Edge deployment imposes further physical boundaries: constrained flash storage, intermittent network connectivity, and non-disruptive model updates dictate tiered caching, where core models reside in local flash while reference data synchronizes asynchronously with cloud endpoints. In production, serving infrastructure must support atomic rollbacks and parallel A/B testing, operational guarantees that depend on tracing every deployed model back to the exact dataset release from which it was trained. Production ML architectures therefore rarely select a single storage technology; mature systems

22 **NVMe (Non-Volatile Memory Express)**: A storage protocol connecting directly to the PCIe bus with 64K command queues, delivering 5–7 GB/s sequential throughput and microsecond-scale latency. The contrast with SATA SSD (500 MB/s, single queue) is a 10× bandwidth gap that can bottleneck a training pipeline when storage service time exceeds compute time.

combine all three, with databases serving point lookups, warehouses running feature extraction, and lakes holding raw captures and intermediate checkpoints.

4.10.2 Storage tiers and cost

Beneath each of these systems sits a physical storage medium, and media span roughly two orders of magnitude in cost and nearly four in bandwidth. Mismatching the storage tier to the access pattern either inflates infrastructure costs with underutilized capacity or starves training accelerators during I/O stalls.

That spread survived a long collapse in absolute price. Figure 4.16 traces the lowest recorded price per terabyte of each medium in constant 2020 dollars. Hard disk storage fell from about $88B per terabyte in 1956 to $10.6 in 2023, roughly 10 orders of magnitude, yet in 2023 DRAM still cost 42× as much as solid-state storage per terabyte, and solid-state storage cost 2.4× as much as hard disk. Capacity became cheap, but since the 1980s the gaps between tiers have not closed, so the choice of tier, rather than raw capacity, sets the cost of keeping a training job fed.

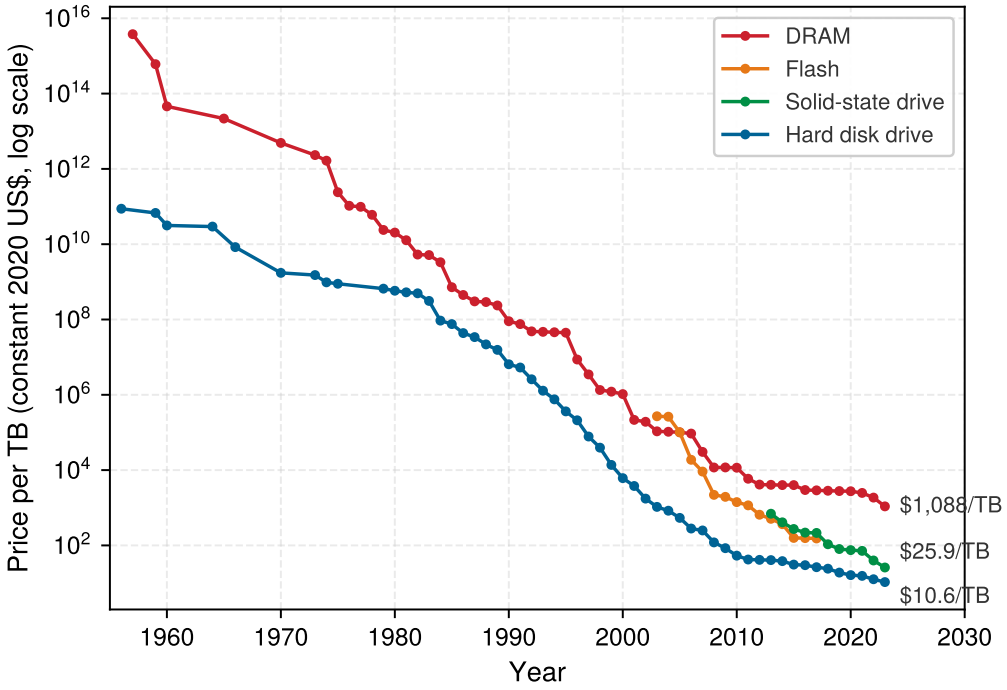


Figure 4.16: Price per Terabyte by Storage Tier, 1956 to 2023: Lowest recorded price per terabyte of DRAM, flash, solid-state drives, and hard disk drives in constant 2020 U.S. dollars on a logarithmic axis. Prices fell by about ten orders of magnitude; since the 1980s, DRAM has stayed roughly two orders of magnitude above disk. Data from Our World in Data (2024), based on McCallum's price records.

ML systems use tiered storage because no single tier is both cheap and fast (table 4.8). Under these 2024 assumptions, storing the KWS reference corpus (748.8 GB) in object storage costs $17.2/month, enabling affordable raw-audio retention, while working datasets on NVMe cost $74.9/month–$224.6/month for active training but load 50× faster.

↪ Why no single medium offers both large capacity and low access latency, the reason storage is built in tiers, is collected for reference in section D.3.1.

Table 4.8: Illustrative Storage Cost-Performance Trade-Offs (2024): These planning ranges vary by provider, region, configuration, and workload. Training data loading requires high-throughput sequential access. Online serving needs low-latency random reads, while archival storage prioritizes cost over access speed for compliance and historical data.

Storage Tier	Cost ($/TB/month)	Sequential Read Throughput	Random Read Latency	Typical ML Use Case
NVMe SSD (local)	$100–300	5–7 GB/s	10–100 µs	Training data loading, active feature serving
Object Storage (S3, GCS)	$20–25	100–500 MB/s (per connection)	10–50 ms	Data lake raw storage, model artifacts
Data Warehouse (BigQuery, Redshift)	$20–40	1–5 GB/s (columnar scan)	100–500 ms (query startup)	Training data queries, feature engineering
In-Memory Cache (Redis, Memcached)	$500–1000	20–50 GB/s	1–10 µs	Online feature serving, real-time inference
Archival Storage (Glacier, Nearline)	$1–4	10–50 MB/s (after retrieval)	Hours (retrieval)	Historical retention, compliance archives

This throughput divergence changes the input-loading component of engineering iteration time. Training that loads data at 5 GB/s completes dataset loading in 149.8 s, compared to 7,488 s at typical object storage speeds. The 50× loading speedup translates into shorter experiments only to the extent that exposed loading time contributes to their duration; transformation and model execution still consume time.

Beyond input datasets, storage must hold what training produces: model parameters, the extra values training keeps for each parameter (its optimizer state), and periodic checkpoints of both. Modern neural networks contain millions to hundreds of billions of parameters, imposing storage and retrieval patterns distinct from tabular data. GPT-3 (Brown et al. 2020) requires approximately 700 GB for model weights when stored in FP32 format (175B parameters times 4 bytes), though practical deployments often use smaller numeric formats such as FP16 (350 GB) to halve memory pressure. Model weights require block-aligned storage formats to support parallel reads across parameter groups during initialization and checkpointing, demanding aggregate storage bandwidth approaching network fabric limits (25 to 100 Gbps) to keep compute units active.

↪ Quantization, which shrinks these weight footprints by storing parameters at lower precision, is developed in section 10.3.

Tracking these artifacts introduces versioning challenges. Git's incremental text diffs fail on multi-gigabyte binaries, where a single weight update produces an entirely new file and ten historical checkpoints of a 10 GB model occupy 100 GB. Production workflows therefore keep lightweight content hashes in Git and the binaries in content-addressed object storage, the same decoupling that section 4.8.2 applies to datasets.

Multi-accelerator training compounds storage pressure through concurrent I/O. When a training job spans multiple accelerators, every rank reads training batches concurrently, and the job periodically writes checkpoints of model and optimizer state, often from a single rank, in bursts that compete with those reads. Storage must absorb reads that scale with the worker count and checkpoint bursts on top of them, preventing I/O serialization that leaves expensive accelerators idle.

↪ The data- and model-parallel strategies that coordinate these workers within one node are developed in section 8.7.1.

4.10.3 The storage bandwidth budget

Each storage tier sets its own ceiling on the feeding problem of section 4.9.3. Host RAM delivers 50 to 200 GB/s on modern server nodes, local NVMe SSDs deliver 5–7 GB/s, and network-attached storage provides 1 to 10 GB/s. Whichever tier serves the training reads caps the data supply rate, so the design question is which tier can sustain the chapter's ResNet-50 scenario, and at which of its two rates.

Napkin Math 4.8: Storage bandwidth budget

Problem: What storage configuration keeps an A100-class accelerator from being data-starved while training ResNet-50? Section 11.6 explains why delivered throughput falls short of an accelerator's advertised peak; here, the point is how a compute ceiling becomes a data-path budget.

Start with the compute ceiling derived in section 4.9.3. The A100's 312 TFLOP/s divided by about 24.6 GFLOP per training image gives 12,682 img/s.

That compute ceiling becomes a storage requirement once each image must arrive from disk or object storage. Storage reads compressed bytes, so the budget uses the 150 KB JPEG rather than the decoded tensor: feeding the ceiling takes approximately 1.9 GB/s, while the 3,200 img/s that the accelerator actually sustains takes 480 MB/s.

Three storage options can now be compared against these two targets:

- S3 Standard delivers about 100 MB/s per connection when it streams large objects such as sharded archives, so feeding the ceiling needs 19 concurrent worker threads before software overhead. Fetching each 150 KB image as its own object is latency-bound and delivers far less.
- SATA SSDs deliver about 500 MB/s sequentially, enough for the sustained rate but a bottleneck at the ceiling.
- NVMe SSDs deliver approximately 5–7 GB/s, which covers the ceiling with headroom.

Systems insight: A SATA SSD caps the pipeline at 500 MB/s divided across 150 KB images, or approximately 3,333 img/s. That clears the sustained 3,200 img/s, so a faster drive buys nothing at today's rate. Once faster kernels or a faster accelerator push the rate toward the ceiling, the same drive holds an A100-class accelerator to 26 percent of it. Each fix to the slowest stage exposes the next, so the storage tier must be sized for the rate the pipeline is heading toward, not the rate it runs at today.

Designing for high-throughput training therefore starts by matching storage throughput to accelerator demand, the storage-tier form of the slowest-stage bound that section 4.9.3 measured as lost training rate. The 500 MB/s figure represents effective SATA III sequential read throughput (the interface ceiling is 550 MB/s), and real-world random read performance with small files can be significantly lower. That caveat reinforces the general principle governing data pipelines: equation 4.4 bounds training throughput by compute capacity and the data supply rate defined in equation 4.5. Let R_{train}, R_{compute}, and R_{data} denote rates in samples per second; let $\text{BW}_{\text{storage}}$ be storage bandwidth in bytes per second, f_{overhead} the dimensionless fraction lost to overhead, and s_{sample} the bytes per sample. Under full overlap, the min-of-rates form corresponds to the $T_{\text{step}} = \max(T_{\text{compute}}, T_{\text{IO}})$ lower bound of section 4.9.3, which the dataloader section applies to host workers; with incomplete overlap, actual step time is higher.

$$R_{\text{train}} \leq \min(R_{\text{compute}}, R_{\text{data}}) \tag{4.4}$$

$$R_{\text{data}} = \frac{\text{BW}_{\text{storage}}(1 - f_{\text{overhead}})}{s_{\text{sample}}} \tag{4.5}$$

Once R_{data} is the smaller rate, additional accelerator compute cannot raise training throughput; the remedy must increase usable storage bandwidth or reduce bytes per sample. The budget assumes every epoch reads from storage. A dataset that fits in host memory, as an ImageNet-sized dataset does on many eight-accelerator servers, is read from storage once and then served from the operating system's page cache, so storage binds only on the first epoch. The budget governs the cases that remain: datasets larger than memory, nodes whose memory several jobs share, and data streamed from remote storage.

When storage bandwidth becomes the limiting factor, teams must either improve storage performance through faster media, parallelization, or caching, or reduce the amount of data that must move. Large language model training may require processing hundreds of gigabytes of text per hour, while computer vision models processing high-resolution imagery can demand sustained data rates exceeding 50 gigabytes per second across distributed clusters. Prefetching hides the time to fetch the next batch behind the computation on the current one, but only when the loader sustains the required supply rate; it cannot create bandwidth that storage lacks.

4.10.4 The dataloader

Between storage and the accelerator sits the host processor, which reads each stored example, decodes it, augments it, and stages it for transfer. The barrier at this stage is the **input/output (I/O) bottleneck**: the accelerator idles whenever the host cannot stage examples as fast as the accelerator consumes them. The slowest-stage bound of section 4.9.3 applies unchanged: in an idealized two-stage model, step time ranges from $\max(T_{\text{compute}}, T_{\text{IO}})$ with full overlap to $T_{\text{compute}} + T_{\text{IO}}$ with no overlap. What changes is the binding resource: while the initial feeding scenario was starved by baseline storage bandwidth, data loading on provisioned storage is more commonly starved by CPU-side decompression and decode (Mohan et al. 2021).

In computer vision, JPEG decode and augmentation on host CPUs represent the typical binding stage; in keyword spotting, MFCC extraction and audio augmentation load the same host threads. This host-side preparation executes within the framework's data loader (such as PyTorch's `DataLoader`), which decodes and transforms raw records across parallel worker processes before staging batches for device transfer. Input-pipeline frameworks such as tf.data treat this stage as a system in its own right, with operators for parallel transformation, prefetching, and caching (Murray et al. 2021). To isolate CPU worker scaling, assume storage and bus transfers are provisioned to satisfy the 480 MB/s compressed input requirement, which a SATA solid-state drive does (section 4.10.3). When storage and interconnect are nonbinding, the training pipeline depends entirely on whether CPU workers can match the accelerator's sustained rate of 3,200 img/s. If each worker process transforms 375 img/s, 9 workers are required to reach the capacity crossing. Below this threshold the CPU input pipeline binds, and adding accelerators yields no speedup, which surprises teams that expect compute investments to scale linearly. Above the crossing, launching additional workers produces no gain because the accelerator binds. The worker count represents a capacity match rather than a hardware constant: actual ResNet-50 requirements on a given accelerator shift with image transformations, host processor architecture, batch size, and runtime configuration. Figure 4.17 plots this capacity crossing, where the starved regime gives way to a compute-saturated plateau.

At eight accelerators the worker count grows eightfold, more decode cores than many hosts can spare. Relieving the choke point takes three mechanisms: multi-process worker pools that scale decoding across host cores, asynchronous prefetching that copies the next batch to the accelerator while it computes on the current one, and hardware decode engines that move image decompression off the host processor entirely. Hardware decode removes the host bound and hands the constraint back to storage bandwidth, where the remaining lever is the number of bytes each sample costs to move.

↪ How asynchronous prefetching and overlapping pipeline stages hide host preparation latency behind accelerator compute is developed in section 8.6.2.

4.10.5 Formats, compression, and partitioning

Scanning a 100-column CSV file when the model uses only 20 columns wastes four-fifths of disk bandwidth on unused text, and opening millions of individual 150 KB JPEG files spends more time on filesystem seeks than on transferring bytes. File format sets the byte count and access pattern, so format selection directly scales the data term $\left(\frac{D_{\text{vol}}}{\text{BW}}\right)$ of the iron law. Columnar formats like Parquet excel for tabular features by allowing column projection and pushdown filtering, whereas shard-based sequential formats like WebDataset or TFRecord pack millions of small binary objects (such as images or audio) into contiguous sequential streams. This sharding eliminates random disk seek overhead (L_{lat}), turning slow random I/O into sustained sequential storage throughput ($\text{BW}_{\text{storage}}$). The price is shuffling. Records within a shard arrive in order, so loaders approximate a random order by shuffling the shard list and mixing records in a buffer, and too small a buffer feeds the model correlated batches. Redesigning the format and the loader together pays off at the scale of this chapter's lighthouse. One such system trains ResNet-50 on ImageNet to 75 percent accuracy in about 20 minutes on a single machine (Leclerc et al. 2023). Quantifying this impact as *format efficiency* (η_{format}) provides a multiplier on effective bandwidth. While Parquet optimizes columnar layout on disk, in-memory representations face a similar serialization bottleneck when passing data between ingestion engines, dataframes, and ML frameworks. The Apache Arrow standard solves this in-memory boundary by defining a language-independent columnar memory layout, enabling zero-copy data sharing across pipeline processes without expensive serialization and deserialization cycles.

↪ Illustrative CPU decoding throughput and deserialization cost across storage formats are collected for reference in section B.1.2.

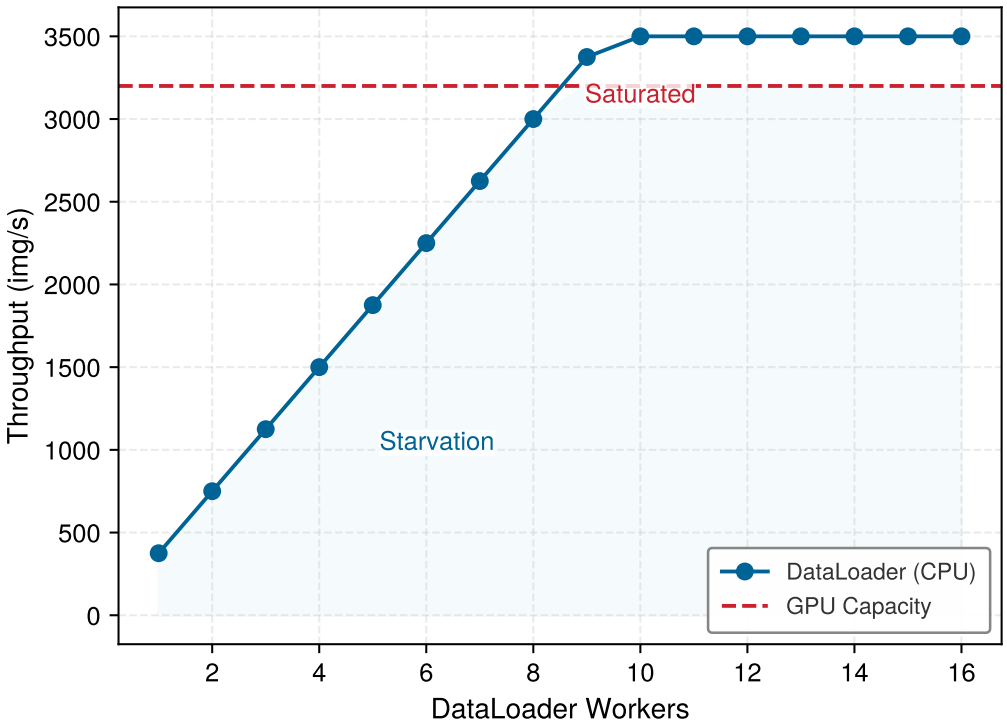

Figure 4.17: The Dataloader Choke Point: Training throughput (img/s) is plotted against DataLoader worker count, with storage and transfer provisioned above the required 480 MB/s rate. The blue CPU-supply curve rises with worker count until it reaches the illustrative input-pipeline cap; the red dashed line marks accelerator consumption capacity. The lower curve is the bottleneck: the accelerator starves to the left of the crossing, while extra workers beyond the crossing do not increase accelerator throughput.

Napkin Math 4.9: Format efficiency

Storage formats determine how much "waste" data must move to retrieve the signal needed for training. Let η_{format} be the dimensionless fraction of bytes read that carry selected features, from 0 to 1. Equation 4.6 shows how that fraction scales physical bandwidth into usable pipeline bandwidth:

$$\text{Effective Bandwidth} = \text{Physical Bandwidth} \times \eta_{\text{format}} \tag{4.6}$$

Values below 1 mean the format spends part of the physical data path on irrelevant bytes. Improving storage layout can therefore raise usable throughput without changing the underlying storage device.

Scenario: Training a fraud model using 20 features from a 100-column table, assuming equal uncompressed byte size per column.

Row-oriented formats (such as CSV) must read all 100 columns to retrieve the 20 required features, giving a useful-byte fraction of 0.2 and wasting 80 percent of disk bandwidth. Conversely, column-oriented formats (such as Parquet) read only the selected columns, achieving $\eta_{\text{format}} \approx 1$ (ignoring metadata overhead) and delivering 5× higher effective throughput.

Systems insight: In this projection-only scenario, switching from CSV to Parquet provides the same effective read-throughput gain as a 5× faster data path.

Columnar storage formats such as Parquet or Optimized Row Columnar (ORC) achieve a 5× to 10× I/O reduction for typical ML workloads through two complementary mechanisms: column projection, and column-level compression that exploits repeated values within a column. Com-

pression is particularly effective for categorical features with few distinct values. A country code column with 200 unique values across 100 million records compresses 20× to 50× through dictionary encoding, while run-length encoding compresses sorted columns by storing only value transitions. Together, projection and compression cut I/O by 20× to 100× compared to uncompressed row formats, shortening training epochs and shrinking storage footprints.

Compression algorithms trade storage density against CPU decompression bandwidth. While gzip achieves higher compression ratios of 6× to 8×, Snappy achieves 2× to 3× compression but decompresses at 500 MB/s, roughly 4.2× faster than gzip's 120 MB/s. Reading a 100 GB dataset compressed with gzip costs 13.9 minutes of CPU decompression per epoch, while Snappy costs only 3.3 minutes. Over 50 epochs, this 10.6 minutes difference per epoch compounds to 9 hours of host CPU time. That CPU time lengthens training only when decompression sits on the critical path, as it does when host-side decode is the binding stage of the dataloader choke point; with spare host cores and prefetching, it hides behind accelerator compute. The trade reverses when storage bandwidth binds instead. Gzip's higher compression ratio means fewer bytes per sample cross the storage path, which raises R_{data} in equation 4.5, so the right codec depends on which stage binds. Snappy suits a CPU-bound loader, and a denser codec suits a storage-bound one.

↪ How row and columnar layouts arrange records on disk, and how projection pushdown reads only the selected column chunks, are collected for reference in section B.1.3.

Beyond format and compression, data partitioning governs retrieval efficiency by aligning storage layout with common access patterns. The KWS corpus can be partitioned by speaker and recording date, so a training run can select a slice without scanning the whole corpus, and the speaker key that assigns splits also governs the storage layout. Partitioning strategies interact directly with distributed training: range partitioning by user ID routes each user's records to one data-parallel rank (workers that each train on a different slice of every batch), which feeds each rank a skewed stream rather than a representative sample, while random partitioning mixes records from the source pool across workers under the sampling policy. It does not remove correlations already present in that pool or prevent leakage between evaluation splits; speaker grouping and other independence constraints must be enforced separately. Granularity is critical: too few coarse partitions limit parallel worker concurrency, while millions of tiny shards add heavy metadata overhead and break sequential disk prefetching. In multi-accelerator training, partition skew creates stragglers. If seven workers in an eight-accelerator job finish loading their batch in 12 ms but one worker reads from an oversized partition and takes 180 ms, that single straggler delays the synchronization step that ends each training step across the entire cluster. Balanced partitioning that matches worker read budgets therefore keeps accelerator efficiency high.

Format, compression, and partitioning complete the delivery path by cutting the bytes each sample costs to move and keeping worker shards balanced. With a storage tier sized for the accelerator, the host matched to its rate, and bytes per sample reduced, both scenarios now have every stage of the pipeline in place, and each can be checked against the targets it started with.

4.11 Accepting the Pipeline

For the keyword spotter, the candidate design of table 4.2 is evaluated as a complete pipeline. The team first records an acceptance contract: the 98 percent keyword detection target on the declared evaluation population, the expected false-wake budget below 1 false wake/month, the 256 KB model limit, and the separate 16 KB preprocessing-state budget. The contract also retains the latency and power requirements of section 4.3. Model bytes alone cannot establish a device fit; peak feature buffers and runtime state must fit the device's total memory allocation.

The false-wake target is a data requirement in its own right. When no false wake is observed, the upper 95 percent confidence bound on the true rate is about three events divided by the hours listened, the zero-event rule of three (Hanley and Lippman-Hand 1983). Supporting a budget of one false wake per month therefore takes about 2,160 hours of representative non-keyword audio, about 248 GB of recordings at 16 kHz. That requirement is as concrete as the label count. The allocation in Notebook 4.2 never costed it, so the team must add an evaluation-collection line, because no amount of training data can stand in for these hours.

To test the choice of 13 rather than 40 MFCC coefficients, both candidates use the same versioned speaker-separated data splits, label budget, and recorded training procedure. Each candidate packages its own fitted preprocessing state with its model. Validation data selects the detection threshold; a separate, untouched evaluation set then measures keyword recognition and false rejection, while

representative nonkeyword streams measure false accepts per hour through the deployed detection path. The team fixes the required statistical confidence and listening duration before evaluation and accepts the false-wake claim only when the upper uncertainty bound, expressed over the same listening duration as the target, meets that target. Insufficient listening time leaves the claim unestablished even if no false wake occurs. Replaying fixed audio through the training and device preprocessing paths checks feature parity, and measurements on the target device establish peak memory, latency, and power.

The budget charges collection and review to the labeling allocation, and generation, retained versions, storage, and processing to their stated allocations. The computed 750K real examples fit only the labeling calculation; additional synthetic data must fit the remaining budget. If the 13-coefficient candidate meets every acceptance condition, the larger representation needs a measured quality benefit worth its added device cost. If the smaller candidate fails quality, the 40-coefficient alternative is acceptable only if it closes that gap while passing the same resource and cost checks. If neither passes, the team revises coverage, representation, or the product requirements and repeats validation; it cannot declare success from the design-space gains alone.

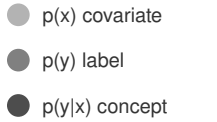
The ResNet-50 scenario has a simpler contract: delivery must not limit the training rate. It passes on a SATA solid-state drive today, provided the images are read as large sequential shards, which lets the drive supply about 3,333 img/s against the 3,200 img/s the accelerator sustains. It fails as soon as faster kernels or a faster accelerator push the rate toward the compute ceiling, which is why the storage tier is sized for the rate the pipeline is heading toward rather than the rate it runs at today.

Acceptance does not end the work of data engineering. In production, input environments continuously drift: sensor hardware shifts, upstream schemas mutate, and annotator pools turn over. Without active operational maintenance, static pipelines quietly degrade over time.

4.12 Operational Data Health

The detection-rate drop that opened section 4.8 can now be traced to its causes. In this illustrative scenario, the keyword spotter launched meeting its 98 percent detection target with verified training-serving consistency. Six months later, the measured detection rate had fallen four percentage points below that target, although no one had touched the model. The decline traces to three silent changes. A new hardware revision's microphone altered the acoustic frequency response, the labels used to measure live performance followed revised guidelines that were never reconciled with the earlier evaluation standard, and an upstream change to the device metadata schema shipped without notice. The changed evaluation labels can alter the measured rate even when predictions for the same inputs stay fixed, so their effect must be separated from the changed inputs. Each failure mode represents a manifestation of **data debt**: accumulated, unmonitored compromises in data quality, schema integrity, and provenance that compound across system boundaries. Unlike traditional software defects that trigger segmentation faults or unhandled exceptions, data debt leaves the execution graph running normally while the underlying statistical distribution decays. Keeping the capability bound true after launch therefore takes two disciplines: watching how the data the system meets drifts away from the data it learned from, and measuring and paying down the debt that accumulates in the pipeline itself. The throughput bound decays more quietly. Datasets grow, preprocessing changes, and a new feature or format can move decode back onto the critical path of training, so the share of each training step spent waiting on input belongs on the same dashboard as the drift metrics, and the arithmetic of section 4.9.3 says which stage to resize when it rises.

4.12.1 Data drift detection and response



The microphone change in that scenario is drift. Production audio stopped resembling the training audio, and because no contract was violated, nothing raised an error. The validation and monitoring techniques in section 4.5.3 can reveal both sudden and gradual problems; data drift detection focuses specifically on changes in distributions that may alter model behavior over time. Drift monitoring is a core data engineering responsibility.

↪ How drift signals and outcome evidence trigger retraining only when its expected benefit exceeds its cost is developed in section 14.6.1.

Section B.2.3 formalizes the divergence metrics used to make the divergence term $\mathcal{D}(P_t \| P_0)$ of the degradation equation (equation 1.1) actionable. The **population stability index (PSI)** quantifies changes in categorical or binned feature distributions, while **Kullback-Leibler (KL) divergence**

measures how far the current distribution departs from the baseline by weighting the log ratio of their probabilities by the current distribution's probability (Kullback and Leibler 1951). KL divergence is asymmetric, and it becomes infinite wherever the current distribution places probability that the baseline lacks, so monitors must fix its direction and smooth empty bins. The two metrics encode different distributional assumptions and scales, and neither by itself supplies a universal cutoff. Teams calibrate metric-specific thresholds against a deployment baseline and monitor them over time. Crossing a threshold signals that the live distribution has moved far enough to warrant investigation and outcome checks; input divergence alone does not establish whether accuracy improved or degraded, or by how much. Mathematically, PSI discretizes a continuous feature into reference bins (typically deciles of baseline P_0) and computes $\text{PSI} = \sum_b (P_t(b) - P_0(b)) \ln\left(\frac{P_t(b)}{P_0(b)}\right)$. Each bin's two factors share a sign, so every shifting bin adds to the index. Practitioners commonly treat $\text{PSI} < 0.1$ as stable, $0.1 \leq \text{PSI} \leq 0.25$ as moderate shift, and $\text{PSI} > 0.25$ as a prompt for investigation; these bands are conventions to calibrate against the deployment baseline, not physical limits.

Targeted detection and mitigation require decomposing drift into its constituent distribution components (Quiñonero-Candela et al. 2009). The first case, **covariate shift** (Shimodaira 2000), changes the input distribution while preserving the relationship between features and labels: $p(x)$ changes but $p(y \mid x)$ stays the same. The keyword spotter in the scenario above meets exactly this case. The words people say, and how they say them, have not changed, but audio from the new microphone has a different frequency response from anything in the training set. Detection therefore compares input feature distributions, using metrics such as PSI or KL divergence. Audio that never triggers the detector stays on the device, so for the keyword spotter the comparison runs on aggregate feature statistics the devices report, such as per-band energy histograms, rather than on the audio itself.

Each drift type traces to the distribution component that shifted.

The second case, **label shift** (Lipton et al. 2018), changes the output distribution while preserving the relationship between labels and features: $p(y)$ changes but $p(x \mid y)$ stays the same. Disease prevalence might change seasonally while symptoms remain consistent predictors of each disease. A recommendation system might see the same pattern when new product categories launch, changing the relative frequency of user preferences without altering what makes products appealing within each category. Detection can often begin without ground truth labels by tracking shifts in the model's prediction distribution.

The hardest case is **concept drift**: the relationship between features and labels changes, so $p(y \mid x)$ evolves over time (Gama et al. 2014). Medical treatment protocols change, user preferences shift as social trends evolve, and fraud patterns adapt as attackers respond to detection systems. Unlike covariate or label shift, concept drift requires ground truth labels for detection because the system must observe whether the feature-to-label relationship itself has changed.

Drift monitoring also depends on what production data reaches the pipeline at all, and the deployed model decides much of that. The keyword spotter uploads audio, with consent, only when it wakes, so the clips that reach the team are dominated by correct detections and false wakes. A spoken wake word that the detector misses leaves no recording; the user simply says it again. The pipeline's own logs therefore under-report the false rejections that matter most, and measuring them takes a separate, consented collection, such as periodic recording studies or reports of failed activations. Labels arrive late for a related reason: whether a logged activation was a real wake word is known only after review. A monitoring plan built only on the data the deployed model sends back sees the model's successes more clearly than its failures.

Putting the PSI and KL divergence metrics to work in production requires connecting them to automated alerts and review workflows. Data engineering is responsible for defining domain-specific drift thresholds from baseline behavior and outcome evidence, selecting monitoring windows that can expose both sudden and gradual changes, and instrumenting pipelines to compute these metrics continuously. When those alerts or the collection gaps around them go unaddressed, the resulting blind spots accumulate alongside schema workarounds and missing provenance as data debt.

4.12.2 Categories of data debt

The edge KWS failure contains four distinct categories of data debt. The hardware-induced acoustic shift left the training set stale relative to the new microphones, which is *freshness debt*; the divergent annotation standard introduces *quality debt*; and the silent metadata modification creates both *schema*

debt and *documentation debt*. Although each category requires its own diagnostics and fixes, all four share a common root cause: hidden coupling across unmonitored boundaries.

Definition 4.6: Data debt

Data debt is the accumulated cost of implicit coupling and missing documentation across an ML data stack.

1. **Significance**: It manifests as silent performance degradation and compounding maintenance overhead caused by unmanaged pipeline dependencies or undetected distribution shifts.
2. **Distinction**: Unlike a code defect, which often surfaces as a compiler error, a failing test, or a runtime exception, data debt permits computation to complete successfully while producing statistically invalid outputs. It is the data-side form of the hidden technical debt that Sculley et al. (2015) identify in ML systems, and it shares that debt's defining property of staying invisible until it is paid.
3. **Common pitfall**: A frequent misconception is that data debt is just "bad data." In reality, it is a systems architecture failure: it occurs when the assumptions of the training distribution are no longer enforced at the system boundary.

The first category is **documentation debt**: data provenance, column meanings, and collection parameters go unrecorded. When datasets omit datasheets or data cards (Gebru et al. 2021; Pushkarna et al. 2022), feature columns lack descriptions, and transformation steps stay undocumented, pipeline maintenance breaks down as soon as team members change. As Sambasivan et al. (2021) demonstrate, missing metadata and unrecorded collection practices trigger compounding data cascades across high-stakes systems. Downstream engineers must reverse-engineer feature meanings from old ingestion scripts, provenance audits fail compliance checks, and unstated assumptions, such as sensor dynamic ranges or unit conventions, cause silent prediction errors when upstream sensors change.

The second category, **schema debt**, grows out of accumulated transformation workarounds and uncoordinated migrations. When upstream services change payload structures or field meanings, teams often apply local patches, such as regex string extraction or fallback NULL coercions, rather than updating data contracts at the producer boundary. Over time, these patches build brittle parsing layers full of version-conditional branches, duplicate timestamp parsers, and defensive type conversions. At the ingestion boundary, an unvalidated schema change can silently alter the assembled tensor rank, drop sparse features, or introduce out-of-vocabulary indices that collide with reserved embedding tokens. As the pipeline jungle analysis showed (section 4.2.1), upstream contract violations often surface downstream as model convergence failures or serving anomalies.

The third category, **quality debt**, consists of known data defects left uncorrected to meet delivery deadlines or compute budgets. A training corpus with a 3 percent label error rate carries concrete quality debt: every training run on that corpus fits the model against corrupted targets. Quality debt compounds when model predictions feed downstream models as features or pseudo-labels, spreading label noise across dependent services. Warning signs include rising annotation disagreements, unaddressed demographic gaps, and unpurged near-duplicate records that inflate validation scores through data leakage.

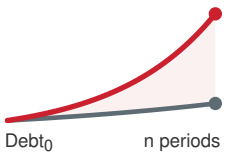
The fourth category, **freshness debt**, arises when static training sets fall behind evolving production distributions. A model trained on historical user behavior may meet changed inputs or feature-label relationships after deployment. Calendar age alone does not prove a quality loss; freshness assessment needs evidence of changed conditions and their effect on predictions. Freshness debt accumulates invisibly because a stale model still runs; it is just wrong more often. Warning signs include training intervals that lag behind the rate of distribution shift, stale caches in online feature stores, and static lookup tables that no longer reflect current domain state. Managing these four liabilities requires setting explicit quantitative thresholds for each one.

4.12.3 Measuring and projecting data debt

Code-level debt can at least be approximated with code complexity metrics; data debt requires measurements of the data and its pipeline. Table 4.9 gives example warning and critical thresholds for each debt category, not universal standards, and makes data debt trackable as an engineering service-level objective (SLO), a target value set for a measured quantity.

↪ How a service-level agreement turns an objective into a contractual commitment is developed in section 12.6.2.1.

Table 4.9: Data Debt Metrics: The thresholds are illustrative triggers for detecting data debt accumulation across four categories. Warning thresholds indicate debt requiring attention in upcoming planning cycles; critical thresholds indicate debt requiring immediate remediation to prevent system degradation. The days-since-retraining row is a review trigger, not evidence of degradation. Crossing it prompts the comparison of elapsed time with the measured shift interval that freshness debt calls for. The PSI row uses common operational drift-monitoring bands, while the remaining rows should be calibrated to the risk tolerance and failure cost of the specific ML system.



Debt Category	Metric	Warning Threshold	Critical Threshold
Documentation	% datasets with data cards	< 80%	< 50%
Documentation	% columns with descriptions	< 90%	< 70%
Schema	Schema version branches	> 3	> 10
Schema	% transformations with try/catch	> 20%	> 50%
Quality	Known label error rate	> 1%	> 5%
Quality	Documented bias metrics	Not measured	Measured but not mitigated
Freshness	Days since last retraining	> 90 days	> 365 days
Freshness	PSI vs. training baseline	> 0.1	> 0.25

Data debt compounds through coupled feedback loops in production pipelines. Model outputs frequently feed downstream data lakes as pseudo-labels or synthetic features; any uncorrected label bias or corrupted prediction in an upstream model is thereby baked into the ground truth of dependent systems. At the same time, ingestion code decays: each defensive workaround added to handle an undocumented schema change adds branching logic that makes later schema migrations more likely to fail. As distribution drift steadily widens the gap between the training baseline and live inference streams, unmaintained systems demand more and more engineering time just to stay running. To model how sensitive pipeline maintenance is to unaddressed debt, measure debt by a concrete proxy: the remediation backlog in engineer-hours needed to bring every row of table 4.9 back below its warning threshold. Let Debt_0 be that backlog today, r its net growth rate per planning period (estimated from how the backlog grew over past periods), and n the elapsed periods. The planning model in equation 4.7 projects the accumulated liability:

$$\text{Debt}_n \approx \text{Debt}_0 \times (1+r)^n \tag{4.7}$$

A small difference in the periodic accumulation rate r becomes a large backlog over time. This geometric formula is a planning heuristic rather than an exact physical law; in production environments, debt often jumps during discrete upstream migrations rather than compounding smoothly.

4.12.4 Remediation strategies

Small differences in growth rate open a widening debt gap over time.

Once the team measures debt per category, engineers can pay it down during regular operational cycles before pipeline failures disrupt downstream services. Each debt category calls for a different technical fix, but all four follow the pipeline from its upstream boundary to its live monitoring loop. Remediation starts at the ingestion boundary, where documentation and schema debt originate. Making dataset metadata part of the release checklist and reserving maintenance time to record data provenance, column meanings, and preprocessing graphs on the most widely shared feature tables gives downstream teams complete schema descriptions and transformation lineage. With those meanings documented, teams can pay down schema debt by enforcing explicit schema contracts at the producer boundary rather than patching downstream code. Validation libraries such as Pandera or Great Expectations check types, value bounds, and null rules before records enter the lake, so failing fast on schema violations keeps defensive null-coercion and string-parsing workarounds from piling up inside transformation scripts.

Once the ingestion boundary is stable, attention shifts to the corpus itself and its alignment with live traffic. Paying down quality debt requires regular workflows that fix known label errors, duplicate records, and demographic coverage gaps; tracking the error backlog and its burn-down rate lets teams schedule data curation alongside model work instead of deferring it indefinitely. Even a clean corpus eventually drifts out of date, so paying down freshness debt pairs automated drift monitoring with an evidence-based retraining schedule. Adding population stability index (PSI) and Kullback-Leibler (KL) divergence monitors (section 4.12.1) to operational dashboards lets pipelines trigger an investigation whenever distribution distance crosses a calibrated threshold, after which outcome evidence and diagnosis decide whether to refresh features, repair a pipeline, or retrain rather than treating input divergence alone as proof of accuracy loss.

Like technical debt in traditional software engineering, data debt is an inescapable trade-off. *Strategic* debt, such as shipping with minimal documentation or deferred deduplication to meet a launch window, can be a deliberate engineering choice. The failure mode is *unconscious* debt: compromises made without measurement that compound silently until fixing them requires rebuilding the pipeline. Managing data health therefore means measuring debt, choosing deliberately which debt to carry, and diagnosing the remaining faults systematically when a deployed pipeline does regress.

4.12.5 Debugging data pipelines

When data debt comes due, it surfaces as an unexplained accuracy drop, an ingestion crash, or a performance gap on a specific user slice. Debugging draws on three earlier results: data cascades (section 4.2.1) show that upstream ingestion flaws cause downstream model anomalies, training-serving skew (section 4.7.1) exposes mismatches between offline feature generation and online serving, and drift detection (section 4.12.1) catches statistical shifts over time. Figure 4.18 arranges four symptom checks across temporal degradation, train-validation gaps, serving skew, and subgroup disparities. A "yes" at any branch points to a candidate cause, not the end of the investigation. Engineers should run through all four checks because multiple faults often occur together, then confirm each cause by comparing fixed artifacts before choosing a fix.

Production ML failures frequently trace to data dependencies and pipeline changes rather than model architecture alone.[23] Checking the data first, for training-serving skew, distribution drift, and label noise, isolates upstream input failures before any costly architectural redesign or hyperparameter sweep. The KWS regression that opened this section therefore needs three separate comparisons. Replay fixed raw recordings through the old and current preprocessing paths, with model weights and fitted state held fixed; changed features or predictions reveal a processing-path effect on those recordings, but do not establish microphone-population drift. Rescore fixed predictions under the old and revised labeling rubrics; a changed score identifies an evaluation-definition effect without proving that the detector changed. Finally, compare old- and new-microphone cohorts using one validated preprocessing path and one evaluation rubric, accounting for differences in speakers and acoustic conditions. A cohort gap warrants investigation of hardware coverage, but the microphone is not established as the cause unless those other conditions are controlled. Confirmed transform defects call for pipeline repair and revalidation; a remaining quality loss on representative new-microphone audio can justify targeted acquisition and a retraining comparison.

[23] **ML failure distribution**: Treat the data-dominance pattern as a practical triage rule rather than a universal law. Data and pipeline checks are good first hypotheses, but they do not rule out code defects, hardware communication bottlenecks, or numerical instability.

Checkpoint 4.4: From data contracts to diagnosis

A training loader delivers examples more slowly than the accelerator can consume them. A preprocessing version has also changed, and monitoring reports input drift, but outcome labels have not yet arrived.

- ☐ **Delivery**: Which rate limits steady-state training throughput, and what storage or transformation measurement would distinguish the cause?
- ☐ **Reproduction**: Which dataset version, preprocessing code, and fitted parameters must be recovered to compare the old and new paths?
- ☐ **Intervention**: What does the drift alert establish, and what additional evidence is needed before choosing pipeline repair or retraining?

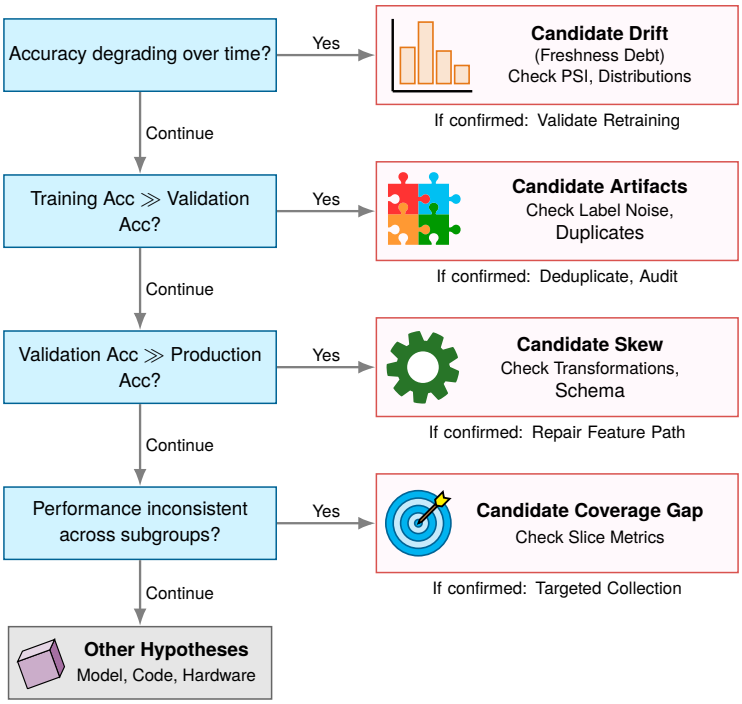


Figure 4.18: Data Pipeline Debugging Flowchart: Four sequential checks prioritize hypotheses involving drift, overfitting or data artifacts, training-serving skew, and subgroup coverage. Each side branch suggests a candidate cause to confirm before applying the indicated repair. Other hypotheses include model, code, and hardware faults.

4.13 Fallacies and Pitfalls

Data engineering pipelines rarely fail with immediate runtime crashes; instead, they silently distort feature distributions, corrupt training state, or starve expensive accelerator clusters. The nine fallacies and pitfalls that follow collect the recurring assumptions behind those failures, pairing each with the pipeline measurement or contract that prevents it.

Fallacy: *More data always improves model performance.*

The bitter lesson says that general methods fed with more data and compute keep winning, but it does not say each new sample is worth as much as the last. Beyond a threshold, additional data yields diminishing returns described by empirical scaling laws, fitted curves relating model error to dataset size. Studies across computer vision, translation, and language modeling find that test loss falls as a power law in dataset size, so each successive error reduction demands a multiplicatively larger volume of samples (Hestness et al. 2017). In the illustrative KWS design space, a tenfold larger training set buys 5–8 percent more detection rate at 10× the labeling cost. In systems terms, repeated examples consume disk I/O, host-to-device bus bandwidth, and accelerator FLOPs without adding distinct observations. Repeated passes can still shift the model slightly, so redundancy must be judged by its measured effect on evaluation rather than assumed to contribute nothing. The task-relevant signal heuristic from section 4.9 captures this trade-off: scaling raw byte volume without preserving information density inflates infrastructure cost while yielding negligible improvements in evaluation loss.

↪ Scaling laws, and the selection methods that decide which samples are worth their training compute, are developed in section 9.1.

Pitfall: *Planning petabyte migration as a bandwidth-only transfer.*

Dividing data volume by network link bandwidth gives the theoretical wire time, about 22 h for the chapter's 1 PB example at 100 Gb/s, but wire transfer is rarely the critical path. Data gravity (section 4.9) binds large datasets to a web of surrounding infrastructure: ingestion transformation pipelines, schema validation checks, access-control policies, and downstream consumers. Moving a petabyte-scale corpus between clouds or data centers requires refactoring pipelines, revalidating

data integrity, re-warming caches, and rebuilding metadata indexes. In practice, the engineering time spent adapting dependent systems dwarfs the raw network transit time.

Fallacy: *Data preprocessing can be finished once and left alone.*

Preprocessing pipelines turn raw observations into tensors using parameters fitted on historical data: tokenization vocabularies, mean and variance scaling vectors, category frequency tables, and numerical clipping bounds. When production distributions drift, these fixed transformations go stale. Tokenizers hit rising out-of-vocabulary rates, fixed normalization constants push scaled features outside the range the model trained on, and static clipping bounds cut off valid signal. Keeping the pipeline accurate requires monitoring input tensors and outcomes, then validating any change to preprocessing together with the model that consumes its features. Recomputing statistics independently at serving time can itself introduce skew.

Pitfall: *Ignoring data serialization cost.*

Profiling often focuses exclusively on accelerator execution while data loaders quietly parse raw JSON or CSV files. Parsing text-based records requires host CPU cores to spend hundreds of cycles per sample on string decoding, tokenization, ASCII-to-float conversions, and heap allocations. This host-side parsing starves the accelerator just as the dataloader choke point does (section 4.10.4). In the chapter's ResNet-50 scenario, JPEG decoding already occupies 9 workers per accelerator, each preparing 375 img/s. A tabular or log-feature pipeline that parses text records pays the string-decoding cost described here on top of any such preparation. Binary serialization formats, such as Apache Arrow or memory-mapped arrays, eliminate parsing overhead by storing numbers directly in machine-native binary layouts that the loader can hand to the accelerator without conversion. For tabular schemas, columnar formats such as Parquet cut disk I/O by reading only the required columns. Benchmarking data ingestion against accelerator consumption rates shows whether host CPU deserialization is throttling training throughput.

Fallacy: *High training accuracy indicates production readiness.*

Training accuracy and held-out validation accuracy both describe the historical distribution the data was drawn from. Production adds edge cases, sensor noise, and live drift, and a model with high validation accuracy still fails if upstream feature pipelines change or inference timeouts trigger fallback defaults. Diagnosing post-deployment regressions requires the symptom checks across temporal drift, label artifacts, and training-serving skew ordered in figure 4.18, rather than reliance on a single offline score.

Pitfall: *Ignoring training-serving skew until deployment.*

Training-serving skew occurs when feature generation logic diverges between the offline training pipeline and the online inference runtime, for example through differences in floating-point precision, time-window aggregation, library versions, or temporal leakage from data timestamped after the prediction point. Because the model still receives valid floating-point vectors, inference raises no runtime exceptions while prediction quality degrades. Avoiding this pitfall requires shared transformation logic, reproducible feature stores, and automated predeployment parity tests that check feature equivalence across offline and online paths.

Fallacy: *Synthetic data can fully replace real-world data collection.*

Synthetic data enriches training sets by generating rare edge cases, controlled physical variations, or privacy-safe samples, but a generator can only sample within the assumptions built into it. When trained exclusively on synthetic data, models overfit to generator-specific artifacts and fail on real-world variation the generator never modeled. In a KWS system, for example, a detector trained entirely on synthesized speech loses accuracy when it meets real room reverberation, unfamiliar accents, microphone distortion, and shifting background noise. Synthetic generation supplements real collection, but representative real-world recordings remain essential for testing whether the system is ready to deploy.

Pitfall: *Neglecting data versioning until model debugging requires it.*

Treating training datasets as mutable object-storage directories destroys experiment reproducibility. When a retrained model loses accuracy, an unversioned pipeline cannot show whether the

cause is a modified labeling rubric, a silent schema change, or genuine distribution shift, and once tables are overwritten or raw logs deleted, the historical training inputs cannot be rebuilt. As established in section 4.8.1, every model checkpoint must link immutably to a specific dataset snapshot, transformation code hash, and configuration file.

Fallacy: *Production logs show where the model fails.*

A deployed system decides much of what data comes back from it. The keyword spotter uploads audio only when it wakes, so its logs fill with correct detections and false wakes, while a wake word it misses leaves no recording at all (section 4.12.1). A team that measures quality from those logs alone sees a false-rejection rate lower than the real one, and retraining on the same logs over-represents the cases the model already handles. Measuring failures requires collection designed for that purpose: consented recording studies, reports of failed activations, and evaluation streams kept independent of the deployed model's choices.

4.14 Summary

A trained model is bounded twice by its data. The capability bound follows from the data-as-code principle (1): a changed dataset changes the trained model even when no algorithmic code changes, and a defect introduced in collection, schema, or labeling amplifies through every later stage as a data cascade. The throughput bound is the physics of the iron law's data term. The pipeline must deliver bytes at the rate the accelerator consumes them, a requirement the feeding loss, the dataloader choke point, and the storage bandwidth budget each quantified at a different tier of the same ResNet-50 scenario. Data engineering therefore works in two overlaps of the D·A·M taxonomy at once. The capability half worked the Data–Algorithm overlap and the throughput half the Data–Machine overlap, and operations exists because the deployment distribution keeps shifting after launch, which reopens both overlaps. Acquisition, labeling, and feature contracts decide what the model can learn and keep training and serving computing the same function, while storage tiers, formats, and loaders decide how fast it learns.

Key Takeaways: Data is the source code

- **Data is code; version it, test it, review it**: Under the data-as-code principle (1), a dataset change is a code change. Give it version control, validation tests, and review.
- **Data cascades make upstream quality the highest-return investment**: The compounding failure arcs in figure 4.1 show how early collection errors bypass intermediate testing, requiring extensive rework across downstream artifacts and, in severe cases, complete pipeline restarts from deployment. The four pillars (quality, reliability, scalability, and governance) organize prevention, while documentation, schema, quality, and freshness debt require continuous remediation.
- **Pipeline architecture choices have large cost implications**: The chapter's provisioning scenario costs streaming above batch, while its matched-retention example trades ETL storage savings against schema-change overhead. Actual costs depend on provisioning, retention, replay, and required freshness. Select ingestion patterns by the value of latency, not the appeal of real time.
- **Labeling can dominate cost and requires substantial resource allocation**: Labeling can cost thousands of times one optimized training run; in the reference calculation in section 4.6.2, the ratio is 2,498× to 4,995×. Labeling can remain a costly scheduling bottleneck even when annotation work is parallelized.
- **Training-serving consistency is nonnegotiable**: Feature transformations shared by training and serving must have equivalent semantics and reuse the same learned state, such as normalization constants and vocabulary mappings.
- **Storage hierarchy sets input-loading time**: The 50× throughput gap between local NVMe (5 GB/s) and one cloud object-storage connection (100 MB/s) changes input-loading time under the stated bandwidth assumptions. Total iteration time also includes transformation and model execution, so the loading ratio is not an end-to-end speedup.

- **The degradation equation becomes actionable through drift and outcome monitoring**: Divergence metrics such as KL measure changes between P_t and P_0, while labeled outcomes or validated proxies determine whether those changes correspond to model degradation.

The keyword spotter carried the capability bound through the chapter, and ResNet-50 carried the throughput bound. The keyword spotter's one-false-wake-per-month target turned an accuracy goal into a per-window false-positive bound whose evaluation requires representative negative audio, sufficient listening duration, and an explicit treatment of measurement uncertainty. Its fixed budget turned "more data" into a costed allocation of labels, storage, and governance. Its MFCC extraction had to agree, within a validated tolerance, between a cloud training cluster and a kilobyte-scale always-on island. Data engineering is the discipline of keeping two contracts at once, a physical contract with the machine that must be fed and a statistical contract with a deployment distribution that keeps moving, and the failures this chapter traced, from a starved accelerator to a silently retyped ZIP code, each came from a pipeline that kept one contract while breaking the other.

What's Next: From data to computation

The data pipeline now delivers a clean, versioned training set at the rate the accelerator consumes it, yet this chapter has treated the model at the end of that pipeline as a consumer of bytes and nothing more. Chapter 5 opens the consumer along the algorithm axis. It begins with the shift from hand-written logic to learned arithmetic, then counts the multiply-accumulate operations, activations, and gradient updates that turn prepared examples into learned behavior, and the memory and compute each one demands of the machine.

II

DEVELOPMENT AND TRAINING

Part II

Development Principles

Building a machine learning system requires more than assembling model components; it requires managing the flow of information and energy through silicon. Part I fixed where a system can run, when its constraints must be known, and how its data is delivered, and it established that data is both the program and a physical anchor of every ML system. With that anchor in place, Part II turns to the algorithm-machine interaction, asking *how* mathematical models are co-designed around the physical limits of the hardware that must execute them. The bitter lesson favors general methods that absorb more computation, but every such method must still fit the machine that runs it. The principles here begin with the accounting that determines why certain architectures succeed while others fail at scale. That accounting, the iron law, has been in use since the introduction; it is stated here as a principle because every chapter of this part measures its decisions against it.

Principle 3: The iron law of ML systems

Decomposition: Let T denote idealized wall-clock time in seconds. Across the D·A·M axes, workload time factors as $T = (\text{Samples/Task}) \times (\text{FLOPs/Sample}) \times (\text{Seconds/FLOP})$, where the first two factors multiply to fix total floating-point operations O. Unpacking how the machine executes those operations into physical terms, where D_{vol} is data volume in bytes, BW is the effective bandwidth of the relevant memory or network path in bytes/s, R_{peak} is peak compute rate in FLOP/s, η_{hw} is dimensionless hardware utilization efficiency, and L_{lat} is fixed latency overhead in seconds (such as a kernel launch or network round trip), gives the serialized sum:

$$T \approx \frac{D_{\text{vol}}}{\text{BW}} + \frac{O}{R_{\text{peak}} \cdot \eta_{\text{hw}}} + L_{\text{lat}}$$

The full treatment appears in section 1.7.

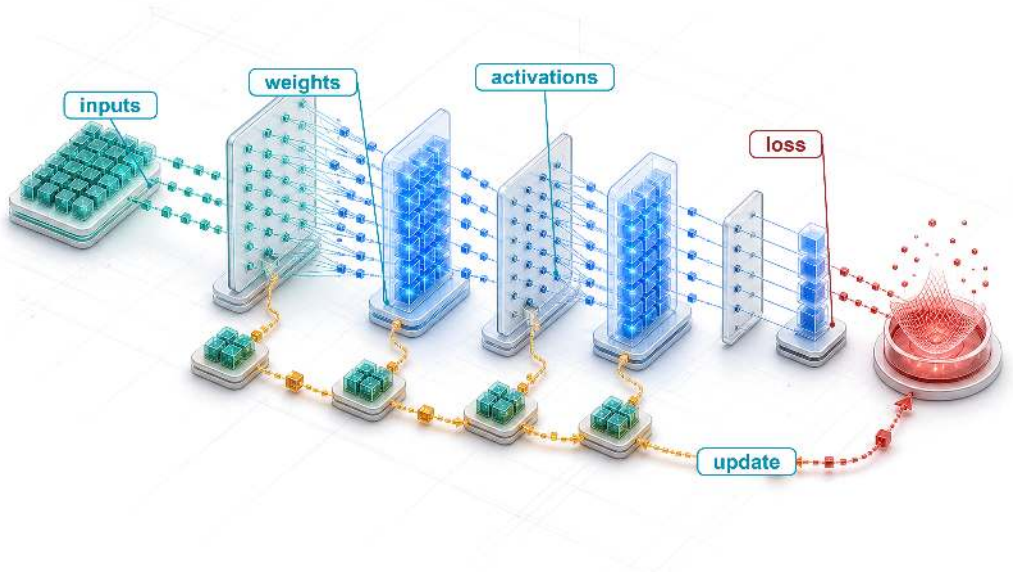
When data movement and compute overlap on modern hardware, wall-clock time follows the critical path and cannot be shorter than the slower of those stages plus any fixed latency that remains outside the overlap. The practical lesson is about dominance, not unconditional summation.

Implication: Optimization is rarely free of trade-offs. Reducing one factor or term often shifts the bottleneck to another. For example, skipping zero-valued weights scattered irregularly through a model (unstructured sparsity) reduces FLOPs/Sample and therefore executed arithmetic O. The model must then also store and read the positions of the surviving weights, however, and that index traffic can increase data-movement time $(D_{\text{vol}}/\text{BW})$ and inflate realized Seconds/FLOP. An optimization improves wall-clock time only to the extent that it shortens the critical path on the target hardware.

The iron law names the terms; it does not say which one a given model will stress. Chapter 2 examined the hardware's side, the terms each deployment tier offers. Choosing the model architecture makes the other side of the commitment, before any code runs.

Principle 4: The silicon contract

Heuristic: The hardware fixes three time limits, a memory bandwidth BW, a peak compute rate R_{peak}, and a fixed overhead L_{lat}, along with a memory capacity that decides what fits at all. Every model architecture, in each workload regime, commits in advance to saturating one of those limits first.



- **ResNet-50**: Assumes high-density floating-point compute. In batched training or inference on accelerators, it is often compute bound: performance is limited by $O/(R_{\text{peak}} \cdot \eta_{\text{hw}})$.
- **GPT-2/Llama**: Assumes high-bandwidth memory access during autoregressive decoding, which generates one token at a time and rereads every weight for each token. At small batch sizes, it is often bandwidth bound: performance is limited by D_{vol}/BW.
- **DLRM**: Assumes massive embedding tables and sparse lookups. It is shaped by both capacity and bandwidth: performance depends on whether embedding tables fit in the available memory hierarchy and how quickly sparse accesses can be served.

Implication: Designing a model without knowing which hardware resource it will saturate is like designing a bridge without knowing the strength of the steel. The design must target the bottleneck.

Together, the iron law and the silicon contract frame every design decision in Part II. Chapter 5 counts the operations, activations, and gradients that a neural model commits the machine to. Chapter 6 shows how arranging those computations sets a model's arithmetic intensity, and with it the architecture's side of the contract. Chapter 7 follows the translation of model operations into hardware execution and locates the fixed overhead that translation spends. Chapter 8 then repeats the resulting step many thousands of times, until memory, time, and cost budgets decide what one machine can train.

Purpose

Why does understanding a neural network's math matter more than reading its code?

Neural network code can look deceptively simple because a few tensor operations hide the workload that every layer of the system must execute. Matrix dimensions determine arithmetic and data movement; intermediate values determine memory pressure; numerical ranges and gradients determine whether learning remains stable. An operation that looks cheap in isolation can dominate a system when repeated across a batch or when its outputs must be retained for learning, so source-code length gives little indication of resource cost. Doubling both input and output dimensions quadruples a dense layer's arithmetic, and keeping activations for the backward pass can multiply memory use several times over, while the code looks no more complicated than before. Two implementations of the same model can run very differently because batch shape, precision, and the target machine change what fits, how quickly it runs, and whether its calculations remain numerically valid. When training stalls or deployment exhausts memory, reading a framework call rarely identifies which resource is the binding constraint. A numerical failure, a memory bottleneck, and an inefficient implementation can produce similar high-level symptoms while demanding different remedies. Diagnosis and planning therefore require reasoning from the underlying operations to the bytes moved, values retained, and work repeated. This view can expose a mismatch before an expensive training run or deployment attempt does, when correcting it still costs an edit rather than a week of lost compute. Those primitives provide a stable vocabulary across architectures and make software abstractions auditable, turning opaque code into a workload that can be measured, diagnosed, and mapped to hardware. In D·A·M terms, neural computation is the interface where algorithmic structure becomes machine work and where physical limits feed back into model design.

Learning Objectives

- Explain why learned arithmetic replaced rule-based logic and why it fails numerically rather than logically
- Compare activation functions by nonlinearity, gradient behavior, and hardware execution cost
- Calculate parameter counts, multiply-accumulate operations, activation storage, and the arithmetic intensity that batching raises in dense layers
- Apply cross-entropy loss and gradient updates to reason about supervised learning dynamics
- Derive forward and backward propagation as matrix operations over batches
- Analyze training vs. inference workloads using compute, memory, and deployment constraints
- Evaluate an end-to-end document-recognition pipeline from preprocessing through decision thresholds and human review

5.1 From Logic to Arithmetic

RECOGNIZING one handwritten digit costs the small network at the center of this chapter 109,184 MACs. A multiply-accumulate (MAC) multiplies one weight by one input value and adds the product to a running sum (acc $\leftarrow$ acc $+ w \cdot x$), and the usual convention counts it as two floating-point operations (1 MAC $= 2$ FLOPs), so the digit costs 218,368 FLOPs. None of that work is a logical branch. A program that once tested pixel thresholds and stroke patterns with if-then-else rules has become a fixed sequence of arithmetic, and how fast it runs now depends on how quickly the machine can supply operands to that arithmetic, whether memory bandwidth or arithmetic capacity runs out first. Such a program also fails differently. It rarely fails logically; it fails numerically, as values grow or shrink until they stop carrying information.

The pipeline of chapter 4 ends with a clean, versioned training set. One example from such a set, a handwritten digit, is where the model's work begins. An example does not learn on its own. The next system boundary is the model, the algorithm axis of D·A·M, where data becomes learned behavior, and this chapter follows what the model does with that one digit. Matrix multiplications and activation functions carry it forward to ten scores, the chain rule carries the error in those scores back as gradients, and an update folds the gradients into the weights.

The silicon contract (principle 4) says which hardware resource a model architecture will saturate first. This chapter supplies the model's side of that contract. The architecture's mathematical operators fix the work to be done and the state to be held. Precision, data layout, implementation, and hardware then fix how many bytes actually move, and therefore the realized latency and energy. Honoring the contract requires understanding both the operators and how they map to the machine.

↩ The hardware's side of the silicon contract, the terms that memory bandwidth, peak compute rate, and fixed overhead set for any model, is established on the single-node stack in section 2.4.1.

The digit passes through five stages in the life of a model. The *forward pass* carries the image through three weight matrices to ten class scores, the *loss* reduces those scores to one number that says how wrong they are, the *backward pass* carries that signal back through the layers with the chain rule, the *update* adjusts every parameter, and *serving* runs the forward pass alone with frozen weights. The iron law of ML systems (principle 3) charges each stage for the bytes it moves, the operations it performs, and its fixed overhead, and table 5.1 shows how differently the five stages spend those terms. The loss costs almost nothing, yet it is the only signal training receives; the update does little arithmetic but touches every parameter; the backward pass cannot run without the activations the forward pass left behind. Training repeats the first four stages millions of times and serving repeats only the first, and that asymmetry produces the chapter's central result, the gap between what training and inference must hold in memory.

Table 5.1: Where Each Stage Spends Its Budget: Work, data movement, and retained state for the five stages in the life of a model, for the running 784-128-64-10 network. Training repeats the first four stages for every batch, while serving runs only the forward pass. Later sections derive each row, and the summary returns to the table.

Stage	Work	Data moved	State left behind	Usually dominant cost
Forward pass	One MAC per weight per example (109,184 MACs per digit)	Every weight read; each layer's activations written and read	Activations, kept until the backward pass	Bytes at small batch, operations at large
Loss	A few operations per class	Ten scores per example	One number per batch	Negligible
Backward pass	Up to twice the forward pass	Weights and saved activations read; gradients written	Gradients	Operations or bytes, as in the forward pass
Update	A few operations per parameter	Every weight, gradient, and optimizer value read and written	Optimizer state	Bytes
Serving	The forward pass alone	Weights plus two short-lived activation buffers	Nothing beyond the weights	Bytes and fixed overhead at small batch

Example 5.1: Running example: MNIST digit recognition

Scenario: A handwritten-digit classifier receives 28×28 grayscale images from the Modified National Institute of Standards and Technology (MNIST) dataset (LeCun et al. 1998), flattens each into 784 pixel values, and maps them through hidden layers of 128 and 64 units to 10 class scores, one per digit ($784 \to 128 \to 64 \to 10$).

Diagnosis: The network holds 109,386 parameters, which occupy 438 KB in 32-bit floating point (FP32), and it spends 109,184 MACs (218,368 FLOPs) to classify one digit. Those three numbers summarize what one classification costs.

Systems lesson: The task is small enough to compute by hand yet exercises every mechanism that larger networks scale up. Each later section either derives one of these numbers or asks what happens to it when the network trains, grows, or ships.

Even this small network is deep in the sense the field uses. Each of its layers computes new features from the layer before, and training learns those features from examples instead of receiving them from a designer.

Definition 5.1: Deep learning

Deep learning is the computational paradigm that learns layered feature representations from data by composing nonlinear transformations. For suitable tasks, those learned representations can reduce manual feature engineering while increasing computation (O) and state.

1. **Significance**: For suitable compositional function classes, depth can represent a hierarchy much more parameter-efficiently than a shallow network. Each layer adds work and state, and the resulting binding constraint may lie on the data, algorithm, or machine axis depending on the workload.
2. **Distinction**: Shallow methods such as logistic regression and support vector machines can work well with appropriate representations. Deep learning instead uses multiple nonlinear stages to learn representations jointly with the prediction task, which can reduce manual feature design and sometimes support transfer across tasks.
3. **Common pitfall**: A frequent misconception is that parameter count alone explains deep learning. Two networks with the same parameter count can differ sharply in what they learn, because architecture, data, optimization, and scale together determine the practical result.

Learning representations end to end also introduces engineering failure modes that conventional software debugging cannot isolate. Deep learning failures produce subtle symptoms: gradient instabilities[1] that halt convergence, numerical precision errors that corrupt parameter state across millions of updates, or inefficient memory access patterns in tensor operations (operations on multidimensional arrays of numbers) that leave accelerator compute units underutilized. Resolving these failures requires reasoning about the physical execution of tensor algebra on hardware rather than stepping through procedural control flow, and those hardware demands depend first on representation: whether patterns are expressed through hand-authored rules, engineered statistical features, or learned parameters.

5.2 Computing with Patterns

One task makes the history concrete: classifying a 28×28 grayscale image of a handwritten digit. Computing has attacked that task with three representation strategies, hand-authored decision logic, engineered feature extractors, and learned neural representations. Under illustrative implementations, one digit costs roughly one hundred comparisons under the first, several thousand arithmetic operations under the second, and more than one hundred thousand MACs under the third. Each approach replaced one whose representations ran out, and each shifted which hardware resource binds.

5.2.1 From rules to engineered features

Writing explicit `if-else` rules to recognize a handwritten digit breaks as soon as a writer tilts a stroke, thickens a line, or leaves a loop open. Rule-based programming requires developers to specify every procedure that maps inputs to outputs: in the classical flow of figure 5.1, human-authored rules and input data enter the program together, and the program deterministically computes the answers.

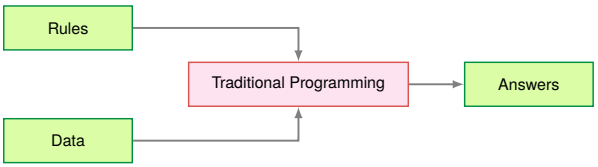

Figure 5.1: Traditional Programming Flow: Answers are the program's output, never its input. This input-output pattern formed the basis for early AI systems but lacks the adaptability needed for complex pattern recognition tasks.

An illustrative rule-based classifier for the digit compares pixel intensities against fixed thresholds, checks stroke patterns in localized regions, and branches on the results. Under this toy implementation, the computation requires roughly 100 comparisons over 784 bytes of pixel data, a workload that is small, predictable, and easily held in an ordinary CPU cache. The comparison establishes a workload baseline, not the accuracy of a production rule system. Rules fail on coverage rather than cost: every new writing style demands new branches, and the expert systems of the 1970s and 1980s stalled on perception tasks because visual competence is implicit and resists explicit rules.

The failures of rule-based systems suggested an alternative. Rather than encoding human knowledge as explicit rules, the system could discover patterns from data, and machine learning took that direction by replacing a rule for every situation with programs that identified patterns in examples. The success of these methods, however, still depended heavily on human insight to define which patterns to look for, a process known as feature engineering.

Feature engineering transformed raw data into representations that expose patterns to learning algorithms. The histogram of oriented gradients (HOG)[2] (Dalal and Triggs 2005) exemplifies this approach. In figure 5.2, the feature-extraction pipeline divides an image into spatial cells and bins local pixel gradient directions into eight orientation histograms, turning raw pixels into shape descriptors that tolerate lighting changes and small shifts in position.

Feature engineering raises the digit's cost while keeping it CPU friendly. For the same 28×28 digit, an illustrative HOG implementation divides the image into a 7 by 7 grid of 4 by 4 cells, computes gradient magnitudes and orientations, bins them into 9 orientation histograms per cell (the diagram

[1] **Gradient instabilities**: In a simplified 20-layer path through sigmoid (S-shaped) activations, the activation-derivative factors alone are bounded above by 0.25^{20}, or 9.1×10^{-13}. The complete gradient also includes weights and other operations, but repeated saturated derivatives can still make early-layer updates negligible. Plateaus or not-a-number (NaN) values can reveal the symptom without identifying the cause; rectified linear unit (ReLU) activations and careful initialization (both taught later in this chapter), together with normalization, better optimizers, and residual connections, all helped make deep networks trainable, and section 6.4.1 treats residual connections in detail.

↩ The succession of logic, knowledge, feature-engineering, and infrastructure bottlenecks that these paradigms answered is established in section 1.3.

[2] **Histogram of oriented gradients (HOG)**: An influential handcrafted descriptor for pedestrian detection before deep learning (Dalal and Triggs 2005). One common configuration computes gradient orientations in 8×8 pixel cells, with cell size and other choices tuned for the task. HOG's fixed computation graph can run efficiently on CPUs with predictable latency, while learned features can reduce descriptor redesign but do not automatically transfer across domains and often benefit from accelerators only as model and batch scale grow.

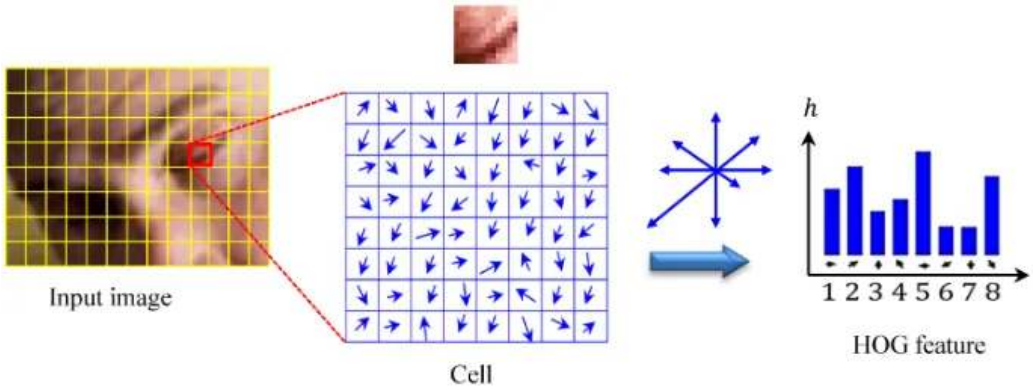

Figure 5.2: HOG Method: A local image patch is divided into cells, gradient orientations are accumulated into a histogram, and the resulting descriptor summarizes local shape while reducing sensitivity to illumination. Source: Figure 5 of Bakheet and Al-Hamadi (2021), licensed under CC BY 4.0.

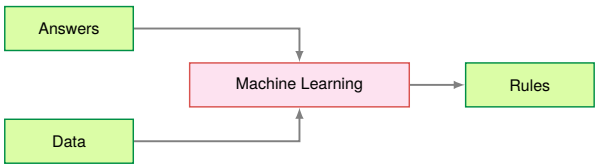
draws eight directions; the bin count, like the cell size, is a tuning choice), and produces a 441-element feature vector. A linear support vector machine (SVM) classifier then performs ten dot products over that vector. The result is roughly 8,000 operations and about 2 KB of working memory, about 80× the work of the toy rule-based baseline, but still structured and well served by CPU vector units using **single instruction, multiple data (SIMD)**. Descriptor size, class count, and implementation all change this cost.

These descriptors carried face and pedestrian detection through the 2000s, but every new problem needed an expert to design a new extractor, and the resulting features missed whatever patterns their designers had not anticipated. Human expertise, not computation, set the ceiling on how much real-world visual variation a system could absorb.

5.2.2 Automatic pattern discovery

Neural networks remove that ceiling by discovering their own features, learning representations directly from raw data instead of following explicit rules or human-designed extractors. Supervised learning inverts the traditional programming relationship. Engineers provide examples and target answers, and optimization produces the decision rules as output rather than taking them as input (figure 5.3). Humans still shape the task through data, objectives, architectures, and evaluation.



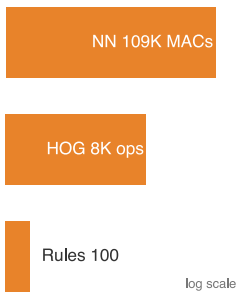


Figure 5.3: Data-Driven Rule Discovery: The flow diagram inverts the traditional programming pattern: data and answers serve as inputs to the machine learning process, which produces a learned decision function as output. This shift replaces a hand-coded decision policy while leaving engineers responsible for the data, objective, architecture, and evaluation.

The same digit, processed by the chapter's three-layer network (784 → 128 → 64 → 10), costs 109,184 MACs, 1,100× the work of the toy rule-based baseline. The 109,386 parameters occupy 438 KB in FP32, more than most L1 caches hold, so even inference creates traffic between cache levels. Training multiplies the cost further. Each image is processed forward and backward before an update, at two to three forward passes of dense-layer arithmetic, repeated over 60,000 images for multiple epochs (full passes over the training set). Dense matrix multiplications now dominate the arithmetic and favor parallel hardware, shifting the engineering challenge from control-flow branching to memory bandwidth, data reuse, and hardware parallelism.

This trade is the bitter lesson at the scale of a single layer. HOG encodes an expert's knowledge of edges and orientations in 8,000 operations that never change; the learned first layer spends far

In this MNIST comparison, learned features spend far more arithmetic.

more arithmetic and lets the data decide which pixel combinations matter. As computation became cheap enough, the general method that converts arithmetic into accuracy overtook the hand-built one. That victory demands the arithmetic, memory traffic, and training infrastructure that the rest of this chapter quantifies.

↩ Why general methods that scale with computation keep overtaking methods built on human knowledge, the bitter lesson, is established in section 1.4.

The escalation matters less for its 1,100× operation count than for what each step does to the binding resource, which moves from branch-heavy CPU control, to batch-oriented feature pipelines, to memory-fed matrix parallelism (table 5.2). Dense matrix work meets the memory wall, the widening gap between compute throughput and off-chip memory bandwidth, whenever an operation performs too little arithmetic per byte it moves. That ratio is the arithmetic intensity introduced alongside the iron law; the forward-pass analysis later in this chapter measures it for the running network, and section 11.6 develops it into a full performance bound.

↩ The memory wall and the physical reasons that off-chip bandwidth lags arithmetic are established in section 2.2.

↪ The AI memory wall, the point at which added FLOP/s stops reducing runtime because data movement dominates, is developed in section 11.5.1.

Table 5.2: System Resource Tendencies: The illustrated implementations shift from control-oriented rules to structured feature pipelines and then to matrix-heavy neural computation. These are workload tendencies rather than requirements of every program in each paradigm.

System Aspect	Traditional Programming	ML with Features	Deep Learning
Computation	Often control-flow oriented	Structured parallel ops	Often matrix-parallel
Memory Access	Workload dependent	Commonly batch-oriented	Large tensor working sets
Data Movement	Program and input dependent	Feature-pipeline movement	Parameter and activation movement
Hardware Needs	Commonly CPU-centric	Often CPU with vector units	Frequently accelerator-friendly
Resource Scaling	Input and program dependent	Descriptor and data driven	Driven by width, batch, state, and reuse

Scale therefore has costs as well as gains. Larger models and training budgets turn arithmetic throughput, memory bandwidth, storage capacity, and communication into potential bottlenecks, and model size is not a decision rule. Choosing a model requires comparing candidates on representative deployment data and on the complete cost of training, serving, monitoring, and maintenance, with the uncertainty in both gains and costs included. The useful question is whether the measured gain from additional scale earns those system costs.

↪ How model size, training data, and compute trade off along a compute-optimal frontier is developed in section 9.2.3.

Systems Perspective 5.1: When to use neural networks

Not every problem benefits from deep learning. Section 3.5 established that a problem definition must require a learned system to improve on an existing baseline by more than its added cost. Table 5.3 lists the conditions under which a neural network tends to win that comparison, and table 5.4 the conditions under which a classical method tends to match it with less training, serving, and maintenance effort.

Table 5.3: Neural-Network Candidates: Conditions under which deep learning is likely to outperform classical methods.

Condition	Evidence to seek	Rationale
Representative data	Training and validation cover deployment conditions	Capacity cannot replace missing coverage
Exploitable structure	Spatial, sequential, or hierarchical patterns	Architecture can encode a useful prior
Baseline gap	Simpler methods miss the required task-quality target	Complexity buys a measured gain
Operational fit	Gain survives latency, memory, and cost limits	Offline accuracy alone is insufficient
Maintenance advantage	Learned features reduce recurring manual updates	Full-system maintenance becomes simpler

Table 5.4: Classical-Method Candidates: Conditions under which simpler models are likely to match or beat a neural network.

Condition	Baseline to test	Reason to prefer it
Limited labeled data	Linear model or tree ensemble	Lower variance and easier validation
Structured tabular inputs	Gradient boosting or linear model	Strong accuracy without learned features
Approximately linear signal	Linear or additive model	Transparent and inexpensive execution
Hard resource bound	Rules or compact classical model	Predictable latency, memory use, and energy demand
Direct auditability needed	Constrained tree or linear model	Decisions are easier to inspect

Systems insight: Establish a simple baseline before building a neural network, and retain the neural approach only when its measured benefit justifies the added system. The document-recognition history in section 5.6 shows why the comparison must include preprocessing, rejection policy, and the cost of human review rather than model accuracy alone.

5.2.3 Why backpropagation waited for systems

Every increase in a neural network's size multiplies its forward operations, saved activations, gradient computations, and parameter updates, which is why backpropagation waited decades for hardware and data to catch up with the algorithm. Paul Werbos applied backpropagation[3] to neural networks in 1974 (Werbos 1974), building on Seppo Linnainmaa's 1970 work on automatic differentiation (Linnainmaa 1970), and Rumelhart, Hinton, and Williams showed in 1986 that hidden units could learn useful internal features (Rumelhart et al. 1986). That demonstration did not resolve the systems cost exposed by the digit classifier: the decades between early backpropagation work and widespread adoption required the maturation of parallel hardware, large datasets, weight initialization, non-saturating nonlinearities, and software frameworks. An algorithm can be viable in principle long before its surrounding system makes it useful in practice. The lesson does not run in reverse: a computationally expensive idea is not vindicated by expense alone, and it must be evaluated together with the data, software, hardware, and task regime that would make it useful.

[3] **Backpropagation**: Short for "backward propagation of errors," the algorithm uses the chain rule to compute how the loss is locally sensitive to millions of weights in one backward traversal. Its systems cost is memory rather than arithmetic, because the backward pass needs the forward-pass activations, which training must store alongside gradients and optimizer state, the several-times-larger footprint quantified in section 5.4.5.5.

↩ How AlexNet, GPUs, and ImageNet ended the feature-engineering era, and why infrastructure became the next bottleneck, is established in section 1.3.3.

Checkpoint 5.1: Understanding deep learning's emergence

Before turning to the primitives that set these costs, verify your understanding of why deep learning emerged when it did:

- ☐ **Adoption lag**: can you explain why backpropagation existed for more than a decade before it was widely used, naming the systems costs that grow with model size?
- ☐ **The cost of feature learning**: can you explain, using the digit-classification operation counts, why replacing hand-engineered features with learned ones raises the arithmetic and memory demand?
- ☐ **Bottleneck shift**: can you use table 5.2 to explain how the binding resource moves from control flow toward data movement as representation moves from rules to learned features?
- ☐ **Baseline first**: can you name two conditions under which a classical baseline should be tried before a neural network, and the evidence that would justify switching?

If any of these concepts remain unclear, review the relevant sections before continuing.

The digit classifier's cost and the adoption lag lead to the same conclusion. What a network costs the machine is fixed by the primitives it is built from, and those primitives are the subject of the rest of this chapter.

5.3 Neural Network Fundamentals

Each of the 109,184 MACs that classify a single digit belongs to some neuron combining its inputs. Individually those operations are trivial. At network scale, a processor spends more time waiting for operands than computing whenever its memory system cannot supply them fast enough, and an accelerator such as a graphics processing unit (GPU) outruns a CPU on suitable neural workloads because it devotes silicon to wide arithmetic arrays and high-bandwidth memory rather than to branch prediction. The structure of the network primitives determines how data flows through that hardware and how memory demands scale during training and inference.

Those primitives (weighted sums, nonlinear activations, and gradient-based learning) anchor the feed-forward networks of this chapter and recur inside the larger architectures that later chapters introduce, which add operators and execution patterns this simple model does not contain. Parallelism and the memory wall, the pressures traced through the paradigm comparison, follow from that structure. Many simple units operate simultaneously on shared inputs, weights change during training, and layers compose low-level features into high-level ones. That structure begins with the artificial neuron.[4] Understanding it plays the role for a neural network that understanding a single transistor plays for a processor.

[4] **Neuron**: McCulloch and Pitts (1943) introduced a mathematical threshold model of nervous activity: inputs combine and an all-or-none output fires when a threshold is met. That logical neuron is an origin point for the artificial-neuron abstraction and for networks built from many simple units. Learned weights, deep hierarchies, and modern fused multiply-add (FMA) accelerator datapaths are later developments that turn this abstraction into the matrix-heavy workloads studied in this chapter.

5.3.1 One neuron

To test whether a 28×28 image contains a particular stroke, a single computing unit must weigh all 784 pixel intensities, sum the evidence, and decide how strongly to fire. That basic unit of neural computation, the **artificial neuron** (or node), began as a simplified mathematical model of nervous activity (McCulloch and Pitts 1943) before digital implementations turned it into a standard arithmetic primitive. Figure 5.4 sets the biological cell and its mathematical counterpart side by side. The left panel draws a biological cell, with branching dendrites that receive signals, a cell body that holds the nucleus, and an axon that carries the output away. The right panel draws the mathematical model, in which the inputs x_1, x_2, and onward, plus a constant input of one that carries the bias, flow along weighted edges into a node that first forms a linear sum z and then applies an activation function f to emit the output y. The column of labels between the panels pairs each biological structure with its arithmetic counterpart: dendrites with inputs, synapses with weights, the soma (cell body) with the linear sum, and axon firing with the activation.

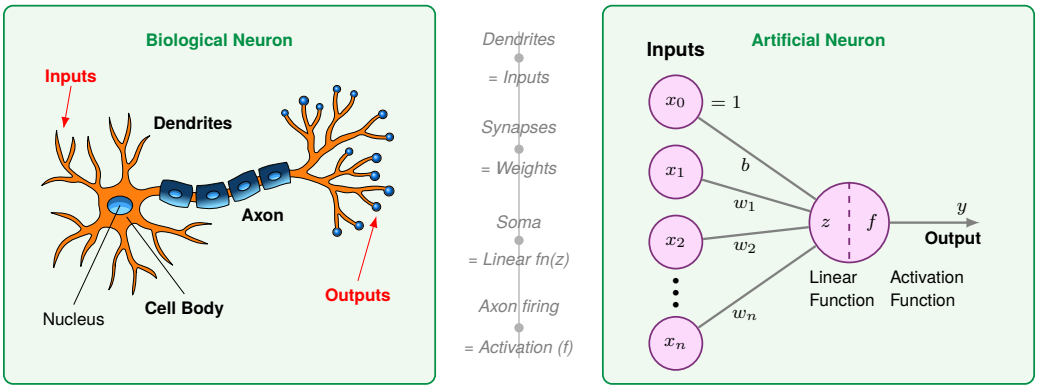

Figure 5.4: Biological-to-Artificial Neuron Mapping: Each biological structure on the left has an arithmetic counterpart on the right. Read the mapping as an abstraction rather than a resemblance claim, since it keeps only what reduces to arithmetic and discards the electrochemistry that produced the behavior.

Read from left to right, the right panel of figure 5.4 carries one signal through four stages, and each stage takes its name from one label pair in the column between the panels:

1. **Input Reception** (Dendrites $\rightarrow x_1, x_2, \ldots, x_n$): The column of circles on the left of the panel is the vector of input features **x** that the artificial neuron receives. In MNIST digit recognition, these represent pixel intensities. The dendrite analogy captures reception of many signals without claiming biological equivalence.

2. **Weighted Modulation** (Synapses $\rightarrow w_1, w_2, \ldots, w_n$): Each input is multiplied by a learnable weight w_i, just as synaptic strengths modulate biological signals. These weights act as "gain" controls, determining how much influence each feature has on the final decision. A bias term b (shown as the top input $x_0 = 1$ in figure 5.4) shifts the activation threshold. Across a network, learned behavior is distributed over many such parameters rather than stored in one weight.
3. **Signal Aggregation** (Cell Body $\rightarrow$ Linear Function z): The left half of the split node, labeled z, integrates the weighted signals, producing a single scalar value $z = \sum(x_i \cdot w_i) + b$. This mirrors how a biological cell body sums incoming electrochemical signals to determine whether the neuron has received enough evidence for a particular pattern.
4. **Nonlinear Activation** (Axon $\rightarrow$ Activation Function f): In the right half of the node, labeled f, the aggregated signal passes through an activation function $f(z)$ and leaves along the output arrow, producing the activation output $a = f(z)$ (often denoted y). This mirrors the axon's all-or-nothing firing decision, since the nonlinearity determines whether the neuron "fires" a signal to the next layer. Unlike the biological case, f can produce graded outputs (ReLU, for example, passes positive values through and zeroes negatives), but the principle of thresholding followed by propagation is the same.

For the machine, one neuron costs d_{in} MAC[5] operations. A direct scalar evaluation loads d_{in} inputs, d_{in} weights, and a bias before writing one output, so without reuse it moves about two values per MAC. Batched and tiled kernels reuse inputs and weights across many neuron evaluations and cut that traffic per MAC, which is why performance at network scale depends on how well the implementation reuses data as much as on how many operations it performs. Once neurons are composed into a network, three constraints appear that a single unit hides. Inside any one layer, neurons can evaluate in parallel, yet moving their parameters and activations across memory often limits throughput before arithmetic capacity runs out; across layers, layer $\ell + 1$ cannot start until layer ℓ finishes, placing a sequential floor under end-to-end latency. Numerical precision cuts across both limits, because narrower formats move fewer bytes and run on denser arithmetic units, provided task quality survives the search for minimum viable precision that chapter 10 develops. The perceptron formalization in section 5.3.2.1 turns the four stages into the equations that this accounting counts.

[5] **MAC (multiply-accumulate)**: Hardware data sheets report fused multiply-add throughput in FLOP/s, so a quoted FLOP/s rate is twice the corresponding MAC/s rate. Layer and batch choices also create activation, communication, and data-movement costs, so MAC count is necessary but not sufficient for a systems budget.

5.3.2 From neurons to layers

Composing neurons into a network turns one neuron's cost into a network's, and each architectural choice, from how neurons connect to how layers are organized, fixes a computational pattern that hardware must then execute. The running network of Example 5.1 is built from exactly these choices, and the subsections below derive its parameter and operation counts one decision at a time, starting with the weighted sum inside each unit.

5.3.2.1 The perceptron's weighted sum

The computational machinery within each dense layer is the **perceptron**,[6] which Rosenblatt introduced as a learning form of the artificial neuron (Rosenblatt 1958). Its signal path (inputs, weights, bias, aggregation, activation) is the one section 5.3.1 traced through its biological origins. What remains is to formalize that path mathematically, because this repeated operation becomes the layer-level kernel that hardware executes. In the MNIST network, a first-layer unit combines all 784 pixel intensities into one activation that may respond to a learned pattern, such as a vertical edge shared by "one" and "seven." Inside one unit (figure 5.5), input features x_i travel along weighted channels w_{ij} and accumulate into a scalar sum with bias b_j, and the resulting linear score z_j passes through an activation f to produce output $\hat{y}$. Different neurons repeat the same structure with different learned weights, allowing one layer to test many patterns against the same input.

Each input x_i has a corresponding weight w_{ij}, and the perceptron multiplies each input by its matching weight. The intermediate output, z_j, is computed as the weighted sum of inputs in equation 5.1:

$$z_j = \sum_i (x_i \cdot w_{ij}) \tag{5.1}$$

[6] **Perceptron**: A machine built to execute a learning algorithm, directly linking hardware and software from the start. A single linear-threshold layer cannot represent nonlinearly separable functions such as XOR, regardless of additional input hardware (Minsky and Papert 1969). Multilayer nonlinear networks expand the representable function class, but they also introduce the training and systems costs developed in this chapter.

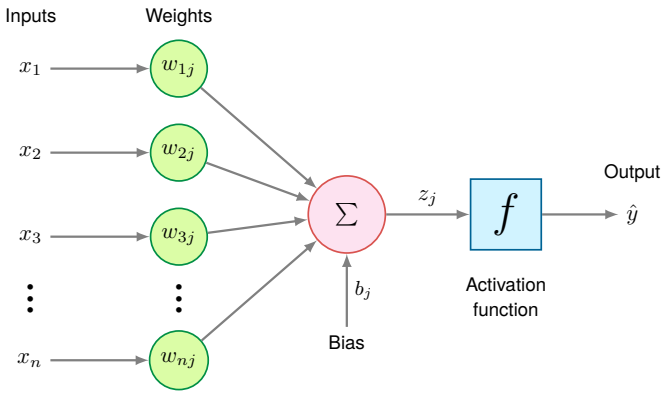

Figure 5.5: Perceptron Architecture: Inputs enter on the left, each scaled by its own weight, and the weighted products plus a bias meet at the summation node before a single activation function produces the output. The multiplies and the accumulation along this path are the per-neuron unit of work that the chapter's layer-cost calculations multiply out.

Here, j identifies the receiving neuron once perceptrons are assembled into a layer, and the sum runs over all input indices i. In plain terms, each input feature is scaled by how important it is (its weight), and the results are summed into a single score. This is the **dot product** of two vectors.

A bias term b_j shifts the linear output up or down, giving the model additional flexibility to fit the data. Thus, the intermediate linear combination computed by the perceptron including the bias becomes equation 5.2:

$$z_j = \sum_i (x_i \cdot w_{ij}) + b_j \tag{5.2}$$

With this weighted sum in hand, a suitable output activation and loss can support regression or classification. A binary linear-threshold classifier selects one of two classes around a threshold; multiclass networks instead produce several scores and commonly normalize them into probabilities with softmax, an output function developed with the other activation functions below.

The formalization turns the neuron's cost into a layer's. A dense layer of d_{out} neurons repeats the weighted sum d_{out} times, so its arithmetic cost is $d_{\text{in}} \times d_{\text{out}}$ MACs, exactly the matrix multiplication $\mathbf{xW}$ that hardware must execute, and the form in which the rest of this chapter counts work. The dot product is the operation that accelerators are built to execute at maximum throughput, which is why neural network performance is quoted in MACs or FLOPs completed per second; how those machines are organized around it is developed in section 11.3.2.1. A weighted sum alone, however, can only draw straight boundaries, and the activation applied to it decides what the layer can represent.

5.3.2.2 Nonlinear activation functions

Without a nonlinearity between layers, a stack of linear weight matrices collapses algebraically into a single linear transformation and can only draw straight decision boundaries, no matter how many intermediate matrices the machine evaluates. **Activation functions** break that collapse by converting each neuron's linear weighted sum into a nonlinear output, making them the point where expressiveness, gradient flow, and hardware cost meet. Applying an activation f to the weighted sum of equation 5.2 yields the generic artificial-neuron computation in equation 5.3:

$$\hat{y}_j = f(z_j) = f\left(\sum_i (x_i \cdot w_{ij}) + b_j\right) \tag{5.3}$$

In figure 5.6, a network without activation functions is constrained to a straight decision boundary (left panel) that misclassifies overlapping point clusters, whereas nonlinear activations allow curved boundaries (right panel) that separate the two classes cleanly. The plot illustrates representational capacity rather than an optimization guarantee; training dynamics and sample coverage still govern whether optimization finds that boundary.

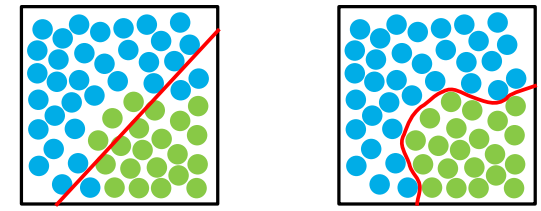

Figure 5.6: Linear vs. Nonlinear Decision Boundaries: Two scatter plots compare the decision boundary a network draws on the same points with and without an activation function.

XOR is the classic function that no single weighted sum can compute, and its four input pairs show why a hidden nonlinear layer changes what a network can represent.

Example 5.2: Building intuition: The XOR problem

Consider a network learning the XOR function, a classic problem that requires nonlinearity. With inputs x_1 and x_2 that can be 0 or 1, XOR outputs 1 when inputs differ and 0 when they are the same.

Setup: Two inputs $\rightarrow$ two hidden neurons $\rightarrow$ one output

Example: With hidden units $h_1 = \text{ReLU}(x_1 + x_2)$ and $h_2 = \text{ReLU}(x_1 + x_2 - 1)$, the output $y = h_1 - 2h_2$ gives 0, 1, 1, 0 for inputs $(0,0)$, $(0,1)$, $(1,0)$, $(1,1)$. The input $(1,1)$ drives both hidden units, and the second one cancels the first. No single weighted sum of x_1 and x_2 can produce that pattern.

Systems insight: Hidden layers do not merely add capacity; they change the class of functions the system can represent. XOR, which no single-layer perceptron can compute (Minsky and Papert 1969), is the small example that makes depth a structural requirement rather than a decorative design choice.

The XOR network is the smallest case of a general result. The **universal approximation theorem**[7] establishes that sufficiently wide networks with suitable activation functions can approximate broad classes of functions arbitrarily well. The theorem, however, states a pure existence result under the assumption of unlimited width; it says nothing about the accelerator executing the computation. ML systems impose hard limits on both dimensions of the width-vs.-depth trade-off. A single hidden layer wide enough to approximate a complex function requires parameter storage and activation memory that can exhaust the accelerator's device memory (VRAM) entirely, and a network too deep to fit its activations in memory stalls the backward pass on the same constraint. The engineering problem is therefore not whether a network of sufficient width or depth exists, but whether it fits within the memory and bandwidth envelope of the target hardware.

Comparing activation functions requires one idea from training, which section 5.4 develops fully. Training adjusts each weight by its *gradient*, a number measuring how much the prediction error would change if that weight moved slightly. That signal travels backward through the network, a pass called *backpropagation*, and is multiplied at each layer by the activation's slope, so an activation whose slope is near zero passes almost no learning signal to the layers before it.

The choice of activation function therefore affects both learning and computational efficiency. ReLU[8] ($\max(0, z)$) became a common hidden-layer activation for feed-forward networks because it is inexpensive, has local derivative one for positive inputs, and can produce sparse activations (Nair and Hinton 2010; Glorot et al. 2011). Earlier differentiable deep networks often used sigmoid or tanh. Their smooth S-curves saturate, a failure the sigmoid discussion below develops. That contrast is not a simple ranking: sigmoid remains appropriate for some binary outputs, tanh remains useful when bounded zero-centered activations are desired, and modern architectures use additional activation families. The relevant design question is which function supplies the required output semantics and gradient behavior at an acceptable execution cost. Figure 5.7 charts the response curves and output

7 **Universal approximation theorem**: Under conditions on the activation, target function, compact domain, and approximation tolerance, a sufficiently wide single-hidden-layer network can approximate the target arbitrarily well (Cybenko 1989; Hornik et al. 1989). This existence result is nonconstructive: it does not specify how to find the weights or how many neurons practical training will require. Why depth can nonetheless beat width is the subject of section 5.3.5.

8 **ReLU (rectified linear unit)**: ReLU's cheap comparison-and-select evaluation and its non-saturating positive branch made deep networks markedly faster to train; in the AlexNet paper, a four-layer convolutional network reached 25 percent training error on CIFAR-10 six times sooner with ReLU than with tanh (Krizhevsky et al. 2012).

ranges of three standard element-wise nonlinearities alongside the vector-level softmax function, contrasting their saturation regimes.

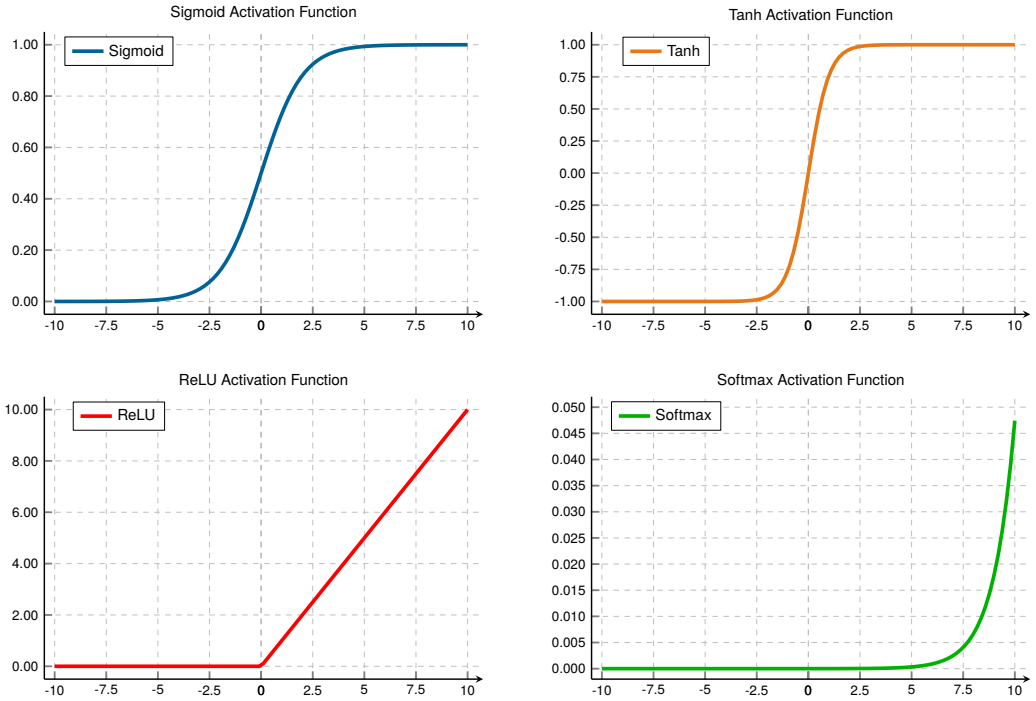

Figure 5.7: Common Activation Functions: Four panels plot nonlinear activation functions with their output ranges. Sigmoid maps inputs to $(0, 1)$ with smooth gradients, tanh provides zero-centered outputs in $(-1, 1)$, and ReLU outputs zero for negative inputs. Softmax (bottom-right) shows one component of a 3-element vector while the other two logits are fixed at 13 and 0. Its magnified y-axis (roughly 0 to 0.05) is not comparable to the other panels, and it shows only one component of a vector whose outputs are interdependent and sum to 1.

Sigmoid The logistic sigmoid function[9] squashes continuous inputs onto the open interval $(0, 1)$ (equation 5.4):

$$\sigma(z) = \frac{1}{1 + e^{-z}} \tag{5.4}$$

The S-shaped curve maps logits, the raw unnormalized scores a layer produces, to $(0, 1)$, so sigmoid can parameterize a binary probability. It approaches one for large positive inputs and zero for large negative inputs. Sigmoid is smooth and differentiable everywhere. Gradient-based learning does not require that smoothness; ReLU, introduced below, has a corner at zero, and implementations simply assign it a slope there.

Sigmoid's main limitation is saturation. For inputs with large absolute values (far from zero), its gradient becomes extremely small, a phenomenon called the **vanishing gradient problem** (Bengio et al. 1994). Even at its peak, sigmoid's derivative is only 0.25, so each sigmoid layer can shrink the activation-derivative part of the gradient by at least a factor of four. During backpropagation these small activation derivatives multiply with weight-dependent factors across layers, the compounding that the chapter's opening footnote evaluated over 20 layers. Repeated saturation can make early-layer gradients and weight updates negligibly small, preventing useful learning along those paths.

Tanh The hyperbolic tangent[10] centers output activations around zero over the interval $(-1, 1)$ (equation 5.5):

$$\tanh(z) = \frac{e^{z} - e^{-z}}{e^{z} + e^{-z}} \tag{5.5}$$

Tanh produces an S-shaped curve similar to sigmoid but centered at zero: negative inputs map to negative outputs and positive inputs to positive outputs, a symmetry that balances gradient flow

[9] **Sigmoid**: From Greek *sigma* + *eidos* ("sigma-shaped"), referring to the S-curve that maps inputs to the bounded (0, 1) range. The mapping requires an exponential approximation, commonly implemented through specialized instructions, lookup tables, or polynomial methods. It is generally more expensive than ReLU's comparison-and-selection operation, although the measured gap depends on precision, vectorization, and hardware. ReLU's adoption reflected both easier gradient flow on its positive branch and cheaper execution.

[10] **Tanh (hyperbolic tangent)**: By centering its output range on zero, `tanh` can reduce the correlated-update behavior associated with all-positive activations. Its computational cost is similar to sigmoid because it also depends on exponential approximations, while its saturation behavior still permits vanishing gradients.

during training and often yields faster convergence than sigmoid. Like sigmoid, tanh is smooth and differentiable everywhere, and it saturates near -1 and 1, so it shares the vanishing gradient problem for inputs with large magnitudes; even so, its zero-centered outputs make it preferable to sigmoid in recurrent neural networks, which reapply the same layer at every step of a sequence and must keep activations balanced across time steps. Both S-curves therefore carry two costs, saturation during training and an exponential evaluation in hardware, whereas ReLU removes saturation for positive inputs and replaces the exponential with a comparison.

ReLU ReLU sets negative values to zero while maintaining linear identity for positive inputs (equation 5.6):

$$\text{ReLU}(z) = \max(0, z) = \begin{cases} z & \text{if } z > 0 \\ 0 & \text{if } z \leq 0 \end{cases} \tag{5.6}$$

ReLU's characteristic shape, a straight line for positive inputs and zero for negative inputs, provides three advantages. First, its local derivative is one for positive inputs, avoiding activation saturation on that branch; the complete network gradient can still shrink or grow through weights and other operations. Second, ReLU introduces deterministic activation sparsity by setting negative values to zero. Third, ReLU uses a comparison and selection, `output = (input > 0) ? input : 0`, rather than an exponential approximation. These are local properties of the operator, while end-to-end performance depends on how it is fused with neighboring work.

ReLU is not without drawbacks. The **dying ReLU problem** occurs when neurons become stuck in the inactive state, permanently outputting zero and ceasing to learn. If a neuron's weights evolve during training such that the preactivation $z = \mathbf{x}\mathbf{w} + b$ is consistently negative across all training examples, the neuron outputs zero for every input. Since ReLU's gradient is also zero for negative inputs, no gradient flows back through this neuron during backpropagation. The weights cannot update, and the neuron remains dead. This can happen when the learning rate, the step size that scales each weight update, is large enough to push weights into unfavorable regions. Careful initialization (He et al. 2015), moderate learning rates, leaky ReLU variants, and normalization layers[11] help mitigate dying ReLUs by keeping preactivation distributions well scaled.

Softmax Unlike *element-wise* activation functions that operate independently on each value, softmax[12] is a *vector-level* function that considers all values together to produce a probability distribution. In simple classifiers, softmax is commonly used in the output layer rather than as an element-wise hidden activation; it also normalizes learned importance-score vectors in attention architectures. The softmax function is defined in equation 5.7:

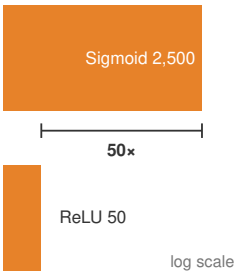
$$\text{softmax}(z_i) = \frac{e^{z_i}}{\sum_{j=1}^{K} e^{z_j}} \tag{5.7}$$

For a vector of K values (often called logits[13]), softmax transforms arbitrary real-valued scores into K normalized predicted probabilities that sum to 1, although those values are not necessarily calibrated confidence estimates. As plotted in the bottom-right panel of figure 5.7, individual softmax components grow exponentially across logit values while the denominator couples all vector elements so that the class with the largest logit receives the highest probability. Because this mapping from logits to probabilities is differentiable, gradients flow cleanly back through softmax during training, and combining softmax with cross-entropy loss (section 5.4.3) yields simple gradient expressions that guide learning effectively.

Activation choice also carries a silicon cost, a **transistor tax** paid in circuit complexity, area, and switching energy; a ReLU datapath needs only a sign-bit comparator and a multiplexer, roughly 50 transistor equivalents, whereas an exponential approximation for sigmoid or tanh is modeled here as a stylized budget of 2,500 transistor equivalents, 50× the comparator, an order-of-magnitude teaching ratio rather than a constant across manufacturing nodes. Logic area is only half the cost, because an element-wise activation run as its own kernel is limited by memory traffic rather than arithmetic, a gap the forward-pass analysis later quantifies, so compilers fuse it into the preceding matrix multiplication, and ReLU's backward pass needs only one bit per unit recording whether the unit was active. A dead ReLU unit still occupies weight memory and still costs MACs on every inference while contributing nothing to the output, and ReLU's zeros save no work in a dense kernel

11 **Batch normalization**: Normalization layers (Ioffe and Szegedy 2015) stabilize intermediate activations across training batches, permitting higher learning rates and reducing the risk of dying ReLUs. Section 6.4.2 examines the trade-offs among normalization variants, and section 10.4.1 shows how batch normalization folds into adjacent weights for inference.

12 **Softmax**: The name, coined by Bridle (1990), reflects its role as a "soft" or differentiable version of `argmax`, a function that must evaluate an entire vector to find its maximum value. This vector-wise operation is not used as a drop-in replacement for element-wise nonlinearities such as ReLU, but it is central whenever a model must normalize a vector of scores, including classification heads and attention layers. Direct exponentiation can overflow in 32-bit floating point, so stable implementations subtract the largest logit first (section 5.4.3.3).



13 **Logits**: In multiclass neural classifiers, logits are unnormalized output scores. Score differences correspond to log probability ratios after softmax, while an individual multiclass logit is not itself a calibrated log-odds quantity. Because `argmax` over logits and `argmax` over softmax probabilities select the same class, inference can skip softmax when only the top class is needed.

unless sparse hardware or routines exploit them. One neuron is now complete, and the next question is how many of them run side by side.

5.3.2.3 Layers and connections

Neurons run side by side in layers, collections of units that execute in parallel across shared inputs, and the power of neural networks comes from that organization rather than from any single unit. An input layer ingests raw feature tensors; one or more hidden layers transform those representations through successive matrix multiplications and nonlinear activations; and an output layer emits task-specific predictions or decision logits.

In the feedforward schematic of figure 5.8, the task fixes only the two ends. The input layer's width matches the four input features and the output layer's width matches the two predictions. The hidden layers between them can widen and narrow freely, which is why hidden width is a design decision rather than a property of the data. Each hidden layer applies a parameterized linear transformation followed by an element-wise nonlinearity, progressively constructing higher-level abstractions from raw input signals.

Sigmoid's exponential datapath dwarfs ReLU in transistor-equivalents (illustrative).

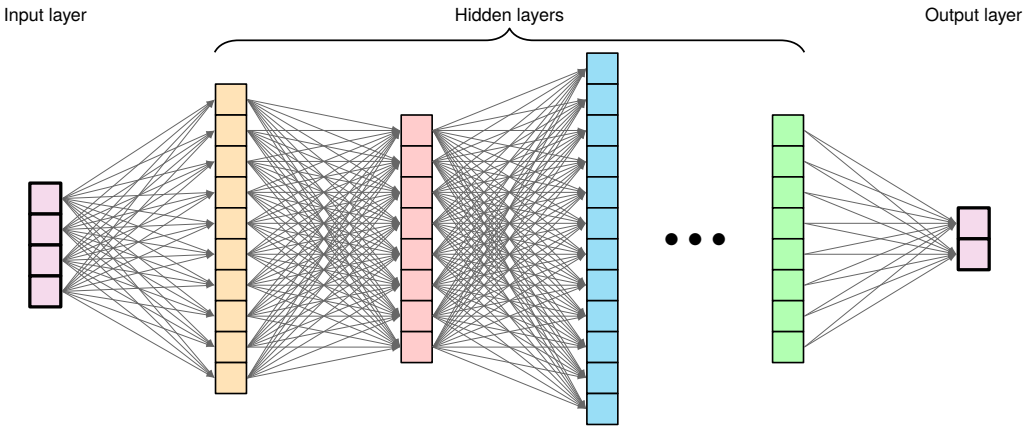


Figure 5.8: Layered Network Architecture: Deep neural networks transform data through successive layers, enabling the extraction of increasingly complex features and patterns. Each layer applies nonlinear transformations to the outputs of the previous layer, ultimately mapping raw inputs to desired outputs.

As data flows through the network, it is transformed at each layer to extract meaningful patterns. Each layer applies the neuron's weighted sum and activation in parallel across all its neurons, and its outputs become the next layer's inputs. Simple features detected in early layers combine into increasingly complex patterns in deeper layers.

On the machine, a layer is one matrix multiplication over all of its neurons at once, and the boundary between layers is where data moves and waits. Each layer writes its output as an activation tensor that the next layer must read, inference can discard that tensor once the next layer has consumed it, and training must keep it until the backward pass. The next layer cannot start until that tensor exists, which is the source of the latency floor that no amount of parallel hardware inside a layer removes. Figure 5.9 traces that translation in three steps. One neuron is a dot product of d_{in} MACs; stacking a layer's neurons and a batch of B examples (inputs processed together in one pass) turns those dot products into one matrix multiply of $B \cdot n_{\ell-1} \cdot n_{\ell}$ MACs (for the first MNIST layer at batch 32, $(32{\times}784) \cdot (784{\times}128)$); and the hardware executes that multiply by holding a tile of weights in an array of multiply-accumulate units while rows of inputs stream past, so each weight fetched from memory serves every example in the batch. What each of those multiplications reads besides the activations is the layer's parameters.

5.3.3 Parameters

Each of those multiplications reads the layer's learnable parameters,[14] its weights and biases, alongside the incoming activations. The parameters decide which transformation a layer applies, and their organization fixes both what the network can learn and how many bytes every pass must move.

[14] **Parameter memory cost**: Parameter count is a misleading proxy for memory importance. The normalization layers that section 6.4.2 introduces, for example, add a few learned scale and shift parameters per layer that barely affect byte budgets but can strongly affect model behavior when training choices change. Conversely, the bulk of parameters in dense weight matrices require extra state during training: gradients plus optimizer bookkeeping beyond the stored weights themselves. A model that fits in memory for inference may therefore require several times more memory for training, a cost quantified later in the training memory budget.

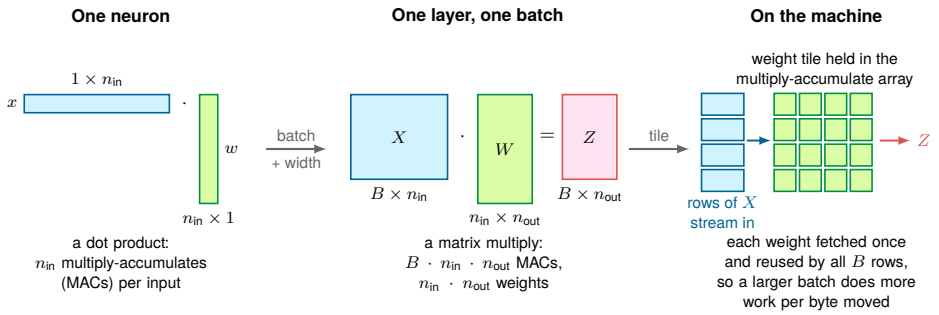

Figure 5.9: From Neuron to Machine: One neuron is a dot product between an input row and a weight column. A layer applied to a batch stacks those dot products into one matrix multiply whose cost is the product of batch size, input width, and output width. On an accelerator, a tile of the weight matrix stays inside an array of multiply-accumulate units while input rows stream through, so the batch, not the neuron, sets how much arithmetic each fetched weight pays for.

5.3.3.1 Weight matrices

In a dense layer with d_{in} input features and d_{out} neurons, the weights form a matrix $\mathbf{W} \in \mathbb{R}^{d_{\text{in}} \times d_{\text{out}}}$ whose column j holds neuron j's weights, so the layer computes all d_{out} preactivations as the single product in equation 5.8:

$$\mathbf{z} = \mathbf{x}\mathbf{W} + \mathbf{b} \tag{5.8}$$

The canonical case studied here connects each neuron in a layer to every neuron in the previous layer, forming a "dense" or "fully connected" layer. This pattern allows each neuron to use all features from the previous layer. Fully connected layers establish the mathematical principles needed here, while alternative connectivity patterns exploit structure in the data and can reduce work or improve statistical efficiency.

Figure 5.10 details this dense interconnect topology on a concrete two-layer network ($3 \to 4 \to 2$ units). Layer counts in this chapter count layers of weights, not layers of units, so this network has two and the MNIST network ($784 \to 128 \to 64 \to 10$) has three. The figure labels every scalar weight w_{ij} and layer bias b_j alongside intermediate node activations. Reading the incoming edges for any single destination neuron isolates one column of the weight matrix, while evaluating all destinations in parallel forms the complete matrix-vector multiplication. The numerical values illustrate parameter placement rather than an active inference pass; the essential systems property is the matrix dimension. For layers of widths (n_0, n_1, n_2), with n_0 the input width, the weight matrices span $\mathbf{W}^{(1)} \in \mathbb{R}^{n_0 \times n_1}$ and $\mathbf{W}^{(2)} \in \mathbb{R}^{n_1 \times n_2}$, requiring $n_0 n_1 + n_1 n_2$ weights before biases.

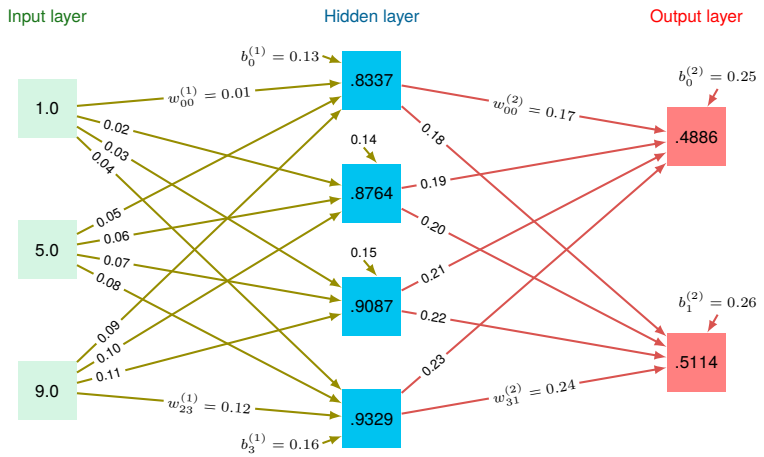

Figure 5.10: Fully Connected Layers: A two-layer network (three layers of units) connects every neuron to all neurons in the preceding layer. Labeled edges and nodes illustrate the organization of weights, biases, and activations; they are not a worked numerical forward pass.

These products account for most of the work in a dense feed-forward network; whether they are compute bound or memory bound depends on their dimensions, batch size, precision, implementation, and target hardware. The layer looks elementary, yet the same dense layer is the feed-forward block inside every transformer layer and the towers of the deep learning recommendation model (DLRM), so the arithmetic counted here is the arithmetic those lighthouses spend. A transformer layer whose feed-forward block widens to four times the model width d holds $8d^2$ feed-forward weights against $4d^2$ in its attention projections (the four square weight matrices that prepare the layer's attention inputs and combine its outputs), so the feed-forward block holds 67 percent of the layer's weights; in the GPT-2 lighthouse, with d = 1,600, that is about 20.5M of each layer's 30.7M weights. Chapter 6 develops both architectures in full.

5.3.3.2 Bias terms

Alongside its column of weights, each neuron in a layer carries one more parameter, a bias term[15]. For a layer with d_{out} neurons, these parameters form a vector $\mathbf{b} \in \mathbb{R}^{d_{\text{out}}}$ added to the weighted sum in equation 5.8: while weights determine the relative importance of inputs, each entry of $\mathbf{b}$ shifts its neuron's activation threshold independently at the cost of one addition per output value. The arithmetic is negligible, but its placement is not: run as a separate step, the bias addition would read the layer's entire output tensor from memory and write it back for one addition per value, so optimized libraries apply it, together with the activation, while each output tile is still on chip at the end of the matrix multiply.

[15] **Bias terms**: Biases add one parameter per neuron, compared with d_{in} weights for a neuron with d_{in} inputs, so they account for $1/(d_{\text{in}}+1)$ of that layer's parameters. Their model-wide share and effect on accuracy depend on layer widths, architecture, and normalization. Some modern architectures omit biases in layers followed by batch normalization because the normalization transform includes a learned shift.

The organization of weights and biases across a feed-forward network follows a systematic pattern. For each parameterized affine layer ℓ, three components define its computation; the weights and biases are learned, while the activation function is usually chosen by the designer:

- A weight matrix $\mathbf{W}^{(\ell)}$
- A bias vector $\mathbf{b}^{(\ell)}$
- An activation function $f^{(\ell)}$

This yields the complete layer computation in equation 5.9:

$$\mathbf{a}^{(\ell)} = f^{(\ell)}(\mathbf{z}^{(\ell)}) = f^{(\ell)}(\mathbf{a}^{(\ell-1)}\mathbf{W}^{(\ell)} + \mathbf{b}^{(\ell)}) \tag{5.9}$$

Here, $\mathbf{a}^{(\ell)}$ (written as $\mathbf{A}^{(\ell)}$ for batches) represents the layer's activation output. The row-vector convention is adopted throughout: each sample is a row, and the weight matrix $\mathbf{W}^{(\ell)} \in \mathbb{R}^{n_{\ell-1} \times n_\ell}$ maps from the previous layer's width to the current layer's width. With equation 5.9, one layer is fully specified, and what remains is choosing the layers themselves: how many, how wide, and how connected.

5.3.4 Choosing a topology

A single layer of neurons cannot even compute XOR (Example 5.2), yet adding or widening hidden layers to gain capacity immediately multiplies the parameters and activations the machine must store and move. Network topology, how neurons organize into layers and connect across them, fixes both what the network can represent and what it costs to run. The chapter's MNIST digit recognizer shows how problem structure fixes the input and output dimensions while leaving the hidden layers as a systems design choice.

5.3.4.1 Feedforward network architecture

Applying the three-layer architecture to MNIST reveals how data characteristics and task requirements constrain network design. The dual-panel layout in figure 5.11 contrasts the conceptual and physical representations of this input mapping: panel (a) sets a 28×28 pixel grayscale image of digit 7 beside the input units and ten class outputs, while panel (b) illustrates the physical flattening of those 784 pixels into a contiguous one-dimensional column vector before feeding the input layer. Fully connected layers assign an independent weight to every coordinate of this 784-element vector, flattening out spatial coordinates and discarding pixel adjacency. Convolutional architectures instead encode spatial locality directly. That choice is an *inductive bias*, a built-in structural assumption about the data (here, that nearby pixels matter together) which restricts the functions a model can learn toward those expected to be useful (Mitchell 1980). The fully connected network makes almost

no such assumption, so it must learn from data the structure that a stronger bias would supply, and that learning requires more parameters.

The two ends of the network are fixed before any architecture search begins: the data format sets the input layer's width, so a 28 by 28 pixel image requires 784 input neurons (one per pixel intensity in the flattened vector), while the task sets the output layer's width, so 10-class digit recognition provisions 10 output neurons (one for each digit 0–9) whose logits a softmax can convert into predicted class probabilities. Between those fixed endpoints, the number of hidden layers and their respective widths remain open engineering choices. Adding layers increases the network's depth so that it can compose more abstract features through successive transformations, whereas widening a layer expands its capacity to represent distinct features at that level of abstraction.

↪ How spatial locality and weight sharing replace the parameter overhead of fully connected layers is developed as a spatial inductive bias in section 6.3.

Widening both hidden layers from 100 to 1000 neurons, comparing a $784 \to 100 \to 100 \to 10$ network with a $784 \to 1000 \to 1000 \to 10$ network, increases parameters from ~89.6K to ~1.8M (~358 KB vs. ~7 MB in FP32). Whether the wider network improves accuracy requires training and evaluation; the storage increase alone already matters for mobile deployment budgets.

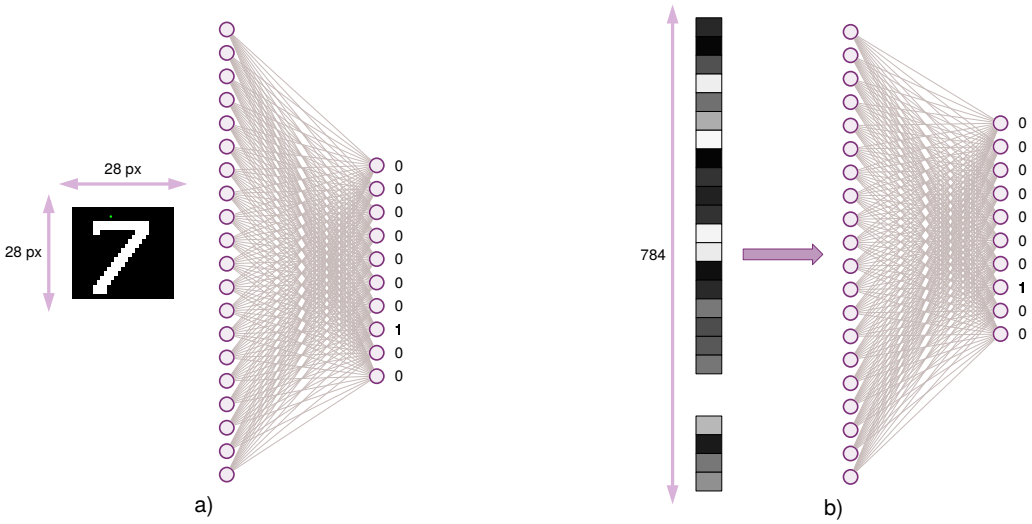

Figure 5.11: MNIST Network Topology: Both panels draw the same network; only the form of the input changes, from a two-dimensional image in panel (a) to the flattened vector the input layer actually receives in panel (b).

5.3.4.2 Layer connectivity design patterns

The fully connected architecture in section 5.3.3 maximizes flexibility by connecting every neuron to every neuron in the next layer, but connectivity itself is an engineering decision. Dense, sparse, and skip patterns trade learning flexibility against parameter count, locality, and gradient flow.

Dense connectivity represents the standard pattern where each neuron connects to every neuron in the subsequent layer. In the MNIST example, connecting the 784-dimensional input layer to a hidden layer of 128 neurons requires 100,352 weight parameters (784×128). This full connectivity enables the layer to learn arbitrary linear combinations of its inputs, which nonlinear activations between layers extend to nonlinear relationships, and it maps directly onto the dense matrix-multiplication kernels that accelerators are built to execute. Because the parameter count grows as the product of adjacent layer widths, however, widening one layer scales parameters linearly while widening both scales them quadratically.

Sparse connectivity cuts that parameter growth by restricting each neuron to a subset of the inputs in the adjacent layer, much as biological neurons connect only to nearby cells; in visual processing tasks like MNIST, neurons might connect only to nearby pixels to reflect the local nature of visual features. Although sparse connections reduce theoretical parameter counts and FLOPs, a sparse weight matrix does not automatically execute faster than a dense one on standard hardware. Unless the hardware supports a regular, structured sparsity pattern that its kernels can predict (developed

in section 11.4.5.3), the arithmetic reduction does not translate into a proportional reduction in execution time.

Whereas sparse connections prune links within a layer, skip connections add direct paths between nonadjacent layers (He et al. 2016a) to keep deeper networks trainable. As networks grow deeper, the longer path from input to output complicates gradient flow; skip connections supplement the standard layer-by-layer progression so that later layers in a digit recognition pipeline can reference both high-level patterns and earlier representations while preserving the backward gradient paths that very deep architectures depend on.

5.3.4.3 Model size and computational complexity

Every connectivity choice ends in a parameter count. How parameters (weights and biases) are arranged determines both learning capacity and computational cost. The parameter count, its numerical precision, and the operations it requires are the concrete terms of the model's side of the silicon contract. Parameter count grows with network width and depth, and table 5.5 lays it out for the running network layer by layer.

Table 5.5: MNIST Parameters and MACs by Layer: Weight, bias, parameter, and per-image multiply-accumulate counts for the 784-128-64-10 network. A dense layer performs one MAC per weight for each input, so the weight and MAC columns match. Layer 1 (Input → Hidden1) dominates both because it multiplies the 784-dimensional input by 128 hidden units; deeper layers shrink rapidly as the representation compresses toward the 10-class output.

Layer	Weights	Biases	Parameters	MACs per Image
Input → Hidden1	$784 \times 128 = 100{,}352$	128	100,480	100,352
Hidden1 → Hidden2	$128 \times 64 = 8{,}192$	64	8,256	8,192
Hidden2 → Output	$64 \times 10 = 640$	10	650	640
Total	109,184	202	**109,386**	**109,184**

The first layer alone holds 100,352 of the 109,184 weights. Because a dense layer performs one multiply-accumulate per weight for each input, the same table also counts the arithmetic per image, and the parameter and MAC columns differ only by the 202 biases. At four bytes per FP32 value, the 109,386 parameters occupy 438 KB. Each must be stored in memory, read on every forward pass, and updated during learning, and the training and inference memory estimates later in this chapter start from this table rather than recounting it.

5.3.5 Why depth matters

A single-layer network attempting to classify handwritten digits must map all 784 raw pixels directly to ten class labels in one step, relearning every stroke pattern separately for each digit. The running network spreads its weights over three layers instead so that deeper layers can exploit **compositionality**, in which complex patterns decompose into simpler patterns that themselves decompose further. In image recognition, learned representations can progress from local edges and textures toward parts and objects; such hierarchical regularities occur in many datasets and motivate layered models, although a trained network need not recover this exact sequence.

Consider recognizing the digit "seven" in the MNIST example. Rather than mapping all 784 pixel values directly to a decision, a deep network can compute the decision more parameter-efficiently by reusing intermediate features:

- **Layer 1** learns simple edge detectors: vertical lines, horizontal lines, diagonal strokes
- **Layer 2** combines edges into shapes: the horizontal top stroke of a "seven," the diagonal downstroke
- **Layer 3** combines shapes into complete digit patterns

Each layer builds on the previous, allowing later computations to reuse earlier features. The same edge detectors learned for "seven" can also contribute to recognizing "one," "four," and other digits. This **parameter reuse** helps explain why depth is an effective design choice without implying a fixed parameter advantage for every task. The choice between adding layers and widening existing ones is not symmetric, however, because depth and width contribute to representational capacity through different mechanisms and cost the machine different things.

Systems Perspective 5.2: The depth vs. width trade-off

For certain function classes, depth provides an exponential representational advantage: a network with N_L layers can represent functions that require exponentially more units in a shallow network (Telgarsky 2016). This restricted theoretical result explains why nonlinear composition can be parameter-efficient; it is not a universal guarantee for every task.

Modern architectures balance depth against width. A network with 10 layers of 100 neurons has the same 1,000 total hidden units as one with 2 layers of 500, but not the same parameter count, function class, or execution graph. Both expose parallelism within each layer; the deeper network adds sequential dependencies and may represent some compositional functions more efficiently.

The cost side of that trade-off follows from counting. For a fully connected network with layer widths running from n_0 (the input) to n_{N_L} (the output), each layer ℓ holds a $n_{\ell-1} \times n_\ell$ weight matrix and n_ℓ biases, and its forward pass performs one MAC per weight for every example. The training pass must also retain each layer's output for every example in a batch of B, so the parameter count P, the forward operations per example O (two FLOPs per MAC), and the retained activation memory $M_{\text{activations}}$ follow equation 5.10:

$$P = \sum_{\ell=1}^{N_L} (n_{\ell-1} + 1)\, n_\ell, \qquad O = 2 \sum_{\ell=1}^{N_L} n_{\ell-1}\, n_\ell, \qquad M_{\text{activations}} \propto B \sum_{\ell=1}^{N_L} n_\ell \tag{5.10}$$

When every hidden layer has the same width d, the sums collapse. Parameters and operations grow as $N_L d^2$, linear in depth and quadratic in width, while retained activations grow as $BN_L d$, linear in both. Figure 5.12 plots the two sweeps on the running network's input and output widths. Holding the network at two hidden layers and doubling their width from 2,048 to 4,096 multiplies MACs per example by 3.4×, short of four only because the input layer's share still grows linearly, while holding the width at 512 and doubling depth from 16 to 32 hidden layers multiplies MACs by 2.0× and retained activations by 1.9×.

Depth and width add capacity on different terms. Depth adds capacity at linear cost in parameters, operations, and activation memory, but every added layer is another step that must finish before the next begins, so depth raises the latency floor of a single example, lengthens the list of activations that training must hold until the backward pass, and lengthens the path a gradient must survive on its way back to the first layer. Width adds capacity at quadratic cost in parameters and operations (activation memory still grows only linearly), yet all of it lands inside one matrix multiplication whose rows and columns can be spread across parallel hardware, so a wider layer keeps an accelerator busy without adding a sequential step. Choosing between them is therefore a choice between paying in serialized steps and memory or paying in arithmetic, and the batch size B, which multiplies only the activation term, decides how heavily the memory side weighs during training.

Checkpoint 5.2: Neural network architecture fundamentals

Before proceeding to training, verify your understanding of the foundational concepts:
Use the MNIST architecture $784 \to 128 \to 64 \to 10$ as the running check.

- ☐ **Neuron equation**: can you write the neuron equation, including weighted sum, bias, and activation function?
- ☐ **ReLU vs. sigmoid**: can you explain why ReLU is computationally cheaper than sigmoid while still providing the nonlinearity a multilayer network needs?
- ☐ **Layers to matrices**: can you map input, hidden, and output layers to the corresponding weight matrices $\mathbf{W}^{(\ell)} \in \mathbb{R}^{n_{\ell-1} \times n_\ell}$?
- ☐ **Parameter count**: can you calculate the total parameter count, including both weights and biases?

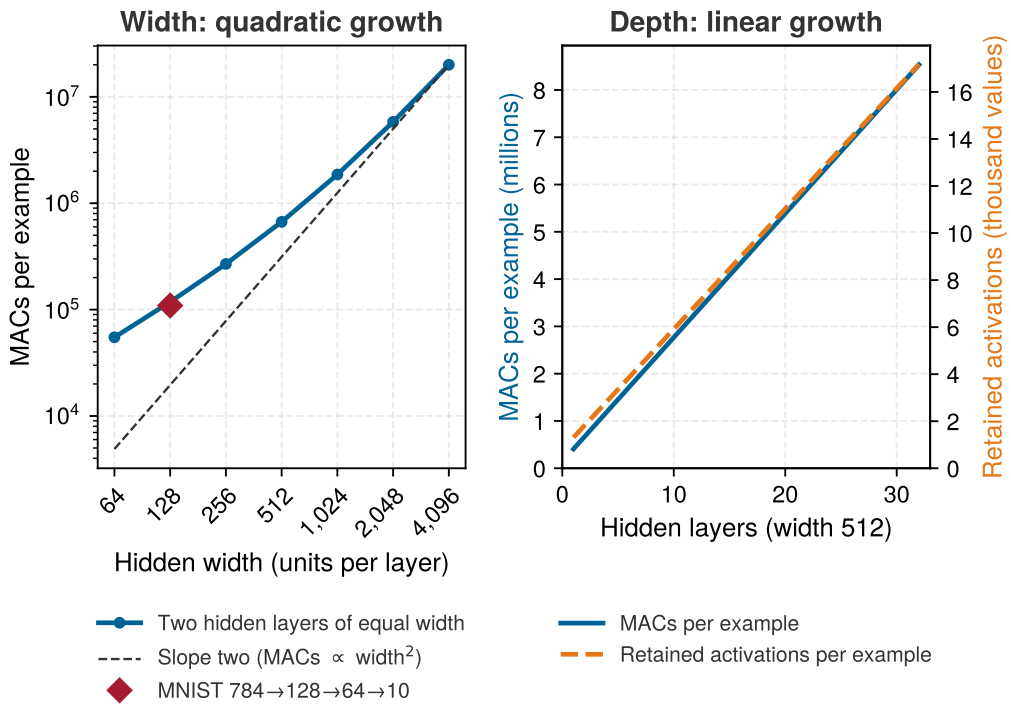

Figure 5.12: Width Costs Quadratically, Depth Costs Linearly: Forward multiply-accumulate operations (MACs) per example for fully connected networks on the MNIST input (784) and output (10) widths. Left: two hidden layers whose shared width sweeps from 64 to 4,096 on log-log axes; once the hidden-to-hidden matrix dominates, the curve follows the dashed slope-two guide, and the running 784-128-64-10 network sits near the narrow end. Right: hidden width fixed at 512 while depth sweeps from 1 to 32 hidden layers; MACs per example (left axis) and activations retained per example for training (right axis) both rise in a straight line.

- ☐ **Width, depth, cost**: can you explain how layer width, depth, and connectivity change memory footprint and arithmetic cost?

If any of these feel unclear, review the earlier sections on neural network fundamentals, artificial neurons, and parameters before continuing. The upcoming sections on training and optimization build directly on these foundations.

Network architecture, neurons, and parameters are now in place, but nothing yet explains how randomly initialized parameters become useful. Architecture answers *what* the model computes; training answers *how* it learns. The mechanics reveal systems constraints because training adds backward computation, saved activations, gradients, and optimizer state. Batch size then becomes a joint statistical and hardware choice, because it changes gradient noise, activation memory, data reuse, and parallel efficiency at once.

5.4 Learning Process

The MNIST network currently holds 109,386 parameters set to random values, numbers that encode no knowledge at all. Learning turns them into a working classifier by repeating one short cycle of computation millions of times, and that repetition multiplies every cost the previous sections counted for a single forward pass.

5.4.1 Supervised learning from labeled examples

At that starting point the network classifies digits no better than guessing among ten classes (about 10 percent accuracy). Transforming it into a 95 percent-accurate classifier requires supervised learning:

showing the network labeled examples and adjusting its weights based on the errors it makes. For the MNIST digit recognition task, the dataset contains 60,000 training images, each a 28×28 pixel grayscale image paired with its correct digit label. To close that accuracy gap, training runs as a loop where each iteration processes a subset of training examples called a batch through four operations: forward computation through the network layers generates predictions, a loss function measures prediction error under the chosen objective, backpropagation computes parameter gradients, and an optimizer uses those gradients to update the weights.

Definition 5.2: Mini-batch

Mini-batch is the subset of B training examples that pass together through one forward and one backward pass and whose gradients are averaged into a single parameter update; during training, an unqualified *batch* in this book means a mini-batch.

1. **Significance**: The batch size B is the training loop's main systems knob. It sets how many examples share each weight read from memory, it multiplies the activations that training must keep until the backward pass, and it fixes how many updates one pass over the training set produces, so doubling B roughly doubles activation memory and halves the updates per pass.
2. **Distinction**: Full-batch gradient descent uses the entire training set for every update, and purely stochastic gradient descent uses a single example. A micro-batch is a slice of a mini-batch whose gradients are accumulated before the one update, and an inference batch groups incoming requests without updating anything.
3. **Common pitfall**: A frequent misconception is that a larger batch is free throughput. Each request waits longer, and beyond some size the optimizer needs more passes over the data to reach the same accuracy.

Tracing dataflow along the red horizontal arrow in figure 5.13 shows forward activations traversing the layers to evaluate loss, whereas the orange arrow running the opposite way carries gradients backward through the layers; the optimizer then turns those gradients into weight updates. This operational asymmetry creates a central memory obligation: training must retain intermediate forward activations in memory until the corresponding backward pass completes.

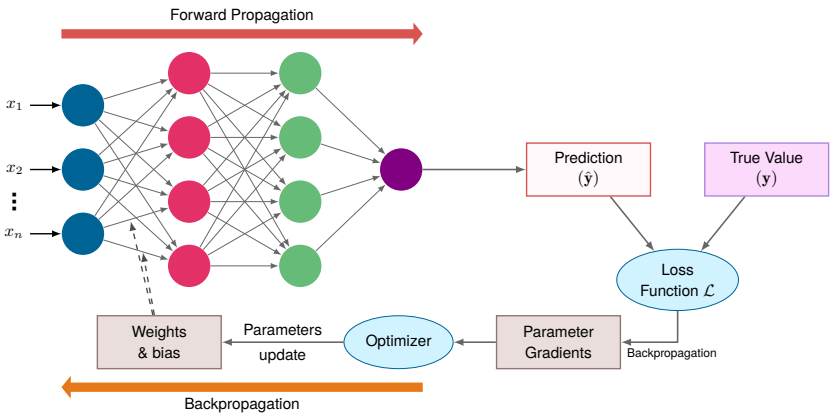

Figure 5.13: Training Loop Architecture: A prediction and true value meet at the loss function; backpropagation computes parameter gradients, and the optimizer turns those gradients into parameter updates for the next forward pass.

The iterative approach can be expressed mathematically. Given an input image $\mathbf{x}$ and its true label $\mathbf{y}$, the network computes its prediction according to equation 5.11:

$$\hat{\mathbf{y}} = f_{\text{net}}(\mathbf{x};\theta) \tag{5.11}$$

This equation encapsulates the entire forward pass: the network f_{net} takes an input $\mathbf{x}$ (say, a 28×28 digit image) and, using its current parameters θ (weights and biases across all layers), produces a prediction $\hat{\mathbf{y}}$ (a vector of ten probabilities, one per digit). The semicolon notation $f_{\text{net}}(\mathbf{x};\theta)$ distinguishes the input $\mathbf{x}$, which changes with every example, from θ, which remains fixed during inference but evolves during training. The network's error is measured by a loss function[16] $\mathcal{L}$ (equation 5.12):

$$\text{loss} = \mathcal{L}(\hat{\mathbf{y}}, \mathbf{y}) \tag{5.12}$$

The error measurement drives the adjustment of network parameters: gradient descent (section 5.4.4) moves each parameter against its loss gradient, and backpropagation (section 5.4.5) computes those gradients. In practice, training operates on batches of examples rather than individual inputs. For the MNIST dataset, each training iteration might process 32, 64, or 128 images simultaneously for reasons developed in section 5.4.4.1. The training cycle continues until the network achieves sufficient accuracy or reaches a predetermined number of iterations, and each iteration begins with the forward pass that turns a batch of input images into predictions.

[16] **Loss function**: Formalized by Abraham Wald in statistical decision theory (Wald 1949) as the "cost" of an incorrect decision, $\mathcal{L}$ quantifies the gap between prediction $\hat{\mathbf{y}}$ and ground truth $\mathbf{y}$. The choice of loss function shapes the optimization geometry: it determines the gradient landscape that backpropagation must navigate. A loss with flat regions near incorrect predictions produces weak gradients that stall learning, while a loss with steep gradients near the decision boundary accelerates convergence where it matters most, a systems consequence explored in section 5.4.3.

↪ How long this cycle takes to reach a target accuracy, the time-to-accuracy measure that training benchmarks prefer over raw throughput, is developed in section 12.5.2.1.

5.4.2 Forward pass computation

An MNIST image becomes ten class scores by moving through weighted layers and nonlinear activations. That computation is **forward propagation**: input data flows through the network's layers to generate predictions. During training, those predictions are paired with ground-truth targets at the loss function, closing the training loop of figure 5.13. The forward pass itself underlies both inference and training.

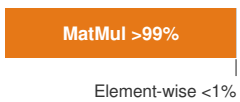
The process begins with the input layer, where each pixel's grayscale value becomes an input feature. For MNIST, this means 784 input values ($28\times28 = 784$), each normalized between 0 and 1. The first layer alone performs 100,352 MACs per sample. When processing multiple samples in a batch, these operations multiply accordingly, requiring careful management of memory bandwidth and computational resources. Accelerators execute these operations efficiently by running many MACs in parallel, a design developed in chapter 11.

5.4.2.1 Individual layer processing

Each layer of the digit classifier turns its input into a more abstract representation in two steps, a linear transformation of inputs followed by a nonlinear activation. The linear transformation applies the same weighted sum operation defined in equation 5.2, but now using notation that tracks layer indices (equation 5.13):

$$\mathbf{Z}^{(\ell)} = \mathbf{A}^{(\ell-1)}\mathbf{W}^{(\ell)} + \mathbf{b}^{(\ell)} \tag{5.13}$$

Here, $\mathbf{A}^{(\ell-1)}$ contains the activations from the previous layer (the outputs after applying activation functions), $\mathbf{W}^{(\ell)} \in \mathbb{R}^{n_{\ell-1}\times n_\ell}$ is the weight matrix for layer ℓ, and $\mathbf{b}^{(\ell)}$ is the bias vector (broadcast across the batch). The superscript (ℓ) keeps track of which layer each parameter belongs to. This row-vector convention matches the single-sample equation in equation 5.2: each row of $\mathbf{A}$ is one sample, and right-multiplying by $\mathbf{W}$ transforms it to the next layer's width.



Following this linear transformation, each layer applies a nonlinear activation function f (here, f or $f^{(\ell)}$ denotes a generic activation function at layer ℓ), as expressed in equation 5.14:

$$\mathbf{A}^{(\ell)} = f(\mathbf{Z}^{(\ell)}) \tag{5.14}$$

This process repeats at each layer, creating a chain of transformations:

$$\text{Input} \to \text{Linear Transform} \to \text{Activation} \to \text{Linear Transform} \to \text{Activation} \to \cdots \to \text{Output}$$

The batch form is what the machine executes. Every one of the B rows of $\mathbf{A}^{(\ell-1)}$ meets the same $\mathbf{W}^{(\ell)}$, so a single read of the weights serves the whole batch, the reuse that figure 5.9 drew. For the digit classifier, the first such product turns the 784-dimensional input into 128 hidden values, and two more produce the ten class scores.

Matrix multiplication is over 99 percent of this network's forward-pass FLOPs.

5.4.2.2 Matrix multiplication formulation

For a network with N_L layers, the complete forward propagation process can be expressed as a composition of layer transformations (equation 5.15):

$$\mathbf{A}^{(N_L)} = f^{(N_L)}\Big(\cdots f^{(2)}\Big(f^{(1)}(\mathbf{X}\mathbf{W}^{(1)} + \mathbf{b}^{(1)})\mathbf{W}^{(2)} + \mathbf{b}^{(2)}\Big)\cdots \mathbf{W}^{(N_L)} + \mathbf{b}^{(N_L)}\Big) \tag{5.15}$$

The nested expression unfolds layer by layer, each step consuming the previous layer's activations:

1. First layer:

$$\mathbf{Z}^{(1)} = \mathbf{X}\mathbf{W}^{(1)} + \mathbf{b}^{(1)}$$
$$\mathbf{A}^{(1)} = f^{(1)}(\mathbf{Z}^{(1)})$$

2. Hidden layers ($\ell = 2, \ldots, N_L - 1$):

$$\mathbf{Z}^{(\ell)} = \mathbf{A}^{(\ell-1)}\mathbf{W}^{(\ell)} + \mathbf{b}^{(\ell)}$$
$$\mathbf{A}^{(\ell)} = f^{(\ell)}(\mathbf{Z}^{(\ell)})$$

3. Output layer:

$$\mathbf{Z}^{(N_L)} = \mathbf{A}^{(N_L-1)}\mathbf{W}^{(N_L)} + \mathbf{b}^{(N_L)}$$
$$\mathbf{A}^{(N_L)} = f^{(N_L)}(\mathbf{Z}^{(N_L)})$$

For a batch of B images in the MNIST network, four tensor dimensions govern the forward pass:

- Input $\mathbf{X}$: $B \times 784$
- First layer weights $\mathbf{W}^{(1)}$: $784 \times n_1$
- Hidden layer weights $\mathbf{W}^{(\ell)}$: $n_{\ell-1} \times n_\ell$
- Output layer weights $\mathbf{W}^{(N_L)}$: $n_{N_L-1} \times 10$

Of the two kinds of operation in that chain, the matrix multiplications dominate AI computation, and arithmetic intensity explains why.

Definition 5.3: Arithmetic intensity

Arithmetic intensity is the ratio of operations a kernel performs to the bytes it transfers across the memory interface being modeled, $I = O/D_{\text{vol}}$ in FLOP/byte.

1. **Significance**: It decides whether a kernel is limited by arithmetic or by data movement. An accelerator can perform far more operations per second than its off-chip memory can deliver bytes, so a kernel that does little work per byte leaves the arithmetic units waiting however fast they are, and the remedy is more reuse per byte (tiling, batching, fusion) rather than more peak compute.
2. **Distinction**: Unlike total FLOPs (a count of operations), arithmetic intensity is a ratio that characterizes the shape of a workload's hardware demand. Two kernels with identical FLOPs but different memory access patterns can have different arithmetic intensities and run at very different speeds on the same hardware.
3. **Common pitfall**: A frequent misconception is that arithmetic intensity is a fixed property of an operation. It depends on implementation and on batch size. A naive matrix multiplication that reloads operands from main memory for each output element has low arithmetic intensity, a tiled implementation that reuses data from on-chip memory has high arithmetic intensity, and a dense layer reaches more of that reuse as the batch grows, because each weight read then serves every example in the batch.

Tiled dense matrix multiplication reuses each loaded value many times, whereas an unfused element-wise operation does little work per byte it moves. Writing s_{elem} for the bytes needed to store one value (4 bytes in FP32), table 5.6 compares their idealized intensities.

Table 5.6: Idealized Arithmetic Intensity of Matrix Multiply vs. Element-Wise ReLU: A tiled dense $N \times N$ matrix multiplication performs $2N^3$ operations while moving at least about $3N^2 s_{\text{elem}}$ bytes for s_{elem} bytes per value, so potential reuse grows with N. A standalone element-wise activation remains at $1/(2s_{\text{elem}})$ FLOP/byte (0.125 FLOP/byte for FP32); implementations often fuse it with a neighboring kernel to avoid a separate memory round trip.

Operation	Operation Count (O)	Minimum Data Movement	Idealized Intensity	Typical Optimization
Matrix Mul $(N \times N)$	$2N^3$	$3N^2 s_{\text{elem}}$ bytes	$\approx 2N/(3s_{\text{elem}})$	Tiling on CPU/GPU/TPU
Element-wise (ReLU)	N^2	$2N^2 s_{\text{elem}}$ bytes	$1/(2s_{\text{elem}})$	Vectorization and fusion

Systems Perspective 5.3: Why matrix multiplication dominates AI

Modern accelerators have large compute arrays relative to off-chip memory bandwidth. They approach peak arithmetic throughput only when operations expose enough reuse and parallel work. Dense and convolutional layers map well to optimized kernels; custom element-wise sequences are often fused so that their intermediate values remain on chip. How accelerators organize their compute arrays around matrix multiplication is developed in section 11.3.

For a single sample, the layer operation **xW** is a **general matrix-vector multiply (GEMV)**. Batching multiple samples turns this into **XW**, a **general matrix multiply (GEMM)**. Accelerators pack wide parallel units and high-bandwidth memory hierarchies optimized for 2D matrix transformations. Because hardware vendors invest the bulk of their silicon area and compiler optimizations in GEMM throughput, almost every neural network layer is structured to execute as matrix multiplication, and section 6.9.3.1 shows how the convolution and attention layers of later chapters lower to that shared primitive. Matrix operations account for over 99 percent of the floating-point operations in this chapter's dense network and dominate modern neural workloads. Model architectures are therefore shaped around the operations that matrix engines execute efficiently, which is the core of hardware-software co-design. The tiling that gives these kernels their data reuse is developed in section 11.7.5, and how GEMM arithmetic intensity grows with matrix dimension is collected for reference in section C.1.3.

5.4.2.3 Step-by-step computation sequence

Consider a batch of 32 images entering the network. Each image starts as a 28×28 grid of pixel values, which flattens into a 784-dimensional vector. For the entire batch, this yields an input matrix $\mathbf{X}$ of size 32×784, where each row represents one image. The values are typically normalized to lie between 0 and 1.

The transformation at each layer proceeds as a shape-changing sequence; the shapes determine both kernel choice and activation storage. The network first takes the input matrix $\mathbf{X}$ (32×784) and transforms it using the first layer's weights. If the first hidden layer has 128 neurons, $\mathbf{W}^{(1)}$ is a 784×128 matrix, so the computation $\mathbf{XW}^{(1)}$ produces a 32×128 matrix. Each element in this matrix then has its corresponding bias added and passes through an activation function. For example, with a ReLU activation, any negative values become zero while positive values remain unchanged. The final layer transforms its inputs into a 32×10 matrix, where each row contains 10 class scores. Let z_j denote the raw score (logit) for digit j and let z_k range over all 10 digits. Often, these scores are converted to probabilities using the softmax function in equation 5.7:

$$\hat{y}_j = \frac{e^{z_j}}{\sum_{k=1}^{10} e^{z_k}}$$

For each image in the batch, the ten values $\hat{y}_j$ form a probability distribution over the possible digits. The digit with the highest probability represents the network's prediction.

Napkin Math 5.1: Counting operations in forward pass

Problem: Determine the total arithmetic operation count (O) for one forward pass through the MNIST network (784 → 128 → 64 → 10) with batch size 32.

Background: A matrix multiplication of dimensions $(M \times K) \times (K \times N)$ requires $2 \times M \times K \times N$ FLOPs (one multiply and one add per output element, summed over K terms). Bias addition adds $M \times N$ floating-point additions. ReLU activation adds $M \times N$ comparisons, so the table reports total operation-equivalent work rather than pure FLOPs for activation rows.

Solution: Table 5.7 breaks down the operation count layer by layer. The total comes to ~7 MOp, or 7 MOp ÷ 32 = ~219 KOp per image. This per-image figure reconciles with the count at the start of the chapter. The three matrix-multiplication rows contribute 218,368 FLOPs per image, exactly two FLOPs for each of the 109,184 MACs, and the bias and activation rows add less than 1 percent on top.

Systems insight:

1. Layer 1 dominates: The first layer accounts for 91.9 percent of all operations because it processes the largest input (784 dimensions). Shrinking the input or the first hidden width is therefore the largest single lever on this network's arithmetic.
2. Compute vs. memory: At batch 1, 219 KOp must amortize a parameter read for only one image, giving an arithmetic intensity of ~0.5 FLOP/byte under this traffic model. At batch 32, one parameter read, one input read, one final-output write, and a write followed by a read for each hidden tensor move ~588 KB and raise the intensity to ~11.9 FLOP/byte. This idealized FP32 model treats each dense layer as a separate kernel with fused bias and activation, and counts transfers across a memory boundary at which no operands remain resident between kernels or batches. A hidden activation contributes twice because its producer writes it and its consumer reads it. Cache residency or cross-layer fusion can reduce traffic at that boundary; extra transfers can increase it. The comparison shows why batching improves reuse, but memory- or compute-bound behavior still depends on the machine's ridge point, the balance $R_{\text{peak}}/\text{BW}$ introduced with the iron law, which the roofline model in section 11.6 develops.
3. Scaling intuition: Doubling the hidden layer widths (784 → 256 → 128 → 10) increases the operation count by about 2.1× to about 15 MOp. This comes from recomputing each layer: layers 1 and 3 double, layer 2 quadruples, so the total roughly doubles rather than quadrupling.

Table 5.7: MNIST Forward Pass Operation Count by Layer: Operation-equivalent breakdown for a single forward pass through the 784-128-64-10 network at batch size 32. Matrix multiplication rows are FLOPs; bias, ReLU, and softmax rows are elementwise operations included to show their negligible contribution. Layer 1's matrix multiply dominates because it multiplies the 784-dimensional input against the widest weight matrix; bias and activation operations contribute under 1 percent of the total.

Layer	Operation	Dimensions	Operations
Layer 1	MatMul	(32×784) × (784×128)	2 × 32 × 784×128 = 6,422,528
Layer 1	Bias + ReLU	32×128	2×4,096 = 8,192
Layer 2	MatMul	(32×128) × (128×64)	2 × 32 × 128×64 = 524,288
Layer 2	Bias + ReLU	32×64	2×2,048 = 4,096
Layer 3	MatMul	(32×64) × (64×10)	2 × 32 × 64×10 = 40,960
Layer 3	Bias + Softmax	32×10	~640 (simplified)
Total			**~7 MOp**

5.4.2.4 Implementation and optimization considerations

Forward propagation is easy to state mathematically, but its implementation is constrained by activation storage, batch size, memory layout, and hardware fit. During training, each layer's activations must stay in memory until the backward pass consumes them. For the MNIST network at batch size 32, the input holds $32 \times 784 = 25{,}088$ values, the hidden layers hold 4,096 and 2,048, and the output holds 320, a total of 31,552 values per batch that section 5.4.5.5 converts into bytes alongside the other training-state terms. Every one of these counts scales linearly with batch size, so doubling the batch to 64 doubles activation storage.

The same batch size sets the other side of the trade. Notebook 5.1 estimated arithmetic intensity rising from ~0.5 FLOP/byte at batch 1 to ~11.9 FLOP/byte at batch 32, because one read of each weight now serves 32 images. Batching therefore trades memory for reuse. Memory capacity bounds how far that trade can go, while gradient noise and per-request latency bound it from other directions. Memory layout and optimized linear-algebra libraries decide how much of that reuse an implementation actually captures, which is why parallel processors that can be fed from on-chip storage run large dense matrix operations substantially faster than CPUs, and why specialized accelerators add reduced-precision arithmetic and dataflows tailored to these patterns. Energy follows the same logic. Power alone does not determine energy per inference; the relevant quantity is power integrated over execution time for the same workload and quality target, and memory hierarchy and data movement often explain most of the difference between platforms.

A roofline (Williams et al. 2009) plots a machine's attainable throughput against arithmetic intensity, with a sloped segment equal to bandwidth times intensity that meets a flat roof at peak compute; section 11.6.1 develops that throughput bound in full. Figure 5.14 places those two intensities on the rooflines of two machines whose FP32 ridge points happen to sit near the same value. At both batch sizes the running network lies on the sloped, bandwidth-limited side of both machines, so its attainable rate is bandwidth times intensity. Batching therefore gains more than an order of magnitude by climbing that slope, and at these intensities the accelerator outruns the CPU because it moves bytes faster, not because it multiplies faster. The plot assumes that every operand streams from main memory, as the notebook's traffic model does; a model this small can instead stay in a CPU's cache, which raises the bandwidth that actually feeds it.

5.4.3 Loss functions

When the MNIST network sees a handwritten "seven" and places a probability of 0.6 on "three" and only 0.1 on "seven," the forward pass alone has no way to turn that mistake into a weight correction. **Inference** needs only the forward pass because a deployed model merely reports its prediction. Training needs one more quantity: an error metric that measures how far the ten predicted class scores fall from the true label. Loss functions supply that metric, turning the gap between prediction and reality into a single number that optimization can minimize.

5.4.3.1 Error measurement fundamentals

A loss function assigns a scalar cost to a prediction and target under a chosen objective. For the machine it is the cheapest stage of the training step, a few operations for each of ten class scores against the 109,184 MACs per image that produced them, so what the system must get right about the loss is its numerical range rather than its cost. Lower loss indicates a better value of that objective on the evaluated examples, but it is not the same as higher accuracy: confidence and calibration can change while the predicted class remains unchanged. During training, gradients of the loss guide parameter updates.

Mathematically, a loss function $\mathcal{L}$ takes two inputs: the network's predictions $\hat{\mathbf{y}}$ and the true values $\mathbf{y}$. For a single training example in digit classification, the loss measures the discrepancy between prediction and truth. When training with batches of data, the system computes the mean loss across all examples in the batch (equation 5.16):

$$\mathcal{L}_{\text{batch}} = \frac{1}{B} \sum_{i=1}^{B} \mathcal{L}(\hat{\mathbf{y}}_i, \mathbf{y}_i) \tag{5.16}$$

where B is the batch size and $(\hat{\mathbf{y}}_i, \mathbf{y}_i)$ represents the prediction and truth for the i-th example. Averaging keeps the loss and mean-gradient scale comparable across batch sizes, although the

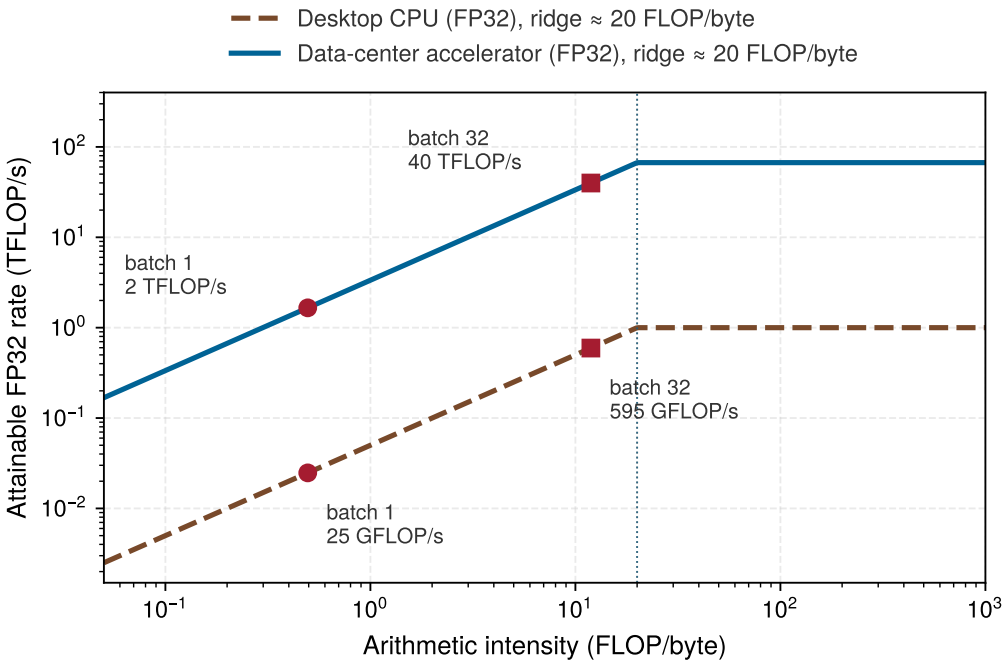


Figure 5.14: The Running Network on the Roofline: Attainable FP32 throughput against arithmetic intensity for a desktop CPU and a data-center accelerator, with the running network's forward pass at batch 1 and batch 32 under the main-memory traffic model of the operation-count notebook. Both points sit left of both ridge points, so batching raises throughput by climbing the bandwidth slope, and at these intensities the accelerator's lead equals its memory-bandwidth advantage rather than its arithmetic advantage.

best learning rate can still change with batch size and optimization regime. The summation also maps naturally to parallel hardware: each example's loss can be computed independently before a reduction combines them.

The choice of loss function depends on the type of task. For digit classification, the loss function must handle probability distributions over multiple classes, provide meaningful gradients that guide learning, penalize wrong predictions in proportion to their severity, and scale efficiently with batch processing. Cross-entropy loss satisfies all four requirements.

5.4.3.2 Cross-entropy and classification loss functions

For classification tasks like MNIST digit recognition, **cross-entropy loss** compares the predicted probability distribution with the true class label. The information-theoretic idea of entropy traces to Shannon (Shannon 1948); in supervised classification, cross-entropy penalizes low probability assigned to the correct class because the logarithm grows sharply as the correct-class probability approaches zero. This shape produces strong gradients for confidently wrong predictions and makes the correct-class probability the objective's central quantity.

For a single digit image, the network outputs a probability distribution over the 10 possible digits. Ground truth is represented as a one-hot vector[17] where all entries are 0 except for a one at the correct digit's position. For instance, if the true digit is "seven," the label is $\mathbf{y} = [0,0,0,0,0,0,0,1,0,0]$.

The cross-entropy loss for this example is defined in equation 5.17:

$$\mathcal{L}(\hat{\mathbf{y}}, \mathbf{y}) = -\sum_{j=1}^{10} y_j \log(\hat{y}_j) \tag{5.17}$$

where $\hat{y}_j$ represents the network's predicted probability for digit j. Because $\mathbf{y}$ is one-hot, this simplifies to equation 5.18:

$$\mathcal{L}(\hat{\mathbf{y}}, \mathbf{y}) = -\log(\hat{y}_c) \tag{5.18}$$

[17] **One-hot encoding**: Representing each class as a binary vector with one entry per class, exactly one of which is 1. The encoding is sparse by construction, and for MNIST's 10 classes, 90 percent of each label vector is zeros. Implementations commonly store an integer class index instead of materializing that vector. For very large output spaces, methods such as sampled softmax can also reduce the output computation.

where c is the index of the correct class. The loss therefore depends only on the predicted probability for the correct digit; the network is penalized based on how confident it is in the right answer.

For example, suppose the network assigns the probabilities in the left panel of figure 5.15 to an image of a "seven." The prediction is a distribution over all ten digits, while the label is a single one at the correct class and zero everywhere else.

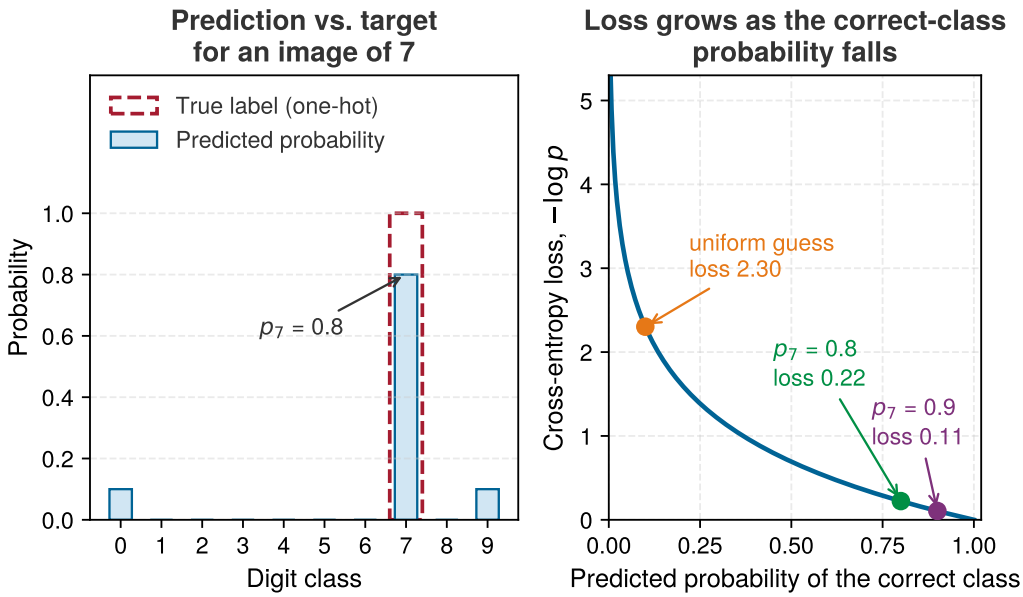

Figure 5.15: Cross-Entropy Compares a Distribution with a One-Hot Label: Left: the network places 0.8 on the correct class and 0.1 each on digits 0 and 9, while the target places all of its mass on the correct class. Right: because the target is one-hot, the loss reduces to the negative log of the correct-class probability. A uniform guess over ten classes costs about 2.3, a confident correct prediction costs little, and the penalty grows without bound as the probability assigned to the truth approaches zero.

The loss is $-\log(0.8)$, approximately 0.223. If the network were more confident and predicted 0.9 for the correct digit, the loss would decrease to approximately 0.105. The right panel of figure 5.15 shows why the logarithm suits training. Raising a correct-class probability that is already high earns little, while a confident mistake, a small probability on the true digit, produces a large loss and therefore a large corrective gradient.

5.4.3.3 Batch loss calculation methods

Evaluating cross-entropy naively across a batch can crash a training run in a single step: if an unshifted softmax rounds a tiny correct-class probability down to zero in finite floating-point arithmetic, $\log(0)$ evaluates to $-\infty$ and subsequent gradient arithmetic produces a not-a-number value (NaN). For a batch of B examples, the cross-entropy objective averages the per-example losses across all examples (equation 5.19):

$$\mathcal{L}_{\text{batch}} = -\frac{1}{B}\sum_{i=1}^{B}\sum_{j=1}^{10} y_{ij}\log(\hat{y}_{ij}) \tag{5.19}$$

Here, i indexes examples in the batch, j indexes the ten output classes, y_{ij} is the one-hot target indicator for class j on example i, and $\hat{y}_{ij}$ is the predicted probability for that class. Averaging over B keeps the loss scale comparable as batch size changes, but each term in the sum must stay within the floating-point format's representable range.

Stable implementations avoid materializing a numerically fragile probability before taking its logarithm:

1. Shift logits before exponentiation, the core of the log-sum-exp trick collected for reference in section C.3.5; equation 5.20 subtracts the largest logit from every exponent:

$$\text{softmax}(z_i) = \frac{\exp\left(z_i - \max(\mathbf{z})\right)}{\sum_j \exp\left(z_j - \max(\mathbf{z})\right)} \tag{5.20}$$

Subtracting the same $\max(\mathbf{z})$ from every logit leaves the softmax probabilities unchanged because the common factor cancels between numerator and denominator. The numerical effect is decisive: the largest shifted logit becomes zero, so the largest exponential is $\exp(0) = 1$ rather than a potentially overflowing value.

2. Prefer fused cross-entropy from logits. For target class c and $z_{\max} = \max(\mathbf{z})$, a stable implementation evaluates

$$\mathcal{L} = -(z_c - z_{\max}) + \log \sum_j \exp(z_j - z_{\max}) \tag{5.21}$$

Equation 5.21 is mathematically equivalent to $-\log \hat{y}_c$ but never rounds a tiny softmax probability to zero first. Clamping a probability or adding ϵ can be a defensive fallback, but it changes the objective and should not replace the stable formulation.

5.4.3.4 Impact on learning dynamics

With a batch size of 32 and 10 output classes, each training step processes 32 sets of 10 scores, computes a loss for each example, and averages them into one batch loss. During training, that value serves two roles: its gradient supplies the update direction, and its trend helps diagnose whether optimization is progressing, stalling, or diverging. For the MNIST classifier, training loss often begins near $\log(10) \approx 2.3$ when class probabilities are close to uniform, falls rapidly during early optimization, and then improves more slowly. Because a low training loss reflects confidence on the training examples rather than proof of generalization, task accuracy, calibration, and validation loss must still be measured separately on held-out data.

The loss function's gradients with respect to the network's output logits provide the initial error signal that drives backpropagation. For one example, when softmax and cross-entropy are combined, each logit gradient has a particularly simple form: the difference between the predicted and target probabilities, $\hat{y}_j - y_j$ for logit z_j. This property makes cross-entropy loss especially suitable for classification, because it provides strong gradients even when predictions are far from the target. The same cancellation is the main reason runtimes fuse softmax and cross-entropy into a single operator, which collapses the backward step to the subtraction $\hat{\mathbf{y}} - \mathbf{y}$, saves a separate kernel and its memory round trip, and avoids an underflow-prone probability tensor.

The choice of loss function also influences other training decisions. Gradient scale interacts with the learning rate, while loss averaging across batches affects gradient noise and thus the useful batch-size regime. Curvature influences optimizer behavior, and convergence decisions require validation metrics and a stopping rule rather than the training-loss trajectory alone.

5.4.4 Gradient descent and parameter updates

The loss gives training a single number to reduce, and gradient descent is the rule for reducing it. Consider one weight w and the batch loss plotted against it, as in figure 5.16. At the current value of w, the curve has a slope $\partial\mathcal{L}/\partial w$, which is the gradient previewed in section 5.3.2.2. A positive slope means that increasing w raises the loss, so the weight should move down; a negative slope means it should move up. Taking a small step against the slope, recomputing the slope, and stepping again walks the weight downhill toward lower loss. A network has one such slope per parameter. Collecting them gives the gradient vector $\nabla_\theta \mathcal{L}$, which points in the direction of steepest loss increase, and each update steps the opposite way.

Definition 5.4: Gradient descent

Gradient descent is the iterative optimization algorithm that updates model parameters in the direction of the negative gradient, $\theta \leftarrow \theta - \eta \nabla_\theta \mathcal{L}$ with learning rate η, trading computational steps (O) for loss reduction.

1. **Significance**: The update rule itself sets a memory floor. Every parameter needs a gradient of the same size, so in FP32 plain gradient descent holds 8 bytes per parameter (the weight plus its gradient) before counting saved activations. Optimizers that keep extra per-parameter state raise that floor, as the training-memory estimate later in this chapter shows, and section 8.4.3.2 develops the complete accounting.
2. **Distinction**: Backpropagation computes gradients (the "what to change" signal); an optimizer applies updates (the "change it" action).
3. **Common pitfall**: A frequent misconception is that gradient descent finds the global minimum. Neural network loss landscapes are nonconvex with many local minima, saddle points, and plateaus. In practice, gradient descent and its variants converge to regions of low loss that generalize well, but the path depends on the learning rate schedule, batch size, and initialization.

Gradient descent turns each parameter's gradient into a parameter change, using each weight's local loss sensitivity to reduce the loss over successive steps. The fundamental update rule is defined in equation 5.22:

$$\theta_{\text{new}} = \theta_{\text{old}} - \eta \nabla_\theta \mathcal{L} \tag{5.22}$$

where θ represents the collection of network parameters (weights and biases), η is the learning rate, and $\nabla_\theta \mathcal{L}$ is the gradient of the loss with respect to those parameters, which backpropagation (section 5.4.5) computes efficiently.

For the digit classifier, the update aims to reduce the chosen loss. If the network frequently confuses "seven"s with "one"s, the loss gradients from those examples guide the weight changes. The learning rate η controls adjustment magnitude. Values that are too large overshoot good parameters, values that are too small converge slowly, and the right value shifts with batch size, a coupling section 8.4.4.1 develops. Figure 5.16 shows the first failure on a single weight, where every step lands on the far side of the minimum.

Plain gradient descent applies equation 5.22 directly to every weight. Practical optimizers refine it by adapting the step size for each parameter or by carrying momentum across iterations. No optimizer is universally best across all possible problems (Wolpert and Macready 1997), so neural-network training depends on choosing update rules and hyperparameters that match the model, data, and hardware constraints.

Despite neural network loss landscapes being highly nonconvex, gradient-based methods often find useful solutions when the model, data, initialization, and optimization regime are well matched. Why they do remains an active research question; one line of work, for example, studies the *implicit bias* of gradient descent, its tendency to settle on simple solutions among the many that fit the training data equally well (Neyshabur et al. 2017). For practical ML systems engineering, the consequence is empirical. Learning rates, initialization, regularization, and the training configuration must be validated together.

5.4.4.1 Mini-batch gradient updates

Applied to mini-batches (Definition 5.2), gradient descent becomes mini-batch gradient descent, which averages the gradients over the batch and performs one update instead of updating the weights after each individual image. For a batch of size B, with $\mathcal{L}_i$ denoting the loss for example i, the mean loss gradient is equation 5.23:

$$\nabla_\theta \mathcal{L}_{\text{batch}} = \frac{1}{B} \sum_{i=1}^{B} \nabla_\theta \mathcal{L}_i \tag{5.23}$$

With a typical batch size of 32, the system performs one forward pass over 32 images, computes 32 per-example losses, averages their gradients, and applies a single weight update. That average

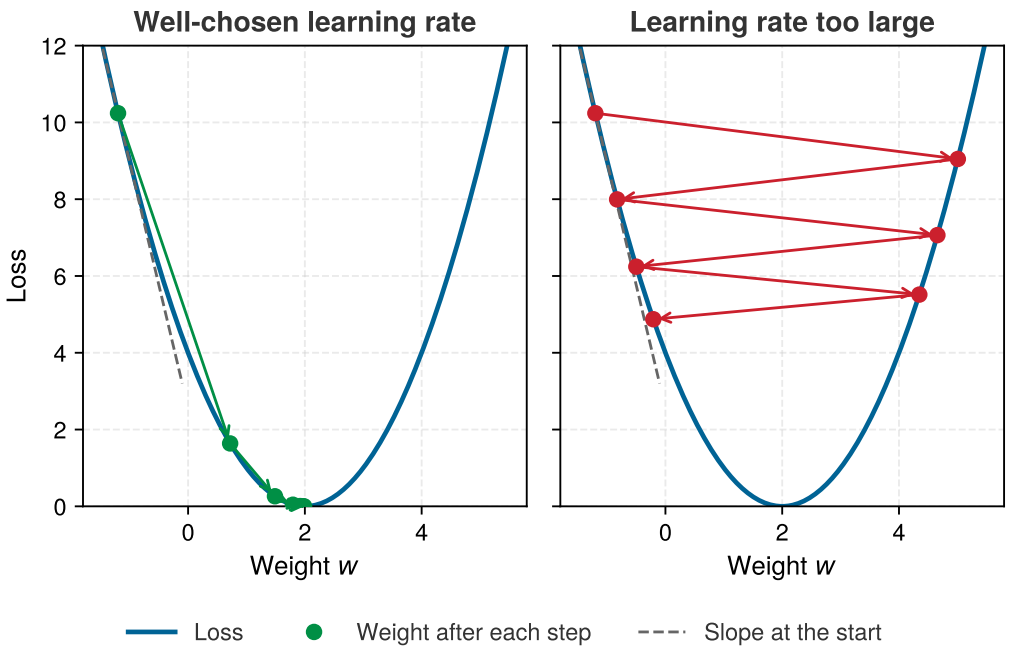

Figure 5.16: Gradient Descent on One Weight: An illustrative loss curve for a single weight, with each step moving the weight against the local slope by an amount proportional to the learning rate. Left: a well-chosen learning rate takes large steps where the slope is steep and smaller ones as the slope flattens near the minimum. Right: a learning rate close to the limit this curve tolerates overshoots the minimum on every step, so the weight oscillates from side to side and approaches the minimum only slowly; a slightly larger rate would diverge.

smooths noisy per-example gradients, but it also means the accelerator must keep the batch's activations available until the backward pass consumes them. Batch size therefore influences available parallelism and utilization together with model shape, kernel implementation, and hardware. When the batch that optimization wants does not fit in accelerator memory, gradient accumulation splits it into micro-batches whose gradients are summed before a single update, a technique section 8.6.5.1 develops with its numerical caveats.

5.4.5 Gradient computation and backpropagation

Gradient descent assumes the gradient is already in hand, but the loss alone does not tell the system how sensitive it is to each parameter. With 109,386 parameters in the MNIST network, estimating every derivative through independent perturbations would be computationally prohibitive. This is the credit assignment problem (Minsky 1961): connecting the final error to the parameters and intermediate values that can change it. Backpropagation solves it by applying the chain rule to compute all of those local sensitivities in one backward traversal.

Definition 5.5: Backpropagation

Backpropagation is the gradient-computation algorithm training systems use to apply the chain rule to a computational graph, using recorded operations and saved or recomputed forward-pass values to compute the gradient of the loss with respect to every parameter in a single backward traversal.

1. **Significance**: For dense layers that require both parameter and input gradients, the backward pass costs on the order of twice the forward-pass FLOPs (a ratio derived from the layer equations later in this section) and requires retaining or recomputing the intermediate values needed by the chain rule. For a model with N_L layers, batch size

B, and layer widths $n_1, \ldots, n_{N_L}$, the stored activations scale, in a simplified count, as $\mathcal{O}\left(B \sum_{\ell=1}^{N_L} n_\ell\right)$. Gradients and optimizer state add further memory, so a model that fits on one accelerator for inference may not fit there for training.

2. **Distinction**: Numerical differentiation requires a perturbed evaluation for each of the model's P parameters. Reverse-mode automatic differentiation computes all P gradients in one backward traversal whose cost is proportional to the computational graph, avoiding P separate forward passes.
3. **Common pitfall**: A frequent misconception is that backpropagation is learning. It is a gradient computation algorithm; gradient descent performs the actual parameter update. Confusing the two hides which one sets activation storage and which sets optimizer state.

A car factory gives a concrete version of the same credit-assignment problem. Vehicles pass through four stations: frame installation (A), engine mounting (B), wheel attachment (C), and final assembly (D). When inspectors find a defective car, they work backward from the defect to trace responsibility through each station: how much D's assembly contributed vs. what it received from C, and how much C's work contributed vs. what came from B. Each station receives adjustment feedback proportional to its contribution, so if Station B's engine mounting was the primary cause, it receives the strongest signal to change.

Backpropagation follows an analogous backward trace, with each layer in the role of a station, but it computes sensitivity rather than causal blame. Starting from the loss, it evaluates how a small change in each layer's inputs would change that loss and propagates those derivatives backward by the chain rule of calculus. The gradient at the output layer plays the part of Station D's adjustment signal, each partial derivative is one station's local sensitivity, and the optimizer later converts the resulting parameter gradients into actual updates.

The sensitivity is local to the current parameter values, input batch, and loss. It answers a counterfactual question, how an infinitesimal change here would change this loss, not whether a weight is permanently important or historically caused the prediction. A framework computes it mechanically by recording each operation in a computational graph and replaying that graph in reverse from the scalar loss, the reverse-mode mechanism that section 7.4.1.2 develops. For a dense network the replay reduces to the layer-by-layer procedure below.

↪ How an eager framework builds that graph on the fly, one operation at a time, is developed in section 7.3.3.

5.4.5.1 Backpropagation algorithm steps

Take the running example in which the network predicts a "three" for an image of a "seven." Backward propagation systematically calculates how the loss would respond to a small change in each weight at the current parameter values. The process begins at the network's output, where the predicted digit probabilities are compared with the true label, and the resulting loss gradient flows backward through the network, giving the local sensitivity of the loss to each layer's values and weights. That calculation follows the chain rule[18] of calculus, breaking down the relationship between weights and loss into local layer steps.

Evaluating these chain-rule products by machine predates modern networks. Wengert presented automatic numerical derivative evaluation without requiring analytical derivative expressions (Wengert 1964), an ancestor of the automatic differentiation that frameworks now perform. The chain rule for composed layers is collected for reference in section C.3.1, which also shows why **reverse-mode automatic differentiation** computes all parameter gradients in a single backward pass. The implementation contract in algorithm 5.1 follows from that order, because the forward pass must save the values that the backward pass will need.

[18] **Chain rule**: The calculus identity $\frac{\partial \mathcal{L}}{\partial w} = \frac{\partial \mathcal{L}}{\partial a^{(N_L)}} \cdot \frac{\partial a^{(N_L)}}{\partial a^{(N_L-1)}} \cdots \frac{\partial a^{(1)}}{\partial w}$ becomes a product of N_L terms for an N_L-layer network. If each partial derivative is slightly less than one, the product vanishes exponentially; if slightly greater, it explodes. This multiplicative structure makes depth a systems constraint rather than an arbitrary design choice: it dictates the numerical precision requirements and initialization strategies (Glorot and Bengio 2010; He et al. 2015) needed to keep training stable.

Algorithm 5.1 Backpropagation training step

Require: mini-batch inputs $\mathbf{X}$, labels $\mathbf{y}$; N_L layers with parameters $\{\mathbf{W}^{(\ell)}, \mathbf{b}^{(\ell)}\}_{\ell=1}^{N_L}$; loss $\mathcal{L}$
Ensure: parameter gradients $\{\nabla_{\mathbf{W}^{(\ell)}}\mathcal{L}, \nabla_{\mathbf{b}^{(\ell)}}\mathcal{L}\}$ for the optimizer
$\mathbf{A}^{(0)} \leftarrow \mathbf{X}$
for $\ell = 1$ to N_L **do** ▷ *forward pass*
    compute $\mathbf{Z}^{(\ell)}, \mathbf{A}^{(\ell)}$; save the values its derivative needs
end for
compute loss $\mathcal{L}(\mathbf{A}^{(N_L)}, \mathbf{y})$; seed the output gradient $\nabla_{\mathbf{A}^{(N_L)}}\mathcal{L}$
for $\ell = N_L$ down to 1 **do** ▷ *same local rule repeats*
    use the saved forward values to compute $\nabla_{\mathbf{W}^{(\ell)}}\mathcal{L}, \nabla_{\mathbf{b}^{(\ell)}}\mathcal{L}$
    propagate $\nabla_{\mathbf{A}^{(\ell-1)}}\mathcal{L}$ only if that input gradient is required
end for
return the accumulated parameter gradients

Saving activations in the forward loop of algorithm 5.1 is where the systems cost enters: each activation stays live until the backward pass reaches its layer, so **activation memory** scales with batch size, layer count, and activation width. This is why training can exceed inference memory even when the parameter count is unchanged.

5.4.5.2 Error signal propagation

The saved activations are consumed by an error signal that travels the network in reverse, starting from the loss at the output layer and computing how the loss is locally sensitive to each layer and, ultimately, each weight.

A scalar case shows the rule before the matrix form. If $v = 3u$ and $u = x^2$, a small change in x changes u by $2x$ per unit, and each unit change in u changes v by 3, so $dv/dx = 3 \cdot 2x$. Backpropagation applies this multiply-the-local-slopes rule layer by layer. With many units per layer, each local slope becomes a matrix of slopes, called a *Jacobian*, but the rule is unchanged. For a network with N_L layers, the gradient flow can then be expressed mathematically. At each layer ℓ, the sensitivity of the final loss to that layer's output is governed by the chain rule and the schematic Jacobian notation in equation 5.24:

$$\frac{\partial \mathcal{L}}{\partial \mathbf{A}^{(\ell)}} = \frac{\partial \mathcal{L}}{\partial \mathbf{A}^{(\ell+1)}} \frac{\partial \mathbf{A}^{(\ell+1)}}{\partial \mathbf{A}^{(\ell)}} \tag{5.24}$$

This computation cascades backward through the network, with each layer's gradients depending on those from the layer above it. Notebook 5.2 traces these equations with numbers on a two-unit network and can be read first if the matrix form is unfamiliar. The reverse order also fixes when memory peaks. The forward pass finishes holding every layer's output, the backward pass releases them from the last layer to the first as it consumes them, and gradients accumulate as it goes. A training step's memory therefore peaks at the turnaround between the two passes when saved activations dominate, or late in the backward pass when parameter state and accumulated gradients do, and section 5.4.5.5 shows both cases for the running network.

5.4.5.3 Initialization and numerical range

Setting all initial weights to zero causes every neuron in a layer to compute the exact same output and receive the exact same gradient, locking the layer into symmetric updates that prevent diverse feature learning, while starting with random weights that are systematically too large or too small compounds across layers into exploding or vanishing signals, the same multiplicative failure that saturating activations cause (section 9). Parameter initialization breaks symmetry and controls signal scale from the first step: weights are drawn randomly from variance-scaled distributions such as Xavier/Glorot initialization[19] (Glorot and Bengio 2010) or He initialization (He et al. 2015), while biases start at small constant values or zeros.

Initialization sets the starting scale, but the backward cascade still multiplies it layer after layer. As gradients flow backward through many layers, they can vanish or explode. Vanishing also has a numeric form, because each floating-point format has a smallest magnitude it can store at full precision, 1.18×10^{-38} in FP32 and 6.10×10^{-5} in FP16, the 2-byte half-precision format that halves

[19] **Xavier/Glorot initialization**: For a layer with d_{in} inputs and d_{out} outputs, a common Glorot choice uses weight variance $2/(d_{\text{in}} + d_{\text{out}})$ to balance forward activations and backward gradients (Glorot and Bengio 2010). The fix costs zero additional FLOPs; it is purely a matter of setting the random distribution at startup.

[20] **FP32 and reduced-precision formats**: The IEEE 754 binary32 format uses 32 bits (1 sign bit, 8 exponent bits, 23 fraction bits), whereas 16-bit alternatives split exponent and fraction differently: IEEE 754 FP16 allocates 5 exponent and 10 fraction bits, providing high precision but a narrow dynamic range (6.1×10^{-5} to 65,504), so FP16 training multiplies the loss by a scale factor before the backward pass to keep small gradients representable (dynamic loss scaling). Brain Floating Point (BF16) allocates 8 exponent bits matching FP32's normal exponent range to reduce underflow risk relative to FP16; sufficiently small values can still underflow. The loss-scaling recipe belongs to the mixed-precision training of section 8.6.3; the formats are collected for reference in section D.4.

memory and traffic relative to 4-byte FP32.[20] Below it, values enter the *subnormal* range, where the format gives up precision bits to represent ever-smaller magnitudes. Some accelerator modes skip that range for speed and flush such values straight to zero, and values smaller still underflow to zero on any hardware. A gradient that reaches zero this way stops updating its weight entirely. At the other extreme, values beyond the representable maximum can overflow to `Inf` and propagate `NaN`, destabilizing training.

Arithmetic without branches is not arithmetic without risk, and the danger of an unhandled overflow is not unique to machine learning. Safety-critical systems have failed catastrophically when a numerical invariant was violated.

War Story 5.1: The overflow that became guidance (1996)

Context: The European Space Agency's Ariane 5 Flight 501 reused inertial reference software from Ariane 4, including numeric conversions whose assumptions matched the older vehicle's flight profile (European Space Agency 1996).

Mechanism: Ariane 5's flight profile caused a 64-bit floating-point value to exceed the range of a signed 16-bit integer during conversion, triggering an unhandled operand error.

Impact: About 37 seconds after liftoff, both inertial reference units had shut down, and the on-board computer read the active unit's diagnostic output as flight data. The launcher veered off its flight path, broke up, and self-destructed.

Response: The inquiry recommended limiting software to functions required during flight, reviewing range assumptions, and designing exception handling so a single conversion failure could not disable redundant units (European Space Agency 1996).

Systems lesson: Numerical ranges, exception handling, and reuse assumptions are part of the systems contract. A computation can be syntactically correct and still be invalid for the physical regime in which it runs. ML systems hit this whenever a numerical format's representable range fails to match the magnitudes flowing through it. A low-precision multiplication that overflows produces an Inf or NaN that propagates silently through the rest of the computation, making numerical regimes as important to debugging as control flow.

Range and precision decide whether a gradient survives the backward pass at all. What computing it costs is set by the derivative calculation at each layer.

5.4.5.4 Derivative calculation process

Computing gradients involves calculating several partial derivatives at each layer: how changes in weights, biases, and activations affect the final loss. These computations follow directly from the chain rule of calculus but must be implemented efficiently for practical training. For a hidden layer ℓ with an element-wise activation, backpropagation first transforms the incoming signal and then computes weight, bias, and input gradients:

First, the incoming error signal $\frac{\partial \mathcal{L}}{\partial \mathbf{A}^{(\ell)}}$ is transformed into the preactivation gradient $\frac{\partial \mathcal{L}}{\partial \mathbf{Z}^{(\ell)}}$ by multiplying element-wise ($\odot$) with the local activation function derivative (equation 5.25):

$$\frac{\partial \mathcal{L}}{\partial \mathbf{Z}^{(\ell)}} = \frac{\partial \mathcal{L}}{\partial \mathbf{A}^{(\ell)}} \odot f'(\mathbf{Z}^{(\ell)}) \tag{5.25}$$

For ReLU activations, $f'(\mathbf{Z}^{(\ell)})$ acts as a binary mask, passing gradients through active neurons ($z > 0$) and zeroing out inactive ones. The classifier's softmax output couples coordinates, so it does not use this element-wise rule. Instead, its backward pass begins with the combined softmax/cross-entropy logit gradient stated in section 5.4.3.4, predicted probability minus target for each class. For mean batch loss, each example's predicted-minus-target signal is divided by B at that starting point. The weight, bias, and input products below then propagate the already-normalized signal, applying the batch mean only once.

Weight gradients measure the local sensitivity of the final loss to each weight. With a batch size of B, layer input dimension $n_{\ell-1}$, and layer output dimension n_ℓ, the incoming activation matrix

has shape $\mathbf{A}^{(\ell-1)} \in \mathbb{R}^{B\times n_{\ell-1}}$ and the sensitivity matrix has shape $\frac{\partial \mathcal{L}}{\partial \mathbf{Z}^{(\ell)}} \in \mathbb{R}^{B\times n_\ell}$. The optimizer uses these gradients to determine parameter updates (equation 5.26):

$$\frac{\partial \mathcal{L}}{\partial \mathbf{W}^{(\ell)}} = \mathbf{A}^{(\ell-1)^T} \frac{\partial \mathcal{L}}{\partial \mathbf{Z}^{(\ell)}} \tag{5.26}$$

The matrix product $(n_{\ell-1} \times B) \times (B \times n_\ell) \to (n_{\ell-1} \times n_\ell)$ contracts over the batch dimension B, summing the outer products of activations and sensitivities across all examples in the mini-batch. With the mean-loss normalization already present in the sensitivity matrix, this product needs no further factor of $1/B$.

Bias gradients measure how changing each bias term affects the loss. Since biases shift the activation threshold of neurons, these gradients indicate whether neurons should become more or less easily activated, as expressed in equation 5.27:

$$\frac{\partial \mathcal{L}}{\partial \mathbf{b}^{(\ell)}} = \mathbf{1}^T \frac{\partial \mathcal{L}}{\partial \mathbf{Z}^{(\ell)}} \tag{5.27}$$

Here, $\mathbf{1} \in \mathbb{R}^B$ is an all-ones vector, so left multiplication sums the per-example bias gradients across the batch. Because that contraction reduces the batch dimension without touching $n_{\ell-1}$, the bias gradient requires only $B \cdot n_\ell$ additions rather than a matrix multiply.

Input gradients propagate the error signal backward to the previous layer. Rather than directly updating parameters, these gradients serve as the "adjustment signals" that allow earlier layers to learn from the final prediction error (equation 5.28):

$$\frac{\partial \mathcal{L}}{\partial \mathbf{A}^{(\ell-1)}} = \frac{\partial \mathcal{L}}{\partial \mathbf{Z}^{(\ell)}} \mathbf{W}^{(\ell)^T} \tag{5.28}$$

Here, the product $(B \times n_\ell) \times (n_\ell \times n_{\ell-1}) \to (B \times n_{\ell-1})$ contracts over the output dimension n_ℓ, preserving the per-example activation shape for preceding layers. Together, these equations reveal the physical origin of the classic systems rule that the backward pass requires roughly twice the arithmetic of the forward pass. The forward pass executes one matrix multiplication per dense layer, $\mathbf{A}^{(\ell-1)}\mathbf{W}^{(\ell)}$. The backward pass executes two of the same size, one for the weight gradient (equation 5.26) and one for the input gradient that carries the signal to the preceding layer (equation 5.28). A full training step therefore costs about three times the forward FLOPs, one forward product and two backward products per layer. The weight-gradient product trains that layer's parameters; the input-gradient product supplies the signal needed to train preceding layers. For ordinary parameter training on fixed MNIST images, no preceding trainable layer consumes the gradient with respect to raw pixels, so the first layer's input-gradient product can be omitted.

For the running network, the dense matrix work is therefore three forward-pass counts minus the first layer's forward count, or about 2.08× the forward matrix work for this network, before activation derivatives, bias reductions, loss, and optimizer work. Three times the forward matrix work remains a useful approximation when input gradients are needed throughout, or when the omitted first-layer product is a small fraction of total work. The running network makes the exception visible because its first layer accounts for most of its arithmetic.

The running confusion makes these equations concrete. Suppose that, for an image of a seven, the network assigns probability 0.6 to "three" and only 0.1 to "seven," so the cross-entropy loss, the negative log of the correct-class probability, is about 2.30. The combined softmax and cross-entropy gradient at each logit is the predicted probability minus the target, so the "three" logit receives $+0.6$, a push downward, the "seven" logit receives -0.9, a push upward, and the other eight logits receive their small predicted probabilities. That ten-value error signal first meets the output layer. Equation 5.26 multiplies it by the saved 64-value activation of the second hidden layer to produce all 640 output-weight gradients, and equation 5.28 multiplies it by the transposed output weights to send a 64-value signal back to that hidden layer. The ReLU mask then zeroes the entries of units that were inactive for this image, and the same two products repeat, yielding 8,192 weight gradients and a 128-value signal for the first hidden layer, and finally 100,352 first-layer weight gradients computed from the saved 784 pixel values. No gradient is needed for the pixels themselves. Every step consumed a value saved during the forward pass, which is why training must keep each activation until this trace reaches its layer.

Systems Perspective 5.4: The memory cost of backprop

Activation retention is one component of a broader training-state budget. Under a simplified single-device accounting that excludes temporary workspaces and framework overhead, equation 5.29 captures the four principal byte counts:

$$\text{Training Memory} \approx \text{Model Weights} + \text{Gradients} + \text{Optimizer States} + \text{Activations} \tag{5.29}$$

The derivative equations also record which stored values each step depends on:

- The weight gradient in equation 5.26 needs the incoming activation $\mathbf{A}^{(\ell-1)}$.
- The activation derivative may need $\mathbf{Z}^{(\ell)}$ or a compact mask that records which nonlinear units were active.
- The input gradient in equation 5.28 needs the layer weights $\mathbf{W}^{(\ell)}$.
- The optimizer consumes the completed parameter gradients and may add momentum, variance, or other state after backpropagation has produced them.

A training system can retain these values for the fastest backward pass, recompute selected values to save memory, or offload and partition state across memory tiers or devices. None of these choices eliminates cost: recomputation spends additional FLOPs, while offload and partitioning introduce data movement and synchronization. For deep networks with large batches, wide activations, or high-resolution inputs, this trade-off can dominate accelerator capacity. Section C.3.3 provides the complete training-memory equation and a worked analysis of weights, gradients, optimizer state, and activation costs.

Two inputs, two ReLU hidden units, and one output are enough to trace every backward product with actual numbers.

Napkin Math 5.2: Tracing gradients: A worked backpropagation example

Setup: Consider a network with two inputs, a hidden layer of two neurons (ReLU activation), and one output neuron (no activation, for simplicity). Suppose the current weights and biases are:

- **Hidden layer**: $\mathbf{W}^{(1)} = \begin{bmatrix} 0.5 & -0.3 \\ 0.8 & 0.2 \end{bmatrix}$, $\mathbf{b}^{(1)} = [0,\ 0]$
- **Output layer**: $\mathbf{W}^{(2)} = \begin{bmatrix} 0.6 \\ -0.4 \end{bmatrix}$, $b^{(2)} = 0$

Given input $\mathbf{x} = [1.0,\ 0.5]$ and target $y = 1.0$. Because this toy network produces a single number rather than class probabilities, it uses the simpler squared-error loss, half the squared difference between prediction and target: $\mathcal{L} = \frac{1}{2}(\hat{y} - y)^2$.

Forward pass (to establish the values backpropagation needs):

- Hidden preactivation:

$$\mathbf{z}^{(1)} = \mathbf{x}\mathbf{W}^{(1)} + \mathbf{b}^{(1)} = [1.0 \cdot 0.5 + 0.5 \cdot 0.8,\ 1.0 \cdot (-0.3) + 0.5 \cdot 0.2] = [0.9,\ -0.2]$$

- Hidden activation (ReLU): $\mathbf{a}^{(1)} = [\max(0, 0.9),\ \max(0, -0.2)] = [0.9,\ 0.0]$
- Output: $\hat{y} = \mathbf{a}^{(1)}\mathbf{W}^{(2)} + b^{(2)} = 0.9 \cdot 0.6 + 0.0 \cdot (-0.4) = 0.54$
- Loss: $\mathcal{L} = \frac{1}{2}(0.54 - 1.0)^2 = 0.1058$

Backward pass (applying the chain rule layer by layer):

Step 1: Output layer gradient. The loss gradient with respect to the output is

$$\frac{\partial \mathcal{L}}{\partial \hat{y}} = \hat{y} - y = 0.54 - 1.0 = -0.46.$$

Step 2: Output weight gradients (applying equation 5.26). Since the output layer has no activation function

$$\frac{\partial \mathcal{L}}{\partial z^{(2)}} = \frac{\partial \mathcal{L}}{\partial \hat{y}} = -0.46, \quad \text{and} \quad \frac{\partial \mathcal{L}}{\partial \mathbf{W}^{(2)}} = \mathbf{a}^{(1)^T} \frac{\partial \mathcal{L}}{\partial z^{(2)}} = \begin{bmatrix} 0.9 \\ 0.0 \end{bmatrix} \cdot (-0.46) = \begin{bmatrix} -0.414 \\ 0.0 \end{bmatrix}$$

Step 3: Propagate to hidden layer (applying equation 5.28). The error signal sent backward is:

$$\frac{\partial \mathcal{L}}{\partial \mathbf{a}^{(1)}} = \frac{\partial \mathcal{L}}{\partial z^{(2)}} \mathbf{W}^{(2)^T} = (-0.46) \cdot [0.6, \, -0.4] = [-0.276, \, 0.184]$$

Step 4: Pass through ReLU. The ReLU derivative is one where $z > 0$ and 0 otherwise, so

$$\frac{\partial \mathcal{L}}{\partial \mathbf{z}^{(1)}} = [-0.276 \cdot 1, \, 0.184 \cdot 0] = [-0.276, \, 0.0].$$

The second neuron's gradient is zeroed because ReLU blocked its forward signal.

Step 5: Hidden weight gradients (applying equation 5.26):

$$\frac{\partial \mathcal{L}}{\partial \mathbf{W}^{(1)}} = \mathbf{x}^T \cdot \frac{\partial \mathcal{L}}{\partial \mathbf{z}^{(1)}} = \begin{bmatrix} 1.0 \\ 0.5 \end{bmatrix} \cdot [-0.276, \, 0.0] = \begin{bmatrix} -0.276 & 0.0 \\ -0.138 & 0.0 \end{bmatrix}$$

Weight updates (with learning rate $\eta = 0.1$): Each weight moves opposite to its gradient. For example, $W_{11}^{(1)}$ updates from 0.5 to $0.5 - 0.1 \cdot (-0.276) = 0.5276$, nudging the network toward the correct output. The second hidden neuron's weights receive zero updates for this example because ReLU blocked its activation, illustrating the mechanism that can lead to dead neurons if it happens persistently across the training data.

Systems insight: Backpropagation is a data-dependency graph as well as a calculus procedure. Training systems must preserve the forward activations needed by this backward pass, which is why activation memory becomes a first-order systems cost.

In practice an autograd engine performs this bookkeeping, recording each operation during the forward pass and keeping the values its backward rule needs (section 7.3). What it keeps is the activation memory that the worked example below quantifies.

5.4.5.5 Worked example: Training vs. inference memory

The four terms of equation 5.29 can now be evaluated for the running network. A single forward pass through the $784 \to 128 \to 64 \to 10$ network costs 109,184 MACs, but the memory a training step holds is set by stored state rather than by that arithmetic. At batch size 32 in 32-bit (4-byte) floating-point precision, each of the four terms can be counted in turn.

The first contribution is the model parameters, already tallied layer by layer in table 5.5. The 109,386 parameters at 4 bytes each occupy 437.5 KB.

Activations are the next contribution. Table 5.8 records each layer's activation tensor and its memory cost at batch size 32.

Table 5.8: MNIST Activation Memory at Batch Size 32: Per-layer activation tensor shapes, value counts, and 32-bit float memory cost during a single forward pass. Input activations dominate the activation table at 100.4 KB; for this small MNIST multilayer perceptron (MLP), the total activation footprint remains below the parameter footprint, while larger batches and deeper networks make activations a central training-memory concern.

Layer	Activation Shape	Values	Memory
Input	32×784	25,088	100.4 KB
Hidden1	32×128	4,096	16.4 KB
Hidden2	32×64	2,048	8.2 KB
Output	32×10	320	1.3 KB

Layer	Activation Shape	Values	Memory
Total		31,552	**126 KB**

Training adds two memory contributions that inference never pays. Gradients occupy the same space as the parameters they update, here 437.5 KB, and the optimizer adds its own state. The Adaptive Moment Estimation (Adam) optimizer,[21] a widely used refinement of gradient descent, keeps two running averages for every parameter, one of its recent gradients (the *first moment*) and one of its recent squared gradients (the *second moment*), and uses them to adapt each parameter's step size. Those two buffers occupy twice the parameter size, another 875.1 KB. Table 5.9 summarizes the per-component memory footprint for training vs. inference.

Table 5.9: MNIST Training vs. Inference Memory at Batch Size 32: A simplified FP32 memory estimate for the MNIST MLP. Training retains saved activations and adds gradients plus two Adam buffers; inference uses the peak adjacent-layer buffer. Framework workspace and memory-saving techniques can change the totals.

Component	Training	Inference
Parameters	437.5 KB	437.5 KB
Activations	126 KB	117 KB
Gradients	437.5 KB	—
Optimizer state	875.1 KB	—
Total	**~1.9 MB**	**~554 KB**

Figure 5.17 follows the same memory through one training step. At batch 32 the parameter state of weights, gradients, and Adam buffers sets the peak, and the saved activations are a thin layer on top. Multiplying the batch by 32 leaves the parameter state untouched and multiplies the activation layer by 32, until saved activations are most of the memory and the peak moves to the moment the forward pass ends. The same network and the same arithmetic per example can therefore be parameter-bound or activation-bound in memory, and the batch size decides which.

Scale drives the systems lesson. At batch size 32, training requires 3.4× the inference memory in this simplified estimate; the inference column follows from the buffer-lifetime rule of section 5.5.2. The absolute gap grows with parameter and activation storage; the ratio depends on their balance and on implementation choices such as recomputing some activations instead of storing them, numerical precision, and workspace reuse.

5.4.5.6 Scaling beyond MNIST

The running network is the smallest case in this chapter. Figure 5.18 plots the parameter counts of 725 notable models published since 1950. Until about 2010 the count doubled roughly every 43 months; after 2010, as deep learning took hold, it doubled about every 10 months, and the largest models now hold more than a trillion parameters. Every dense parameter carries the same three obligations as the running network's weights, so the per-parameter bookkeeping counted for a small digit classifier is the arithmetic that sets the memory and bandwidth budgets of the models in later chapters. The parameter climb parallels the growth in training compute that figure 1.6 traced.

The MNIST network's memory is small, but each of its terms grows with network width and batch size, as equation 5.10 showed, and every training step must also move that state, reading parameters, producing gradients, and retaining or recomputing the forward-pass values each layer's backward calculation needs. For modest networks like the MNIST example, this traffic remains manageable. As models grow, memory bandwidth and activation storage can become binding constraints, motivating high-bandwidth memory, narrower number formats for some tensors (mixed precision), partitioning state across devices, and activation recomputation, which discards selected saved activations and recomputes them during the backward pass. Section 8.6.3 develops mixed precision, and section 8.6.5 develops recomputation.

The memory requirements summarized in table 5.9 seem modest for a digit classifier. At production scale the same four terms move a model into a different tier of the memory hierarchy.

[21] **Adam (adaptive moment estimation)**: Maintains per-parameter first- and second-moment estimates of the gradient, requiring 2× additional FP32 memory beyond the parameters themselves (Kingma and Ba 2015). For a 100K-parameter MNIST model this overhead is negligible, but for a 7-billion parameter model it adds ~56 GB, often the difference between fitting on one GPU or requiring partitioning. Adam is widely used because its adaptive updates work robustly across many tasks, but learning rate, schedule, regularization, and memory strategy still require validation.

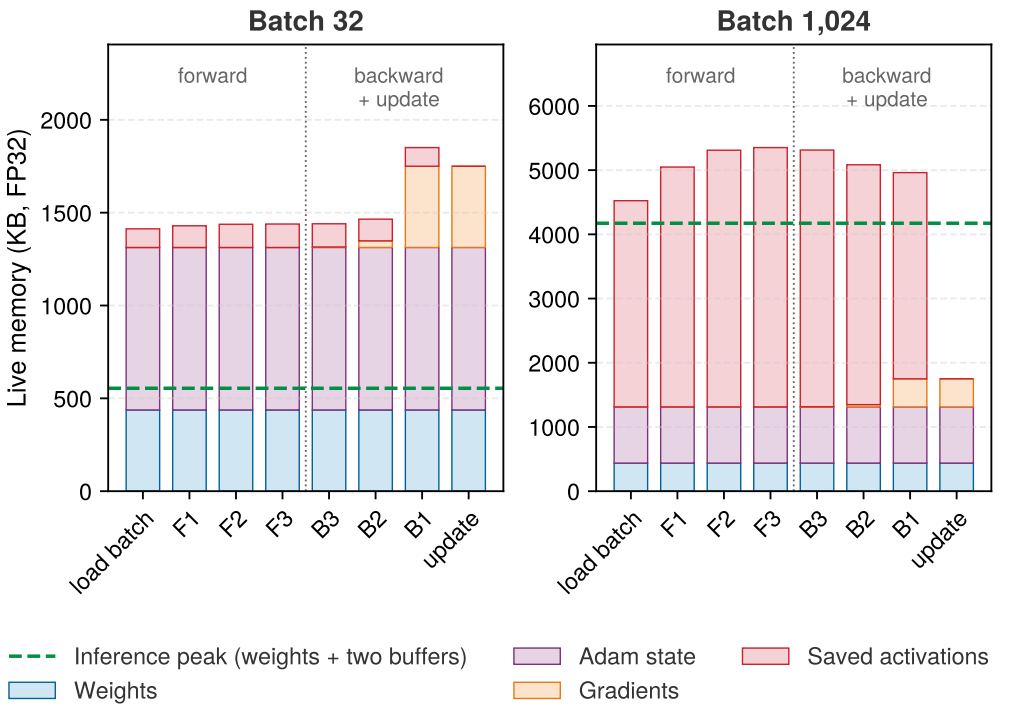

Figure 5.17: Memory Over One Training Step: Live FP32 memory of the running 784-128-64-10 network at each event of a training step, with weights and the two Adam buffers resident throughout. The forward pass (F1 to F3) keeps every layer's output, the backward pass (B3 to B1) releases them as it consumes them while gradients accumulate, and the update leaves only parameter state. The left panel runs batch 32 and the right panel batch 1,024. The dashed line is inference: weights plus the largest pair of adjacent activation buffers.

Lighthouse 5.1: MNIST-to-ResNet-to-GPT-2 memory scaling

The MNIST running example and the GPT-2 lighthouse show how model scale changes the data (D_{vol}) term of the iron law of ML systems (principle 3).

- MNIST (running example): 109,386 parameters at 4 bytes each occupy approximately 438 KB. This entire model fits inside the L2 cache of a modern processor.
- ResNet-50 (lighthouse): 25.6M parameters occupy approximately 102.4 MB in FP32, far beyond any cache but comfortably inside one accelerator's device memory.
- GPT-2 (lighthouse): 1,500,000,000 parameters at 4 bytes each occupy approximately 6 GB before activations and runtime workspace. This exceeds cache capacity and places the model in a device-memory or multi-device regime unless precision is reduced.

Systems insight: Moving from ~109.4K to 1.5B parameters is a 14,000× jump. The increase represents a phase change in engineering, not merely "more parameters." MNIST can keep its weights near the processor; GPT-2 serving must manage a much larger memory working set. Whether a particular layer is compute or memory bound still depends on batch size, precision, reuse, and hardware balance.

Figure 5.19 sets the three footprints against the memory that would hold them. Each step to the right is a step down the memory hierarchy, from a microcontroller's on-chip SRAM through an accelerator's L2 cache to its high-bandwidth memory (HBM), toward storage that is larger, farther from the arithmetic, and slower to read.

↪ Why weights, gradients, and two Adam moments come to 16 bytes per parameter, in plain FP32 and in the mixed-precision recipe alike, is developed in section 8.3.2.3.

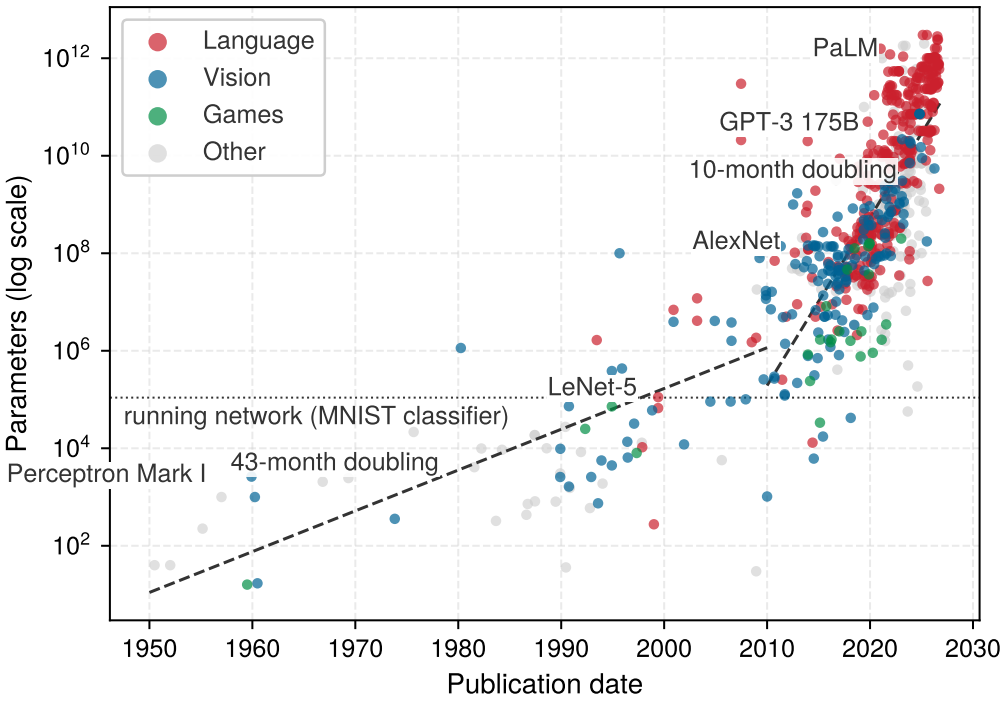

Figure 5.18: Parameter Counts of Notable Models, 1950 to the Present: Each point is one notable model, colored by domain, plotted by publication date on a logarithmic axis. Dashed lines are least-squares fits before and after 2010; the steeper second segment coincides with the rise of deep learning. Data from Epoch AI (2026c).

Engineers also need the same reasoning in seconds rather than minutes. Multiplying parameters by bytes per value and by the number of training-state copies rejects an impossible configuration before any profiling, and section 8.4.3.2 turns those napkin rules into a complete training-memory budget.

Checkpoint 5.3: Backpropagation

The credit assignment problem asks how the loss depends on parameters throughout the network. Backpropagation computes those gradients via the chain rule; verify that the mechanism is clear:

Mechanism

- ☐ **Chain rule**: can you explain how equation 5.24 decomposes a complex error signal into local gradients for each layer?
- ☐ **Gradient decay**: why do gradients often vanish in deep networks?

Training vs. inference

- ☐ **Computational cost**: under what input-gradient assumption does dense training require roughly three times the forward matrix work, and which product can ordinary training on fixed raw inputs omit?
- ☐ **Memory cost**: why must training retain or recompute the forward values needed by the backward pass, and how does this scale with batch size and network depth?
- ☐ **Layer cost**: for a dense layer mapping 4,096 inputs to 4,096 outputs at batch size 32, estimate its forward FLOPs and its FP16 output-activation bytes to one significant figure, then say what doubling the batch does to each of them and to the layer's weight bytes.

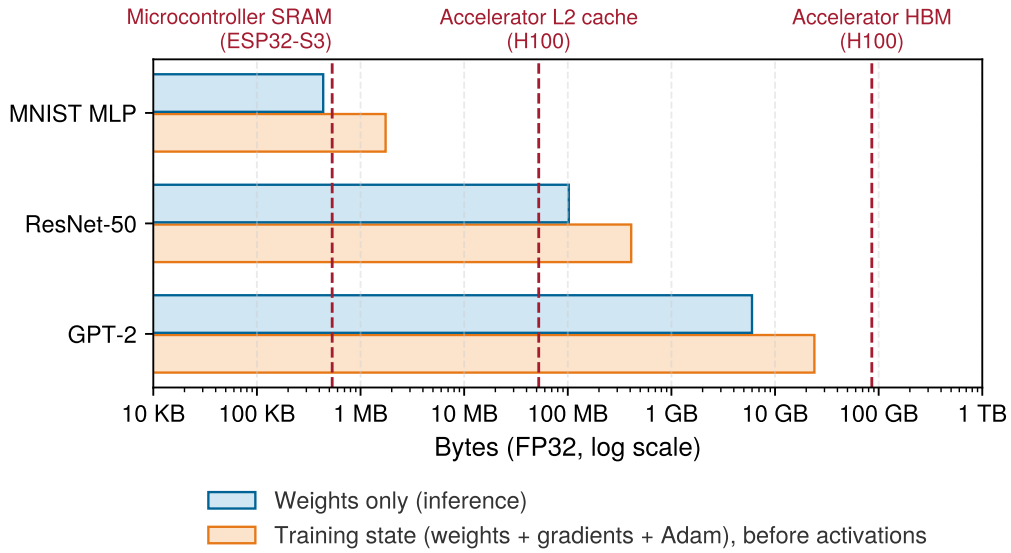

Figure 5.19: Where the Bytes Live: FP32 footprints of the MNIST network and the ResNet-50 and GPT-2 lighthouses on a log scale, for weights alone (inference) and for weights plus gradients plus two Adam buffers (training, before activations). Dashed lines mark the capacity of a microcontroller's on-chip SRAM, an accelerator's L2 cache, and its high-bandwidth device memory. MNIST's training state crosses a tier boundary that its weights do not; ResNet-50 and GPT-2 sit in device memory either way, and what changes is how much of it they claim.

5.4.6 Iterative learning process

The cost of one training step is now known in operations and in bytes. Training repeats that step, forward propagation, backward propagation, and a weight update, in a loop that runs until the network achieves satisfactory performance or reaches a predetermined number of iterations.

A single pass through the entire training dataset is called an epoch.[22] For MNIST, with 60,000 training images and a batch size of 32, each epoch consists of 1,875 batch iterations. Algorithm 5.2 lays out the loop of mini-batch stochastic gradient descent (SGD) (Robbins and Monro 1951), so called because each update follows a gradient estimated from a random sample of the data rather than the full dataset. Each epoch shuffles the data, steps through it one mini-batch at a time with a forward and backward pass, and applies a single parameter update per batch.

[22] **Epoch**: The number of passes is a direct multiplier on total work, so a 100-epoch MNIST run executes 100× more forward and backward passes than a single epoch. Large language-model training is often specified by a token budget rather than a simple epoch count because data sources may be mixed and sampled at different rates. The same accounting still applies: every additional training token adds another forward and backward computation.

Algorithm 5.2 Mini-batch stochastic gradient descent

Require: training set $\{(\mathbf{x}_i, \mathbf{y}_i)\}_{i=1}^{D}$; rate η; batch size B; epochs N_{epochs}; initial θ_0
Ensure: trained parameters θ

$\theta \leftarrow \theta_0$
for $e = 1$ to N_{epochs} **do**
  shuffle the training set ▷ *reduce order-dependent patterns*
  for each mini-batch $\mathcal{M}$ of size B **do**
    $\hat{\mathbf{y}}_i \leftarrow f(\mathbf{x}_i; \theta)$ for all $(\mathbf{x}_i, \mathbf{y}_i) \in \mathcal{M}$ ▷ *one MAC per weight per example; every activation saved*
    $\mathcal{L}_{\mathcal{M}} \leftarrow \frac{1}{B} \sum_{(\mathbf{x}_i, \mathbf{y}_i) \in \mathcal{M}} \mathcal{L}(\hat{\mathbf{y}}_i, \mathbf{y}_i)$ ▷ *a few operations per class; negligible*
    $g \leftarrow \nabla_\theta \mathcal{L}_{\mathcal{M}}$ ▷ *backward: up to twice the forward MACs; reads the saved activations*
    $\theta \leftarrow \theta - \eta\, g$ ▷ *reads and writes every parameter; almost pure data movement*
  end for
  evaluate on validation; stop if the convergence criterion is met
end for
return θ

The mini-batch loop makes the batch size B a hardware unit of work: a larger B can improve matrix utilization and accelerator occupancy but raises activation memory, and because the update fires once per batch rather than once per example, B also sets the gradient-update cadence. The inner loop in algorithm 5.2 is the unit that the hardware repeatedly executes, and its comments carry the chapter's cost accounting line by line. The forward line spends the MACs of table 5.5 for every example in the batch and leaves activations behind, the backward line spends up to twice that and consumes those activations, and the update line does little arithmetic but touches every parameter, so its cost is set by bytes moved rather than operations performed. (In the algorithm, D counts logical training examples, the Samples/Task factor of the iron law, rather than the physical bytes moved D_{vol} in its memory term.) Notebook 5.3 evaluates one full epoch of this loop in seconds and joules on two machines, charging every operation the fixed dispatch cost whose mechanism section 7.3.4 develops.

Napkin Math 5.3: One epoch on two machines

Problem: How long does one training epoch of the running network take on a desktop CPU and on a data-center accelerator, which term of the iron law sets that time, and where does the energy go?

Background: One epoch at batch 32 is 1,875 steps of about 14.5 MFLOP each, the forward work of table 5.5 scaled by the training-step ratio derived earlier. At batch 32 the network's arithmetic intensity sits below both machines' ridge points (figure 5.14), so each step runs at the bandwidth-limited rate. Every operation a step launches also pays a fixed cost: about 10 µs for the framework to dispatch it and, on the accelerator, about 5 µs more to launch it, across roughly 12 operations per step.

Solution: The arithmetic and data movement of a whole epoch take about 46 ms on the CPU and 0.7 ms on the accelerator, a 67× advantage. The fixed per-operation costs add about 225 ms on the CPU and 337.5 ms on the accelerator, so the totals come to about 271 ms and 338 ms. On the accelerator, 99.8 percent of the epoch is overhead, and the CPU finishes first. Energy tells a parallel story. With the energy constants introduced alongside the iron law (Horowitz 2014), about 160 pJ per byte moved from dynamic random-access memory (DRAM) and 2.3 pJ per FP32 operation (the average of a multiply and an add), moving a step's bytes costs 5.8× the energy of its arithmetic at batch 32, and 141× at batch 1.

Systems insight: At this scale the third term of the iron law, fixed overhead, decides the run, and the accelerator's bandwidth advantage disappears behind it; a network this small trains at least as fast on a CPU. Larger models, larger batches, and fewer, fused operations shift the balance back toward the work terms, which is how frameworks gain their speed (chapter 7), while the energy result anticipates why reuse, batching, and narrower formats matter as much to power as to time (section 1.7).

5.4.6.1 Overfitting, regularization, and convergence

A network that reaches 99.5 percent accuracy on its training batches while stalling at 85 percent on held-out examples has memorized quirks of its training sample instead of learning patterns that transfer to unseen inputs. Training loss tracks the optimization objective on recent batches, whereas validation accuracy measures task performance on a separate held-out validation set (with the test set reserved for final evaluation after model and hyperparameter choices are fixed); a widening gap between the two is the primary symptom of overfitting.

Definition 5.6: Overfitting

Overfitting is a generalization failure in which performance on the training sample improves while performance on relevant unseen data does not.

1. **Significance**: The diagnostic signature is measurable: training loss continues to fall while validation loss rises or the relevant validation metric plateaus, creating a widening

generalization gap. Data coverage, architecture, optimization, regularization, and the relationship between train and deployment distributions all matter. Parameter count alone does not decide whether a model overfits. Past the point where a model can fit its training set exactly, test error can fall again as capacity grows, a pattern called double descent (Belkin et al. 2019; Nakkiran et al. 2019).

2. **Distinction**: Unlike underfitting (where the model lacks the capacity to capture the target function and both training and validation error remain high), overfitting produces low training error but high validation error.
3. **Common pitfall**: More data helps only when it is representative of the behavior the system must generalize to. Additional examples, augmentation, regularization, and early stopping are possible interventions, but each must be evaluated on held-out data from the relevant operating regime.

Regularization controls overfitting by constraining what the network can fit. The most common form adds a penalty on weight magnitude to the loss. An ℓ_2 term $\lambda_{\text{reg}} \sum w^2$, where λ_{reg} sets the penalty strength, shrinks every weight slightly at each step, which is why it is also called **weight decay**. An ℓ_1 term $\lambda_{\text{reg}} \sum |w|$ pushes weights toward zero, producing the unstructured sparsity that chapter 10 exploits. Neither penalty needs persistent state of its own. **Dropout** (Srivastava et al. 2014) zeroes a random fraction of activations at every training step so that no unit can rely on a single upstream partner; it costs a fresh random mask per activation during training and disappears at inference. Early stopping, halting training once validation loss stops improving, is the third common control, and it depends on the periodic validation and checkpointing that close this section.

Convergence monitoring provides essential feedback during training and continues into production deployment. A flattening training-loss curve signals slowing optimization, but it does not identify the cause: the run may be approaching a useful solution, encountering an optimization limit, or underfitting. A validation plateau is similarly diagnostic rather than conclusive. The gap between training and validation performance helps distinguish overfitting from improvements that transfer to held-out examples. For the machine, the quantity that matters is time to a target accuracy, which is the number of steps the optimizer needs times the time each step takes. Batch size pulls the two factors in opposite directions. A larger batch means fewer steps per epoch (1,875 for MNIST at batch 32) and better weight reuse per step, but each step costs more time and activation memory, and past some size the optimizer needs more epochs to reach the same accuracy. The useful batch is the one that minimizes that product within the memory available for training.

Selecting a stopping point also requires periodically evaluating the model on the validation set and saving its weights to durable storage, a practice called checkpointing (not to be confused with activation recomputation, which some frameworks also call checkpointing) that section 8.4.5 develops. For the MNIST network a checkpoint write is negligible; for a model whose parameters occupy tens to hundreds of gigabytes, every checkpoint and every validation pass is a recurring storage and compute cost whose frequency must be balanced against recovery and model-selection needs.

The complete training pipeline runs from forward propagation through loss computation to gradient-based weight updates. Training, however, is preparation, not the end goal. Once parameters are optimized, deploying the model for real-time predictions changes the resource profile entirely.

Checkpoint 5.4: Neural network learning process

The complete training cycle provides the mathematical machinery that enables neural networks to learn from data. Before moving to inference and deployment, verify core understanding of the training cycle:

Use the MNIST network ($784 \to 128 \to 64 \to 10$) and a batch size of 32 as the running check.

- ☐ **Forward pass**: can you trace the forward pass using $\mathbf{Z}^{(\ell)} = \mathbf{A}^{(\ell-1)}\mathbf{W}^{(\ell)} + \mathbf{b}^{(\ell)}$ and $\mathbf{A}^{(\ell)} = f(\mathbf{Z}^{(\ell)})$?

- ☐ **Cross-entropy loss**: can you explain what cross-entropy loss measures and why batch loss is averaged across examples?
- ☐ **Generalization**: using training and validation loss, can you tell overfitting apart from slow optimization, and name one control that limits overfitting?
- ☐ **Update rule**: can you write the gradient descent update rule and explain how batch size trades memory, throughput, and gradient stability?
- ☐ **Cost of an epoch**: can you say which term of the iron law sets the time of one training epoch of this network on an accelerator, and why larger batches or fused operations change the answer?

If any concepts feel unclear, review the earlier sections on forward passes, loss functions, backpropagation, and learning before continuing. These mechanisms form the foundation for the training-vs.-inference distinction that follows.

5.5 Inference Pipeline

Training transforms randomly initialized weights into parameters that encode useful patterns, but deployment executes those parameters under a different resource profile. During inference,[23] the same mathematical operators face a different operating regime: online latency deadlines or offline throughput targets replace the training objective, gradients and optimizer state disappear from memory, and target execution environments range from milliwatt edge processors to multi-accelerator cloud servers. This transition reshapes how memory bandwidth, compute capacity, and pipeline stages govern system performance. Because ordinary inference never updates the weights, a deployed model adapts to a changing world only through monitored data collection, validation, and retraining, a loop that operations practice owns.

The training memory estimate of section 5.4.5.5 counted four kinds of state. Inference keeps exactly one of them, the weights, and replaces the saved activations with a pair of short-lived buffers. Persistent weights plus rolling activations are the whole of inference memory for a feed-forward network. Batching then trades latency for reuse, and once the network itself is fast, the stages around it can dominate.

5.5.1 Operational phase differences

The two phases differ first in what they execute and how long their state lives. Inference executes only the forward pass, evaluating inputs against static parameters with batch sizes dictated by incoming traffic. Training couples that forward pass with backpropagation for gradient computation and parameter updates, selecting batch sizes to maximize accelerator occupancy and gradient stability. Unlike inference, training must retain intermediate activations, gradients, and optimizer state simultaneously, multiplying working memory demands. The underlying network weights are identical, but the execution graph changes. Training-only regularizers such as dropout are stripped away, while adjacent matrix operations and activations can be fused or quantized into specialized execution kernels. In figure 5.20, training couples large-batch processing with a bidirectional loop in which output errors trigger a reverse gradient pass, whereas inference executes a strictly unidirectional forward pass over smaller, variable batch sizes without backward state retention.

These differences determine which hardware each phase runs on and how it is deployed. Training clusters rely on high-bandwidth, high-memory accelerators backed by hundreds of watts per socket and dedicated data-center cooling.[24] Inference deployments on constrained hardware prioritize bounded tail latency and energy efficiency across diverse platforms: mobile devices execute on low-power neural processing units (typically 2–4 W), edge servers employ dedicated inference accelerators,[25] and cloud instances use reduced numerical precision to saturate dedicated matrix-multiply units (NVIDIA's versions are called Tensor Cores). At scale, production serving introduces operational requirements that do not arise in isolated training runs, including dynamic request batching, load balancing, and failure isolation. At the memory level, training retains all forward activations until backward passes consume them, whereas inference discards or overwrites intermediate buffers as execution advances through the graph; table 5.10 summarizes this resource profile.

[23] **Inference**: From Latin *inferre* ("to bring in, to conclude"), borrowed from logic where it means deriving conclusions from premises. The ML usage marks a systems boundary: training executes forward and backward passes and maintains optimizer state, while ordinary inference executes the forward graph with frozen parameters. Removing gradients, optimizer state, and most saved activations can reduce memory and computation substantially, but the ratio depends on architecture, batch size, precision, runtime workspace, and serving strategy.

↪ When monitored drift should trigger retraining, and what each retraining cadence costs, is developed in section 14.6.1.

[24] **Training GPU power budget**: The "high-memory" requirement is driven by the need to hold parameters, gradients, optimizer state, and activations simultaneously. The corresponding power draw dictates the "dedicated data-center cooling infrastructure," as a single high-end training GPU consumes 400 W–700 W. Even compared with a 4 W mobile inference chip, that is at least 100× the power budget.

[25] **Edge inference accelerators**: Google's edge Tensor Processing Unit (TPU), the Edge TPU (Google Coral), operates in the mobile/embedded tier at about 2 W, delivering 4 TOPS through an INT8 datapath. Edge servers sit in a different tier: Jetson AGX Orin reaches 275 TOPS at 15 W–60 W, about 68.8× more throughput but with wired-power assumptions.

↪ Tensor Cores, which execute a small matrix multiply-accumulate per instruction and set the reduced-precision peak rates quoted for data center GPUs, are developed in section 11.4.2.

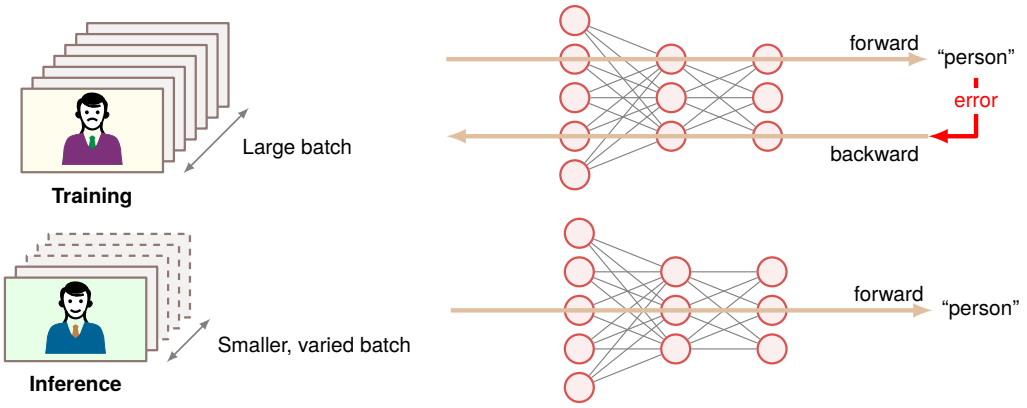

Figure 5.20: Inference vs. Training Flow: Both flows run the same fully connected network; the batch outlines (dashed and varied for inference, solid and uniform for training) mark the two operating regimes.

Table 5.10: Training vs. Inference Forward Pass: Both phases execute the same forward equations, but they manage state differently. Training must retain or recompute the values required by the backward pass and also carries gradients and optimizer state. Inference can reuse a rolling pair of layer buffers.

Characteristic	Training Forward Pass	Inference Forward Pass
Activation Storage	Retains values required by the backward pass	Retains the current input and output buffers
Memory Pattern	Saves or recomputes selected intermediate states	Reuses buffers as successive layers complete
Computational Flow	Same matrix products; each layer input is kept	Same matrix products; each input freed after use
Resource Profile	Weights, gradients, optimizer state, saved inputs	Weights plus the largest adjacent buffer pair

5.5.2 Memory and computational resources

Inference has two memory obligations. The first is persistent: the trained weights and biases must remain available for every request. The second is transient: in this sequential feed-forward graph, each layer produces an activation buffer that is needed only until the next layer consumes it. This distinction is the reason inference can be much leaner than training, even though the arithmetic in the forward pass is the same.

For the canonical MNIST network ($784 \to 128 \to 64 \to 10$), the persistent parameter block contains 109,386 parameters, or about 438 KB at 32-bit floating point precision. The layer-level counts in table 5.5 show why inference is cheap to plan. Each fully connected layer performs one multiply-add for each weight, so parameter memory and arithmetic scale together.

The transient side is where inference saves the most. Under the retained-activation training scheme used here, activation tensors persist until backpropagation reaches their corresponding layers, producing cumulative memory consumption across the entire network depth ($\sum_\ell M^{(\ell)}_{\text{activations}}$, where $M^{(\ell)}_{\text{activations}}$ is the byte size of layer ℓ's activations). In a sequential feed-forward graph, inference needs a layer's input buffer only until that layer has produced its output. Once layer $\ell+1$ finishes execution, the activation buffer for layer ℓ is dead and its storage can be overwritten, so peak transient activation memory falls from the cumulative total to the largest adjacent pair, $\max_\ell \left(M^{(\ell)}_{\text{activations}} + M^{(\ell+1)}_{\text{activations}}\right)$. A skip connection or any other later consumer extends a buffer's lifetime and must enter that plan; the static memory planners that serving runtimes build on this property are developed in section 13.6.2.2.

For the running network at batch size 32, that rule produces the inference column of table 5.9. Inference holds the 438 KB parameter block plus a rolling activation pair of about 117 KB, roughly 554 KB in all. The training step of table 5.9 holds about 1.9 MB, 3.4× as much, for the same weights and the same forward arithmetic. The entire difference is state that training keeps and inference

does not: saved activations, gradients, and optimizer buffers. Fixed parameters and short buffer lifetimes also make inference easier to optimize, and batching is the first lever.

5.5.3 Optimizing inference throughput and latency

Serving one request at a time ($B = 1$) turns every fully connected layer into a matrix-vector product that reads each weight from memory only to use it in a single multiply-accumulate ($z_j \leftarrow z_j + x_i W_{ij}$), leaving arithmetic intensity at about 0.5 FLOP/byte (notebook 5.1). Because inference freezes parameters and eliminates backward state, runtime engines can plan batching, memory layout, operator scheduling, and numerical precision against the physical limits of the target processor.

Input batching trades per-request latency against hardware efficiency. Aggregating requests into a batch turns that matrix-vector product into a matrix-matrix product that reuses each loaded weight across all B inputs, raising the MNIST network's intensity to about 11.9 FLOP/byte at batch 32. Weight reuse matters most when parameters stream from off-chip memory and the workload sits below the machine's ridge point; a model as small as MNIST can instead keep its weights in cache from one request to the next.

Batching also increases the activation values produced: the MNIST network produces 202 layer-output values per image (986 values including the input), or 6,464 layer-output values for a batch of 32. These are cumulative counts across layers; simultaneous storage follows the rolling-buffer rule of section 5.5.2. Production systems serving interactive traffic must also limit the wait to accumulate inputs according to their service-level latency budget.

↪ How serving systems batch incoming requests dynamically to amortize parameter transfers is developed in section 13.5.3.

The stages around the network have an entirely different computational profile from the forward pass. While neural network execution exploits massively parallel matrix units on accelerators, preprocessing (such as image decoding and normalization) and postprocessing (such as argmax reduction, threshold checking, and message serialization) often execute on the host CPU, although implementations can parallelize or accelerate them. Amdahl's law, met in the introduction and developed for accelerated systems in section 11.1, bounds end-to-end speedup by the fraction of time that is not accelerated, so as accelerator kernels drive forward-pass execution times toward zero, these unaccelerated CPU stages and their associated Peripheral Component Interconnect Express (PCIe) data transfers can come to dominate end-to-end request latency.

Three further mechanics complete the inference design space, and each has an owning chapter. Kernel fusion keeps a layer's intermediate results in on-chip storage instead of writing them to off-chip memory between the matrix multiply, the bias addition, and the activation (section 7.3.2). Quantization stores frozen weights in fewer bits, which inference tolerates better than training because no small gradient updates must survive (section 10.3.3.1). Autoregressive transformers add a key-value cache of intermediate results from earlier tokens that grows with every token generated (section 6.7.4.2).

The complete lifecycle of the running network, from architecture through training to inference, is now a set of operations with quantifiable costs. Those estimates were made in a controlled setting, with clean data, no deadline, and an unchallenged machine. A production deployment, where none of those conditions holds, is the real test of whether they are complete.

Checkpoint 5.5: Complete neural network system

Before turning to how these mechanics first performed in deployment, verify your understanding of the complete neural network lifecycle:

Use the MNIST classifier ($784 \to 128 \to 64 \to 10$) as the running production system.

- ☐ **System lifecycle**: can you trace the lifecycle from architecture design to training loop to trained model to inference deployment?
- ☐ **Training vs. inference memory**: at a matched batch size, can you explain why this estimate gives training roughly 3.4× the memory of inference, naming the gradients, optimizer state, and saved-activation terms?
- ☐ **End-to-end trace**: can you trace one digit image through preprocessing, forward propagation, and postprocessing to a final prediction, and say which of those stages usually run on the host CPU rather than the accelerator?

- ☐ **Bottleneck spotting**: if the forward pass became ten times faster while preprocessing on the host CPU stayed unchanged, which stage would set the end-to-end rate, and what bound does Amdahl's law place on the overall speedup?
- ☐ **Batching trade**: can you explain why batching raises arithmetic intensity at batch size $B > 1$, what it costs in activation memory and per-request latency, and why serving systems cap the wait to fill a batch?

Recognizing a digit was not always a benchmark. Decades before large datasets and specialized accelerators, the same task ran in production, in the mail-sorting and check-reading systems where neural inference first met a physical deadline.

5.6 Handwritten Digit Recognition

In the late 1980s, LeCun and colleagues demonstrated backpropagation-based recognition of handwritten ZIP-code digits from USPS-supplied images (LeCun, Boser, et al. 1989). Related convolutional document-recognition work later supported commercially deployed bank-check readers (LeCun et al. 1998). These were distinct systems, but they exposed the same engineering pattern: preprocessing normalized variable handwriting, neural inference produced candidate digits, rejection thresholds sent uncertain predictions to human review, and downstream logic converted accepted predictions into operational decisions. That shared pipeline is the chapter's running digit task, deployed. It tests every cost estimate the chapter has built, because preprocessing, model structure, and rejection policy must interact under a physical throughput constraint, and its first obligation is to turn the network's scores into decisions.

5.6.1 From scores to decisions

Neural network outputs become useful only after they are converted back into decisions a conventional system can act on. Preprocessing bridges real-world data into tensor form; postprocessing maps neural outputs into labels, decision thresholds, validation logic, error handling, and downstream messages. For the running network, raw logits are not enough. A digit-recognition system needs the most likely digit class, a confidence score whose calibration has been evaluated, and a fallback route that directs ambiguous or low-confidence predictions to human review or a secondary recognizer.

↪ Calibration, the agreement between a classifier's confidence scores and its observed accuracy, is measured in section 12.9.1.2.

That fallback route is itself a design decision with a measurable trade. A confidence threshold on the top-class probability sends every prediction below it to a person. Raising the threshold reduces the accepted fraction and increases review workload. For a fixed set of scored inputs, it cannot increase the number of accepted mistakes, but the error rate among the remaining accepted predictions can rise or fall because both the error count and the accepted count change. Engineers therefore measure a risk-coverage curve, plotting error among accepted predictions against the fraction of inputs accepted, on held-out data that resembles deployment traffic. A usable operating point must meet the error budget while keeping rejected traffic within review capacity. Softmax probabilities need not be calibrated, and distribution shifts can change both counts, so the selected threshold and its review workload require monitoring.

Confidence thresholds determine the division of labor between automation and human review. An expected-cost rule (Chow 1970) chooses threshold τ to minimize $r_{\text{manual}}(\tau)\,C_{\text{manual}} + r_{\text{error}}(\tau)\,C_{\text{error}}$ subject to throughput and latency constraints, where $r_{\text{manual}}(\tau)$ and $r_{\text{error}}(\tau)$ are the fractions of all arriving items sent to manual review and accepted with a wrong automated classification, and C_{manual} and C_{error} are their per-item costs. Both fractions count against every arriving item, so an error rate reported only among accepted items must first be multiplied by the accepted fraction. The 1989 ZIP-code system reported one measured point on this curve, examined in section 5.6.4.

5.6.2 The document-recognition challenge

In a physical postal sorter, envelopes move past optical scanners along mechanical belts at fixed speed, leaving only tens of milliseconds per item to capture the image, isolate the digits, evaluate the network, and trip the physical diverter gates. A misrouted envelope or misread check incurs

costly manual re-handling or financial reconciliation, yet raw accuracy on uncontrolled handwriting cannot reach 100 percent, so the pipeline must pair automated inference with an explicit rejection rule that routes ambiguous digits to human operators. The sample grid in figure 5.21 shows this handwriting variation across real postal envelopes, where character segmentation and recognition must handle heavy cursive slant, uneven stroke widths, broken loops, and patterned envelope backgrounds across city names and five-digit ZIP codes.

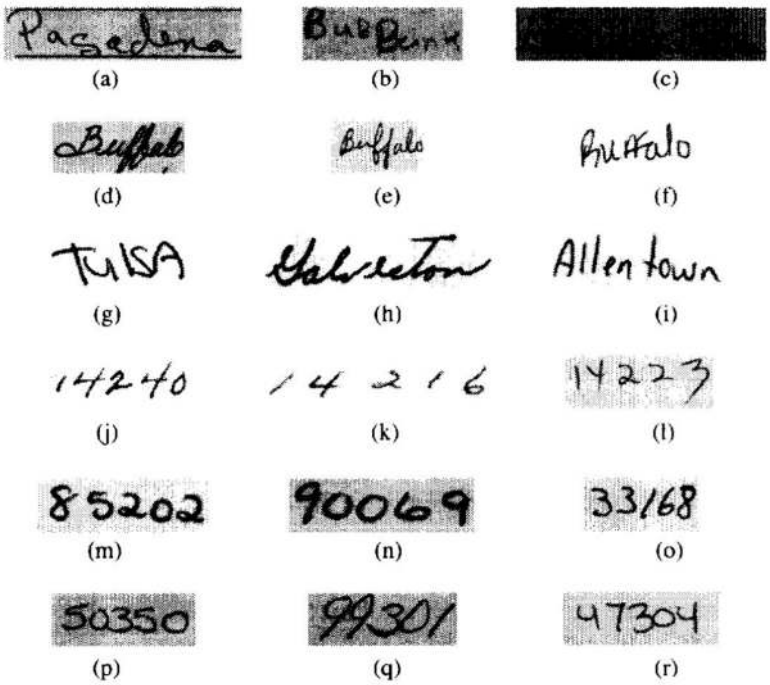

Figure 5.21: Handwritten Address Variability: Address and ZIP-code samples show wide variation in stroke width, slant, spacing, and character formation. A document-recognition pipeline must absorb this variation without confusing legitimate writing differences with changes in the intended characters. Source: CEDAR CD-ROM 1 USPS Office of Advanced Technology database.

No single stage can absorb all of that variation alone, and the dataset histories behind the task must also remain separate. Early ZIP-code research used postal digit images supplied for that task (LeCun, Boser, et al. 1989), whereas MNIST was later constructed from National Institute of Standards and Technology (NIST) handwritten-digit databases and standardized into size-normalized benchmark images (LeCun et al. 1998), not collected from live envelopes under varying colors, textures, lighting, and orientations. Both histories nonetheless imposed the same engineering requirements. Preprocessing had to reduce irrelevant variation without erasing the stroke information needed for recognition, and training had to cover handwriting variation, with augmentation exposing the model to additional plausible variation, rather than optimize only for a curated test set.

↩ Why evaluation on curated data must be validated against field conditions is established in section 3.8.

5.6.3 Shared pipeline architecture

Feeding raw envelope scans straight into a digit classifier fails because the network expects isolated, size-normalized characters rather than full addresses on textured paper, and its raw scores still need a rejection rule before they can trip a sorting gate. The composite six-stage pipeline in figure 5.22 separates the work shared by postal ZIP-code research and deployed bank-check readers (rather than reconstructing a single historical machine): upstream preprocessing segments and normalizes the scanned digits, the neural network scores each candidate digit, and downstream postprocessing compares those scores against confidence thresholds, passing accepted digits to the sorter while routing ambiguous ones to human review.

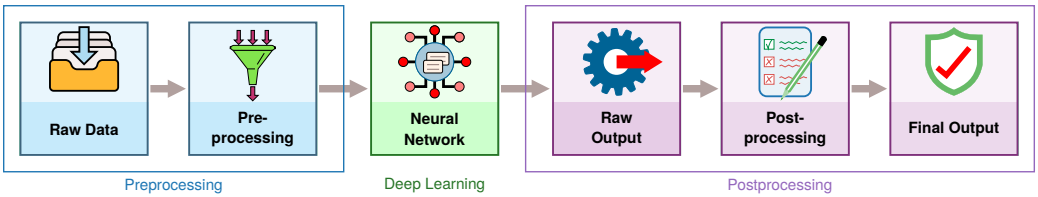

Figure 5.22: Document-Recognition Pipeline: A composite six-stage flow distilled from postal ZIP-code research and deployed check-reading systems. Image acquisition and conventional preprocessing prepare handwritten digits for neural inference, and raw scores then pass through postprocessing to the final application output.

The upstream boundary pairs image acquisition with conventional preprocessing. In postal research, the raw input was an image of a handwritten ZIP-code region, and deployed check readers similarly began with scanned document images; acquisition quality determines how much variation the downstream stages must absorb. Preprocessing then locates the relevant field, separates or identifies its characters, and normalizes the resulting images through conventional techniques such as thresholding, connected-component analysis, and size normalization. (The chapter uses standardized 28×28 images for its MNIST calculations as a teaching convention, not a claim about every postal or check-reading deployment.)

Once the digits are normalized, the neural network scores each candidate image and hands those scores to postprocessing. The 1989 ZIP-code research system used an early LeNet variant (LeCun, Boser, et al. 1989) with approximately 10,000 parameters, occupying approximately 40 KB in single precision, an order of magnitude smaller than the 109.4K in this chapter's fully connected MNIST network. Downstream postprocessing then converts those digit scores into application decisions with the threshold rule of section 5.6.1: for a ZIP-code task, a single uncertain digit can route the entire code to further processing or human review. Because every stage from acquisition to that downstream action counts against the reader's end-to-end timing constraint, throughput depends on the complete pipeline rather than neural-network latency alone.

5.6.4 Performance outcomes and operational impact

The 1989 ZIP-code study reported its model, recognition, throughput, and training measurements as one experimental system. Table 5.11 keeps those measurements together, revealing how rejection policy and preprocessing affect the meaning of raw classifier speed (LeCun, Boser, et al. 1989).

Table 5.11: Early ZIP-Code Recognition Results: Measurements from the 1989 backpropagation system applied to USPS-supplied digit images. The rejection result shows why an operational error rate must be read together with the fraction of inputs withheld from automatic classification (LeCun, Boser, et al. 1989).

Metric	Reported Result
Error and rejection	1% classification error after rejecting 12.1% of test digits
Throughput	10–12 classifications/sec including acquisition; over 30/sec after normalization
Model parameters	~10,000
Training	23 passes; about 3 days on a Sun-4/260 workstation

These measurements highlight three systems trade-offs across the pipeline:

First, the measured rate depended on the measurement boundary. The system exceeded 30 classifications per second after normalization but processed 10 to 12 per second including acquisition. The reciprocal rates are completion intervals, not necessarily individual-digit latencies when stages overlap. The comparison exposes surrounding acquisition and preprocessing work, but does not allocate that work among mechanical handling, scanning, and segmentation. Stage timings are needed before choosing which part of the complete path to accelerate.

Second, operational reliability depended on an explicit rejection pathway. The experiment rejected 12.1 percent of test digits rather than forcing a classification for every input, and rejecting this tail of high-uncertainty predictions reduced the observed classification error on the remaining automated

stream to 1 percent. That is one point on the risk-coverage curve of section 5.6.1, and the expected-cost rule there decides whether it is the right one; the 12.1 percent becomes a review workload that the rule must account for.

Third, training-time cost constrained the exploration of model sizes. Training 10,000 parameters required 23 passes across roughly three days on a Sun-4/260 workstation. That measurement shows the cost of the reported configuration; it does not establish a universal maximum model size for the era. Larger candidates would require a new compute, memory, and training-time budget.

Maintaining these systems in production introduces lifecycle requirements beyond model training. Changes in scanner optics, ink formulations, envelope textures, or regional writing styles cause input distributions to drift over time. Production monitoring must track input image statistics and rejection rates alongside raw classification latency, prompting investigation when rejection threatens review capacity. Whether the remedy is data collection, preprocessing repair, threshold adjustment, or retraining depends on the cause and on validated error costs.

↪ How production monitoring detects silent degradation from input drift while code and weights stay unchanged is developed in section 14.5.

5.6.5 Key engineering lessons and design principles

Across postal ZIP-code research and deployed check readers, neural computation succeeded only when the surrounding pipeline shared its operating constraint. Each of the chapter's mechanisms reappears in that pipeline at system scale. The forward-pass operation count set the cost of inference, but the gap between more than 30 classifications per second after normalization and 10 to 12 per second including acquisition is the Amdahl effect of the boundary stages that the inference section predicted. The network's output scores became decisions only through a threshold whose position traded automated volume against residual error. The convolutional reader's parameter footprint, an order of magnitude below the fully connected network's, shows that connectivity patterns, not layer depth alone, govern the state a model must store. A layer that slides one small set of weights across every image position stores far fewer parameters than one that gives every pixel its own weight, although fewer weights do not guarantee smaller activation tensors, and chapter 6 builds its architectures on that choice of connectivity.

Modern edge systems face different power, latency, and deployment budgets, but the same three obligations hold. Preprocessing must absorb the variability of the physical world before the network sees it, confidence thresholds must protect the downstream error budget, and end-to-end throughput, not model latency alone, governs how much model capacity the system can afford. The deployed reader worked because its data, network, and machine fit each other, and the running network's own numbers show that alignment one axis at a time.

5.7 D·A·M Reading of Neural Computation

↩ The D·A·M taxonomy and its three diagnostic axes are established in section 1.5.

In the D·A·M taxonomy, each axis fixes one of the running network's headline numbers, and the data axis fixed the largest weight matrix before any design choice was made. A 28×28 image flattens to 784 inputs, so the first layer holds 100,352 weights and performs 91.9 percent of the network's arithmetic. The same digits scanned at 56×56 would quadruple that matrix to 401,408 weights without changing the model's depth or the task. Data also decides whether those weights are worth learning. USPS ZIP images, MNIST digits, and check images share digit semantics but come from different scanners, thresholds, and layouts, and no preprocessing step can synthesize handwriting styles that the training set never contained.

The algorithm axis set how that matrix meets the machine. Batch size is an algorithmic choice, and it moved the forward pass's arithmetic intensity from about 0.5 FLOP/byte at batch 1 to about 11.9 FLOP/byte at batch 32, because one read of each weight now serves 32 images. The same choice multiplied the activations that training must keep, which is why training holds 3.4× the memory of inference at matched batch size.

The machine axis decided whether learning survives at all. A gradient smaller than its format's smallest normal value, 6.10×10^{-5} in FP16 against 1.18×10^{-38} in FP32, loses precision or flushes to zero and stops updating its weight, and a value beyond the format's maximum overflows to `Inf`. Narrower formats halve or quarter memory traffic and unlock faster matrix units, but only while gradients and activations still fit the format's range.

No axis can be tuned alone. A larger input improves fidelity but grows the first weight matrix, a larger batch improves reuse but grows training memory, and a narrower format speeds the machine

but endangers the gradients. Diagnosing an accuracy shortfall, a latency violation, or an out-of-memory fault therefore starts with a hypothesis on each axis and ends with a measurement of the quantity that binds, because an intervention on one axis routinely moves the binding constraint to another. Teams that skip that measurement tend to fall into a small set of recurring traps.

↪ Screening heuristics that narrow these competing hypotheses, each confirmed against profiler traces and hardware counters, are collected for reference in section A.5.1.

5.8 Fallacies and Pitfalls

Statistical learning adds failure modes that line-by-line code inspection alone cannot reveal. Each of the recurring mistakes below treats a property of the data, the optimization, or the machine as if the model's source code alone decided it.

Fallacy: *Neural networks are entirely opaque and cannot be debugged.*

Neural networks do not offer the line-by-line causal trace of traditional code, but they are not beyond diagnosis. Activation visualization can reveal learned patterns, gradient analysis measures local input sensitivity, and ablation studies estimate component contributions. These tools provide partial evidence rather than a complete explanation: gradient-based saliency maps (per-input sensitivity heat maps) can be unstable, correlated features complicate attribution, and an ablation may change the behavior it is meant to probe. For the MNIST classifier in section 5.3.2, first-layer weights can still provide a useful check on what patterns the model has learned. Debugging a statistical system therefore combines model-level probes with data slices, controlled interventions, and end-to-end evaluation.

Pitfall: *Discarding domain expertise because a deep model is available.*

Teams assume automatic feature learning removes the need for domain knowledge. Successful systems require domain expertise at every stage: architecture selection, training objective design, dataset curation, and output interpretation. The document-recognition history in section 5.6 shows why confidence thresholds must reflect operating economics and route uncertain cases to human operators. Without domain knowledge, teams can deploy networks that look strong on a test set but fail in production because their thresholds, fallback paths, or error costs are wrong.

Fallacy: *Deeper networks are always more accurate than wider ones.*

Engineers assume that stacking more layers is the primary path to higher accuracy, since depth enables hierarchical feature extraction. In practice, depth alone encounters diminishing returns. ResNet showed that very deep residual networks can train effectively, yet its 1,202-layer CIFAR-10 network tested worse than its 110-layer counterpart (He et al. 2016a). EfficientNet, a family of image classifiers, later demonstrated that compound scaling of width, depth, and input resolution can outperform depth-only scaling at a given resource budget (Tan and Le 2019). Depth is not the problem. Teams should profile capacity utilization and scale the dimension that gives the best accuracy per FLOP, since depth adds sequential steps and saved activations while width adds arithmetic inside each step (equation 5.10).

Fallacy: *Training data distribution issues can be fixed after model design.*

Teams treat training as mechanically feeding data through architectures. Networks on imbalanced datasets often perform poorly on the minority class: a fraud detector with 99:1 imbalance achieves 99 percent accuracy by always predicting "not fraud" while catching zero fraud cases. The unweighted batch average of equation 5.16 can underweight rare but critical classes unless sampling, weighting, loss design, and evaluation address the imbalance. Teams that skip exploratory data analysis may deploy models with strong aggregate metrics but unacceptable minority-class performance.

Pitfall: *Deploying research models to production without addressing system constraints.*

Production adds constraints absent from research: latency budgets (50–100 ms end-to-end), memory limits (2–4 GB for edge devices), and concurrent loads (100–1,000 requests per second (RPS)). The complete pipeline includes preprocessing, inference, and postprocessing (section 5.5). A model achieving 20 ms inference fails its 50 ms budget when preprocessing adds 25 ms and postprocessing adds 10 ms (55 ms total). Separating model development from system design therefore wastes effort on accuracy while ignoring deployment feasibility.

Fallacy: *More compute automatically means faster training.*

Teams purchase expensive GPUs expecting proportional speedups, but memory traffic or launch overhead may bind performance instead. Arithmetic intensity tests that hypothesis (figure 5.14). The MNIST forward pass in table 5.7 reaches only about 11.9 FLOP/byte at batch 32 (notebook 5.1) and less at batch 1, while the ridge point $R_{\text{peak}}/\text{BW}$, the intensity a workload needs before peak compute can bind, sits above it on both machines at FP32 and far higher at the reduced-precision peak rates of data-center accelerators. A faster chip therefore leaves this workload waiting on memory, or on kernels too small to fill the machine; the roofline model in section 11.6 makes the condition precise, and measured speedup remains the final test.

Pitfall: *Extrapolating accuracy improvements without considering diminishing returns.*

Teams may extrapolate a 5-point gain from scaling 10K parameters to 100K into another 5-point gain at 1M. Empirical improvement instead diminishes with scale according to the task, metric, data quality, model family, and scaling regime. Published benchmark histories cannot settle the question either. ImageNet top-5 error fell from AlexNet's 15.3 percent to 3.6 percent for a ResNet ensemble (Krizhevsky et al. 2012; He et al. 2016a) while training compute rose by more than an order of magnitude (Amodei and Hernandez 2018a), but those systems mix new architectures with more compute, so they do not isolate the return on scale alone. Teams must therefore measure marginal return within one model family in their own regime rather than extrapolate linearly.

These fallacies and pitfalls share a common root: treating statistical behavior as if code behavior alone determined it. Recognizing them early directs attention toward the appropriate measurements and diagnostics.

5.9 Summary

Neural computation turns layer equations into physical work on a processor. Linear algebra and calculus determine operation cost under the iron law of ML systems ($T = \frac{D_{\text{vol}}}{\text{BW}} + \frac{O}{R_{\text{peak}} \cdot \eta_{\text{hw}}} + L_{\text{lat}}$). Forward propagation establishes the computational work O, often dominated by matrix multiplications, while the complete training step adds backward computation and optimizer updates. Backpropagation needs saved or recomputed forward values and gradient storage; the optimizer may add persistent state. Architecture, batch size, precision, optimizer, and recomputation strategy determine the state footprint. Residency, reuse, and execution then determine the bytes transferred, D_{vol}, which need not equal that footprint. These mechanics make memory footprints, arithmetic intensities, and latency limits estimable before deployment. Table 5.1, from the chapter's opening, now reads as a summary of where each stage spends them, and every row has been derived for the running network.

Replacing hand-written decision rules with parameters learned from data turns feature engineering into matrix arithmetic. Layered compositions of weighted sums, nonlinear activations, and gradient updates form hierarchical representations that convert raw inputs into predictions. Training adjusts connection weights through iterative optimization, while inference applies fixed parameters to incoming data. The two phases make very different demands on the machine. In this chapter's FP32 estimate, a batch-32 training step requires ~3.4× the memory of batch-32 inference because training retains saved activations and gradients alongside the optimizer's additional buffers. In production, as the document-recognition case study demonstrated, these mathematical kernels do not run in isolation; preprocessing, neural inference, rejection, and postprocessing must jointly satisfy a single end-to-end latency and reliability budget.

Key Takeaways: The math behind the model

- **Each paradigm shift changes the systems cost of representation**: In this 28×28 digit example, the operation count rises from ~100 comparisons (rule-based) through ~8,000 operations (classical ML) to 109,184 MACs (deep learning), a 1,100× scenario increase that reshapes hardware requirements.
- **The loss is cheap but seeds every update**: Cross-entropy costs a few operations per class score, yet its gradient, the predicted probability minus the target, is the error signal

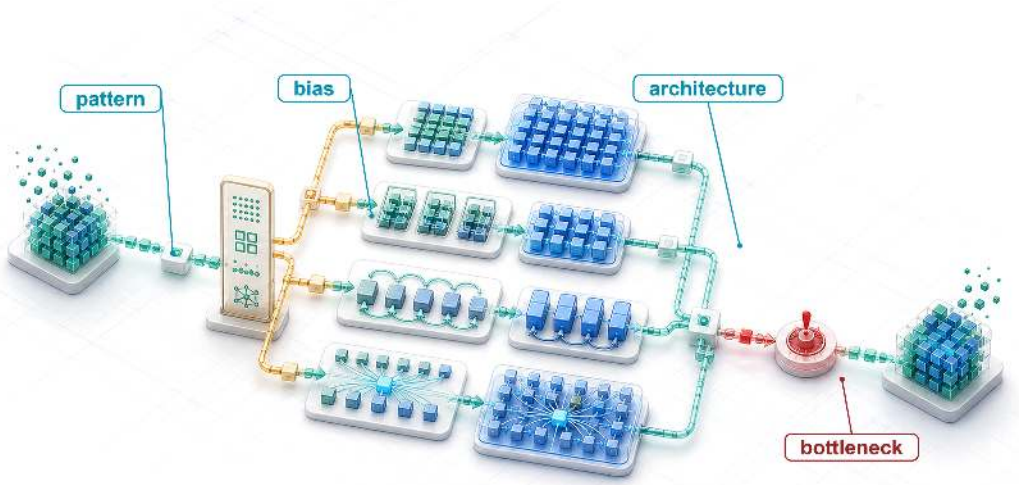
from which every gradient update descends. What the system must protect is the loss's numerical range, which is why runtimes fuse softmax with cross-entropy.

- **Training and inference often emphasize different objectives**: Training commonly favors efficient throughput across repeated updates, while online inference commonly favors per-request latency; offline inference may favor throughput instead. Batch size links utilization, memory, throughput, latency, and statistical behavior across these regimes.
- **Activations are math and hardware**: ReLU is generally cheaper to implement than sigmoid or tanh, and its unit gradient for positive inputs avoids activation saturation on that branch. Its practical advantage combines implementation cost with optimization behavior.
- **Forward propagation often centers on matrix work**: Dense matrix kernels exceed 99 percent of FLOPs in this chapter's dense-network example and dominate many important neural workloads, which is why specialized matrix hardware can substantially outperform general-purpose execution for those operations.
- **Backpropagation needs the path**: Solving credit assignment requires retaining or recomputing the values used by the backward pass, so memory cost often determines whether a model can be trained on a given device and motivates techniques that reduce, recompute, or partition training state.
- **The complete ML pipeline determines end-to-end performance**: Preprocessing, neural computation, and postprocessing all contribute to latency and reliability. The document-recognition examples demonstrated that production success depends on the entire pipeline operating within real-world constraints, not on model accuracy on a test set alone.

The escalation from hand-written rules to learned features is the algorithm axis of the D·A·M taxonomy made concrete. Learning representations instead of writing them spends arithmetic and memory in place of human design effort, and every systems dimension in table 5.2 shifts as a result. The bitter lesson predicts that this exchange wins once computation is cheap enough to afford it, but making the exchange still requires a measured gain that justifies its cost on the intended machine.

The multilayer perceptrons analyzed in this chapter expose a direct resource law, in which dense connectivity forces both parameter storage and multiply-accumulate count to scale with the product of adjacent layer dimensions. That dense connectivity contains no explicit prior for spatial locality, so the model must learn from data which nearby and distant pixel relationships matter, while paying memory bandwidth and storage to evaluate every connection.

Reading the code reveals what a network is asked to do; reading the math reveals what it will cost to execute. That arithmetic is where the algorithm meets the machine: weights must be stored and transferred, dense layers map to matrix execution engines, and saved activations claim accelerator memory that determines whether training fits on device. Under the silicon contract (principle 4), the math commits in advance to operations the machine must execute. Auditing that contract allows systems engineers to calculate binding bottlenecks from first principles before profiling confirms where the execution stalls.



What's Next: From universal to specialized

Real-world data is rarely structureless. Images have spatial locality, text contains sequential dependencies, and audio signals follow temporal patterns, yet a fully connected layer charges memory volume D_{vol} and compute work O for every connection regardless. Chapter 6 assembles the same weighted sums, activations, and gradients into architectures shaped like their data, from convolutional and recurrent networks to transformers and embedding-heavy recommenders, each encoding its structural assumption as an inductive bias. Tailoring network topology to data structure reduces redundant data movement and improves weight reuse, but introduces new trade-offs in activation storage, arithmetic intensity, and accelerator parallelization.

Purpose

Why is choosing a neural network architecture an infrastructure commitment as well as a modeling decision?

Selecting a neural network architecture is both a modeling decision and a contract with physics. The commitment begins with the structure in the data. An architecture that matches that structure can learn with fewer parameters and examples, while a poor match spends additional data and machine time compensating for the wrong computational pattern. Convolution, attention, recurrence, and embedding lookup do not merely encode different assumptions about data; they create different patterns of computation, state, and data movement. Those patterns determine whether work parallelizes cleanly, whether intermediate state fits in memory, and whether training and serving remain affordable at the required scale. Attention compares every element of a sequence with every other, so doubling the input length roughly quadruples that work, while the cost of a convolution grows in proportion to its input. Two architectures can deliver similar predictive quality yet impose different memory footprints and latency profiles while exposing different opportunities for later efficiency techniques. Benchmark accuracy alone therefore cannot reveal which design remains viable. Architectural commitments also propagate beyond the model. Data pipelines adopt particular input structures, training infrastructure is provisioned around the model's compute profile, serving systems are tuned to its request path, and monitoring inherits its failure modes. Once those dependencies accumulate, replacing the architecture can mean rebuilding much of the surrounding system, a cost that grows with every month the design stays in service. An architecture decision is sound only when its predictive gains remain compatible with the full deployment context. In D·A·M terms, architecture is algorithm-machine co-design at its root, with the mathematical graph determining the work the machine must perform and the machine budget limiting which graphs remain practical.

Learning Objectives

- Explain how an architecture's inductive bias matches the structure of images, sequences, and tabular data
- Distinguish how MLPs, CNNs, RNNs, transformers, and DLRM-style recommenders lower onto matrix multiplication and which operations remain memory bound
- Explain why skip connections and normalization make deep networks trainable and what each costs the machine
- Calculate the weights, multiply-accumulates, and memory of dense, convolutional, recurrent, attention, and embedding layers
- Analyze which iron-law term binds a workload, including transformer prefill and decode, from its arithmetic intensity
- Apply the architecture selection framework to a deployment's data, memory, latency, and power budgets
- Critique architecture-selection fallacies about operation counts, context length, and training-versus-serving bottlenecks

6.1 Architectural Principles

THREE requests reach the same accelerator: a camera frame for an image classifier, a prompt for a language model, and a click for a recommender. The silicon is identical, yet the first request keeps the arithmetic units busy, the second leaves them waiting on memory bandwidth, and the third cannot begin until the system decides where its multi-gigabyte embedding tables can live. What differs is the network architecture, the way each model arranges the same arithmetic around the structure of its data, and this chapter explains how each family of architectures sets the demands its requests place on the machine.

Chapter 5 built the operations that every network shares (matrix multiplication, activation functions, and gradient computation) and assembled them into a dense multilayer perceptron (MLP) that pays for a weight between every pixel and every hidden unit, including relationships an image rarely needs. Architectures remove that waste by arranging the same operations into computational graphs shaped like the data. Under the silicon contract (principle 4), that shape is also an implicit agreement with hardware, trading computational patterns for efficiency on particular problem classes.

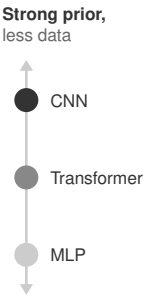
Every neural network architecture decides how computation should be organized to match the inherent structure in the data. Images have spatial locality, language has sequential dependencies, and tabular records often lack a fixed spatial or sequential organization. The architecture encodes assumptions about these patterns directly into the computational graph, and those assumptions influence parameter count, hardware utilization, and deployment feasibility. Architecture selection is therefore a systems engineering problem that directly affects the iron law terms: the number of operations O and the volume of data movement D_{vol}. The structural assumptions that each architecture encodes are known as **inductive biases**,[1] and each architecture in this chapter is defined by its choice of bias.

Definition 6.1: Inductive bias

Inductive bias is a structural constraint built into a model architecture that restricts the hypothesis space, enabling generalization from finite data by encoding domain-specific assumptions (such as spatial locality or sequential ordering) directly into the computational graph.

1. **Significance**: Inductive bias can reduce the dataset size (D) required for generalization. A detector that looks for a small pattern, such as an edge, can either give every pixel of the image its own weight or apply one small set of weights at every position. For a 224×224 RGB image, a shared 3×3 filter uses roughly 5,575× fewer parameters than one

[1] **Inductive bias**: From Latin *inducere*, "to lead into." Encoding a structural assumption "leads" the model toward a smaller solution space, and every architecture discussed here (multilayer perceptron (MLP), convolutional neural network (CNN), recurrent neural network (RNN), and transformer) is defined by its choice of bias. A CNN's locality bias cuts parameters by orders of magnitude vs. an equivalent MLP, directly shrinking the iron law's O and D_{vol} terms, while global attention trades quadratic score computation for long-range connectivity.



dense feature detector, reducing parameter storage and often the data required to avoid overfitting.

2. **Distinction**: Unlike regularization (which penalizes hypothesis complexity at training time via L1/L2 terms), inductive bias restricts the hypothesis space at architecture design time, before any training begins.
3. **Common pitfall**: A frequent misconception is that stronger inductive bias is always better. A strong locality bias (CNN) excels on spatial data but represents long-range dependencies in language less directly than global attention.

A convolutional neural network (CNN) encodes an inductive bias of spatial locality: nearby pixels matter more than distant ones. A transformer lets each element attend to any other, enabling long-range relationships at quadratic score-computation cost. These biases help architectures learn efficiently by restricting the space of functions they represent. Without an appropriate bias, a model may require substantially more data and compute to learn the same structure. That exchange is the bitter lesson seen from inside a single architecture. Built-in structure does part of the learning in advance, while the transformer's weak priors assume that data and compute will keep growing, an assumption that has held at scale. Section 6.9 returns to this ordering when choosing among families.

Machine learning systems face a core engineering trade-off: **representational power vs. computational efficiency**. Under the iron law of ML systems (principle 3), architectural choice is the primary determinant of the algorithmic work per sample (FLOPs/Sample), and thus of the operation-count term O. Attention enables global relationships at a higher operation count, while a CNN exploits spatial locality to reduce operations to linear scaling in the number of spatial positions. Architecture selection means matching the bias to the data while staying inside an operation budget.

Choosing an architectural backbone sets the primary memory layout and compute pattern for downstream hardware. Table 6.1 contrasts the five major neural network families across the data structure each targets, its core innovation, and the system bottleneck it exposes in representative regimes.

A stronger prior substitutes engineered structure for data and compute.

↩ The bitter lesson, that general methods which scale with computation outpace hand-built structure, is established in section 1.4.

Table 6.1: Neural Architecture Families: Each family targets a data structure and exposes characteristic resource demands. The bottleneck column names representative regimes: streamed dense weights stress bandwidth, convolutional reuse raises arithmetic intensity, recurrence creates serial dependencies, dense attention computes quadratic score interactions, and large embedding tables stress capacity. Batch size, precision, kernel implementation, and the target machine determine which demand binds in a deployment.

Architecture	Data Type	Core Innovation	System Bottleneck
MLPs	Tabular/Unstructured	Dense connectivity	Bandwidth with streamed weights at small batch
CNNs	Spatial (images)	Local filters + weight sharing	Compute throughput with sufficient reuse
RNNs	Sequential (time series)	Recurrent state	Sequential dependencies
Transformers	Relational (language)	Dynamic attention	Quadratic score compute; optional S^2 storage
DLRM	Categorical (recommendations)	Embedding tables	Capacity when tables exceed device memory

The five lighthouse models introduced with the iron law return here with their architectures exposed: ResNet-50 for compute throughput, GPT-2 for memory bandwidth, DLRM for memory capacity, MobileNetV2 for compute within a mobile power envelope, and keyword spotting (KWS) for an always-on power envelope. Earlier chapters used them as named workloads and mapped them onto workload archetypes (section 2.3.2), such as the compute-bound and bandwidth-bound archetypes; this chapter opens each one up inside the family that builds it, to show which architectural choice puts it in its archetype. MobileNetV2 sits on the empirical Pareto frontier plotted in figure 6.1, the set of models that no other plotted model beats on both accuracy and compute at once, while ResNet-50 sits well below it. The frontier bounds ImageNet[2] top-1 accuracy against logarithmic compute cost, measured in GMACs (billions of multiply-accumulate operations) per image. The

2 **ImageNet**: The image-classification benchmark on which convolutional networks first proved themselves at scale. AlexNet's 2012 victory in the ImageNet Large Scale Visual Recognition Challenge posted 15.3 percent top-5 error against 26.2 percent for the second-place entry, on the 1000-class challenge with roughly 1.3 million training images (Krizhevsky et al. 2012); the original ImageNet release contained 3.2 million images across 5,247 synsets (Deng et al. 2009). Subsequent architectures improved accuracy through changes in architecture, optimization, data, and compute budgets, illustrating the interaction between inductive bias and infrastructure cost.

other three lighthouses sit off this plot because they were chosen for the bottlenecks they isolate rather than for image-classification accuracy.

↩ The five lighthouse models, and the bottleneck each one isolates, are established in section 1.7.1.

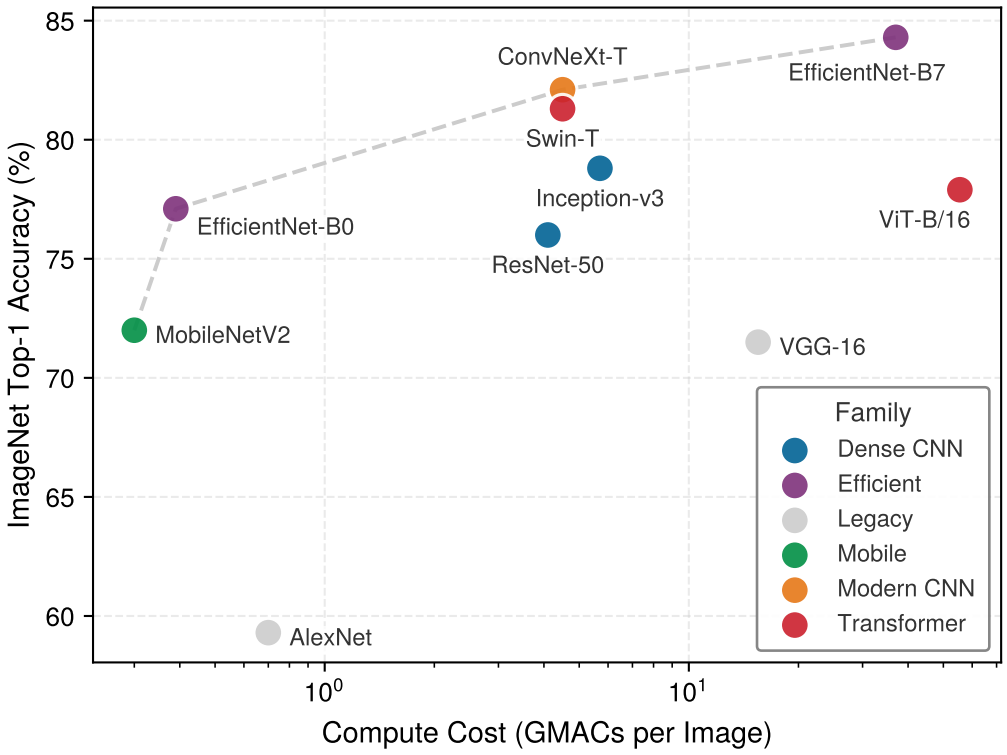


Figure 6.1: The Efficiency Frontier: ImageNet top-1 accuracy plotted against computational cost in GMACs per image. Representative points are compiled from published model reports for AlexNet, VGG, ResNet, Inception, MobileNetV2, EfficientNet, ViT, Swin Transformer, and ConvNeXt (Krizhevsky et al. 2012; Simonyan and Zisserman 2015; He et al. 2016a; Szegedy et al. 2015; Sandler et al. 2018; Tan and Le 2019; Dosovitskiy et al. 2021; Liu et al. 2021; Liu et al. 2022). The dashed Pareto frontier is an illustrative trade-off curve rather than a benchmark rerun; exact accuracy and reported compute values vary by model variant, training recipe, implementation, and operation-counting convention (multiply-accumulates vs. floating-point operations). The legend distinguishes six families: legacy CNNs (gray), dense CNNs (blue), efficient Mobile architectures (green), EfficientNet-class models (violet), modern CNNs (orange), and Transformers (red). The frontier is led by the efficient and modern-CNN families; the Transformers trade substantial compute for flexible long-range modeling without dominating it, and ViT-B/16 sits below the frontier. AlexNet is the single-model result, and ViT-B/16 is plotted at the 384-pixel resolution at which its accuracy was measured.

Across the frontier plotted in figure 6.1, successive architecture families occupy distinct computational cost regimes, from dense CNNs that prioritized accuracy regardless of operation count, through compact mobile networks engineered to minimize GMACs, to vision transformers (such as Swin-T and ViT-B/16) that trade compute for long-range spatial mixing. The plotted models are historical milestones rather than case studies; only ResNet-50 and MobileNetV2 receive detailed architectural breakdowns in this chapter. Architectural choices made at design time dictate where a system lands along this frontier.

Each family section that follows reads its architecture through the same four questions: the data pattern it targets, the computation it performs, how that computation maps onto hardware, and the bottleneck it exposes. The sequence begins with the family that assumes the least about its data, the dense multilayer perceptron. After CNNs, a short section explains the two blocks that make depth trainable; after the recommendation model, the closing section compares all five families on one machine and turns the comparison into a selection procedure.

6.2 MLPs: Dense Pattern Processing

The MNIST digit classifier of chapter 5 is the purest example of dense processing: each of its 784 pixel inputs connects to every hidden unit, and each hidden unit to every unit in the next layer. The same all-to-all pattern suits tabular inputs, such as the sender reputation, link count, and keyword features a spam filter scores, where no feature has a fixed neighbor. **MLPs**[3] represent the fully connected architecture of that classifier, now examined through the four-part systems lens.

MLPs embody an inductive bias: *they impose no specific spatial or temporal connectivity pattern, allowing any input to relate to any output*. This architectural choice provides flexibility across input relationships, making MLPs versatile but potentially costly compared to alternatives that exploit matching structure. Their representational capacity was established theoretically by the universal approximation theorem (UAT)[4] (Cybenko 1989; Hornik et al. 1989), introduced in chapter 5. This theorem states that a sufficiently large MLP with nonlinear activation functions can approximate any continuous function on a compact domain, given suitable weights and biases. The *multilayer perceptron* combines theoretical universality with dense connectivity.

> Definition 6.2: Multilayer perceptrons
>
> ***Multilayer perceptrons*** are feed-forward neural network architectures that apply fully connected layers in sequence, where every neuron in one layer connects to every neuron in the next, without imposing a specific spatial or temporal connectivity pattern.
>
> 1. **Significance**: The lack of structural prior gives dense layers quadratic parameter scaling in layer width: a single layer mapping 1,024 inputs to 1,024 outputs requires 1,048,576 parameters and about 2.1 MB of weight memory in FP16. Every input gets its own weight to every output, which makes MLPs inefficient for high-dimensional structured inputs like images.
> 2. **Distinction**: Unlike convolutional neural networks, which exploit spatial locality to reduce parameter count, MLPs treat all input elements symmetrically, making them the architecture of choice for tabular data where no spatial or sequential structure is present.
> 3. **Common pitfall**: A frequent misconception is that MLPs are too simple to matter for complex tasks. Dense layers carry much of the arithmetic inside the most complex models: every transformer block contains a position-wise feed-forward MLP, and recommendation models such as DLRM run dense MLP towers on their features. The other families add structure around dense layers (weight sharing, recurrence, attention) rather than replacing them.

6.2.1 Representation vs. learnability

Although the Universal Approximation Theorem guarantees that a wide enough MLP can represent any continuous function on a bounded domain, it gives no guarantee that gradient descent can find those weights from a finite dataset or fit the required width in memory. *Representation capacity* refers to the functions an architecture can express given unlimited resources, and the UAT guarantees that MLPs have universal representation capacity. The *manifold hypothesis*,[5] which holds that high-dimensional data lies near a much simpler low-dimensional surface, explains why real-world functions have structure worth exploiting. *Learnability* refers to whether gradient descent can find good weights given finite training samples and compute budgets. A function may be representable in theory yet unlearnable in practice.

This distinction resolves the apparent paradox between universal approximation and architectural progress. Specialized architectures such as CNNs and their deep ResNet descendants improve learnability by embedding inductive biases that match the structure of the data, even when doing so restricts representational capacity. Two factors create this *learnability gap*:

1. **Sample complexity**: The UAT bounds neither the training examples nor the width needed, and some function classes require widths that grow rapidly with input dimension. For 28×28 images, an MLP receives 784 pixel values without built-in local connectivity or spatial weight sharing. It can learn spatial correlations, as the digit classifier of chapter 5 shows, but must learn

[3] **Perceptron**: Formed from "perception" and the device suffix "-tron" (as in *cyclotron* and *klystron*), coined by Frank Rosenblatt (Rosenblatt 1957) for the atomic unit of neural computation: a weighted sum followed by a nonlinear activation, extending the earlier McCulloch-Pitts neuron. MLPs are composed entirely of these units arranged in fully-connected layers, so the efficiency of this single operation, a multiply-accumulate, determines system throughput. Modern accelerators execute over 10^{14} of these operations per second, making the perceptron the computational primitive that the entire ML hardware ecosystem is optimized around.

[4] **Universal approximation theorem (UAT)**: This theorem establishes representational capacity for continuous functions on a compact domain, given suitable nonlinear activations. The systems-level catch is that the existence guarantee supplies neither an efficient training procedure nor a practical width for a particular task. For a generic smooth target with no further structure, the width needed to reach a fixed accuracy can grow exponentially with input dimension (the curse of dimensionality), which is why the guarantee alone says little about a 256×256 image; useful structure in the target is what keeps practical networks small.

[5] **Manifold hypothesis**: The assumption that high-dimensional data lies near a low-dimensional surface embedded within the full space; a 256×256 image lives in a 65,536-dimensional space, but "valid cat images" may occupy a much smaller structured region. Learned representations can expose that structure. The systems consequence is a potential reduction in the data and computation needed for learning; useful structure can also take other forms, such as a target depending on only a few input features.

relationships that a CNN encodes structurally. When those priors match the task, a CNN can reach a target accuracy with fewer examples and represent the function more compactly. The sample requirement depends on the target function, data distribution, and learning procedure.

2. **Optimization difficulty**: Even when optimal weights exist, gradient descent may not find them. Without architectural constraints to regularize the search space, MLP loss surfaces contain many poor local minima and flat regions. Specialized architectures narrow the search space and introduce symmetries that gradient descent can exploit. The classic MNIST handwritten digit benchmark illustrates this gap between representation and learnability concretely.

Example 6.1: MNIST: Representation vs. learnability

Scenario: Classifying 28×28 MNIST digits with a fully connected MLP vs. a CNN.

Diagnosis: Whole-network parameter counts depend mostly on width choices. The 784-128-64-10 MLP has 109,184 weights, fewer than the 421,408 of a small two-convolution CNN, whose dense classifier head holds 96 percent of them. The locality saving appears per feature detector. A dense unit learns one weight for every pixel, so 32 features cost 25,088 weights; a convolutional layer learns one 3×3 filter per feature, 288 weights in total, and reuses each filter at all 784 positions. At equal feature count, the convolutional layer needs 87× fewer weights.

Systems lesson: Inductive bias buys parameter efficiency per feature and reuse per weight. Fewer weights per detector reduce the data needed to learn spatial structure, and each weight fetched from memory feeds hundreds of multiply-accumulates, which raises arithmetic intensity.

The learnability gap motivates the core design principle of this chapter: embed inductive biases that match data structure. Each architecture sacrifices theoretical generality for practical learnability. The No Free Lunch theorem[6] (Wolpert and Macready 1997) formalizes this trade-off: the bias that helps one task may hurt another. A bias that ignores where a pattern appears in an image aids image classification but impairs tasks where absolute position matters, such as locating an object. Choosing an architecture means choosing a bias that fits the data.

Appropriate inductive biases reduce parameter counts (enabling edge deployment), accelerate convergence (reducing training costs), and produce structured computation patterns that map efficiently to specialized hardware. The MNIST comparison earned its per-detector saving by matching architecture to data structure, not by shrinking the network. Understanding where dense connectivity remains necessary requires identifying the data patterns that lack structural shortcuts.

[6] **No free lunch theorem**: Wolpert and Macready's 1997 result proved that no optimization algorithm outperforms random search across all possible problems: averaged over every conceivable function, all algorithms are equivalent. The ML systems consequence is that an inductive bias (locality, equivariance, attention) can improve performance on problems matching that bias while hurting performance when its assumptions do not hold, making architecture selection an engineering commitment to a problem class.

6.2.2 Pattern processing needs

In a tabular dataset such as customer records or a credit risk model, any input column (income, account age, or recent transaction count) can interact with any other, and the columns have no spatial neighbors or time order. Because the data carries no grid or sequence structure, the network cannot restrict computation to local windows or sequential steps. Every output neuron must be free to combine every input feature, leaving gradient descent to learn which connections matter.

When an MLP processes an image dataset like MNIST, it flattens each 28×28 image into an unstructured 784-element vector. Flattening throws away the two-dimensional grid, so the layer treats adjacent pixels and pixels on opposite corners identically. While this lets every hidden unit relate any pixel to any class, the network must rediscover spatial adjacency from scratch during training. That all-to-all requirement leads directly to the matrix operations that define the MLP.

6.2.3 Algorithmic structure

Letting every input feature interact with every output unit requires complete connectivity between adjacent layers. In an MLP, this takes the form of a sequence of fully connected layers where every neuron connects to every neuron in the preceding layer. Dense connectivity translates directly into matrix multiplication, the formulation that makes dense layers executable on parallel hardware. The fully connected graph on the left of figure 6.2 becomes the matrix-vector product on its right: each

hidden neuron's activation is the dot product of the input with one entire column of the weight matrix.

↩ The matrix multiplication formulation of a dense layer's forward pass is established in section 5.4.2.2.

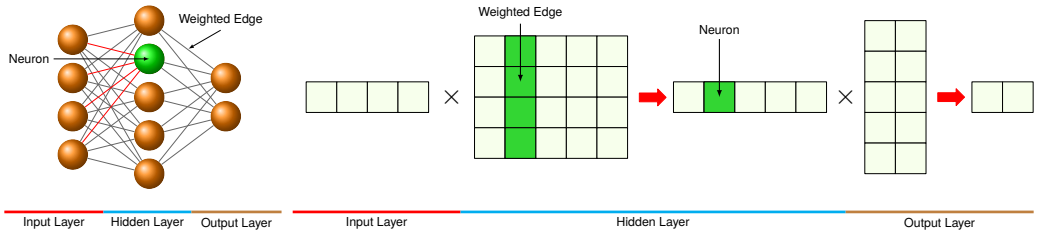

Figure 6.2: Multilayer Perceptron Architecture: A three-layer network in which every neuron connects to all neurons in adjacent layers. The highlighted neuron receives weighted contributions from all inputs, illustrating the dense $\mathcal{O}(d_{\text{in}} \times d_{\text{out}})$ connectivity pattern implemented through matrix multiplications. For MNIST classification, a 784-dimensional input ($d_{\text{in}} = 784$) connects to 128 hidden neurons ($d_{\text{out}} = 128$) through a 784×128 weight matrix, requiring 100,352 multiply-accumulate operations per sample. Adapted from Reagen et al. (2017).

Equation 6.1 expresses the dense layer's affine transformation followed by its activation.

$$\mathbf{h}^{(\ell)} = f(\mathbf{h}^{(\ell-1)}\mathbf{W}^{(\ell)} + \mathbf{b}^{(\ell)}) \tag{6.1}$$

$\mathbf{h}^{(\ell)}$ represents the layer ℓ output, $\mathbf{h}^{(\ell-1)}$ represents the input from the previous layer, $\mathbf{W}^{(\ell)}$ denotes the weight matrix for layer ℓ, $\mathbf{b}^{(\ell)}$ denotes the bias vector, and $f(\cdot)$ denotes the activation function. The dimensions of these operations reveal the computational scale of dense pattern processing. The input vector $\mathbf{h}^{(0)} \in \mathbb{R}^{d_{\text{in}}}$ (treated as a row vector in this formulation) represents all potential input features. Weight matrices $\mathbf{W}^{(\ell)} \in \mathbb{R}^{d_{\text{in}} \times d_{\text{out}}}$ capture all possible input-output relationships. The output vector $\mathbf{h}^{(\ell)} \in \mathbb{R}^{d_{\text{out}}}$ produces transformed representations. A four-pixel example turns this bookkeeping into arithmetic.

Example 6.2: Concrete computation example

Consider a simplified 4-pixel image processed by a 3-neuron hidden layer:

Input: $\mathbf{h}^{(0)} = [0.8, 0.2, 0.9, 0.1]$ (4 pixel intensities)

Weight matrix:

$$\mathbf{W}^{(1)} = \begin{bmatrix} 0.5 & 0.1 & -0.2 \\ -0.3 & 0.8 & 0.4 \\ 0.2 & -0.4 & 0.6 \\ 0.7 & 0.3 & -0.1 \end{bmatrix} \quad (4 \times 3 \text{ matrix})$$

Computation:

$$\mathbf{z}^{(1)T} = (\mathbf{h}^{(0)}\mathbf{W}^{(1)})^T = \begin{bmatrix} 0.5 \times 0.8 + (-0.3) \times 0.2 + 0.2 \times 0.9 + 0.7 \times 0.1 \\ 0.1 \times 0.8 + 0.8 \times 0.2 + (-0.4) \times 0.9 + 0.3 \times 0.1 \\ (-0.2) \times 0.8 + 0.4 \times 0.2 + 0.6 \times 0.9 + (-0.1) \times 0.1 \end{bmatrix} = \begin{bmatrix} 0.59 \\ -0.09 \\ 0.45 \end{bmatrix}$$

After ReLU: $\mathbf{h}^{(1)} = [0.59, 0, 0.45]$ (negative values zeroed)

Systems insight: Each hidden neuron combines all input pixels with different weights, demonstrating unrestricted feature interaction. Dense layers buy generality by paying the maximum connectivity cost.

The MNIST example makes this scale concrete. The 784-dimensional input connects to every one of the 128 neurons in the first hidden layer of the 784-128-64-10 network from chapter 5, a 784×128 weight matrix of 100,352 parameters, where each weight represents a learnable relationship between an input pixel and a hidden feature. This layer is the reference MNIST layer for the computational analysis in the rest of this chapter.

The matrix form specifies every input-output interaction, but it leaves the execution schedule open. Evaluating one sample at a time streams weights with little reuse; grouping samples lets several outputs share each fetched weight. The loop structure makes these alternatives visible.

6.2.4 Computational mapping

The layer equation fixes what a dense layer computes, not the order in which a processor computes it. At the framework level the whole layer is a single matrix call (listing 6.1).

Listing 6.1: MLP Layer in Matrix Form: Framework-level matrix operations hide $\mathcal{O}(B \times d_{\text{in}} \times d_{\text{out}})$ multiply-accumulate complexity behind a single function call, enabling hardware-optimized BLAS libraries to use dense matrix hardware efficiently.

```
def mlp_layer_matrix(X, W, b):
    """MLP forward pass using framework-level matrix operations."""
    # X: input matrix (batch_size by num_inputs)
    # W: weight matrix (num_inputs by num_outputs)
    # b: bias vector (num_outputs)

    # Single GEMM call: frameworks dispatch to optimized BLAS/cuBLAS
    # For MNIST: 784 * 128 = 100,352 MACs per sample
    H = activation(matmul(X, W) + b)
    return H
```

The function `mlp_layer_matrix` mirrors equation 6.1 directly, using high-level matrix primitives to express the forward transformation while delegating tile scheduling and execution to framework backends. Beneath this software interface, dense matrix multiplication lowers to a canonical three-deep loop nest that determines memory access locality, parallelization boundaries, and register allocation (listing 6.2). The outermost loop iterates across batch samples, the middle loop iterates over output neurons, and the innermost loop executes repeated multiply-accumulate (MAC) operations[7] that pair each input feature with its weight.

Listing 6.2: Dense Layer Computation: Nested loops reveal $\mathcal{O}(B \times d_{\text{out}} \times d_{\text{in}})$ complexity where each output neuron requires num_inputs multiply-accumulate operations, so the reference MNIST input layer requires 100,352 MACs per sample.

```
def mlp_layer_compute(X, W, b):
    """Explicit loop structure exposing MLP computational patterns."""
    # Loop 1: Process each sample independently (parallelizable)
    for batch in range(batch_size):
        # Loop 2: Compute each output neuron
        for out in range(num_outputs):
            Z[batch, out] = b[out]  # Initialize with bias

            # Loop 3: Accumulate weighted inputs (innermost loop)
            # This is the MAC operation: result += input * weight
            for in_ in range(num_inputs):
                Z[batch, out] += X[batch, in_] * W[in_, out]
            # Total per output: num_inputs MACs +
            # num_inputs memory reads

    H = activation(Z)  # Element-wise nonlinearity
    return H
```

In the reference MNIST layer, computing 128 hidden neurons requires 100,352 MACs in total; each individual output neuron requires 784 multiply-accumulate operations and 1,568 logical operand reads (784 for inputs, 784 for weights). Registers and caches can serve repeated reads, so this count is not a DRAM-traffic estimate. Production implementations call optimized matrix libraries such as Basic Linear Algebra Subprograms (BLAS),[8] but the same nested-loop pattern still determines the system design problem. The hardware architectures that accelerate these matrix operations, including GPU Tensor Cores[9] and specialized AI accelerators, are covered in section 11.3.2.2.

[7] **MAC (multiply-accumulate)**: The atomic operation of neural networks: multiply two values and add to a running sum. In Horowitz's 45 nm reference, an FP32 multiply plus add costs about 4.6 pJ, while a 32-bit off-chip DRAM access costs about 640 pJ (Horowitz 2014). These technology-specific values illustrate why data movement can dominate arithmetic energy; they are not universal constants for current hardware.

[8] **BLAS (basic linear algebra subprograms)**: This standard API for matrix operations enables the use of highly optimized libraries (for example, cuBLAS) to accelerate the 784 multiply-accumulates per neuron. The 784×128 matrix in the MNIST example may use the hardware less efficiently than larger, well-aligned transformer matrices because utilization depends on matrix shape, batching, datatype, library, and accelerator.

[9] **Tensor Cores**: Specialized units in NVIDIA GPUs that accelerate the thousands of multiply-accumulate operations described by fusing them into single, highly parallelized matrix instructions. Tensor Cores are most efficient when matrix dimensions meet datatype- and architecture-specific alignment multiples; modern cuBLAS/cuDNN can still use Tensor Cores for many nonaligned cases, often with lower efficiency or internal padding. The architectural lesson is vendor-independent: specialized matrix units reward dense, aligned general matrix multiplication (GEMM) workloads and penalize small, irregular shapes that cannot keep the units full.

6.2.5 System implications

While the reference MNIST layer (784×128) needs only 100,352 parameters, a single dense layer connecting 2048 inputs to 2048 outputs requires 4,194,304 parameters (16.8 MB at FP32), and evaluating one sample uses each weight only once. Because every input connects to every output, $\mathcal{O}(d_{\text{in}} \times d_{\text{out}})$ weight storage dominates the memory footprint, and when those weights exceed on-chip cache and stream from DRAM on every request, memory bandwidth becomes the bottleneck. Dense layers therefore concentrate hardware pressure across three dimensions: memory capacity for weight storage, compute throughput on matrix engines, and memory bandwidth for weight movement.

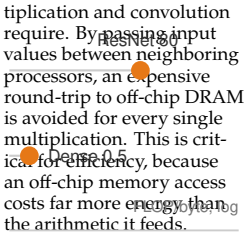
The core computation is a dense matrix-vector product (GEMV), or a matrix-matrix product (GEMM) when batched. This computation is regular and parallelizable, but the arithmetic intensity (FLOP/byte) is low for small batches. A larger batch size amortizes weight-loading cost over more computations. Modern processors optimize dense layers with single instruction, multiple data (SIMD) units such as AVX-512 on CPUs or with dense matrix engines such as Tensor Cores on GPUs and systolic arrays[10] on Tensor Processing Units (TPUs) (Jouppi et al. 2017), amortizing control overhead over large blocks of parallel arithmetic.

Section 5.4.2.4 measured this weight-loading cost on the running network, where at batch one each weight read serves a single multiply-accumulate. For the reference layer, which reads 784×128 weights to compute 128 hidden values, a weight-only model that counts one FP32 read per weight and omits input, output, bias, and cache traffic gives roughly 0.5 FLOP/byte at batch one. Equation 6.2 restates that ratio, where d_{in} and d_{out} are the input and output widths. The memory tier serving those reads determines the relevant bandwidth.

$$I \approx \frac{2 \cdot d_{\text{in}} \cdot d_{\text{out}} \text{ FLOPs}}{4 \cdot d_{\text{in}} \cdot d_{\text{out}} \text{ bytes}} = 0.5 \text{ FLOP/byte} \tag{6.2}$$

If these weights stream from off-chip memory, a machine with an off-chip ridge point in the hundreds of FLOP/byte cannot supply them fast enough to reach peak arithmetic throughput. The small MNIST layer may instead remain cached across requests; its traffic must then be compared with the bandwidth of that cache, and dispatch overhead may matter more than off-chip bandwidth. Batching raises the weight-bound intensity in proportion to the batch size until input and activation traffic begin to dominate, but where it crosses the machine's balance depends on matrix shape, precision, implementation, and hardware. This is why fully connected layers can become inference bottlenecks despite performing fewer total FLOPs than convolutional layers.

The same intensity sets the energy per inference. With the energy constants introduced alongside the iron law (Horowitz 2014), about 160 pJ per byte read from DRAM and 4.6 pJ per FP32 multiply-accumulate, a batch-one dense layer that streams its weights spends about 139× more energy moving each weight than computing with it. Batching divides that ratio by the batch size until activation traffic takes over, so the knob that raises throughput also cuts energy per inference.



Because dense connectivity offers little weight reuse within a single-example forward pass, applying MLPs to high-dimensional structured signals forces an undesirable trade-off between parameter explosion and memory starvation. When data possesses inherent physical organization (spatial coordinates in images, sequential order in time series), specialized architectures replace all-to-all connectivity with structural priors that simultaneously raise accuracy and computational efficiency. The most established of these spatial architectures is the convolutional neural network.

6.3 CNNs: Spatial Pattern Processing

The MLP's assumption that every input may interact directly with every output proves particularly costly for spatially structured data like images. Connecting every pixel of a high-resolution input to every hidden unit creates a parameter footprint that exhausts accelerator memory and drives arithmetic intensity so low that the layer becomes bandwidth bound. The earlier MNIST comparison showed the remedy at small scale: a shared filter needs 87× fewer weights per feature detector than a dense unit that treats every pixel independently.

CNNs[11] build that remedy into the network itself (Fukushima 1980; LeCun et al. 1998; Krizhevsky et al. 2012). Rather than materializing an all-to-all connectivity matrix, a CNN restricts each output activation to a local spatial patch and slides identical filter weights across the entire input aperture.

[10] **Systolic array**: Named for the heart's rhythmic contraction (Kung 1982), the array's lockstep "pulse" of data through a grid of multiply-accumulate processors directly implements the data reuse that matrix multiplication and convolution require. By passing input values between neighboring processors, an expensive round-trip to off-chip DRAM is avoided for every single multiplication. This is critical for efficiency, because an off-chip memory access costs far more energy than the arithmetic it feeds.

A batch-one dense layer sits far below convolution's weight reuse.

[11] **Convolution**: From Latin *convolvere* ("to roll together"), describing a filter that slides across an input, combining local elements at each position. This "rolling together" enforces a locality constraint that is the source of the operation's efficiency: a single 5×5 kernel reuses its 25 weights at every spatial position instead of learning a separate weight for every pixel.

Weight sharing spares convolution the fully-connected parameter explosion.

This spatial inductive bias translates into two structural constraints on the computation graph. Parameter sharing applies the same small filter weights across every spatial position, reducing parameter storage from millions of distinct weights to a compact kernel that fits within on-chip caches. Local connectivity limits each neuron's receptive field to a spatially adjacent neighborhood, eliminating computation on distant, uncorrelated pixels. Together, these constraints define the convolutional family.

Definition 6.3: Convolutional neural networks

Convolutional neural networks (CNNs) are architectures that exploit translation equivariance and spatial locality to share learned filters across all spatial positions, decoupling parameter count from input resolution.

1. **Significance**: Weight sharing produces dramatic parameter reduction. A 3×3 convolutional layer with 64 input and 64 output channels requires $3 \times 3 \times 64 \times 64 \approx 37{,}000$ parameters regardless of whether the input image is 224×224 or 1024×1024. A fully connected layer mapping a $224\times224\times64$ input to 64 scalar outputs would require $224^2 \times 64 \times 64 \approx 205$ million parameters, a roughly 5,575$\times$ difference. These output shapes differ: convolution reuses its 64 detectors across a spatial feature map, while the dense layer produces 64 scalars. Weight sharing keeps the filter budget constant as resolution grows, although feature-map storage still grows with image area.
2. **Distinction**: Unlike MLPs, which connect every input element to every output element (global connectivity), CNNs restrict each output to a local spatial neighborhood, encoding the assumption that nearby pixels are more relevant than distant ones. This restriction eliminates entire hypothesis classes at architecture design time rather than penalizing them during training.
3. **Common pitfall**: A frequent misconception is that CNNs are vision-only models. The convolution operation applies to any data with a grid-like topology: 1D convolutions process audio waveforms and time series, 2D convolutions process images and spectrograms, and 3D convolutions process video and volumetric data.

CNNs give up the all-to-all generality of MLPs for practical efficiency whenever data has local geometry. Seeing why that trade-off works on images begins with the spatial structure of a photograph.

6.3.1 Pattern processing needs

In a photograph, neighboring pixels carry closely related brightness and color values that together form local edges, corners, and textures, whereas pixels on opposite sides of the frame have almost nothing in common on their own. Stacking local filters lets a network build larger features out of smaller ones: early layers combine nearby pixels into edges, middle layers combine edges into contours and surface textures, and deeper layers assemble those patches into object parts and whole objects. From stage to stage the spatial grid shrinks while the number of channels grows, so each later feature summarizes a wider patch of the image, until the features flatten into one vector for a dense classifier (figure 6.3).

This hierarchical composition appears across multiple physical domains: localized pixel neighborhoods forming contours in computer vision, local time-frequency clusters identifying phonemes in speech spectrograms, and contiguous voxel blocks isolating tissue boundaries in volumetric tomography. The architecture works because images compose from local parts, whether or not it resembles biological vision.

In image processing, recognizing an object requires two distinct computational guarantees. First, the architecture must capture local geometric primitives over bounded receptive fields. Second, because an object retains its semantic identity regardless of where it appears in the frame, the network must identify those primitives across arbitrary coordinate translations. Convolutional networks satisfy both requirements by combining localized kernels with parameter sharing, enforcing translation equivariance at intermediate stages while pooling enables downstream invariance

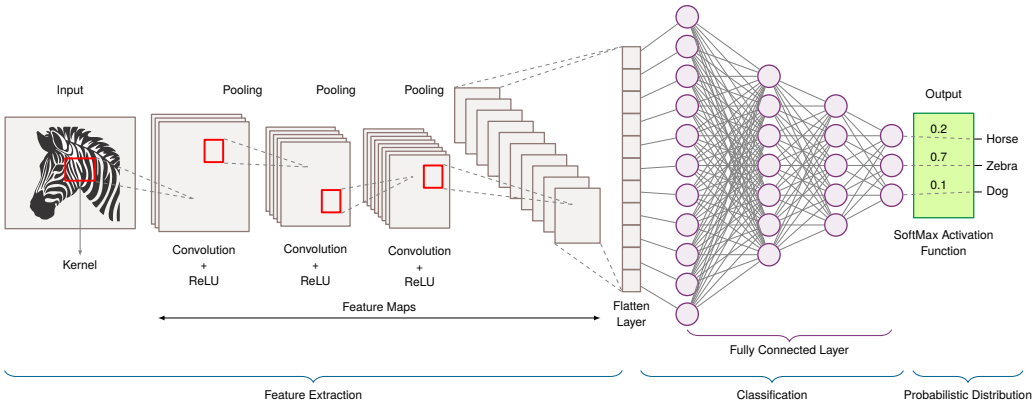


Figure 6.3: Spatial Feature Extraction: A zebra image passes through repeated convolution, ReLU, and pooling stages that form progressively deeper feature maps, followed by flattening, fully connected layers, and a softmax classification over Horse, Zebra, and Dog.

(LeCun, Boser, et al. 1989; Krizhevsky et al. 2012).[12] These architectural constraints, introduced by LeCun[13] (LeCun, Boser, et al. 1989), replace unconstrained dense matrix multiplications with structured spatial stencils.

6.3.2 Algorithmic structure

A convolutional layer's weights form a four-dimensional tensor, and the reason is easiest to see by building one output feature in two stages, spatial filtering followed by channel accumulation. Consider a single RGB image with three input channels ($C_{\text{in}} = 3$). A single output feature (such as an edge detector) requires its own dedicated $K \times K$ spatial filter for the Red channel, another for Green, and a third for Blue:

1. **Spatial filtering**: Each 2D filter slice slides across its corresponding color channel, computing multiply-accumulate dot products over local spatial windows as in a classic image filter.
2. **Channel accumulation**: At each spatial coordinate (i, j), the dot-product outputs of all three input channels sum into a single scalar value.

This two-step process produces exactly one 2D output feature map. If the layer demands $C_{\text{out}} = 64$ distinct features, the system repeats this procedure 64 times using 64 independent filter volumes. Thus, the weight tensor naturally requires four physical dimensions: $\mathbf{W} \in \mathbb{R}^{K \times K \times C_{\text{in}} \times C_{\text{out}}}$ (Kernel Height $\times$ Kernel Width $\times$ Input Channels $\times$ Output Channels).

In formal terms, equation 6.3 evaluates this forward pass by computing local, channel-wise dot products across every spatial coordinate:

$$H^{(\ell)}_{i,j,k} = \phi\left(\sum_m \sum_n \sum_c W^{(\ell)}_{m,n,c,k} H^{(\ell-1)}_{i+m,j+n,c} + b^{(\ell)}_k\right) \tag{6.3}$$

Here, $H^{(\ell)}_{i,j,k}$ denotes the activation at spatial position (i, j) in output channel k of layer ℓ. The triple summation iterates across the filter dimensions: spatial offsets (m, n) span the local kernel window (defining the layer's local receptive field),[14] while c ranges over all input channels. The entries $W^{(\ell)}_{m,n,c,k}$ of the weight tensor store the kernel weights connecting channel c to channel k, and $b^{(\ell)}_k$ is the per-channel bias. Because the kernel weights $\mathbf{W}^{(\ell)}$ do not depend on the spatial coordinates (i, j), the same filter parameters are reused at every coordinate.

Convolutional layers typically use small spatial kernels (3×3 or 5×5) to maintain compact parameter footprints while stacking layers to widen the effective receptive field. Each output activation depends on one small window of the input. In figure 6.4, a 3×3 receptive field in a 7×7 input produces one value of the 5×5 output map, and sliding the same filter to every position fills in the rest. The interactive CNN Explainer tool (Wang et al. 2021) visualizes how these stacked sliding windows extract per-channel activation patterns across layers.

[12] **Translation equivariance**: An inherent property of the convolution operation where shifting the input guarantees a corresponding spatial shift in the resulting feature map. This is distinct from *invariance*, which pooling or later aggregation can approximate by discarding precise positional data. For example, 2×2 pooling with stride 2 reduces the number of spatial elements by 75 percent.

[13] **Yann LeCun and LeNet**: LeCun's architecture directly addressed the intractable scaling of applying dense networks to images by enforcing the principles of local connectivity and parameter sharing. These constraints reduced the parameter count for an image-like input layer by over 95 percent, enabling LeNet-5 to achieve production-grade accuracy on commercial tasks like check reading with only ~60,000 total parameters.

[14] **Receptive field**: The input region influencing a particular output neuron. With 3×3 filters, receptive fields grow by 2 pixels per layer, so a neuron at layer 3 "sees" a 7×7 region. This growth rate constrains architecture depth: detecting objects spanning 100+ pixels in a 224×224 image requires either deep stacks of small filters (more layers, more memory for activations) or larger kernels (more parameters per layer), a fundamental depth-vs.-width trade-off in CNN design.

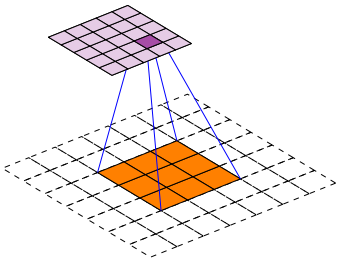

Figure 6.4: Convolution Operation: A 3×3 orange receptive field in a dashed 7×7 input maps to one cell of the violet 5×5 valid-convolution output. Applying a 3×3 filter to that receptive field requires 9 multiply-accumulate operations per input channel for each output value. Sharing the filter across positions encodes translation equivariance: the same edge detector works at any image location.

Applying a CNN to 28×28 MNIST images demonstrates the difference in state representation. Rather than flattening the image into a 784-element vector that destroys spatial adjacency, each convolutional layer applies a bank of filters (for example, 32 filters of size 3×3) directly to the 2D grid. The *stride* is how many positions the filter moves between evaluations, and *padding* adds a border of zeros so that a filter centered on an edge pixel still has a full window. With unit stride and padding to preserve border dimensions, the layer outputs a $28\times28\times32$ activation tensor preserving the spatial grid. Each coordinate holds 32 distinct feature measurements extracted from its immediate neighborhood. Between groups of convolutional layers, a *pooling* layer summarizes each small window, typically 2×2, by its maximum or average, shrinking the grid by a factor of four in area while keeping the channels, so later layers see a coarser map that covers more of the image at a quarter of the activation memory.

Preserving spatial topology changes how execution units access memory. Instead of loading an unshared weight matrix once per sample as in an MLP, a convolutional layer streams input feature maps through hardware registers while keeping compact filter weights pinned in fast on-chip SRAM or register files. This arithmetic pattern drives the memory-hierarchy optimizations of AI accelerators, where loop tiling (splitting the loops into blocks whose data fits on chip, developed under data movement below) and parallel channel reduction relieve high-bandwidth memory (HBM) traffic.

Weight sharing is what guarantees this reuse. Because the same filter applies at every coordinate, the computational schedule and memory access geometry are identical across spatial positions. The same sharing gives the layer a mathematical property, translation equivariance: translating the input produces an identical spatial translation in the output feature map.

Equivariance and invariance govern how an architecture responds to spatial transformations. An operator f is *equivariant* to a transformation $\mathcal{T}$ if transforming the input transforms the output by the same operator (equation 6.4):

$$f(\mathcal{T}(\mathbf{x})) = \mathcal{T}(f(\mathbf{x})) \tag{6.4}$$

For a stride-1 convolutional layer without boundary padding effects, translating the input by vector $\mathbf{v} = (v_1, v_2)$ shifts the resulting feature maps by exactly $\mathbf{v}$. Spatial coordinate information propagates deterministically through the layer. By contrast, an operator is *invariant* to $\mathcal{T}$ if transforming the input leaves the output unchanged (equation 6.5):

$$f(\mathcal{T}(\mathbf{x})) = f(\mathbf{x}) \tag{6.5}$$

A global average pooling layer over an entire feature map is translation-invariant: shifting the input alters the spatial locations of activations, but averaging across all spatial positions collapses coordinates into a scalar that is identical regardless of where the features appeared. This mathematical distinction dictates where equivariance must be maintained and where invariance should be introduced across the network hierarchy. Tasks such as object detection and semantic segmentation require equivariance through the final layer: bounding-box coordinates and per-pixel masks must track object coordinates precisely. Classification tasks, by contrast, require equivariance in intermediate feature extractors to preserve relative spatial relations (“eyes above nose”), while the

final layers introduce translation invariance via pooling to collapse spatial coordinates into a class probability vector.

Re-indexing the convolution sum under a shift confirms that stride-1 convolution is translation equivariant up to boundary conditions. An equivariant convolutional layer preserves coordinate information, whereas an invariant pooling layer discards spatial coordinates entirely. Example 6.3 verifies this tracking through explicit matrix operations.

Example 6.3: Equivariance: Feature detection

Setup: Consider a 7×7 image with a vertical edge at column 3:

$$\mathbf{x} = \begin{bmatrix} 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 \end{bmatrix}$$

Vertical edge detector filter:

$$\mathbf{W} = \begin{bmatrix} -1 & 0 & 1 \\ -1 & 0 & 1 \\ -1 & 0 & 1 \end{bmatrix}$$

Convolving original image:
Output feature map shows positive activation where the filter transitions from dark to bright (left side of edge) and negative activation where it transitions from bright to dark (right side):

$$f(\mathbf{x}) = \begin{bmatrix} 3 & 0 & -3 & 0 & 0 \\ 3 & 0 & -3 & 0 & 0 \\ 3 & 0 & -3 & 0 & 0 \\ 3 & 0 & -3 & 0 & 0 \\ 3 & 0 & -3 & 0 & 0 \end{bmatrix}$$

Shifted input (edge moved to column 5):

$$\mathcal{T}_2\mathbf{x} = \begin{bmatrix} 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 \end{bmatrix}$$

Convolving shifted image:

$$f(\mathcal{T}_2\mathbf{x}) = \begin{bmatrix} 0 & 0 & 3 & 0 & -3 \\ 0 & 0 & 3 & 0 & -3 \\ 0 & 0 & 3 & 0 & -3 \\ 0 & 0 & 3 & 0 & -3 \\ 0 & 0 & 3 & 0 & -3 \end{bmatrix} = \mathcal{T}_2(f(\mathbf{x}))$$

Systems insight: The feature activation shifts by the same amount as the input, demonstrating equivariance. The network knows the edge is at column 5 in the shifted image, not just that an edge exists somewhere.

Parameter efficiency is the most immediate systems consequence of the weight sharing that produces translation equivariance, because sharing decouples parameter capacity from the input resolution. For example, processing a 224×224 RGB image with an MLP requires each hidden neuron to connect to all 150,528 input pixels. A CNN with a 3×3 filter requires only 27 parameters per filter, reused across all 224×224 spatial positions. A compact parameter footprint lets the weights stay resident in accelerator SRAM or L2 cache rather than streaming from external DRAM on every use.

Equivariance also increases sample efficiency, reducing training pipeline overhead. When a network updates a filter to recognize a feature at one coordinate, parameter sharing ensures that the feature is recognized across all spatial coordinates simultaneously. The model does not require separate training examples to learn the same feature at different pixel offsets, functioning as structural data augmentation. This sample efficiency reduces the total training iterations, dataset storage, and host-to-device I/O bandwidth required to reach target accuracy.

Convolution's translation equivariance is one instance of a general principle: data symmetries can be embedded as equivariances in the architecture. Group-equivariant CNNs (Cohen and Welling 2016) extend the construction to rotations and reflections for satellite and medical imagery, where orientation does not determine meaning. For systems engineering, stronger symmetry constraints often produce smaller models, but specialized equivariances may require custom operations, such as rotation convolutions, that need either hardware support or efficient software implementations.

Stacked convolutional layers implement hierarchical representation learning (Bengio, Courville, et al. 2013; Zeiler and Fergus 2014). Early layers detect low-level features (edges and color gradients) across small receptive fields, while successive layers compose these primitives into intermediate textures, object parts, and semantic categories. Each added layer also widens the effective receptive field: with fixed $K\times K$ kernels and unit stride, receptive-field side length grows by $K-1$ pixels per layer, while receptive-field area scales quadratically until it spans the entire input dimension. How efficiently accelerators execute this expanding hierarchy depends on how sliding-window stencils map onto parallel execution pipelines.

6.3.3 Computational mapping

A framework expresses a whole convolutional layer as one call (listing 6.3). Behind that call, the underlying runtime must schedule memory traffic across cache hierarchies and lower sliding-window stencils onto matrix execution hardware.

Listing 6.3: Convolutional Layer Abstraction: Framework-level convolution operations hide the complexity of sliding window computations, typically dispatching to cuDNN or MKL which internally handle im2col transformations or direct convolution algorithms.

```
def conv_layer_spatial(input, kernel, bias):
    """Framework-level convolution.

    Single call dispatches to optimized kernel (often via im2col + GEMM).
    """
    # Convolution applies shared weights across all positions
    # For a 3x3 kernel on 28x28 input (padded): 9 MACs per position x 784 positions
    output = convolution(input, kernel) + bias
    return activation(output)
```

To expose the mechanics that the framework abstraction conceals, listing 6.4 details the canonical seven-deep loop nest required to evaluate a direct 2D convolution. These loops partition into three structural tiers: batch iteration across samples, spatial traversal over feature map coordinates (y, x), and channel accumulation over input and output dimensions $(C_{\text{in}}, C_{\text{out}})$ coupled with kernel offsets (k_y, k_x). Traversing spatial coordinates and output channels defines the grid of independent output

activations. The listing uses unit stride and no padding, with channels stored contiguously at each spatial position (NHWC: batch, height, width, channels). Each output window stays within the input, so the output height and width are the corresponding input dimensions minus the kernel dimensions plus one.

Listing 6.4: Logical Convolution Computation: Seven nested loops expose $\mathcal{O}(B \times H_{\text{img}} \times W_{\text{img}} \times C_{\text{out}} \times K \times K \times C_{\text{in}})$ complexity. The spatial dimensions here count output positions. The scalar order exposes overlapping input reads; tiled implementations exploit this reuse directly or through matrix multiplication.

```
def conv_layer_compute(input, kernel, bias):
    # NHWC input; kernel axes: height, width, input, output channels.
    # Unit stride, no padding; activation follows the convolution.
    batch_size, in_h, in_w, in_channels = input.shape
    kernel_h, kernel_w, _, out_channels = kernel.shape
    out_h, out_w = in_h - kernel_h + 1, in_w - kernel_w + 1
    output = zeros((batch_size, out_h, out_w, out_channels))
    for image in range(batch_size):
        for y in range(out_h):
            for x in range(out_w):
                for out in range(out_channels):
                    result = bias[out]
                    for ky in range(kernel_h):
                        for kx in range(kernel_w):
                            for ch in range(in_channels):
                                result += (input[image, y + ky, x + kx, ch]
                                           * kernel[ky, kx, ch, out])
                    output[image, y, x, out] = result
    return activation(output)
```

The inner three loops execute the kernel dot product at each spatial site. For a 3×3 filter, each output activation accumulates contributions from a local input patch across all input channels. Advancing `x` by one makes the next output read a patch overlapping the previous one, while changing `out` reuses the same patch with a different filter. These repeated accesses offer reuse, but the scalar schedule does not explicitly keep tiles in fast memory or distribute work across execution lanes. Their actual cost depends on which reads the cache serves and how the implementation maps iterations to hardware.

To expose these patches to optimized matrix engines, convolution implementations can use the **im2col** (image-to-column) transformation.[15] By unfolding each receptive-field patch into a contiguous row of an input matrix and stacking filter weights into columns (figure 6.5 lays this out for two input channels), im2col recasts the entire convolution as a dense general matrix multiply (GEMM) that runs on mature, vendor-tuned libraries. To see how the lowering rearranges data in memory, consider a miniature single-channel image ($C_{\text{in}} = 1$) of size 3×3 convolved with a 2×2 filter ($K = 2$) with valid padding:

$$\mathbf{X} = \begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \\ 7 & 8 & 9 \end{bmatrix}, \qquad \mathbf{W} = \begin{bmatrix} w_1 & w_2 \\ w_3 & w_4 \end{bmatrix}$$

The window visits four overlapping 2×2 receptive fields. To evaluate all four in one matrix multiplication, `im2col` flattens each patch into a row vector of length $K^2 = 4$ and stacks the rows into an unfolded matrix $\mathbf{X}_{\text{col}}$:

$$\mathbf{X}_{\text{col}} = \begin{bmatrix} 1 & 2 & 4 & 5 \\ 2 & 3 & 5 & 6 \\ 4 & 5 & 7 & 8 \\ 5 & 6 & 8 & 9 \end{bmatrix}$$

[15] **im2col (image to column)**: Rather than being a new learning algorithm, im2col-style lowering is an implementation technique used by CNN frameworks and libraries such as Caffe and cuDNN (Chellapilla et al. 2006; Jia et al. 2014; Chetlur et al. 2014): it converts convolutions into standard GEMM calls by unfolding overlapping patches into matrix columns. The trade-off is memory: in a simple fully materialized stride-1 $K \times K$ transform, interior input elements can appear in up to K^2 columns (9 times for 3×3 filters), though borders, stride, padding, tiling, and direct-convolution algorithms reduce the realized expansion. This memory-for-simplicity exchange explains why mobile frameworks (TFLite, NNAPI) prefer direct convolution, while data center GPUs with abundant HBM may use GEMM-oriented lowering when it improves throughput.

Flattening the filter weights into a column vector $\mathbf{w}_{\text{col}} = [w_1, w_2, w_3, w_4]^T$, the entire convolution collapses into a single standard matrix product: $\mathbf{Y}_{\text{col}} = \mathbf{X}_{\text{col}}\mathbf{w}_{\text{col}}$. For batched multi-channel inputs, the unfolded matrix has shape $[(B \cdot H_{\text{out}} \cdot W_{\text{out}}) \times (K^2 \cdot C_{\text{in}})]$ and the filters reshape to $[(K^2 \cdot C_{\text{in}}) \times C_{\text{out}}]$. In $\mathbf{X}_{\text{col}}$, input element 5 appears in all four rows, and the miniature input expands from nine elements to sixteen, a storage ratio of $16/9$. For large stride-1 inputs, fully materialized unfolding approaches the kernel area as its expansion factor; the smaller ratio here reflects the borders of a valid convolution. Materializing the buffer trades this additional storage and traffic for access to wide matrix engines optimized for GEMM throughput. Implicit GEMM, described next, avoids allocating the duplicated buffer.

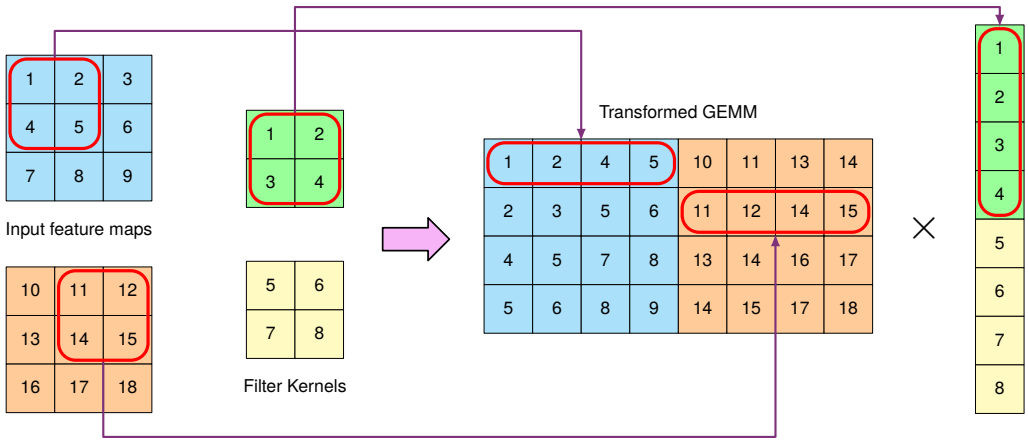

Figure 6.5: im2col Transformation: Lowering converts convolution to GEMM by unfolding image patches into a dense matrix. The two 3×3 input feature maps produce four sliding-window positions, represented here as rows of a 4×8 matrix; the two 2×2 filter kernels stack into an 8×1 column. Their product, not drawn, yields the four output positions. Lowering can exploit optimized matrix kernels but expands memory by an amount that depends on kernel size, stride, padding, and implementation, so its performance benefit is workload dependent.

Implicit GEMM techniques run the same matrix multiplication without building the unfolded matrix. They compute each patch element's address on the fly, inside the processor's registers, so the duplicated buffer is never materialized. With 3×3 filters and 32 output channels, each output coordinate requires only 9 MAC operations per input channel, whereas each output neuron of the reference MLP layer requires 784. The window overlap creates reuse that the memory system must be scheduled to exploit.

6.3.4 System implications

Weight sharing flips the hardware bottleneck of a neural network: compact convolutional filters fit in on-chip cache and are reused across thousands of pixel positions, pushing arithmetic intensity into the compute-bound regime, while the intermediate feature maps they write out dominate off-chip memory capacity and bandwidth. Whether a deep CNN stalls on memory or saturates the matrix units depends on layer depth, how long activations stay live for the backward pass, and whether feature-map tiles remain in on-chip SRAM or spill to external HBM.

6.3.4.1 Memory requirements

On a 224×224 ImageNet input, a convolutional layer with 64 filters of size 3×3 needs only 576 weights per input channel, or 36,864 weights (147.5 KB in FP32) across 64 input channels, which fits comfortably in on-chip L1 or L2 cache, yet produces 3.2M output activation values (about 12.8 MB in FP32 per sample in the batch). Memory consumption in convolutional layers splits sharply between these compact, static filter weights and large, transient feature maps. During training, those feature maps must stay live in memory until backpropagation computes the layer's gradients, making activation memory, not weight capacity, the binding memory constraint for deep CNNs on accelerators.

Accelerators exploit this footprint disparity through hierarchical caching. CPUs retain compact filter weights in L2/L3 caches while streaming activation tensors. GPUs stage filter weights and input tiles in on-chip scratchpad SRAM (shared memory) and register files, reusing loaded weights across thousands of spatial coordinates and eliminating redundant round-trips to off-chip HBM.

↪ The memory hierarchy of register files, on-chip SRAM, and HBM that these caching patterns exploit is developed in section 11.5.3.

6.3.4.2 Compute requirements

Evaluating a convolutional layer requires repeatedly evaluating local dot products across spatial positions. For an ImageNet input with 3×3 filters and 64 output channels, computing a single spatial position requires 576 multiply-accumulate operations per input channel. Summed over 64 input channels and repeated at all 50,176 spatial positions, one such layer performs about 1.85 billion multiply-accumulates. The general count follows the same steps: a layer with $H_{\text{img}}\times W_{\text{img}}$ output positions performs $H_{\text{img}}W_{\text{img}}K^2C_{\text{in}}C_{\text{out}}$ multiply-accumulates, one K^2C_{in} dot product for every output position and every filter. Although each spatial stencil touches fewer parameters than a dense layer, spatial repetition multiplies the total floating-point operation count.

This computational regularity provides rich opportunities for hardware parallelization. Because each spatial coordinate is independent, processors parallelize work along multiple axes simultaneously: across the batch dimension, across spatial coordinates (x, y), and across output channels. CPUs execute vectorized SIMD instructions[16] to evaluate multiple spatial outputs per clock cycle, while GPUs dispatch thread warps across thousands of concurrent execution lanes.

[16] **SIMD (single instruction, multiple data)**: CPU instructions that apply the same operation to multiple data elements simultaneously; AVX-512 can process 16 single-precision values per vector instruction; realized speedup over scalar code also depends on instruction throughput, vectorization, and memory access. For CNN inference on edge CPUs without GPU access, SIMD utilization can affect whether a model meets real-time latency targets. Frameworks like TFLite and Open Neural Network Exchange (ONNX) Runtime use vectorized convolution kernels to exploit this parallelism.

6.3.4.3 Data movement

Data movement in a convolutional layer has an arithmetic intensity profile fundamentally different from that of an MLP. In a fully connected layer at batch size one, each loaded weight is used exactly once, yielding an arithmetic intensity bounded below 1 FLOP/byte. In a 2D convolution, each 3×3 filter weight is reused across all 50,176 positions of the 224×224 feature map. This weight reuse increases operational intensity, shifting computation from the memory-bandwidth-bound regime toward the compute-bound ceiling.

The systems challenge shifts from loading weights to staging activations. Because adjacent spatial receptive fields overlap, a naive memory access pattern would re-fetch each input pixel from memory up to $K^2 = 9$ times. Runtimes avoid this redundant memory traffic by tiling computation into 2D spatial blocks sized to fit inside accelerator SRAM, the technique that section 11.7.5 develops for the accelerator's memory hierarchy. Once an input tile is loaded into shared memory, all overlapping filter dot products for that tile execute in place, amortizing the DRAM/HBM transfer and maximizing the 50,176 reuses of each filter weight. Reuse also moves the energy. Each filter weight fetched from off-chip memory feeds tens of thousands of multiply-accumulates, so once filters and input tiles stay on chip, a convolutional layer spends its energy on arithmetic and on-chip SRAM rather than on DRAM reads, the reverse of the batch-one dense layer.

↪ The hardware ridge point (I_{ridge}), which decides whether spatial filter reuse saturates the arithmetic units or starves on memory bandwidth, is developed in section 11.6.2.

Checkpoint 6.1: Spatial inductive bias

CNNs succeed because they match the structure of image data. Verify you understand how:

- ☐ **Parameter sharing**: how does using the same filter across the image reduce parameter count by orders of magnitude compared to MLPs?
- ☐ **Translation equivariance**: why does shifting the input image result in a corresponding shift in the feature map?
- ☐ **Compute-bound convolution**: how does filter reuse raise arithmetic intensity, and how would comparing that intensity with the target machine's roofline balance establish whether the layer is compute bound?

These memory, compute, and data-movement patterns converge in ResNet-50 (He et al. 2016a), which anchors the chapter's compute-intensive vision lighthouse. The Residual Network (ResNet) addressed the degradation problem in deep plain networks: adding layers could increase training error despite sufficient capacity. By introducing skip connections, shortcut paths that add a block's input directly to its output and so give gradients a route around each block (developed in section 6.4),

it enabled networks of 50, 100, or even 1,000 layers. The ResNet architecture won the ImageNet 2015 competition (with 152-layer models), and ResNet-50 has become a widely used backbone and benchmark workload for computer vision.

Lighthouse 6.1: ResNet-50 (vision lighthouse)

Why it matters: ResNet-50 is a reference point for regular, convolution-heavy vision workloads. Its architecture consists almost entirely of dense convolutional layers, making it highly regular and efficient on GPUs. Under batched execution with good data reuse, ResNet-50 performance is typically limited by floating-point throughput (FLOP/s), making it a useful lighthouse for explaining data parallelism, quantization, and batching strategies. Table 6.2 summarizes the quantitative properties and their system consequences:

Table 6.2: ResNet-50 Systems Profile: Quantitative properties of the vision lighthouse and their system consequences. Under batched convolutional reuse, ResNet-50 has high effective arithmetic intensity and is typically compute-bound, so peak FP throughput on Tensor Cores often sets the ceiling before memory bandwidth does.

Property	Value	System Implication
Parameters	25.6M	102.4 MB model size at FP32; fits comfortably in GPU memory.
FLOPs/Image	8.2 GFLOP (224×224)	3×3 convolutions are the largest single kernel class at roughly 48% of MACs.
Constraint	Compute-heavy when batched	Limited by peak FLOP/s when weight and activation reuse are high; small-batch inference can move toward the memory-bound regime.
Bottleneck	FP Throughput	Benefits maximally from specialized Matrix Units (Tensor Cores).
Profile	High effective arithmetic intensity under reuse	Arithmetic intensity depends on batch size, convolution algorithm, and materialized memory traffic.

6.3.5 Depthwise separable convolutions

ResNet-50's compute-bound profile assumes abundant hardware resources, yet most inference runs on devices with power budgets three orders of magnitude smaller than a data center accelerator. Standard convolutions scale as $\mathcal{O}(N_{\text{pix}} \times K^2 \times C_{\text{in}} \times C_{\text{out}})$, a compute volume that exceeds the strict energy budgets of always-on edge devices. To bridge this gap, efficient architectures like **depthwise separable CNNs (DS-CNN)** decompose the standard convolution into two distinct operations. This factorization, introduced by Sifre in the context of feature extraction (Sifre and Mallat 2014) and popularized by MobileNet (Howard et al. 2017), decouples spatial filtering from cross-channel combination. The depthwise convolution applies filters to each input channel independently ($K \times K \times C_{\text{in}}$ parameters), while the pointwise convolution uses a 1×1 convolution to project channels to the output dimension ($1 \times 1 \times C_{\text{in}} \times C_{\text{out}}$ parameters). Per output position, a standard layer performs $K^2 C_{\text{in}} C_{\text{out}}$ multiply-accumulates, while the factorized pair performs $K^2 C_{\text{in}} + C_{\text{in}} C_{\text{out}}$. Dividing the two shows that the decomposition reduces parameter count and FLOPs to a fraction of roughly $\frac{1}{C_{\text{out}}} + \frac{1}{K^2}$ of standard convolution (a reduction factor approaching K^2, or about 8–9× for 3×3 filters with large C_{out}), making real-time execution feasible on resource-constrained microcontrollers.

MobileNet (Howard et al. 2017) made this factorization the basis of a model family, challenging the trend toward ever-larger networks by designing for the battery and latency budgets of smartphones and embedded devices. MobileNetV2 anchors the chapter's edge-efficiency lighthouse, reaching competitive accuracy at a fraction of ResNet-50's arithmetic, and its small compute footprint made it a natural target for compression and lower-precision deployment, which stores and computes with fewer bits per value.

↪ Compression and lower-precision deployment techniques for compact models such as MobileNet are developed in chapter 10.

Lighthouse 6.2: MobileNetV2 (efficiency lighthouse)

Why it matters: MobileNetV2 represents edge workloads that must meet a latency budget within a power envelope. Its depthwise separable convolutions trade channel-mixing capacity for fewer operations, making it a useful baseline for mobile apps, embedded vision, and neural

architecture search (NAS), automated search over model designs. Table 6.3 summarizes the efficiency lighthouse's quantitative properties:

Table 6.3: MobileNetV2 Systems Profile: Quantitative properties of the efficiency lighthouse and their system consequences. Roughly an order of magnitude smaller than ResNet-50 in both parameters and FLOPs, MobileNetV2's operation shapes and arithmetic intensity make single-image latency sensitive to operator-dispatch overhead and memory access on mobile CPUs.

Property	Value	System Implication
Parameters	3.5M	14 MB at FP32; 7.3× smaller than ResNet-50.
FLOPs/Image	600 MFLOP	13.7× fewer than ResNet-50 for similar accuracy.
Constraint	Latency Target	Single-image inference speed is the priority.
Bottleneck	Overhead/Memory Access	Operator dispatch and memory access can dominate actual compute.
Profile	Low Arithmetic Intensity	Memory access and control logic matter more than peak FLOP/s.

Set side by side, the ResNet-50 and MobileNetV2 profiles show that a model with 13.7× fewer FLOPs does not automatically run 13.7× faster. Whether operational reduction translates into wall-clock speedup depends on arithmetic intensity, operator dispatch overhead, and the hardware's roofline balance. On data center GPUs engineered for high arithmetic intensity, MobileNetV2 often achieves only a modest speedup because its fragmented depthwise operations underutilize Tensor Cores. Architectural efficiency techniques like depthwise separable convolutions and pruning (removing redundant weights or channels) alter this hardware mapping balance, and Perspective 6.1 addresses the central fallacy linking FLOP counts directly to execution latency.

Systems Perspective 6.1: Misconception: FLOPs equal speed

Fallacy: "MobileNetV2 has 13.7× fewer FLOPs than ResNet-50, so it must run 13.7× faster."

Resolution: On high-end GPUs at small batch, MobileNetV2 gains far less than its FLOP advantage suggests, and in some framework configurations runs no faster than ResNet-50. MobileNetV2's depthwise separable convolutions have low arithmetic intensity: they move more data relative to computation. GPUs optimized for dense matrix operations may use their compute units poorly on these kernels. FLOPs measure *work*; throughput depends on how well that work *maps to hardware*.

KWS (Warden 2018) pushes the same factorization to the microcontroller end of the spectrum and anchors the always-on TinyML lighthouse. A continuous audio stream is first converted by a short-time Fourier transform into a 2D time-frequency spectrogram (or Mel-frequency cepstral coefficients), so 2D convolutional filters can slide across time and frequency bins to detect acoustic phoneme signatures. Models that listen for "Hey Siri" or "Ok Google" run on always-on microcontrollers with kilobyte-scale memory and milliwatt power budgets (Warden and Situnayake 2020; C. R. Banbury et al. 2021; C. Banbury, Reddi, Torelli, Holleman, Jeffries, Kiraly, et al. 2021), so their designers count every byte and cycle.

Lighthouse 6.3: KWS (TinyML lighthouse)

Why it matters: Keyword spotting models (like DS-CNN) represent the power-constrained end of the spectrum. Used in always-on applications like smart doorbells that wake a larger vision pipeline only after an audio trigger, these models must run on microcontrollers with milliwatt power budgets.

At 200K parameters, a DS-CNN keyword spotter's 800 KB of FP32 weights already exceeds the few hundred kilobytes of memory a typical microcontroller can devote to a model, so the model fits only after 8-bit quantization cuts it fourfold. KWS is therefore the lighthouse

for extreme quantization (INT8/INT4) and specialized architectural primitives (depthwise separable convolutions) that trade theoretical representational power for maximum efficiency per watt.

From ResNet-50's compute-heavy standard convolutions through MobileNet's depthwise separable variants to KWS's micro-power deployment, CNNs demonstrate how architectural constraints transform data structure into hardware efficiency. Local connectivity and weight sharing reduce parameter storage and expose reuse. Depth is what lets those stacks compose edges into objects, and ResNet-50's fifty layers depend on two building blocks that make depth trainable at all.

6.4 Skip Connections and Normalization

When plain convolutional networks are stacked beyond roughly 20 layers, adding more layers can make *training* error worse rather than better: gradients vanish or explode on the way back through the stack, and the scale of intermediate activations drifts on the way forward. Convolution made deep vision networks affordable in parameter count, and two building blocks made them trainable. Skip connections keep gradients alive through dozens of layers, and normalization keeps the activations those layers produce within a stable numerical range. Both arrived with deep CNNs, both carry their own memory and bandwidth costs, and both reappear in the deep families that follow, most visibly the transformer.

6.4.1 Skip connections and gradient flow

As networks grew deeper, repeated matrix multiplications and activation derivatives drove gradient signals either toward numerical underflow or toward floating-point overflow. Skip connections resolve this optimization barrier with additive identity shortcuts that bypass the layer transformations.

The depth problem follows from the chain rule, whose layer-by-layer Jacobian form appears in section 5.4.5.2. For a deep network with layers $f_1, f_2, \ldots, f_{N_L}$, the gradient of the loss $\mathcal{L}$ with respect to the weights in layer 1 is:

$$\frac{\partial \mathcal{L}}{\partial \mathbf{W}^{(1)}} = \frac{\partial \mathcal{L}}{\partial \mathbf{a}^{(N_L)}} \cdot \frac{\partial \mathbf{a}^{(N_L)}}{\partial \mathbf{z}^{(N_L)}} \cdot \frac{\partial \mathbf{z}^{(N_L)}}{\partial \mathbf{a}^{(N_L-1)}} \cdot \ldots \cdot \frac{\partial \mathbf{z}^{(2)}}{\partial \mathbf{a}^{(1)}} \cdot \frac{\partial \mathbf{a}^{(1)}}{\partial \mathbf{z}^{(1)}} \cdot \frac{\partial \mathbf{z}^{(1)}}{\partial \mathbf{W}^{(1)}}$$

where $\mathbf{z}^{(\ell)}$ represents the preactivation and $\mathbf{a}^{(\ell)} = \sigma(\mathbf{z}^{(\ell)})$ the postactivation output of layer ℓ. Each layer contributes both a weight transformation and an activation derivative $\sigma'(\mathbf{z}^{(\ell)})$. With sigmoid activations, whose derivative peaks at 0.25 (section 9), the activation-derivative factors alone contribute at most $(0.25)^{N_L}$ along a path. The full gradient also depends on the intervening weight matrices; when their transformations do not offset this attenuation, early layers receive negligible updates. Exploding gradients are the destabilizing counterpart. If each layer Jacobian expands a shared direction by about 1.5, that component grows exponentially, producing overflow, NaN (not-a-number) values, and training divergence rather than a silent stall.

ReLU removes the activation's share of this decay, since its derivative is one on active paths (section 11), and that change made networks of 10–20 layers trainable. It does not remove the problem. Inactive units pass zero gradient, and a poorly initialized weight or a large update can leave a unit permanently dead; more fundamentally, ReLU does nothing to regulate the singular values of the weight matrices, which continue to attenuate or amplify gradients across depth. The original ResNet study showed the consequence on CIFAR-10: a 56-layer plain network had higher training and test error than a 20-layer plain network throughout training (He et al. 2016a). Because the deeper network was worse on the *training* set, the failure was an optimization barrier, not overfitting.

A residual block gives the gradient a direct path back through its input. Equation 6.6 adds the identity path $\mathbf{x}$ to the residual mapping $\mathcal{F}(\mathbf{x})$:

$$\mathbf{y} = \mathcal{F}(\mathbf{x}) + \mathbf{x} \tag{6.6}$$

where $\mathcal{F}(\mathbf{x})$ represents the residual function (typically two convolutional layers with batch normalization and ReLU) and $\mathbf{x}$ is the identity skip connection. The original post-activation ResNet block

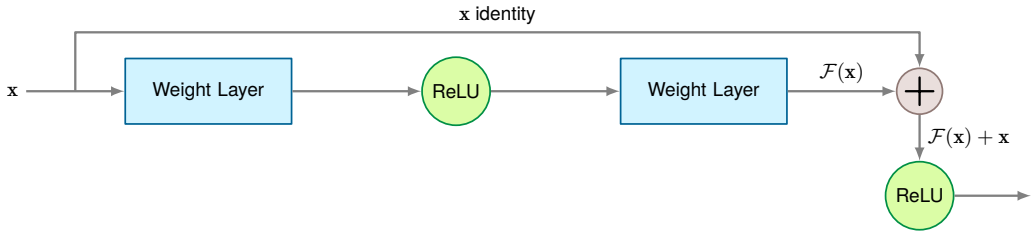

Figure 6.6: Residual Connection Block (Original Post-Activation Form): The original ResNet block (He et al. 2016a) implements $\mathbf{y} = \text{ReLU}(\mathcal{F}(\mathbf{x}) + \mathbf{x})$, where an identity shortcut bypasses the weight layers before a final ReLU activation. In later pre-activation variants (He et al. 2016b) and modern transformer blocks, the nonlinearity moves inside $\mathcal{F}(\mathbf{x})$, making the addition a completely clean identity shortcut $\mathbf{y} = \mathcal{F}(\mathbf{x}) + \mathbf{x}$ that matches the unobstructed gradient flow in equation 6.6.

(figure 6.6) routes an identity shortcut around two weight layers and the ReLU between them, adds it back at a junction, and then applies the final activation.

During backpropagation, the gradient flows through this addition, and applying the chain rule gives:

$$\frac{\partial \mathcal{L}}{\partial \mathbf{x}} = \frac{\partial \mathcal{L}}{\partial \mathbf{y}} \cdot \left(\frac{\partial \mathcal{F}(\mathbf{x})}{\partial \mathbf{x}} + \mathbf{I} \right) = \frac{\partial \mathcal{L}}{\partial \mathbf{y}} \cdot \mathcal{F}'(\mathbf{x}) + \frac{\partial \mathcal{L}}{\partial \mathbf{y}}$$

Here $\mathbf{I}$ is the identity matrix, and the gradient decomposes into two additive terms. Even if the residual term $\frac{\partial \mathcal{L}}{\partial \mathbf{y}} \mathcal{F}'(\mathbf{x})$ attenuates, the identity term passes $\frac{\partial \mathcal{L}}{\partial \mathbf{y}}$ directly to the earlier layer. While the residual branch can partially interfere with the identity signal, keeping $\|\mathcal{F}'(\mathbf{x})\|$ small keeps the block Jacobian close to identity and bounds its condition number. Through N_L residual blocks, the gradient becomes:

$$\frac{\partial \mathcal{L}}{\partial \mathbf{x}^{(0)}} = \frac{\partial \mathcal{L}}{\partial \mathbf{x}^{(N_L)}} \cdot \prod_{\ell=1}^{N_L} (\mathcal{F}'_\ell(\mathbf{x}^{(\ell-1)}) + \mathbf{I})$$

Each factor $(\mathcal{F}'_\ell + \mathbf{I})$ contains the identity term, keeping the factor near identity when the residual-branch Jacobian is small. A plain network instead multiplies arbitrary layer Jacobians, and if their average gain is even slightly below one the product vanishes exponentially ($0.9^{50} \approx 0.005$). ResNets multiply near-identity factors. The deviations can still compound, and the additive path does not guarantee exact unit gain across arbitrary depth, but this structure improves conditioning enough to make networks with 100+ layers trainable. The CIFAR-10 experiments confirm it: a 56-layer residual network reached about 7.0 percent test error against 8.8 percent for its 20-layer residual counterpart, reversing the degradation seen in plain networks (He et al. 2016a). There is no single depth at which skip connections suddenly become mandatory; trainability also depends on initialization, normalization, optimizer dynamics, and block architecture (He et al. 2016b).

The shortcuts carry a concrete hardware cost that every deep network pays. Evaluating $\mathbf{y} = \mathcal{F}(\mathbf{x}) + \mathbf{x}$ requires the input tensor $\mathbf{x}$ to remain resident in memory throughout the execution of every operation in the branch $\mathcal{F}(\mathbf{x})$. This extended liveness window increases peak activation memory in accelerator HBM during the forward pass and preserves $\mathbf{x}$ for backpropagation unless activation checkpointing is used (section 8.6.5.1). The elementwise addition is also memory-bandwidth bound. It performs one addition per two loaded operands and one stored result, about 0.08 FLOP/byte in FP32 (one FLOP per 12 bytes), so un-fused residual merges become memory stalls.

Residual connections stabilize the backward gradient path, but they do not constrain the forward scale of intermediate activations. Unbounded variance across depth can still destabilize layer inputs, which calls for a complementary block: normalization.

6.4.2 Normalization and activation stability

Without normalization, small weight updates in early layers compound across depth, shifting and amplifying intermediate activations until later nonlinearities saturate or overflow and training requires tiny learning rates. Skip connections protect the backward pass, and normalization steadies the forward pass by re-centering and re-scaling those intermediate activations at each block. Batch normalization in CNNs[17] (Ioffe and Szegedy 2015), layer normalization for sequence models, and

[17] **Batch normalization (BatchNorm)**: The original normalization layer (Ioffe and Szegedy 2015), which re-scales activations using per-mini-batch statistics. In one ImageNet experiment, it reached the target accuracy with 14× fewer training steps. Its batch-size dependency and training-serving skew (switching from batch statistics to running averages at inference) are systems limitations that motivated alternatives: LayerNorm removed batch dependency for transformers, and RMSNorm removed mean centering.

[18] **RMSNorm (root mean square normalization)**: Introduced by Zhang and Sennrich (2019) at NeurIPS, RMSNorm simplifies LayerNorm by normalizing with the root mean square alone, dropping the mean-centering step. Across the paper's tested models and implementations, RMSNorm reduced overall running time by 7–64 percent relative to LayerNorm. LLaMA-family and Mixtral-style transformer reports use RMSNorm (Touvron, Lavril, et al. 2023; Touvron, Martin, et al. 2023; Jiang et al. 2024), illustrating why a simpler normalization kernel matters at large language model scale.

RMSNorm[18] for large language models illustrate different choices of reduction axes and statistics.

Batch normalization standardizes activations using statistics computed across the mini-batch for each feature or channel during training. For fully connected activations, the reduction axis is the batch dimension. For convolutional activations, implementations compute per-channel statistics over both the batch and spatial positions ($B \times H_{\text{img}} \times W_{\text{img}}$). For a mini-batch $\mathcal{B} = \{a_1, \ldots, a_B\}$ of activations at a particular layer, the transformation proceeds in two stages, starting with the mini-batch mean and variance:

$$\mu_{\mathcal{B}} = \frac{1}{B}\sum_{i=1}^{B} a_i \qquad \sigma^2_{\mathcal{B}} = \frac{1}{B}\sum_{i=1}^{B}(a_i - \mu_{\mathcal{B}})^2$$

The second stage normalizes each activation over the batch and applies a learned scale and shift. The normalization step in equation 6.7 centers and scales activations, while equation 6.8 lets the network learn a useful output scale and offset:

$$\hat{a}_i = \frac{a_i - \mu_{\mathcal{B}}}{\sqrt{\sigma^2_{\mathcal{B}} + \epsilon}} \tag{6.7}$$

$$y_i = \gamma \hat{a}_i + \beta \tag{6.8}$$

The parameters γ (scale) and β (shift) are learned during training, while ϵ (typically 10^{-5}) prevents division by zero. The affine transform restores learned scale and shift flexibility, but fixed γ and β cannot exactly invert varying statistics for every batch. Normalization permits larger learning rates by preventing intermediate activations from exploding into saturating non-linear regimes, accelerating convergence relative to unnormalized networks.

While batch normalization enabled training of much deeper CNNs, it needs batch-wide statistics, which constrains distributed and sequence workloads. When a mini-batch is split across several accelerators, computing true mini-batch statistics requires an all-reduce, a collective that sums every accelerator's partial statistics and returns the total to all of them, adding communication latency to every normalized layer. If instead computed locally on small per-accelerator batches, noisy empirical statistics destabilize optimization. Furthermore, batch normalization cannot handle variable-length sequences or text generation, which produces one token at a time, without complex padding masks and training-serving skew. Layer normalization resolves these limitations by normalizing across the feature dimension rather than across the batch (Ba et al. 2016).

↪ The AllReduce collective and its communication cost are developed in section 8.7.1.1.

For an input vector $\mathbf{x} \in \mathbb{R}^d$ with d features, layer normalization first computes the mean and variance across those d components:

$$\mu_{\text{LN}} = \frac{1}{d}\sum_{i=1}^{d} x_i \qquad \sigma^2_{\text{LN}} = \frac{1}{d}\sum_{i=1}^{d}(x_i - \mu_{\text{LN}})^2$$

With those per-token statistics in hand, equation 6.9 defines the complete layer normalization operation, where $\odot$ denotes element-wise multiplication:

$$\text{LayerNorm}(\mathbf{x}) = \frac{\mathbf{x} - \mu_{\text{LN}}}{\sqrt{\sigma^2_{\text{LN}} + \epsilon}} \odot \gamma + \beta \tag{6.9}$$

Because each token or sample is normalized independently, the computation stays within an accelerator's on-chip SRAM and registers, with no cross-sample or cross-device communication. That independence makes layer normalization the standard choice for transformers, where sequences vary in length and text generation evaluates a single token at a time. Table 6.4 contrasts the three variants along the machine and operational dimensions that decide between them.

Table 6.4: Normalization Variant Comparison: Different normalization techniques trade off between computational efficiency, batch size sensitivity, and architectural compatibility. RMSNorm (Zhang and Sennrich 2019), used in LLaMA-family and other efficient transformer architectures (Touvron, Lavril, et al. 2023; Touvron, Martin, et al. 2023), omits mean centering: $\text{RMSNorm}(\mathbf{x}) = \mathbf{x}/\sqrt{\frac{1}{d}\sum_i x_i^2 + \epsilon} \odot \gamma$.

Characteristic	BatchNorm	LayerNorm	RMSNorm
Normalization Axis	Batch and, for CNNs, spatial positions	Feature dimension	Feature dimension
Batch Size Dependency	High (noisy for small batches)	None	None
Typical Use Case	CNNs, vision models	Transformers, RNNs	LLaMA, efficient transformers
Computation Cost	Higher (mean + variance)	Higher (mean + variance)	Lower (RMS only)
Training/Inference	Different (running stats)	Identical	Identical

The computational profile of normalization is defined by its arithmetic intensity. Because normalization applies elementwise operations to large activation tensors, execution is memory-bandwidth bound rather than compute bound. A straightforward LayerNorm kernel makes two reductions across the hidden dimension d, one for the mean μ_{LN} and one for the variance σ^2_{LN}, although Welford's algorithm can compute both in a single pass. RMSNorm drops the mean-centering reduction, leaving a single sum of squares, which simplifies the kernel and eases fusion with neighboring operations; its authors report 7–64 percent lower running time across the models they tested.

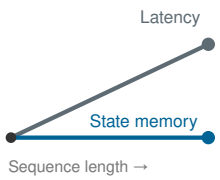
The table's last row is an operational cost. BatchNorm keeps nonlearned running mean and variance buffers and switches from mini-batch statistics in training to those running statistics at inference, so a mismatch between the buffers and deployment data is a frequent source of training-serving skew. LayerNorm and RMSNorm compute identically in both modes and carry no running state. With skip connections and normalization in place, depth stops being an optimization barrier.

↪ Kernel fusion, which collapses memory-bound normalization and activation chains into single kernels whose intermediates stay on chip, is developed in section 7.3.2.

Checkpoint 6.2: Making depth trainable

- ☐ **Gradient path**: can you explain why the identity term in a residual block keeps gradients from vanishing across many layers?
- ☐ **Liveness cost**: why does a skip connection raise peak activation memory, and why is an unfused residual addition memory-bandwidth bound?
- ☐ **Normalization choice**: why does layer normalization suit sequence models and token-by-token generation better than batch normalization?

Depth extends how far a network's view reaches across its input, but a convolutional stack still sees only its receptive field, whether that field spans pixels or the time bins of a spectrogram. A streaming system that must carry information across variable time spans within a fixed state budget motivates a different trade-off: updating a compact recurrent state as each observation arrives.



6.5 RNNs: Sequential Pattern Processing

An MLP requires a fixed-width input vector and a CNN sees only a bounded spatial window, so neither can process a continuous audio stream or a sentence of arbitrary length without padding, truncating, or stacking layers until activation memory overflows. Where convolutional networks exploit *spatial* structure, many real-world signals carry *temporal* structure, in which sequential order and prior context determine meaning. Recurrent networks process these variable-length streams within a fixed memory budget by carrying and updating a persistent state vector from one time step to the next.

Definition 6.4: Recurrent neural networks

Recurrent neural networks (RNNs) are sequence-processing architectures that maintain a hidden state $\mathbf{h}_t = f(\mathbf{h}_{t-1}, \mathbf{x}_t)$ updated at each time step, encoding the assumption that the current output depends on all prior inputs through this fixed-size state vector.

1. **Significance**: The fixed-size state provides $\mathcal{O}(1)$ inference state memory regardless of sequence length (processing a 10,000-token sequence requires the same state memory as a 10-token sequence), but the sequential update rule forces all S recurrent transitions to execute in order. Separate per-step kernels (compiled accelerator routines, a different sense of the word from a convolution kernel) add launch overhead (L_{lat}); fusion can reduce those launches while preserving the serial dependency chain.
2. **Distinction**: Unlike MLPs, which require a fixed-dimensional input vector, or CNNs, which restrict context to a fixed spatial window, RNNs compress an unbounded history into a fixed-size bottleneck state, so they accept sequences of any length without widening the input layer. Gradient signals pass back through the recurrent steps, where repeated Jacobian products can attenuate or amplify them (derived below).
3. **Common pitfall**: A frequent misconception is that RNNs are obsolete. For streaming inference on resource-constrained hardware, such as keyword spotting on a microcontroller, a model that must keep every past input to see the whole stream needs memory that grows with stream length, which can be prohibitive. An RNN's $\mathcal{O}(1)$ state size makes it a candidate when a fixed state budget is required.

RNNs hold state memory fixed, but latency grows with sequence length.

Expanding a convolutional receptive field to cover long sequences requires either stacking dozens of layers or applying dilated kernels, both of which scale parameter count and intermediate activation storage regardless of whether the intervening tokens contain relevant information. Recurrent architectures, from simple recurrent networks to gated variants such as long short-term memory (LSTM) networks (Elman 1990; Hochreiter and Schmidhuber 1997), address this constraint by introducing a temporal inductive bias: execution order encodes causal direction, and history compresses into a recurring state. Instead of processing each input vector in isolation, the network carries an internal state vector across successive time steps. This inductive bias establishes an explicit engineering trade-off: it provides variable-length temporal context within a fixed memory budget, but it introduces loop-carried data dependencies that serialize execution on parallel accelerator hardware.

6.5.1 Pattern processing needs

A word like "bank" cannot be disambiguated on its own: "river bank" refers to a shoreline, whereas "investment bank" refers to a financial institution. Only the preceding words resolve which meaning applies. Acoustic waveforms and sensor telemetry behave the same way: a single audio sample or temperature reading is ambiguous without the history that came before it.

Data with this sequential structure imposes three requirements on a model:

1. **Variable-length inputs**: Sequences arrive with different lengths S, ruling out a single fixed-width input layer.
2. **Long-range memory**: The model must carry relevant signals across many time steps without requiring a fixed window size.
3. **Continuous state updates**: Internal representations must update as each new token arrives, folding in new evidence while dropping stale history.

A fixed-input MLP requires windowing, padding, or truncation to process variable-length sequences, and a CNN reaches a long history only by stacking or dilating layers, at a cost in activation storage. Recurrence meets all three streaming requirements by making a persistent, fixed-size state part of its dataflow.

6.5.2 Algorithmic structure

To meet the requirements of section 6.5.1, recurrent neural networks introduce directed cycles in their computational graph. Rather than mapping inputs directly to outputs through feedforward layers, an RNN maintains a persistent vector, the **hidden state**, that updates iteratively at each time step. The hidden state is a running summary of the past.

The fundamental state transition in equation 6.10 computes the current hidden state $\mathbf{h}_t$ by combining the incoming token vector $\mathbf{x}_t$ with the preceding state $\mathbf{h}_{t-1}$:

$$\mathbf{h}_t = \phi(\mathbf{W}_{\text{hh}}\mathbf{h}_{t-1} + \mathbf{W}_{\text{hx}}\mathbf{x}_t + \mathbf{b}_{\text{h}}) \tag{6.10}$$

where $\mathbf{h}_t$ denotes the hidden state at time t, $\mathbf{x}_t$ denotes the input at time t, $\mathbf{W}_{\text{hh}}$ contains the recurrent weights, $\mathbf{W}_{\text{hx}}$ contains the input weights, $\mathbf{b}_{\text{h}}$ is the hidden-state bias vector, and ϕ is the activation function. The equation uses column vectors; the later listings use row-major batched tensors, so their weight multiplications appear on the right. Unrolled across time (figure 6.7, right), the loop becomes a chain of transitions $\mathbf{h}_{t-1} \to \mathbf{h}_t \to \mathbf{h}_{t+1}$ in which every link reuses the same recurrent weight matrix $\mathbf{W}_{\text{hh}}$, so no step can begin until the one before it has finished.

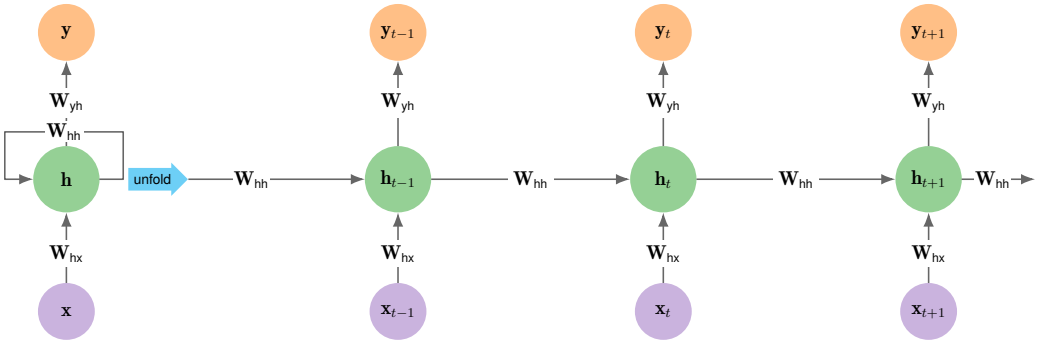


Figure 6.7: Recurrent Neural Network Unfolding: The compact recurrent loop (left) unfolds into one copy of the cell per time step (right). Three weight matrices are shared across all steps: $\mathbf{W}_{\text{hx}}$ (input-to-hidden), $\mathbf{W}_{\text{hh}}$ (hidden-to-hidden), and $\mathbf{W}_{\text{yh}}$ (hidden-to-output). These matrices are reused at every step, so the parameter count is independent of sequence length. For a 128-dimensional hidden state and a 100-dimensional input, each time step requires 16,384 MACs for recurrent connections plus 12,800 for input projection.

Unfolding the recurrent loop across S steps reveals the algorithmic properties of recurrence. Parameter count remains independent of sequence length S because the weight matrices $\mathbf{W}_{\text{hh}}$ and $\mathbf{W}_{\text{hx}}$ are shared across all time steps. However, sharing weights across time establishes a loop-carried dependency: step t cannot evaluate $\mathbf{h}_t$ until step $t-1$ finishes producing $\mathbf{h}_{t-1}$. This dependency forms a critical path of length $\mathcal{O}(S)$ serial operations that prevents hardware accelerators from parallelizing across the sequence dimension.

This sequential structure produces fundamentally different memory characteristics between inference and training. During streaming inference, an RNN evaluates one step at a time, discarding prior raw inputs and retaining only the current hidden state. State memory overhead remains strictly $\mathcal{O}(d)$ in the hidden dimension d, regardless of whether the sequence spans 10 or 10,000 steps. In contrast, training via backpropagation through time (BPTT) (Werbos 1990) unrolls the graph across the entire sequence of length S. Computing gradients via the chain rule requires evaluating the Jacobian product across all intermediate transitions:

$$\frac{\partial \mathcal{L}}{\partial \mathbf{h}_0} = \frac{\partial \mathcal{L}}{\partial \mathbf{h}_S} \prod_{t=1}^{S} \frac{\partial \mathbf{h}_t}{\partial \mathbf{h}_{t-1}}$$

Ordinary BPTT retains the intermediate activations $\mathbf{h}_1, \mathbf{h}_2, \ldots, \mathbf{h}_S$ for these Jacobian products. This retained-state scheme converts an $\mathcal{O}(d)$ runtime state into an $\mathcal{O}(S \cdot d)$ training footprint; recomputing saved intermediates trades additional work for memory. Repeated Jacobians combine activation derivatives with $\mathbf{W}_{\text{hh}}$, and their products can attenuate or amplify gradients over long horizons, limiting the effective context window of simple RNNs. Gated variants such as the LSTM answer

this with learned gates, elementwise valves that decide at each step how much of the stored state to keep, overwrite, or expose; a kept state passes to the next step without being multiplied by $\mathbf{W}_{hh}$, which gives gradients a path that does not shrink at every step.

6.5.3 Gated recurrence

A gate is an elementwise valve. It applies a sigmoid to a learned projection of the current input and the previous state, producing values between zero and one that multiply the quantity the gate controls, so a value near one passes that quantity through and a value near zero blocks it. LSTMs[19] (Hochreiter and Schmidhuber 1997) keep a separate cell state beside the hidden state and use three such **gates** (input, forget, and output) together with a candidate update; because the forget gate can carry the cell state forward almost unchanged, gradients cross many steps without being multiplied by $\mathbf{W}_{hh}$ each time. GRUs[20] (Cho et al. 2014) merge the same idea into two gates. For the machine, an LSTM step computes four affine transformations of the input and previous state instead of one, so it holds four times the recurrent weights, performs four times the multiply-accumulates per step, and carries twice the state (hidden and cell). Runtimes fuse the four projections into one matrix multiply four times as wide, which raises its arithmetic intensity without shortening the serial chain of steps.

6.5.4 Computational mapping

In hardware, a recurrent step is two matrix products followed by an elementwise update. Convolution reuses each weight across a grid of positions available all at once (section 6.3.4.3); a recurrent step reuses its weights only across time, and each step must wait for the state the previous step produces.

Listing 6.5 demonstrates the single-time-step mechanism using framework-level matrix operations: combine the previous hidden state with the current input, add the bias, and apply the activation to produce the next hidden state. The code is intentionally local to one step because the systems cost is not the step itself, but the dependency chain that prevents parallel execution across time.

Listing 6.5: RNN Layer Abstraction: Framework-level implementation combining two matrix multiplications, $\mathbf{h}_{t-1}\mathbf{W}_{hh}$ and $\mathbf{x}_t\mathbf{W}_{hx}$, per time step. For 128-dimensional hidden state and 100-dimensional input, each step requires 16,384 + 12,800 = 29,184 MACs, but sequential dependencies prevent parallelization across time.

```
def rnn_layer_step(x_t, h_prev, W_hh, W_hx, b):
    # x_t: input at time t (batch_size × input_dim)
    # h_prev: previous hidden state (batch_size × hidden_dim)
    # W_hh: recurrent weights (hidden_dim × hidden_dim)
    # W_hx: input weights (input_dim × hidden_dim)
    h_t = activation(matmul(h_prev, W_hh) + matmul(x_t, W_hx) + b)
    return h_t
```

At the framework level, `rnn_layer_step` hides the underlying loop structure and memory traffic behind high-level matrix multiplications (`matmul`). In hardware, evaluating this step requires moving weights and activations through the memory hierarchy. To see where execution serializes and where parallelism remains, listing 6.6 expands the matrix operations into explicit loop nests down to scalar multiply-accumulate operations.

[19] **LSTM (long short-term memory)**: Invented by Hochreiter and Schmidhuber in 1997, LSTMs introduced a "Constant Error Carousel," a gated cell state that protects error signals from exponential decay during backpropagation through time. The systems cost is that a standard LSTM computes input, forget, and output gates plus a candidate cell update, giving roughly four affine transformations per time step vs. one in a vanilla RNN. Transformers replaced LSTMs in many large-scale language workloads not because attention costs less arithmetic, since it costs more, but because it parallelizes across sequence positions where a recurrence cannot.

[20] **GRU (gated recurrent unit)**: Cho et al. (2014) describes a gated hidden unit for encoder-decoder translation that uses reset and update gates to control how the hidden state is updated. Relative to an LSTM's input, forget, and output gates plus candidate cell update, this gives a simpler gated recurrence. The broader systems lesson: architectural simplification can reduce state and matrix operations when it preserves task performance, a principle that recurs in efficiency-oriented designs from MobileNet to distilled transformers.

Listing 6.6: RNN Layer Computation: Nested loops expose the sequential dependency structure. Loop 1 enables batch parallelism, but Loops 2-3 must complete before Loop 4's activation; because each time step depends on the previous step's output, the resulting $\mathcal{O}(S)$ sequential depth prevents GPU parallelization across the time dimension.

```
def rnn_layer_compute(x_t, h_prev, W_hh, W_hx, b):
    # Initialize next hidden state
    h_t = np.zeros_like(h_prev)

    # Loop 1: Process each sequence in the batch
    for batch in range(batch_size):
        # Loop 2: Compute recurrent contribution (h_prev × W_hh)
        for i in range(hidden_dim):
            for j in range(hidden_dim):
                h_t[batch, i] += h_prev[batch, j] * W_hh[j, i]

        # Loop 3: Compute input contribution (x_t × W_hx)
        for i in range(hidden_dim):
            for j in range(input_dim):
                h_t[batch, i] += x_t[batch, j] * W_hx[j, i]

        # Loop 4: Add bias and apply activation
        for i in range(hidden_dim):
            h_t[batch, i] = activation(h_t[batch, i] + b[i])

    return h_t
```

The loop structure exposes the concurrency boundaries of recurrent execution. Batch instances in Loop 1 are independent, so sequences within a batch parallelize across accelerator cores without cross-talk. Within each batch instance, Loops 2 and 3 execute the recurrent transformation ($\mathbf{h}_{t-1}\mathbf{W}_{hh}$) and input projection ($\mathbf{x}_t\mathbf{W}_{hx}$). Both reductions must accumulate fully before Loop 4 can apply the elementwise bias addition and activation function to produce $\mathbf{h}_t$.

For an input dimension of 100 and a hidden state dimension of 128, each step executes two matrix multiplications: a 100×128 input projection and a 128×128 recurrent transformation. When batch size is large ($B \gg 1$), these operations execute as general matrix-matrix multiplications (GEMM) that reuse each loaded weight across all B samples. When batch size is small ($B = 1$, typical of real-time streaming inference), they collapse into the same weight-streaming matrix-vector products as the batch-one dense layer of equation 6.2, which starve accelerator compute units.

6.5.5 System implications

The hard physical constraint that recurrent architectures impose is sequential dependency. In the update $\mathbf{h}_t = \tanh(\mathbf{W}_{hh}\mathbf{h}_{t-1} + \mathbf{W}_{hx}\mathbf{x}_t)$, the recurrent transformation at time step t needs the state produced by step $t-1$. An input sequence of length $S = 1{,}000$ therefore requires $1{,}000$ ordered state updates, even when a fused kernel executes several or all updates within one launch. Hardware can parallelize across batch instances and within each matrix operation; input projections can also be computed across time when the inputs are available. Faster arithmetic or memory shortens individual steps, while the recurrent dependency chain remains.

During inference, recurrent networks need little state memory. Because the recurrent state compresses history into a fixed-size vector $\mathbf{h}_t$, inference state memory scales as $\mathcal{O}(d)$ (for example, 2 KB for a 512-dimensional FP32 state), remaining completely flat whether sequence length S is 10 or 10,000 tokens. This constant memory footprint contrasts sharply with attention mechanisms (section 6.6), whose stored context grows with every token generated, an $\mathcal{O}(S \cdot d)$ store that the transformer section sizes. For streaming deployments on memory-constrained edge hardware, such as microcontrollers, an RNN's $\mathcal{O}(1)$ runtime state avoids the growing context store that limits attention-based models.

Recurrent execution splits the memory hierarchy between two behaviors: high temporal locality for parameters, and low operational intensity under standard framework dispatch. Weight matrices $\mathbf{W}_{hh}$ and $\mathbf{W}_{hx}$ are reused at every time step, residing comfortably in SRAM or L2 cache if the model fits on-chip. However, naively launching separate kernels for input projection, recurrent projection, bias addition, and activation at each time step incurs severe kernel-launch overhead

and forces intermediate tensors back and forth across HBM. To mitigate this memory-bandwidth bottleneck, production recurrent runtimes fuse the projections, bias addition, and activation into a single monolithic kernel that maintains $\mathbf{h}_t$ within GPU registers and shared memory throughout the sequence execution. At batch one, each recurrent step is the dense layer's matrix-vector product again, with the same energy profile. Unless the recurrent weights stay on chip from step to step, every step pays DRAM energy for every weight, about 139× the energy of its arithmetic, which is a second reason streaming runtimes keep those weights resident.

↪ What a fused kernel that holds its state in registers and shared memory costs in on-chip capacity and occupancy is developed in section 11.7.7.

Checkpoint 6.3: Recurrent state and the serial chain

Recurrence trades parallelism for a fixed memory budget. Check your understanding:

- ☐ **Serial chain**: why can a faster accelerator not remove the 1,000 ordered updates of a 1,000-step sequence, and which parts of the work can still run in parallel?
- ☐ **Fixed state**: why does an RNN's inference memory stay flat as a stream grows, while training through time stores state for every step?
- ☐ **Gates**: what does an LSTM step cost the machine compared with a plain recurrent step, and what does fusing its four projections change?

This architectural tension between fixed-capacity state and serialized execution defined sequence processing before transformers. While recurrent networks maintain constant memory overhead regardless of sequence length, the sequential dependency prevents hardware from parallelizing across time steps, the fixed-capacity state becomes an information bottleneck in which early inputs fade over long spans, and gradients through long chains of recurrent steps vanish or explode (the vanishing gradient problem) (Bengio et al. 1994). State-space models such as Mamba (Gu and Dao 2023) later revived recurrence for exactly its systems strength, a fixed-size state at decode time where an attention model's stored context grows, while training with a parallel scan instead of a step-by-step loop. Overcoming the serial chain and the fading state in general, however, required an architecture capable of establishing direct, content-addressable links across arbitrary sequence positions without intervening recurrent steps: the attention mechanism (section 6.6).

6.6 Attention: Dynamic Processing

Recurrent networks serialize execution along the sequence dimension and compress all historical context into a fixed-capacity hidden state vector (section 6.5.5). In a sentence such as "The cat, which was sitting by the window overlooking the garden, was sleeping," the subject "cat" and predicate "sleeping" are separated by ten intervening words, yet they form the core syntactic and semantic relationship. An RNN must process all intervening tokens sequentially, risking information loss across intermediate recurrent transitions while preventing hardware from parallelizing across time steps. This constraint motivates an alternative computational pattern: an operation that directly computes relevance between any two positions regardless of distance.

Attention mechanisms[21] address this limitation (Bahdanau et al. 2015) by introducing dynamic connectivity patterns that adapt to input content. The setting was sequence-to-sequence translation, built as an encoder-decoder pair. An encoder network reads the input sentence into one representation per input position, and a decoder network generates the output sentence one token at a time, carrying its own recurrent decoder state. Recurrent versions of that pair passed only the encoder's final state to the decoder. Rather than forcing all context through that single fixed-capacity vector, encoder-decoder attention computes similarity scores between the decoder state at each output step and all encoder positions, routing information dynamically across the sequence. A single decoder step compares one query with every encoder position. In full-sequence self-attention, each position queries all positions in the same sequence, so the number of score interactions grows quadratically with sequence length.

[21] **Bahdanau attention**: This approach broke the "fixed-length vector" bottleneck of prior sequence-to-sequence models. The core trade-off was accepting a linear, $\mathcal{O}(S)$ memory cost to store all input states in exchange for overcoming the information loss inherent in a single vector.

Definition 6.5: Attention mechanisms

Attention mechanisms are neural network operations that compute a weighted sum of value vectors, where the weights are derived from learned similarity scores between a query vector and a set of key vectors, enabling dynamic, content-dependent information routing between any two positions in a sequence.

1. **Significance**: Attention connects any two tokens in $\mathcal{O}(1)$ depth but computes S^2 score interactions. If those scores are materialized, a 4,096-token sequence with 16-bit scores consumes 33.6 MB per layer per head (about 16.8M scores at 2 bytes each), directly increasing the iron law's D_{vol} term.
2. **Distinction**: Unlike RNNs, which compress all prior context into a single fixed-size state vector, attention mechanisms retain every token's representation and compare tokens directly. When a model generates text one token at a time, it keeps the key and value vectors of earlier tokens rather than recomputing them, and that **key-value (KV) cache** grows as $\mathcal{O}(Sd)$; the transformer section explains generation and sizes the cache.
3. **Common pitfall**: A frequent misconception is that attention is a general-purpose weighting scheme that can be applied freely. Quadratic score computation is a hard scaling constraint: doubling the context quadruples score interactions. Naive implementations also quadruple score storage; tiled exact algorithms such as FlashAttention avoid the full matrix, while sparse variants reduce the scores computed (Child et al. 2019).

The ability of attention to connect any position to any other made the recurrent structure unnecessary for many sequence tasks. The transformer[22] (Vaswani et al. 2017) removed recurrence entirely, trading the RNN's $\mathcal{O}(S)$ sequential path for constant path length between positions within one attention layer and thereby enabling parallelization across sequence positions on high-throughput accelerators.

Attention functions as a computational primitive rather than an independent architecture family. The transformer (section 6.7), the family built around it, inherits its core systems properties directly from attention: content-dependent routing, parallel sequence execution, and quadratic score scaling. Evaluating those properties begins with the dynamic pattern-processing problem that attention addresses.

[22] **Transformer**: The founding paper, "Attention Is All You Need," made the explicit systems claim that a parallel attention mechanism could fully replace sequential recurrent processing. This architectural trade eliminates an RNN's $\mathcal{O}(S)$ path length constraint on parallelism but introduces $\mathcal{O}(S^2)$ dense score computation, a quadratic cost that continues to shape context-window engineering.

6.6.1 Pattern processing needs

In "the trophy did not fit in the suitcase because it was too big," the word "it" refers to "trophy," but if "big" changes to "small," "it" refers to "suitcase." The same positions, at the same distances, need different links depending on what the words mean. Neither a CNN's fixed spatial window nor an RNN's step-by-step hidden state can route information directly between arbitrary positions based on content. Dynamic sequence processing needs an operation that scores relationships from the tokens themselves, letting each word draw directly on the words that matter to it regardless of how far apart they sit (figure 6.8).

The bipartite connection lines in figure 6.8 illustrate how the pronoun "they" could receive information from "student" and "finish." The hypothetical weights demonstrate a direct routing path, not a measured coreference result. Pairwise connections can be evaluated in parallel, allowing a single layer to connect these positions without propagating intermediate state across intervening tokens.

Input-dependent processing extends well beyond language. In protein structure prediction, amino-acid interactions depend on chemical properties and spatial arrangement, not only chain position; in document analysis, connections between sections depend on semantic content rather than proximity. Graph convolutional networks (GCNs) (Kipf and Welling 2017) share attention's input-dependent routing but gather features along the sparse edges of each input graph, producing irregular memory access that can bind execution on memory bandwidth and cache misses rather than compute throughput.

Input dependence does not imply all-to-all connectivity. Dense attention scores every pair of sequence elements, whereas a GCN restricts aggregation to edges in the observed graph. The

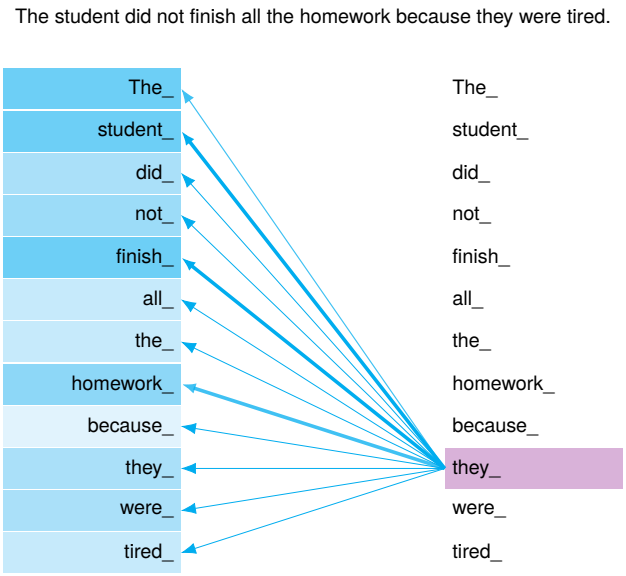

Figure 6.8: Illustrative Attention Pattern: A schematic attention pattern for the pronoun "they." Line thickness represents hypothetical attention-weight magnitude, with stronger links to "student," "finish," and "homework." One attention layer connects all positions directly and can compute their dense interactions in parallel.

common systems challenge is that the computation or memory-access pattern responds to the input rather than following a fixed stencil. Even when tensor dimensions stay fixed, content-dependent scores determine which information is emphasized. Attention provides one mechanism for learning such relationships, and dense self-attention forms the foundation of the transformer architecture.

6.6.2 Algorithmic structure

To route information dynamically (section 6.6.1), the network needs an operator that turns a variable-length sequence into content-dependent weights (Bahdanau et al. 2015). The transformer architecture computes these weights with the scaled dot-product attention operator introduced by Vaswani et al. (2017):

$$\text{Attention}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) = \text{softmax}\left(\frac{\mathbf{Q}\mathbf{K}^T}{\sqrt{d_{\text{head}}}}\right)\mathbf{V}$$

For this self-attention case, the inputs $\mathbf{Q}$ (queries), $\mathbf{K}$ (keys), and $\mathbf{V}$ (values)[23] are learned linear projections of the token representations ($\mathbf{Q} = \mathbf{X}\mathbf{W}_Q$, $\mathbf{K} = \mathbf{X}\mathbf{W}_K$, $\mathbf{V} = \mathbf{X}\mathbf{W}_V$). Attention uses three separate projection matrices rather than computing dot-product affinities directly between raw tokens ($\mathbf{X}\mathbf{X}^T$) for two architectural reasons:

1. **Asymmetric relationships**: Direct token dot products $\mathbf{x}_i \cdot \mathbf{x}_j$ are symmetric ($\mathbf{x}_i \cdot \mathbf{x}_j = \mathbf{x}_j \cdot \mathbf{x}_i$), whereas relationships in language are not. In "the chef cooked the meal," the verb "cooked" looks for its direct object ("meal"), while "meal" plays a different role, so the two directions of the pair need different scores. Splitting the projection into a query (what a token looks for) and a key (what a token offers) lets $\mathbf{q}_{\text{cooked}} \cdot \mathbf{k}_{\text{meal}}$ be high while $\mathbf{q}_{\text{meal}} \cdot \mathbf{k}_{\text{cooked}}$ stays low.
2. **Separating where to look from what to pass on**: The dot products $\mathbf{Q}\mathbf{K}^T$ decide *where* to look (routing weights), while the value projection $\mathbf{V}$ decides *what* information to retrieve. Without a separate value projection, a token that serves mainly as a structural marker (such as a preposition or punctuation mark) would pass its entire raw embedding into later layers. Projecting through $\mathbf{W}_V$ lets the network strip away surface token identity and pass along only the features downstream layers need.

For an input sequence of length S projected to a dimension d_{head} (here the full width d; the transformer's multi-head attention later splits that width across several parallel attention computations

[23] **Query-key-value (QKV)**: The terminology is borrowed from information retrieval, explaining why the equation uses three distinct learned projections to calculate pairwise scores. Creating these projections requires three independent weight matrices, costing $3 \times d^2$ parameters per layer. Storing the key and value projections of earlier tokens is what produces the key-value (KV) cache of autoregressive serving (section 6.7.4.2).

called heads), the dot product $\mathbf{QK}^T$ computes all S^2 pairwise token similarities. Scaling by $1/\sqrt{d_{\text{head}}}$ prevents dot products from growing large in magnitude at high dimensions, which would push softmax into regions with vanishingly small gradients. The softmax operator[24] normalizes each row of the score matrix into a probability distribution over key positions. Finally, multiplying these normalized weights by $\mathbf{V}$ produces output vectors formed as weighted combinations of the value representations.

Figure 6.9 traces this dataflow for a sequence of length $S = 6$: cyan query rows match against red key columns to populate the 6×6 similarity matrix, whose rows subsequently weight the green value vectors to produce the contextualized output vectors on the right. Each row of the resulting $S\times S$ matrix determines how strongly an individual token attends to every token in the sequence. In a trained model, the largest affinity values reflect strong contextual dependencies, while near-zero entries suppress irrelevant positions.

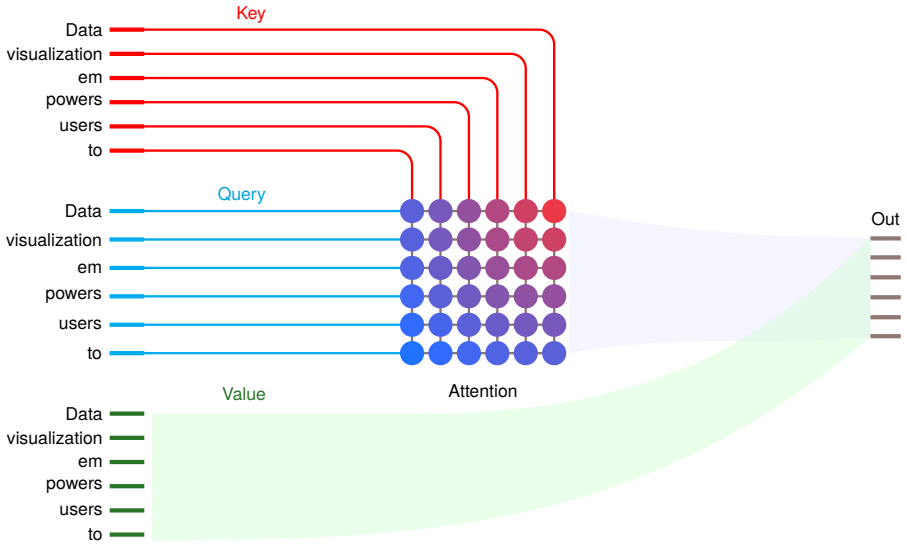

Figure 6.9: Query-Key-Value Attention Mechanism: For a 6-token sequence, queries (cyan) match against keys (red) to produce a 6×6 attention matrix with $\mathcal{O}(S^2)$ entries. The six tokens are the pieces a tokenizer cuts from "Data visualization empowers users to," which is why "empowers" appears as "em" and "powers." Cell color runs from blue to red across the grid as an illustrative gradient rather than as computed weights. Each output position aggregates information from all values (green) weighted by its own row of that matrix. The matrix structure reveals both the computational pattern (thirty-six similarity computations) and the naive memory bottleneck (storing S^2 attention weights). Adapted from Transformer Explainer (Cho et al. 2025).

While attention weights vary dynamically with the input tokens, generating the query, key, and value vectors requires static linear projections against learned parameter matrices. In accelerator implementations, these three operations are fused into a single batched matrix multiplication to maximize Tensor Core saturation and reduce kernel launch overhead. Packing the three weight matrices side by side turns three projections into one (figure 6.10): the 6×768 token embedding matrix (one learned 768-value vector per token) multiplies a 768×2304 weight matrix whose three 768-column blocks hold the query, key, and value weights, and adding the bias yields a 6×2304 output that contains all three projections, computed in a single kernel pass.

6.6.3 Computational mapping

Lowering the attention operator $\text{Attention}(\mathbf{Q},\mathbf{K},\mathbf{V}) = \text{softmax}(\mathbf{QK}^T/\sqrt{d_{\text{head}}})\mathbf{V}$ to physical execution exposes the system cost of data-dependent connectivity. Evaluating pairwise alignments requires two distinct matrix multiplications per attention head: the score GEMM ($\mathbf{QK}^T$) and the context GEMM ($\mathbf{AV}$, where $\mathbf{A} = \text{softmax}(\mathbf{QK}^T/\sqrt{d_{\text{head}}})$). For an input of sequence length S and head dimension d_{head}, each phase executes $S^2 d_{\text{head}}$ multiply-accumulate operations, yielding $\mathcal{O}(S^2 d_{\text{head}})$ computational complexity per head.

[24] **Softmax**: Named as a "soft" (differentiable) version of argmax, with mathematical roots in Boltzmann's statistical mechanics, softmax normalizes each query row over all S scores and therefore requires a reduction over each row. Online softmax lets that reduction run over tiles with running statistics, which is why it need not force quadratic storage (section 6.6.4.1).

↪ The dot product as a similarity measure is collected for reference in section C.1.2.

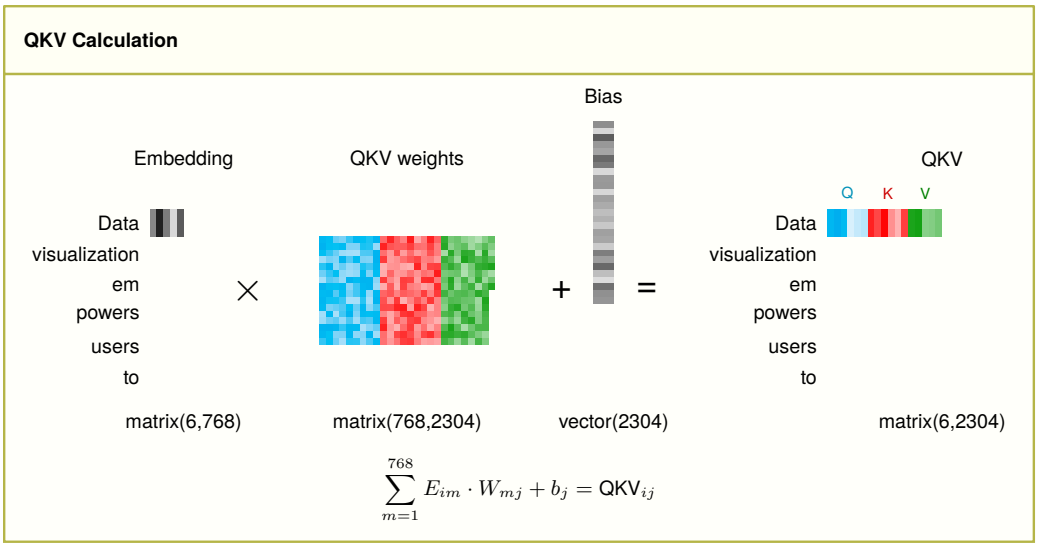

Figure 6.10: QKV Projection Computation: The embedding matrix (6×768) multiplies with QKV weight matrices (768×2304) plus bias to produce combined projections (6×2304). The 2304 output columns hold the query, key, and value projections side by side, 768 each, colored as in figure 6.9; only the first token's output row is drawn. This single batched matrix multiplication, requiring $6 \times 768 \times 2304 = 10.6$ million MACs, replaces three separate projection operations for efficiency. Adapted from Transformer Explainer (Cho et al. 2025).

Listing 6.7 contrasts the high-level matrix formulation with an explicit loop implementation that exposes this quadratic scaling. The matrix version lowers to optimized GEMM routines on accelerator Tensor Cores, whereas the loop version reveals the underlying physical execution structure: batch iterations, quadratic query-key inner products, row-wise softmax reductions, and the final value accumulation pass across all sequence positions.

Listing 6.7: Attention Computation: Two implementations showing the same $\mathcal{O}(S^2 \times d_{\text{head}})$ complexity. The matrix form (top) uses optimized GEMM, while the nested loops (bottom) expose the quadratic pairwise comparisons: for sequence length 512 and head dimension 64, computing attention scores requires $512 \times 512 \times 64 = 16.8$M MACs per attention head, plus another 16.8M MACs for value aggregation.

```
def attention_layer_matrix(Q, K, V):
    # Q, K, V: (batch_size × seq_len × d_head)
    # Compute attention scores
    scores = matmul(Q, K.transpose(-2, -1)) / sqrt(d_head)
    weights = softmax(scores)  # Normalize scores
    output = matmul(weights, V)  # Combine values
    return output

def attention_layer_compute(Q, K, V):
    # Initialize outputs
    scores = np.zeros((batch_size, seq_len, seq_len))
    outputs = np.zeros_like(V)

    # Loop 1: Process each sequence in batch
    for b in range(batch_size):
        # Loop 2: Compute attention for each query position
        for i in range(seq_len):
            # Loop 3: Compare with each key position
            for j in range(seq_len):
                # Compute attention score
                for d in range(d_head):
                    scores[b, i, j] += Q[b, i, d] * K[b, j, d]
                scores[b, i, j] /= sqrt(d_head)

        # Apply softmax to scores
        for i in range(seq_len):
            scores[b, i] = softmax(scores[b, i])

        # Loop 4: Combine values using attention weights
        for i in range(seq_len):
            for j in range(seq_len):
                for d in range(d_head):
                    outputs[b, i, d] += scores[b, i, j] * V[b, j, d]

    return outputs
```

6.6.4 System implications

Attention eliminates the latency-bound serial path of RNNs, but a naive implementation replaces it with an $S \times S$ attention-score matrix that grows quadratically with sequence length S. In iron law terms, dense attention trades serial recurrent steps for pairwise score arithmetic and heavy intermediate data movement. Some of these costs are inherent to computing all-to-all interactions; others come only from materializing the full score matrix in memory.

6.6.4.1 Memory requirements

Materializing an $S \times S$ attention-weight matrix for every sequence and head creates a quadratic memory bottleneck that quickly dwarfs both the $S \times d$ activations and the fixed-size projection weights on long inputs. Tiled exact-attention kernels such as FlashAttention stream score blocks through on-chip SRAM and avoid writing the full score matrix to HBM, while still computing all S^2 dense interactions (section 8.6.4 develops the I/O-aware tiling in full, and section C.4.2 collects the online softmax recurrence for reference). This distinction separates the unavoidable quadratic compute cost of dense attention from the avoidable quadratic memory footprint of storing the full score matrix in HBM.

Doubling context quadruples score interactions and naive score storage.

Napkin Math 6.1: The quadratic bottleneck

Problem: How much memory does a materialized attention matrix require at sequence length $S = 100{,}000$ (context window)?

Math:

1. **Matrix size**: The attention score matrix ($\mathbf{QK}^T$) has dimensions $S \times S$ per head, across N_{heads} heads (12 heads in this example).
2. **Elements**: 100,000 × 100,000 × 12 heads = 1.2×10^{11} elements.
3. **Memory**: At FP16 (2 bytes/element): $1.2 \times 10^{11} \times 2$ bytes = 240 GB.
4. **Retained layers**: 240 GB per layer × 32 retained layers = 7,680 GB.

Systems insight: A materialized attention matrix consumes 240 GB per layer. Naive training that retains all 32 layers' scores for backward would require 7,680 GB, far exceeding any single GPU's capacity. This memory wall motivates two broad implementation strategies: avoid materializing the full matrix by tiling the computation, or reduce the number of scores computed in the first place.

6.6.4.2 Computation and data movement

Attention computation splits into two primary GEMM phases interleaved by a row-wise reduction: generating pairwise query-key scores and computing weighted sums over values. Query-key inner products require $B \times N_{\text{heads}} \times S^2 \times d_{\text{head}}$ MAC operations, mirrored symmetrically by the value-aggregation stage. The intervening softmax requires row-wise maximum finding, exponentiation, and summation. Unlike static weight convolutions where filter weights are reused across fixed grid positions, attention computes transient, input-dependent affinity matrices that must be refreshed for every token configuration.

Data movement in attention creates memory access patterns distinct from fixed-stencil operations. Evaluating attention requires projecting and streaming query, key, and value tensors, then routing value vectors according to dynamically evaluated scores. In naive implementations, staging the intermediate $S \times S$ score matrix in global HBM/DRAM turns score materialization into the dominant bandwidth bottleneck. While static convolutions benefit from deterministic cache lines and RNNs reuse weights across time, naive attention generates massive, short-lived activation footprints that challenge standard on-chip cache capacities.

Checkpoint 6.4: Quadratic scaling intuition

Long-context scaling is shaped by the cost of attention. Verify your intuition:

- ☐ **Quadratic growth**: can you explain why doubling sequence length quadruples dense score interactions and a materialized score matrix?
- ☐ **Tiling boundary**: can you explain why long-context dense attention remains more expensive even when tiling removes full-matrix storage?

Attention replaces the serialized hidden-state bottleneck of recurrent models with dynamic, constant-depth routing, but shifts the system burden to score arithmetic and memory bandwidth traffic. Built into a full architecture without recurrence, this primitive enables end-to-end parallel sequence processing on modern accelerators. The transformer architecture (section 6.7) builds directly on this foundation, establishing the dominant architectural paradigm for modern large-scale machine learning systems.

6.7 Transformers: Parallel Sequence Processing

Attention provides the computational primitive of dynamic, content-dependent routing between positions, yet it was originally layered on top of recurrent architectures, inheriting their sequential bottleneck. The transformer architecture removes recurrence and makes attention the operation that mixes information between positions in every layer. This enables parallel computation across

sequence positions during full-sequence processing while retaining dynamic connectivity. This architectural shift introduces distinct physical costs: quadratic attention-score cost over long inputs, a store of per-token state that grows while the model generates text, and memory-bandwidth pressure when it generates one token at a time.

Definition 6.6: Transformers

Transformers are neural network architectures that combine self-attention, feed-forward layers, residual connections, normalization, and positional information without recurrence, enabling parallel processing across sequence positions during training and prompt processing.

1. **Significance**: Parallelism is the systems payoff. An RNN processing an S-token sequence executes S sequentially dependent steps. A transformer processes all positions of a sequence concurrently, mapping token interactions to large matrix multiplications (GEMMs) that maximize accelerator compute utilization. Dense self-attention retains the pairwise score cost (section 6.6.4.1).
2. **Distinction**: Unlike attention used inside a recurrent backbone, which inherits the host architecture's $\mathcal{O}(S)$ sequential path, transformers use attention as the primary mixing operation between positions, alternating it with position-wise feed-forward networks.
3. **Common pitfall**: A frequent misconception is that transformers have "infinite context." Two distinct memory footprints matter: the $\mathcal{O}(S^2)$ attention-score activation matrix when it is materialized over a long input, and the $\mathcal{O}(S)$ key-value (KV) cache that accumulates while the model generates text. At long sequence lengths, the KV cache footprint can rival or exceed the static model weights, turning KV cache management and memory-bandwidth efficiency into dominant engineering constraints.

6.7.1 Pattern processing needs

The recurrent sequence-to-sequence hybrids that first carried attention (Sutskever et al. 2014; Bahdanau et al. 2015) fixed the information bottleneck of section 6.5.5 but not its serialization. Step t still waited on step $t-1$, so a 1,000-token input still paid 1,000 ordered state updates no matter how many execution units the accelerator offered. Removing that chain requires replacing sequential state propagation with all-to-all interactions among positions, giving up the RNN's bounded per-step memory in exchange for parallel accelerator execution. The transformer architecture (Vaswani et al. 2017) establishes self-attention as the primary mixing primitive across positions, paired with positional encodings to inject sequence order, trading the spatial parameter efficiency of CNNs and the bounded $\mathcal{O}(1)$ step state of RNNs for unconstrained sequence parallelism during training and prompt processing.

6.7.2 Algorithmic structure

The core building block of a transformer is the self-attention layer. Unlike encoder-decoder attention, where queries come from the target sequence and keys and values come from the source sequence, self-attention projects queries, keys, and values from the same input sequence $\mathbf{X}$. Drawing all three projections from the same sequence lets the model link tokens across any distance in a single step, without passing state through intermediate recurrent steps. Equation 6.11 writes this operation:

$$\text{SelfAttention}(\mathbf{X}) = \text{softmax}\left(\frac{\mathbf{X}\mathbf{W}_Q(\mathbf{X}\mathbf{W}_K)^T}{\sqrt{d_{\text{head}}}}\right)\mathbf{X}\mathbf{W}_V \tag{6.11}$$

Here, $\mathbf{X}$ is the input sequence, and $\mathbf{W}_Q$, $\mathbf{W}_K$, and $\mathbf{W}_V$ are learned weight matrices for queries, keys, and values respectively. Without positional information or an attention mask, matrix multiplication and row-wise softmax operate symmetrically across the token dimension, making self-attention permutation-equivariant: shuffling the rows of $\mathbf{X}$ merely shuffles the output rows identically, treating the sequence as an unordered set. Positional encodings, whether added as sinusoidal vectors or applied via rotary position embeddings (Su et al. 2024), inject sequence order and relative distance.

Transformers extend single-head self-attention by executing multiple attention operations in parallel through multi-head attention. Instead of computing a single set of attention weights over d dimensions, the architecture projects queries, keys, and values into N_{heads} distinct lower-dimensional subspaces of dimension $d_{\text{head}} = d/N_{\text{heads}}$. Each head can learn a different pattern. Their outputs are concatenated and projected through an output matrix $\mathbf{W}_O$, as formalized in equation 6.12:

$$\text{MultiHead}(\mathbf{X}_Q, \mathbf{X}_K, \mathbf{X}_V) = \text{Concat}(\text{head}_1, \ldots, \text{head}_{N_{\text{heads}}})\mathbf{W}_O \tag{6.12}$$

where each attention head is computed as follows. In this multi-head notation, $\mathbf{X}_Q$, $\mathbf{X}_K$, and $\mathbf{X}_V$ denote the source representations before the head-specific projections; for self-attention, all three are $\mathbf{X}$. The head matrices apply the projections once:

$$\text{head}_i = \text{Attention}(\mathbf{X}_Q\mathbf{W}_{Q,i}, \mathbf{X}_K\mathbf{W}_{K,i}, \mathbf{X}_V\mathbf{W}_{V,i})$$

The $\sqrt{d_{\text{head}}}$ scaling introduced with the attention operator follows from a variance argument. Assuming query and key components are independent random variables with zero mean and unit variance, their inner product $\mathbf{q}_i \cdot \mathbf{k}_j = \sum_{m=1}^{d_{\text{head}}} q_{im}k_{jm}$ has zero mean and variance d_{head}, so dividing by $\sqrt{d_{\text{head}}}$ restores unit variance and keeps softmax out of its saturated, near-zero-gradient region at large head dimensions.[25]

[25] **Attention scaling ($\sqrt{d_{\text{head}}}$)**: This normalization directly counteracts the linear growth in variance (d_{head}) of the query-key dot product, preventing the softmax function from saturating where gradients would otherwise vanish. The systems consequence is most acute in mixed-precision training: when activations grow large, unscaled dot products can produce logits that overflow the 16-bit float range, destabilizing or halting learning entirely.

Conceptually, attention implements a differentiable content-addressable memory. Whereas conventional memory architectures retrieve stored values at explicit addresses, self-attention uses the query vector $\mathbf{q}_i$ to score similarity against all candidate keys $\mathbf{K} \in \mathbb{R}^{S \times d_{\text{head}}}$. The resulting softmax distribution generates a continuous interpolation over the value vectors $\mathbf{V} \in \mathbb{R}^{S \times d_{\text{head}}}$, functioning as a differentiable lookup operation.

Although individual attention heads often specialize in distinct syntactic or semantic patterns (Clark et al. 2019), adapting the effective connectivity graph to each input sequence, empirical analyses reveal substantial head redundancy and acute numerical sensitivity in reduced-precision formats. These hardware-relevant behaviors motivate structural pruning, low-rank factorization, sparse attention patterns, and specialized quantization strategies.

To build deep networks from these dynamic projections, the transformer places self-attention inside a repeating block (figure 6.11). Each block wraps multi-head attention and position-wise feed-forward sublayers with residual connections and layer normalization. Sinusoidal positional encodings combine with token embeddings at the base of both towers, feeding repeated multi-head attention and feed-forward stages before terminating in linear and softmax output heads. Because all positions can be processed in parallel rather than sequentially, the architecture trades recurrent state for large matrix operations that map well to accelerator training. A decoder-only model such as GPT-2 keeps only the right-hand tower of this figure, without the attention that reads an encoder's output: tokens enter as embedding vectors, pass through the stack of blocks, and leave as a probability distribution over the vocabulary for the next token. The residual paths and normalization layers in this stack are shared building blocks rather than transformer inventions; section 6.4.1 and section 6.4.2 explain why they make deep stacks trainable and what each costs the machine.

Language models built from this block are usually *autoregressive*: they produce text one token at a time and feed each new token back as input for the next. Given the prompt "The cat sat on," a model predicts "the," appends it, predicts "mat" from the longer context, and continues until it emits an end token. A *causal mask* keeps that process honest. It sets the attention scores for later positions ($t' > t$) to negative infinity before the softmax, so each position attends only to itself and earlier tokens, exactly the information that will exist when the model generates.

The same mask is what lets training run in parallel. During next-token training the whole target sequence is already known, so shifting it right by one position pairs every input token with its successor (figure 6.11), and the mask guarantees that position t cannot see later tokens. An accelerator therefore evaluates every position at once with dense matrix multiplications instead of stepping through a serial time loop as an RNN must.

Generation splits into two phases with different machine profiles, drawn in figure 6.12. *Prefill* processes the whole prompt in one pass: every prompt token is known, so the model evaluates them in parallel, as in training, and stores each token's keys and values. *Decode* then produces the

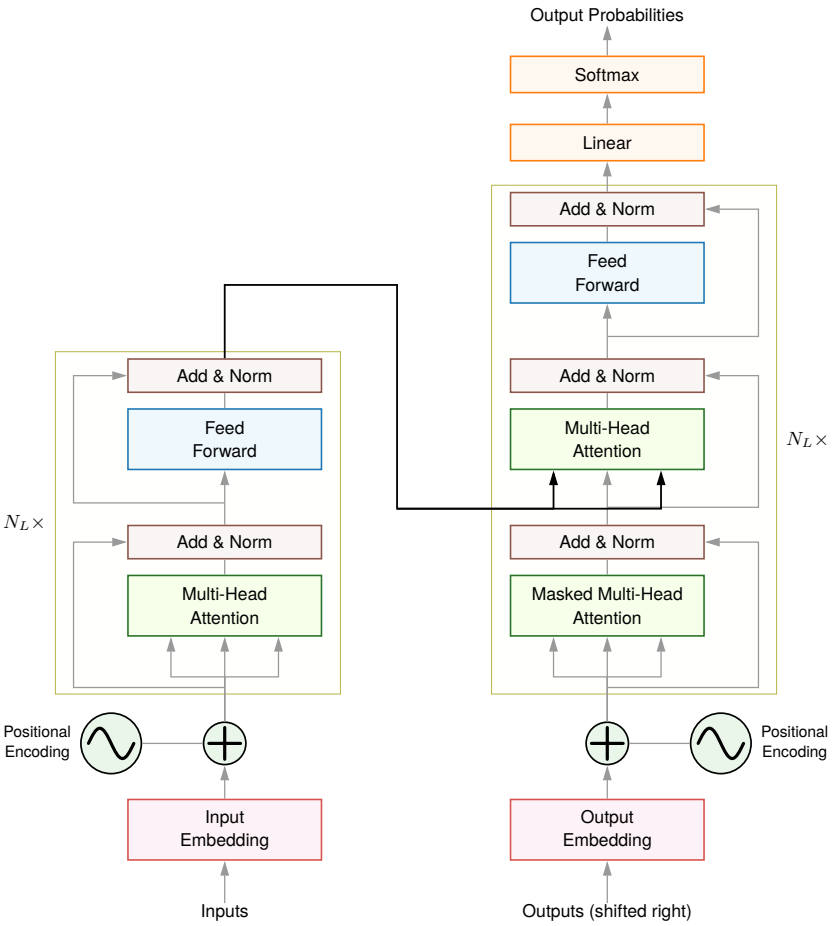

Figure 6.11: Transformer Architecture (Encoder-Decoder): The encoder (left, repeated N_L times) consists of multi-head attention followed by feed-forward layers, each with residual connections (arrows bypassing blocks) and layer normalization. The decoder (right) adds masked attention to prevent attending to future tokens during training and autoregressive generation. Positional encodings (sine waves) inject sequence order information absent from the permutation-equivariant attention operation. This design enables training parallelism across all positions while the decoder maintains autoregressive causality during inference. Adapted from Vaswani et al. (2017).

remaining tokens one per step. Each step feeds a single token through the model, so its projections shrink from matrix-matrix to matrix-vector products, and its attention reads the stored keys and values of every earlier token instead of recomputing them. That store is the key-value (KV) cache, and section 6.7.4.2 shows why decode, not prefill, usually sets a language model's serving cost.

6.7.3 Computational mapping

In code, self-attention is three projections of the same input followed by the attention operator, and multi-head attention runs several smaller copies side by side before a final projection (listing 6.8). Writing both layers side by side shows how the multi-head variant partitions the hidden dimension across heads without changing the per-head attention kernel.

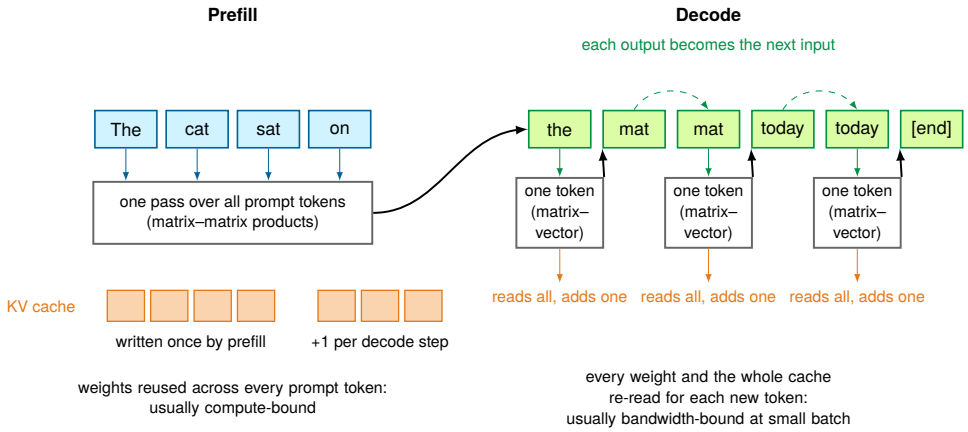

Figure 6.12: Prefill and Decode: Prefill (left) runs the whole prompt through the model in one pass of matrix-matrix products, reusing every weight across all prompt tokens, and writes each prompt token's keys and values to the KV cache. Decode (right) then generates one token per step: each output becomes the next input, each step runs matrix-vector products that re-read every weight, and each step reads the whole cache and appends one entry. The first phase is usually compute-bound; the second is usually bandwidth-bound at small batch.

Listing 6.8: Self-Attention and Multi-Head Attention: Self-attention (top) derives **Q**, **K**, and **V** from the same input **X** through three projections, then computes attention as before. Multi-head attention (bottom) runs N_{heads} parallel attention heads with dimension $d_{\text{head}} = d/N_{\text{heads}}$, then concatenates and projects. For GPT-2 (768-dim, 12 heads), each head operates on 64 dimensions, partitioning the projected feature dimension across heads while enabling diverse relationship patterns.

```
def self_attention_layer(X, W_Q, W_K, W_V, d_head):
    # X: input tensor (batch_size × seq_len × d_model)
    # W_Q, W_K, W_V: weight matrices (d_model × d_head)

    Q = matmul(X, W_Q)
    K = matmul(X, W_K)
    V = matmul(X, W_V)

    scores = matmul(Q, K.transpose(-2, -1)) / sqrt(d_head)
    attention_weights = softmax(scores, dim=-1)
    output = matmul(attention_weights, V)

    return output

def multi_head_attention(X, W_Q, W_K, W_V, W_O, num_heads, d_head):
    outputs = []
    for i in range(num_heads):
        head_output = self_attention_layer(
            X, W_Q[i], W_K[i], W_V[i], d_head
        )
        outputs.append(head_output)

    concat_output = concat(outputs, axis=-1)
    final_output = matmul(concat_output, W_O)

    return final_output
```

The attention listing accounts for information mixing across positions, but a complete block also transforms features within each position. An ordinary position-wise feed-forward network applies a dense projection from hidden width d to an intermediate layer output width d_{out}, a nonlinear activation, and a second dense projection back to d. For a sequence of length S, its tensor shapes follow $S\times d \to S\times d_{\text{out}} \to S\times d$. The same two weight matrices apply independently at every position, so the MLP accounting gives $2Sdd_{\text{out}}$ MACs and an intermediate tensor with Sd_{out} elements.

For one full-sequence block at batch one, with one standard multi-head self-attention sublayer and that two-layer feed-forward network, the query, key, value, and output projections together require $4Sd^2$ MACs. The two attention products add $2S^2d$ MACs across all heads, whose widths sum to d. Adding the feed-forward cost completes the block's matrix-product account; these counts omit biases, softmax, normalization, nonlinear activations, and residual additions, and assume dense evaluation of all position pairs. At fixed widths, projections and the feed-forward network grow linearly with sequence length, while the pairwise products grow quadratically. Which part dominates therefore depends on both the sequence length and the chosen widths, even before memory traffic is measured.

During autoregressive inference, generating output tokens step-by-step reintroduces sequential serialization. At batch one, projection matrix multiplications become matrix-vector operations with less weight reuse, making off-chip bandwidth a likely limit when weights exceed cache capacity, as quantified in section 6.7.4 via the GPT-2 XL lighthouse.

6.7.4 System implications

The quadratic bottleneck analyzed in section 6.6.4 manifests differently across execution regimes. Because full-sequence training and prompt prefill operate on known token sequences under causal masking, accelerators evaluate all positions concurrently using dense matrix multiplications. Autoregressive decoding, by contrast, must generate each token before predicting the next. That loss of token concurrency reduces weight reuse and can shift the primary performance limit from arithmetic throughput to memory bandwidth and state retrieval; sequence length, batch size, and memory hierarchy limits determine whether that transition occurs.

6.7.4.1 Training and prefill

During training and prompt prefill, all token positions are processed in parallel, allowing accelerator Tensor Cores to achieve high floating-point utilization, but dense attention's score computation grows as $\mathcal{O}(S^2)$ with sequence length S. I/O-aware tiling such as FlashAttention (Dao et al. 2022) keeps the score matrix out of HBM (section 6.6.4.1), so the quadratic arithmetic, not its storage, is the wall that remains.

That wall arrives later than its name suggests. By the block account of section 6.7.3, with a feed-forward width four times the model width, a block's projections and feed-forward network cost $12Sd^2$ multiply-accumulates against $2S^2d$ for the attention products, so attention's arithmetic dominates only once the sequence passes about six times the model width, near 9,600 tokens for GPT-2 XL. Shorter training sequences are bound by the ordinary dense matrix multiplies, and the quadratic wall is a long-context phenomenon.

Expanding sequence length S challenges accelerator memory hierarchies because full-sequence self-attention cost grows with context length. Product context windows grew from 2K tokens to beyond 128K and into the 1M-token range within a few years (OpenAI 2023c; Anthropic 2023; Google 2024a), and the decoding discussion below sizes what that growth demands of memory. Longer context windows shift complexity from external retrieval and document chunking pipelines into accelerator memory capacity and bandwidth budgets. Exact tiling changes how much attention state is stored; sparse attention instead reduces the interactions computed (section 6.6.4.1).

Example 6.4: The quadratic wall

Scenario: BERT was pretrained with 512 learned position embeddings, so its deployments enforced a hard 512-token input limit (Devlin et al. 2019).

Diagnosis: Inputs beyond the pretrained positions are undefined for the model, however much memory is available. The limit itself was chosen partly because attention cost grows quadratically with sequence length. Extending from 512 to 4,096 tokens would multiply materialized score memory by 64×.

Systems lesson: Super-linear scaling turns algorithmic complexity into a hardware constraint that becomes fixed in the model itself once pretraining chooses it. No serving-time memory fix extends BERT past 512 positions, so its longer inputs must be truncated or split into windows.

A model meant for long inputs must be pretrained with longer positions, and tiled or sparse attention is what keeps that training and its serving within the HBM activation budget.

6.7.4.2 Autoregressive decoding

Autoregressive decoding generates one token at a time and often becomes memory-bandwidth bound at batch one ($B = 1$) or small batch sizes when weights exceed on-chip memory. During prompt prefill or training, weight reuse across many token positions produces dense GEMMs with much higher arithmetic intensity. A large request batch ($B \gg 1$) supplies many such positions, but prefill can obtain this reuse even for a single request with a long prompt.

During single-token generation ($B = 1$), however, each projection layer collapses into a matrix-vector multiplication (GEMV). In the streamed-weight regime, the processor reads each projection weight from DRAM to multiply it by a single new token vector. This is the batch-one regime that equation 6.2 already derived for the MNIST layer at 0.5 FLOP/byte in FP32. Halving the weight width to 2 bytes in FP16, while still executing one multiply-accumulate operation (1 MAC = 2 FLOPs) per weight read, doubles that weight-only arithmetic intensity to exactly:

$$I_{\text{GEMV}} = \frac{2 \text{ FLOPs}}{2 \text{ bytes}} = 1.0 \text{ FLOP/byte}$$

↩ The 1.0 FLOP/byte intensity of batch-one GEMV in 16-bit precision, and 0.5 FLOP/byte in FP32, is established in section 5.5.3.

Because modern accelerators require tens to hundreds of FLOPs per byte to reach peak compute throughput, running at 1.0 FLOP/byte leaves compute cores idling for the vast majority of execution time, waiting for weights to arrive across the memory bus. To generate each token, the system must first stream every model parameter from off-chip memory into registers (for example, a 70B-parameter model streams 140 GB of FP16 weights per token, and GPT-2 XL makes that cost concrete below), then execute the projection matrix-vector products at an arithmetic intensity capped at 1.0 FLOP/byte, and finally append the new key and value vectors to the KV cache while streaming all historical keys and values from memory.

The KV cache[26] introduced with prefill and decode grows linearly with sequence length ($\mathcal{O}(N_L \times 2 \times N_{\text{heads}} \times S \times d_{\text{head}})$ per request, distinct from the $\mathcal{O}(S^2)$ attention score matrix during training), storing the key and value vectors for all previous tokens to avoid recomputing them (Pope et al. 2023; Kwon et al. 2023). Keys and values from past tokens are retained because the newly generated token's query ($\mathbf{q}_t$) must attend across all historical context ($\mathbf{k}_1 \dots \mathbf{k}_{t-1}$ and $\mathbf{v}_1 \dots \mathbf{v}_{t-1}$) to compute its next representation. Prior queries ($\mathbf{q}_1 \dots \mathbf{q}_{t-1}$) are safely discarded because past tokens never attend forward to future tokens, while caching past keys and values avoids re-running the entire model forward pass over the full prompt at every generated token. For long contexts, this cache can become massive (for example, 100+ GB), and each decoding step reads prior keys and values. The resulting bandwidth pressure depends on context length, batching, attention architecture, cache layout, and hardware.

[26] **KV cache memory scaling**: For a 7-billion-parameter transformer in FP16, model weights consume ~14 GB; a single request's cache requires 32 layers × 2 (K,V) × 32 heads × 2,048 positions × 128 dimensions × 2 bytes, or about 1.07 GB. At 8 concurrent users, the cache is ~8.6 GB, a substantial addition to the weights. Because the cache grows linearly with context and concurrency, scaling throughput forces choices such as grouped-query attention (Ainslie et al. 2023), shorter contexts, or KV paging and offloading (Kwon et al. 2023). Paging and offloading preserve model outputs, whereas grouped-query attention changes the architecture and shorter contexts truncate historical context.

↪ Budgeting KV cache memory across concurrent requests on a serving node is developed in section 13.9.5.

For one model shape, the three memory regimes diverge sharply as context grows (figure 6.13). The weights do not grow with context at all, the KV cache grows linearly with every token a request keeps, and materialized attention scores grow with the square of the context. The cache overtakes the weights near 10,000 tokens, and one layer's scores alone would fill an accelerator near 41,000 tokens, which is why serving systems size the cache per request and training kernels never materialize the scores.

GPT-2 (Radford et al. 2019) anchors the chapter's bandwidth-bound language lighthouse. It is a decoder-only transformer, the same design as today's large language models such as Llama, yet small enough that every weight and every byte of its decoding traffic can be counted by hand. Unlike BERT, an encoder-style transformer that reads its whole context in both directions, GPT-2 generates text one token at a time, so batch-one decoding reads every weight for every token it produces. Two differences from current decoders matter for the machine. GPT-2 gives every attention head its own keys and values, so it stores 307.2 KB of KV cache per token in FP16, while newer models share keys and values across groups of heads (Ainslie et al. 2023) and store several times less per parameter. Batching also amortizes weights across requests but not caches, because each sequence keeps its own, which is why serving at scale binds on KV bytes as well as weight bytes. At GPT-2 XL's size, one decoding step reads its weights in about 0.9 ms on a data-center accelerator, a few times shorter

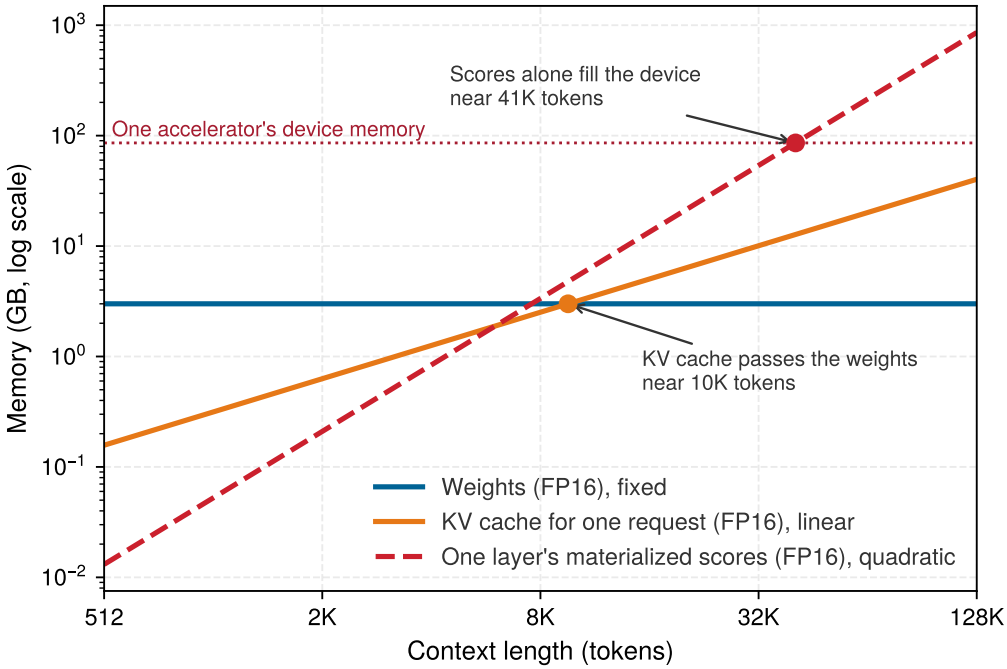

Figure 6.13: Three Memory Regimes of a Long Context: Memory against context length for a model with GPT-2 XL's shape (48 layers, width 1,600, 25 heads) in FP16, evaluated past its trained context to expose the scaling. The weights are fixed, the KV cache that serving keeps for one request grows linearly, and a single layer's materialized attention scores grow quadratically. The cache overtakes the weights near 10,000 tokens, and one layer's scores alone would fill one accelerator's device memory near 41,000 tokens, which is why tiled attention avoids materializing them.

than the time to launch the step's many small kernels (chapter 7), so bandwidth dominates cleanly only as models grow toward tens of billions of parameters.

Lighthouse 6.4: GPT-2 XL (bandwidth lighthouse)

Why it matters: GPT-2 XL exemplifies **memory-bandwidth-bound** batch-one decoding. In the weight-only model used here, each decoding step reads 6 GB of FP32 weights and performs matrix-vector operations. The resulting arithmetic intensity is about 0.5 FLOP/byte with FP32 weights or 1 FLOP/byte with FP16 weights. Batching can amortize this weight traffic, while KV-cache and activation traffic add to it. Table 6.5 summarizes the bandwidth lighthouse's quantitative properties:

Table 6.5: GPT-2 XL Systems Profile: Weight-only estimates for batch-one autoregressive decoding. Under these assumptions, each step reads the model weights at roughly 0.5–1 FLOP/byte, so HBM bandwidth strongly constrains generation throughput.

Property	Value	System Implication
Parameters	1.5B	Weight loading dominates inference latency.
Model Size	6 GB (FP32)	Fits on one GPU but saturates HBM bandwidth.
Compute	3 GFLOP/token	Low per-token compute; bottleneck is data movement, not math.
Constraint	Memory Bandwidth	Weight-bound batch-one tokens/s depends strongly on HBM bandwidth.
Profile	Bandwidth-Bound (small-batch decoding)	Larger batches can amortize weight traffic and shift the bottleneck.

Across training and inference, transformers expose different opportunities for reuse. Full-sequence processing parallelizes across token positions while dense attention adds pairwise score cost, whereas small-batch autoregressive decoding stresses memory bandwidth when weights stream from off-chip memory.

Checkpoint 6.5: Prefill and decode

- ☐ **Two regimes**: why does the same transformer bind on arithmetic during prefill but on memory bandwidth during batch-one decoding?
- ☐ **KV cache**: what does serving keep for every earlier token, why can it discard earlier queries, and how does the cache grow with context length and concurrency?
- ☐ **Long context**: in the memory-against-context figure, which of the three curves sets the limit first, and what does tiled attention change?

Yet dense, spatial, and sequence models do not cover the full spectrum of production workloads. Large-scale recommendation systems depart from standard arithmetic-dominated pipelines by coupling sparse embedding lookups (where memory capacity and irregular access distributions govern throughput) with downstream dense interaction layers. This hybrid matters at production scale: Meta reported that recommendation models accounted for most of its AI inference cycles (Gupta et al. 2020), even though such workloads receive less academic attention than language or vision models.

6.8 Sparse Architectures: Recommendation Systems

When a user opens a streaming service or e-commerce platform, the system must select a handful of recommendations from a catalog of millions within an end-to-end budget of tens of milliseconds. The engineering challenge requires mapping both users and items to dense vectors in a shared embedding space, then evaluating interaction probabilities at scale.

Large-table recommendation models expose a regime governed first by memory capacity. An accelerator engineered for dense matrix multiplication, such as an 80 GB data-center accelerator providing hundreds of teraflops of arithmetic throughput alongside 80 GB of HBM, cannot hold terabytes of embeddings locally. The sparse stage gathers rows from these tables, placing different demands on the machine than the batched convolution and streamed-weight decoding regimes examined above.

6.8.1 Pattern processing needs

A recommendation model must process user IDs across billions of accounts and item IDs across millions of products, yet raw integer IDs carry no inherent distance: user 1042 is no closer to user 1043 than to user 9,000,000, so a dense network cannot infer relationships from the numbers themselves. A single request also carries many such categorical features at once (the items a user recently viewed, the categories they follow), so one prediction can require dozens of separate ID lookups.

Embeddings solve the representation problem by mapping each discrete ID to a dense vector called an **embedding**[27] (Mikolov et al. 2013). The vectors are ordinary learned parameters: each row of an embedding table is a weight vector that gradient descent updates whenever its ID appears in a training example, so users and items with similar behavior end up near one another, and the dot product of a user vector with an item vector becomes a learned score for how well they match. The system cost is that every lookup becomes an irregular read into a table spanning tens or hundreds of gigabytes. Recommendation models therefore encounter a capacity wall and a memory-bandwidth bottleneck before the first dense feedforward layer executes.

6.8.2 Algorithmic structure

The DLRM architecture (Naumov et al. 2019) organizes this computation into a four-stage pipeline split between dense and sparse paths. Continuous features such as user age or time of day first flow through a bottom MLP, a compute-intensive but memory-light stage dominated by dense matrix

[27] **Embedding**: Deriving from the mathematical embedding of one space into another, neural embeddings map discrete tokens (such as user IDs or vocabulary words) into continuous vector spaces where geometric proximity captures semantic similarity. Word2vec popularized neural word embeddings in 2013. For systems, embedding tables create a distinctive memory access pattern: each lookup is an irregular read into a potentially terabyte-scale table, producing a sparse, bandwidth-bound workload that makes DLRM fundamentally different from compute-bound architectures like ResNet.

multiplications. In parallel, categorical IDs index into dedicated embedding tables, which is where the memory capacity wall appears.

For example, an embedding table for one billion users with 128-dimensional vectors requires $10^9 \times 128 \times 4$ bytes ≈ 512 GB of memory. This stage is memory-intensive but compute-light because each lookup is a memory copy with zero arithmetic reuse. The interaction layer then combines the dense activations from the bottom MLP with the gathered sparse embedding vectors through pairwise dot products that capture user-item correlations. Finally, a top MLP processes the concatenated interaction representations through feedforward layers to predict a target probability such as click-through rate. Each of the four stages stresses a different part of the machine (figure 6.14), and section 6.8.3 quantifies the capacity-bound profile that results.

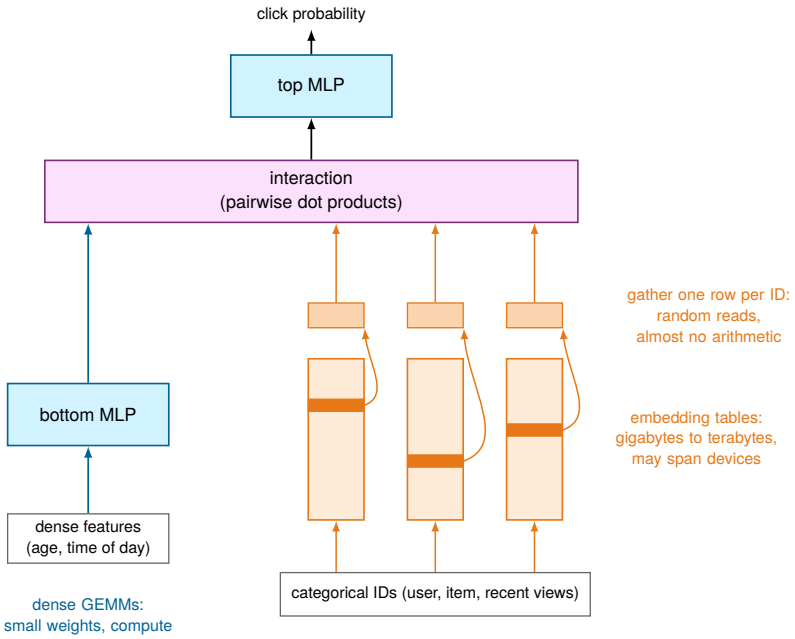

Figure 6.14: DLRM Pipeline: Dense features pass through a bottom MLP of small weight matrices, while each categorical ID selects one row of a large embedding table. The gathers are random reads with almost no arithmetic, and the tables can exceed one device's memory. An interaction stage takes pairwise dot products among the dense output and the gathered vectors, and a top MLP turns the result into a click probability.

6.8.3 Computational mapping and system implications

DLRM's computational mapping splits into two regimes that stress different hardware subsystems. The dense MLPs execute standard GEMM operations, identical to the MLP computational mapping discussed in section 6.2.4 and handled efficiently by Tensor Cores. The sparse embedding lookups, however, are qualitatively different. They are index-based memory gathers that copy parameter data with zero arithmetic reuse. An isolated lookup is bound by memory access latency; but when a batch executes hundreds of lookups across features and samples, aggregate throughput becomes memory-bandwidth bound as concurrent requests saturate the memory bus. This operational throughput limit is distinct from the capacity constraint: total table size dictates whether parameters fit in accelerator memory or must spill across PCIe to host DRAM, whereas available bandwidth governs how fast gathered rows arrive. Within each selected row, an embedding vector is contiguous (for instance, 128 FP32 elements spanning 512 bytes), allowing the downstream pooling loop to consume every transferred byte. Across rows, however, data-dependent categorical IDs lack predictable spatial locality, defeating hardware prefetchers between row accesses. Access popularity remains heavily skewed: a small set of hot rows (popular items, frequent users) shows strong temporal locality in on-chip caches, while the long tail of rarely touched rows misses to main memory. Listing 6.9 writes this sparse stage as a loop nest parallel to those of the other families.

Listing 6.9: Embedding-Bag Gather: Four nested loops expose DLRM's sparse stage. Loops 1 and 2 parallelize across samples and features, but Loop 3 takes its addresses from the input IDs, so hardware cannot predict them, and Loop 4 performs one addition per 4-byte FP32 value loaded. Batching raises that intensity only when samples share hot rows.

```
def embedding_bag_compute(sparse_ids, tables):
    # Loop 1: Process each sample in the batch (parallelizable)
    for b in range(batch_size):
        # Loop 2: Each categorical feature has its own table
        for f in range(num_features):
            pooled[b, f, :] = 0
            # Loop 3: Multi-hot feature, one gather per active ID
            for idx in sparse_ids[b][f]:  # data-dependent address
                row = tables[f][idx]  # irregular read, little reuse
                # Loop 4: Pool (sum) the gathered rows
                for d in range(embed_dim):
                    pooled[b, f, d] += row[d]
    return pooled  # feeds the interaction layer
```

DLRM (Naumov et al. 2019), which Meta open-sourced as a reference for this hybrid architecture, anchors the chapter's recommendation lighthouse. Its combination of gigabyte-scale embedding tables and small multilayer perceptrons serves as the standard benchmark for memory capacity and irregular sparse access in the data center.

↪ The share of DLRM serving latency spent on embedding lookups is developed in section 13.3.2.

Lighthouse 6.5: DLRM (recommendation lighthouse)

Why it matters: DLRM exemplifies **memory-capacity-bound** workloads. Its massive embedding tables often exceed the memory of a single accelerator or server, so the system must decide where those tables live before it can optimize arithmetic throughput. The interaction layer then gathers selected embedding vectors and combines them with dense features, making capacity and irregular data movement the dominant constraints. This capacity-first decision differs from the batched convolution and streamed-weight decoding regimes examined here, requiring different hardware and deployment choices. Table 6.6 summarizes the recommendation lighthouse's quantitative properties.

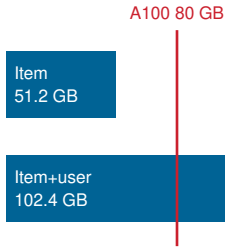

Table 6.6: DLRM Systems Profile: Quantitative properties of the recommendation lighthouse and their system consequences. Embedding tables holding billions of values push the model past single-device memory, creating a capacity-bound regime that decides which bandwidth the iron law's data term must pay.

Property	Value	System Implication
Embedding Parameters	25B	Parameters × 4 bytes; dominates total model size.
Model Size	100 GB (FP32)	May exceed one device's fast memory.
Constraint	Memory Capacity	Model size > Single GPU Memory.
Bottleneck	Irregular Data Movement	Gather operations dominate sparse feature processing.
Profile	Mixed (Sparse/Dense)	Combines memory-heavy lookups with compute-heavy MLPs.

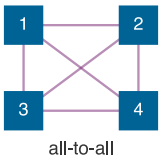
Once embedding tables exceed one device, capacity, not arithmetic, becomes the primary systems constraint. While a ResNet-50 (102.4 MB) fits on a single accelerator and a dense language model like GPT-3 (Brown et al. 2020) (350 GB) fits within a single multi-GPU node, production recommendation models reach terabytes of embedding parameters. In iron law terms, capacity acts as a feasibility constraint that comes before either execution term. It decides where the tables live, and therefore which bandwidth the data term D_{vol}/BW must use: HBM when the tables fit, host DRAM over PCIe or a peer accelerator over NVLink when they do not.

The architecture therefore breaks the single-device assumption that holds for smaller dense models, leaving systems designers three ways to resolve the capacity wall: they can **shrink the tables** through compression, hashing, or pruning at the risk of losing information on long-tail users and items; **move the tables** to host DRAM or external key-value stores at the cost of slower

remote lookups over PCIe or Ethernet; or **partition the tables** across multiple accelerators so that no single device stores the full model, trading local memory pressure for cross-device communication. Architecturally, DLRM turns recommendation into a capacity-management challenge before it becomes a compute-optimization task. Training-time model partitioning and hardware-accelerated interconnects address these distributed layouts, and the baseline sizing calculation begins with a single table.

One embedding table fits an 80 GB A100; a second breaches the capacity wall.

Napkin Math 6.2: The capacity wall



Problem: Consider a recommendation system for a store with 100M items using an embedding size of 128. How much memory does the item table alone require?

Math:

1. **Table entries**: 100M items.
2. **Vector size**: 128 elements.
3. **Precision**: FP32 (4 bytes per element).
4. **Table size**: 100M items $\times$ 128 $\times$ 4 bytes $\approx$ 51.2 GB.
5. **Capacity share**: 51.2 GB $\div$ 80 GB = 64 percent of device capacity.
6. **Two-table check**: Two tables at 64 percent each exceed 100 percent of device capacity.

Systems insight: A single embedding table for one feature (items) already consumes 64 percent of an 80 GB A100 GPU. Adding a user table of the same size means the embedding tables no longer fit on a single 80 GB accelerator, motivating table compression, off-device memory, or partitioning across devices. DLRM is capacity bound: the primary systems question is not how many FLOP/s the accelerator can deliver, but where the embedding state can physically reside.

Once the tables no longer fit on one device, sparse lookups cross memory and interconnect boundaries. A request may need rows owned by several accelerators, forcing the device executing the downstream MLP to wait while the system gathers them across PCIe or NVLink. Within a multi-accelerator server, gathering rows distributed across multiple GPUs turns memory routing into an interconnect bandwidth bottleneck, because every accelerator may need rows held by every other, an all-to-all exchange. The architectural consequence is that a recommendation model's memory layout directly determines its cross-accelerator data-transfer traffic, creating coordination overhead for both training and serving.

Sharded tables can turn lookups into all-to-all accelerator traffic.

↪ Partitioning a model that exceeds one device's memory across accelerators, and the communication that partition boundaries add, is developed in section 8.7.1.2.

Checkpoint 6.6: DLRM and capacity-bound lookups

Recommendation systems stress a different part of the machine than CNNs or transformers.

- ☐ **Capacity-bound**: Can you explain why embedding tables push DLRM into a memory capacity regime where "FLOPs" is not the binding constraint?
- ☐ **Sparse access**: Can you explain why embedding lookups defeat prefetching, and why popularity skew still lets a cache capture the hot rows?
- ☐ **Placement logic**: If a single embedding table does not fit in fast device memory, can you describe which state must move, shrink, or be partitioned?
- ☐ **Data-movement bottleneck**: Can you explain why sparse embedding lookups can dominate even when the dense MLP has modest FLOP cost?

With DLRM, the roster of five families is complete, and each has been analyzed on its own terms: the pattern it targets, the computation it performs, the mapping it induces, and the bottleneck it exposes. A deployment rarely gets to examine one family in isolation. The same accelerator that serves a vision model today may serve a language model or a recommender tomorrow, and the architecture decides which of its resources gives out first.

6.9 Comparing and Choosing Architectures

The three requests that opened this chapter can now be costed in numbers. A single ResNet-50 frame performs about 8.2 GFLOP of arithmetic against 102.4 MB of FP32 weights, and each convolutional filter is reused across its feature map, creating opportunities to keep arithmetic units busy. A single GPT-2 token at batch size one performs about 3 GFLOP/token against 3 GB of FP16 weights. Streaming those weights once gives a weight-only arithmetic intensity of roughly 1 FLOP/byte, making bandwidth a likely limit. A DLRM request gathers a handful of embedding rows from tables totaling 100 GB, more than the accelerator's 80 GB of memory, so before any question of speed arises the system must decide where those tables live.

The silicon is identical in all three cases, but the demands differ. Convolutional reuse favors arithmetic throughput, streamed token projections stress bandwidth, and oversized embedding tables impose a capacity constraint that decides which bandwidth their lookups pay. The iron law (section 1.7) then predicts which term binds, given the execution conditions and machine balance.

Each of those costs comes from a counting rule derived in its family's section. Table 6.7 collects the rules in exact form, so that a new model can be estimated on paper in the same order: count the weights, count the multiply-accumulates, count the bytes that must move or stay resident, then compare those counts with the machine.

Table 6.7: Cost Formulas by Building Block: Counting rules for inference, one per building block, in the notation of the family sections. A FLOP count is twice the multiply-accumulate count; arithmetic intensity divides FLOPs by bytes moved; and a step can finish no faster than the larger of its FLOPs divided by the peak rate and its bytes divided by the bandwidth. For GPT-2 XL, the KV-cache rule gives 307.2 KB per token in FP16, the figure quoted in the transformer section.

Building block	Weights	Multiply-accumulates per example	Bytes that move or stay resident
Dense layer	$d_{\text{in}} d_{\text{out}}$	$d_{\text{in}} d_{\text{out}}$	Every weight read once per batch, so weight-only intensity grows with batch size
Convolution layer	$K^2 C_{\text{in}} C_{\text{out}}$	$H_{\text{img}} W_{\text{img}} K^2 C_{\text{in}} C_{\text{out}}$	Output activations, $H_{\text{img}} W_{\text{img}} C_{\text{out}}$ values per example
Depthwise separable convolution	$K^2 C_{\text{in}} + C_{\text{in}} C_{\text{out}}$	$H_{\text{img}} W_{\text{img}} (K^2 C_{\text{in}} + C_{\text{in}} C_{\text{out}})$	Same activations as a standard layer for far fewer operations
Recurrent step	$d^2 + d d_{\text{in}}$	$d^2 + d d_{\text{in}}$ per step, S steps in order (four times for an LSTM)	State of d values at inference; Sd kept for training
Transformer block	$4d^2 + 2dd_{\text{ff}}$	$4Sd^2 + 2S^2 d + 2Sdd_{\text{ff}}$ for S tokens	S^2 scores per head if materialized
Decoding one token	All of the model's weights	About one per weight	Every weight read per step, plus a KV cache of $2N_L d$ values per token
Embedding lookup	Rows × vector width	Almost none (rows are copied)	Whole table resident: rows × width × bytes per value

6.9.1 Arithmetic intensity across workloads

Each family section measured reuse in its own terms: filters reused across a feature map, weights streamed once per decoded token, rows gathered from a table. Arithmetic intensity, the FLOP/byte ratio set against a machine's balance, puts them on one scale and shows whether each workload is likely to be compute or memory bound.

↩ Arithmetic intensity and the system balance it is compared against are established in section 2.4.

The calculation here is a weight-only proxy rather than a complete measurement of main-memory traffic. It divides floating-point work by FP32 model-weight bytes, omitting activation, intermediate, and KV-cache traffic. Batching can amortize weight traffic across examples or tokens, while additional state movement can lower realized intensity. Section C.1.5 gives the per-operation FLOP and parameter formulas used in the proxy. Under these assumptions ResNet-50's proxy exceeds GPT-2 XL's by roughly 160×, the widest gap among the lighthouses in table 6.8.

The intensity proxy is one input to architecture selection; deployment constraints extend beyond the FLOP-to-byte ratio, and batch size, precision, sequence length, and target hardware decide

whether the proxy predicts the deployed bottleneck. Table 6.8 sets the proxy beside parameter footprint, inference cost, and the governing hardware constraint for all five canonical workloads: compute throughput, memory bandwidth, memory capacity, latency, and power. For compute- and bandwidth-bound workloads, the iron law directly maps the primary bottleneck to operations (O) or data movement (D_{vol}). For capacity-, latency-, and power-constrained workloads, physical boundaries dictate where and within what budget those operations must execute, determining which optimization strategies prove effective.

Table 6.8: Lighthouse Model Comparison: Quantitative characteristics and analytical roles of the five canonical workloads. Memory is FP32 weight storage, and FLOPs are per inference except for GPT-2 XL, which is quoted per generated token; the DLRM row reports embedding-table entries rather than dense parameters. Intensity is the weight-only FP32 proxy (FLOPs per weight byte), which omits activation and KV-cache traffic; it is not defined for DLRM's embedding lookups. The bottleneck column indicates the primary system constraint each model reveals: compute-bound models like ResNet stress arithmetic throughput, while bandwidth-bound models like GPT-2 stress memory transfer rates.

Model	Domain	Params	FLOPs/Inf	Memory	Intensity (weight-only)	Bottleneck	Role in Textbook
ResNet-50	Vision	25.6M	8.2 GFLOP	102.4 MB	80.1 FLOP/byte	Compute	Dense vision throughput
GPT-2 XL	Language	1.5B	3 GFLOP/token	6 GB	0.50 FLOP/byte	Mem. Bandwidth	Token-by-token serving
DLRM	Recommender	25B	Low	100 GB	n/a	Mem. Capacity	Embedding tables and capacity planning
MobileNetV2	Edge Vision	3.5M	600 MFLOP	14 MB	42.8 FLOP/byte	Compute	Depthwise convolutions and efficiency
KWS (DS-CNN)	Audio	200K	20 MFLOP	800 KB	25 FLOP/byte	Power	Always-on power budget

Architecture selection is ultimately an engineering trade-off between math (O) and memory movement (D_{vol}). The mechanisms behind the intensities in table 6.8 explain why each lighthouse sits where it does on the intensity spectrum. ResNet-50 earns its high intensity because convolutional layers reuse each weight many times across the spatial dimensions of an image (individual deeper ResNet layers reach 100–200+ FLOP/byte). Arithmetic throughput becomes the limit when effective intensity exceeds the target machine's compute-to-bandwidth balance. GPT-2 sits at the opposite extreme during batch-one decoding with streamed weights: each projection loads weights for one token's matrix-vector product, making bandwidth a likely limit. MobileNet lands between the two at the whole-model level, with individual depthwise layers falling lower once activation traffic is included: depthwise separable convolutions reduce total O but move more data relative to that work, which fits mobile hardware well yet often "starves" high-end GPUs optimized for dense math.

Checkpoint 6.7: Arithmetic intensity and architecture

Match the architectural choice to its systems implication:

- ☐ **One accelerator, three requests**: can you say which iron-law term binds a batched ResNet-50 frame, a batch-one GPT-2 token, and a DLRM lookup, and name one change that would move each?
- ☐ **Batching**: why does batching move the dense-layer and decode workloads toward the machine's balance point while leaving the embedding gather's bottleneck in place?

Comparing this spectrum with the target machine's balance helps determine whether faster arithmetic or faster memory would improve performance. The roofline model (Williams et al. 2009) plots achievable throughput against arithmetic intensity to show where a workload turns from memory bound to compute bound. This chapter needs only the comparison introduced with

system balance, a workload's intensity set against the machine's ratio of peak compute to memory bandwidth. The full construction, including the ridge point of an H100 and how the same operation falls on either side of it, is collected for reference in section D.2.1.1.

↪ The roofline model's analytical treatment, from the memory-bound slope to the ridge point, is developed in section 11.6.

Intensity is one column of a fuller profile. Persistent state, per-request state, the axis along which the work parallelizes, and the iron-law term that binds complete the comparison.

6.9.2 Workload profiles

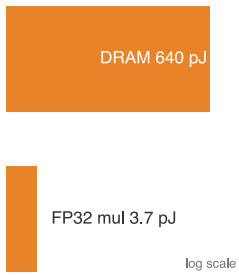
Table 6.9 collects that fuller profile. Each row is a family in a representative execution regime; the transformer takes two rows because prefill and decode reuse the same weights differently (section 6.7.4.2). The binding-term column applies the workload archetypes of section 2.3.2 to each family. The compute-bound rows assume sufficient reuse to exceed the machine's balance, the bandwidth-bound rows assume streamed operands, and the capacity-bound row assumes oversized tables. The columns follow a request through the machine: persistent state, per-request state, arithmetic intensity, parallel axes, and the likely limiting term under those assumptions.

Table 6.9: Architecture Workload Profiles: State, per-request activations, intensity regime, parallel axis, and binding iron-law term for each family in its common execution regime. Symbols follow the family sections: B is batch size, S sequence length, d the hidden dimension, d_{in} and d_{out} a layer's input and output widths, d_{ff} the feed-forward width, K kernel size, C_{in} and C_{out} input and output channels, and $H_{\text{img}} \times W_{\text{img}}$ the feature-map size. Intensity regimes are qualitative; table 6.8 gives weight-only proxies for the lighthouses. The $\mathcal{O}(BS^2)$ prefill term assumes materialized attention scores (section 6.6.4.1).

Family	Parameters	Activations	Intensity	Parallel Axis	Binding Term	Lighthouse
MLP	$\mathcal{O}(d_{\text{in}} d_{\text{out}})$ per layer	$\mathcal{O}(B\, d_{\text{out}})$	Low at batch one (GEMV); high when batched (GEMM)	Batch	D_{vol}/BW at small batch	None (DLRM's dense MLPs)
CNN	$\mathcal{O}(K^2 C_{\text{in}} C_{\text{out}})$ per layer, independent of image size	$\mathcal{O}(B\, H_{\text{img}} W_{\text{img}} C_{\text{out}})$	High (filters reused across positions); lower for depthwise	Batch and spatial positions	$O/(R_{\text{peak}}\, \eta_{\text{hw}})$	ResNet-50; MobileNetV2 and KWS
RNN	$\mathcal{O}(d^2 + d d_{\text{in}})$, shared across steps	$\mathcal{O}(B\, d)$ state; $\mathcal{O}(BSd)$ in training	Low at batch one; higher with batching	Batch and within-step work; recurrent time is serial	Serial step cost; dispatch adds L_{lat} unless fused	None
Transformer (prefill)	$\mathcal{O}(d^2 + d d_{\text{ff}})$ per block	$\mathcal{O}(BSd)$; $\mathcal{O}(BS^2)$ if scores are materialized	High (GEMM over all S tokens)	Batch and sequence positions	$O/(R_{\text{peak}}\, \eta_{\text{hw}})$, with an S^2 attention term	GPT-2 (prompt)
Transformer (decode)	Same weights, reread for every token	KV cache, $\mathcal{O}(BSd)$ per layer	Low (GEMV per token at small batch)	Batch only; tokens are serial	D_{vol}/BW (weights and KV cache)	GPT-2 (generation)
DLRM	Embedding tables, one row per category, dominate; dense MLPs are small	Pooled embedding vectors per feature	Very low (gathers with little arithmetic)	Batch; tables sharded across devices	Capacity first, then D_{vol}/BW	DLRM

Table 6.9 states memory as growth rates; for the lighthouses the bytes are concrete (table 6.10). Deployment usually stores weights in a narrow format, so INT8 cuts every row by four. Training moves the other way: each FP32 weight also carries a gradient and two optimizer moments, so the parameter state alone is four times the FP32 weights before any activation is saved (section 8.3.2.3 itemizes this 16 bytes per parameter), and a model that serves from one accelerator may not train on it.

Table 6.10: Lighthouse Memory: Bytes for each lighthouse's parameters at serving and training precision. Training state counts FP32 weights, gradients, and the two Adam moments, and excludes saved activations, which add to it with batch size; the fit column compares that state with one 80 GB accelerator. The last column names the per-request state that sits on top of the weights.



Model	FP32 Weights	INT8 Weights	Training State (16 Bytes per Parameter)	Fits One Accelerator for Training	Grows per Request With
ResNet-50	102.4 MB	25.6 MB	409.6 MB	Yes	Feature maps for each image in the batch
GPT-2 XL	6 GB	1.5 GB	24 GB	Yes	KV cache, 307.2 KB per token in FP16
DLRM	100 GB	25 GB	400 GB	No	Gathered embedding rows for each lookup
MobileNetV2	14 MB	3.5 MB	56.1 MB	Yes	Feature maps for each image
KWS (DS-CNN)	800 KB	200 KB	3.2 MB	Yes	Feature maps for each audio window

The parameter and activation columns of table 6.9 decide how data reaches the arithmetic units, and the pattern of access matters as much as the volume. Three patterns cover the table. Sequential access, the streaming of contiguous weight rows in an MLP layer or a transformer projection, lets DRAM deliver long bursts and lets hardware prefetchers run ahead, so it approaches the interface's peak bandwidth. Strided access, which a convolution produces when its window steps across a layout that does not keep the window contiguous, fetches whole cache lines to use a fraction of each; im2col lowering (section 6.3.3) moves that gather into a separate copy pass so the matrix multiply itself reads sequentially, at the cost of up to K^2-fold duplication (because overlapping sliding windows copy the same input pixels into multiple rows). Random access characterizes the DLRM row. Sparse IDs index arbitrary rows across multi-gigabyte tables; while each selected embedding vector is contiguous and fully consumed by pooling, row selection lacks predictable spatial locality between rows, which defeats hardware prefetchers and leaves sparse lookups exposed to memory latency unless many concurrent requests are in flight. Achieved bandwidth depends on vector width, alignment, and request concurrency, which is why caching popular rows is critical to reduce off-chip traffic. Attention is not random access despite its content-dependent weights, because its queries, keys, and values sit in contiguous tensors that tiled kernels stream through on-chip SRAM.

Whether an access incurs DRAM traffic at all depends on the working set, the data the execution units need at once. Small layers, such as the 784×128 reference layer at 401.4 KB in FP32, fit in on-chip SRAM. Production-width layers of tens of megabytes do not, which is why unbatched MLP inference and transformer decode stream their weights from off-chip memory on every request. Accelerators answer both ends of the table with memory hierarchy rather than arithmetic. HBM stacks DRAM dies beside the processor to supply the streaming rows at more than an order of magnitude above standard DDR channels, and multi-megabyte on-chip SRAM, often an explicitly managed scratchpad, lets compilers stage tiles so that reuse happens on chip. The intensity column measures how much a family can profit from that staging, and it doubles as an energy column.

Systems Perspective 6.2: Reuse sets each family's energy cost

Moving a 32-bit value from DRAM costs far more energy than one arithmetic operation on it (table 4.6 in section 4.9.3); against the full multiply-accumulate that a dense layer performs, the gap is about 139×, the basis used for the MLP and RNN above. How much of that cost each family pays depends on reuse, so low-intensity rows are energy-dominated by DRAM traffic. An unbatched MLP or a decode step loads each weight once per request and spends most of its energy moving it. A CNN amortizes each filter load over $H_{\text{img}} \times W_{\text{img}}$ applications, so the locality that makes it compute bound also makes it energy efficient, unless a fully materialized im2col buffer inflates temporary traffic by up to K^2. An RNN keeps its compact state in SRAM

Moving a 32-bit value from DRAM costs far more energy than one FP32 multiply.

but idles execution units across serial steps, which raises energy per token. Tiled attention keeps score blocks on chip, so its energy tracks matrix multiplication rather than DRAM round-trips.

The parallel-axis column determines how data must move among processing elements once the work is spread out. Four data movement patterns (broadcast, scatter, gather, and reduction; figure 6.15) govern how tensors travel among processing elements, whether those are units on one chip or several accelerators in one server. Batch parallelism in MLPs, CNNs, and prefill broadcasts stationary weight tiles to many units, each working on a different example or position, and compilers tile loops to reuse each broadcast value as often as possible. Spatial and model partitioning scatter a tensor across tiles or devices; mixture-of-experts models, which route each token to a few of many feedforward subnetworks, make the scatter input-dependent, so a popular expert can overload one accelerator while others idle. DLRM gathers embedding rows from wherever the sharded tables live, and each attention query gathers keys and values from every position in its sequence. Reductions combine values through sums or maxima (softmax denominators, normalization statistics, and the summing of gradients across accelerators that each trained on a different slice of the batch), and tree-structured reduction hardware finishes a reduction over n values in $\mathcal{O}(\log n)$ stages rather than $\mathcal{O}(n)$. The rows with a serial axis, RNNs and decode, are the rows these collectives cannot rescue, because no amount of broadcast or reduction bandwidth shortens a dependency chain.

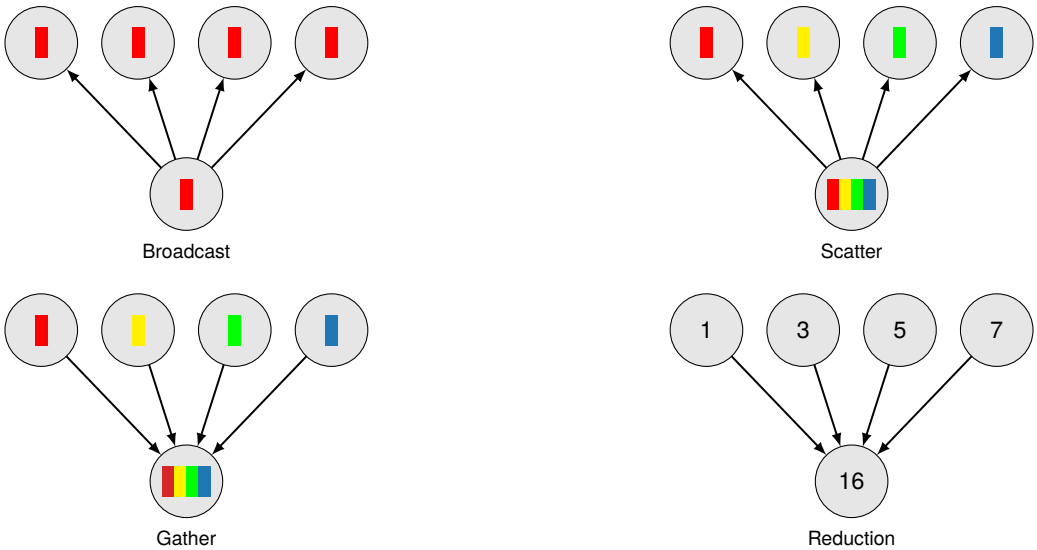


Figure 6.15: Data Movement Primitives: Four fundamental patterns govern information flow in neural network computation. Broadcast (top-left) replicates a single value to all destinations, used when sharing weights across batch elements. Scatter (top-right) distributes distinct elements to different destinations, enabling work partitioning. Gather (bottom-left) collects distributed values to a single location, as in attention pooling. Reduction (bottom-right) combines multiple values through aggregation (sum, max), appearing in gradient synchronization and attention scoring. Because moving data costs more than computing on it, these patterns are primary optimization targets.

The last column applies the iron law under each row's execution assumptions. When effective intensity exceeds the machine's balance and parallel work is sufficient (batched CNNs, prefill), the compute term $O/(R_{\text{peak}}\,\eta_{\text{hw}})$ binds. Below that balance (streamed small-batch MLPs, decode), the data term D_{vol}/BW binds, favoring fewer transferred bytes, more reuse, or higher bandwidth. RNNs add a serial chain of state updates: faster arithmetic, memory, and reduced launch overhead (L_{lat}) can shorten each step without removing the dependency. DLRM adds a constraint that sits in front of the equation. Capacity decides where the tables live and thus which bandwidth the data term pays. ResNet-50, GPT-2, and DLRM isolate these representative regimes. MobileNetV2 and KWS share the CNN row, with depthwise layers pulling their intensity down; they stand for latency and power, deployment budgets that bound the whole execution rather than one term. No lighthouse occupies the RNN row, whose serial chain the recurrent family section analyzes directly.

6.9.3 Shared building blocks

The rows of table 6.9 differ, but the operators inside them repeat. Each block was taught with the family that first needed it: dense projections with MLPs, skip connections and normalization with ResNet-50 (section 6.4.1 and section 6.4.2), and gating with recurrent networks (section 6.5.3). Table 6.11 connects each building block to a representative context and to other architectures that use it. Each block brings its hardware cost with it, so an optimization for residual additions or normalization kernels can transfer across families.

Table 6.11: Cross-Architecture Building Blocks: Engineering primitives illustrated by one architecture family and reused across many designs. The example contexts identify familiar applications rather than historical firsts. Each building block solves a recurring problem (gradient flow, activation stability, signal routing), though not every architecture uses every primitive.

Building Block	Example Context	Problem Solved	Now Used In
GEMM	MLPs	Universal function approximation	All architectures (feedforward layers)
Parameter Sharing	CNNs	Spatial efficiency	Transformers (shared projections), RNNs (weight reuse across time)
Skip Connections	ResNets (CNNs)	Gradient flow at depth	Transformers, DenseNets, U-Nets, many modern deep networks
Normalization	CNNs (BatchNorm)	Activation stability	LayerNorm (Transformers), RMSNorm (root-mean-square normalization), GroupNorm (grouped channels)
Gating	LSTMs (RNNs)	Selective signal routing	Transformers (mixture-of-experts routing), GRUs, highway networks

6.9.3.1 Dense projections

General matrix multiplication is the one primitive every row of the profile shares. It is the feedforward layer inside every transformer block, the 1×1 pointwise convolution in MobileNets, the input and recurrent projections inside every RNN cell, and the bottom and top MLPs of DLRM. Convolution reaches the same path through the im2col patch unfolding of figure 6.5, and dedicated matrix engines, such as GPU Tensor Cores and the systolic arrays of TPUs, exist because this one primitive dominates the operation count of nearly every workload. Its hardware cost depends on shape rather than on the family that invokes it. Batching therefore acts on every family that reaches this path as it acts on the dense layer measured in section 5.4.2.4, converting a matrix-vector product into a matrix-matrix product with greater reuse. The higher intensity can cross the target machine's balance point, which is why batch size changes the modeled regime of three rows of the table.

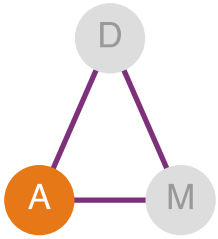
Dense connectivity supplies a common cost baseline, but each family changes a different part of the workload. Convolution shares filters across spatial positions; attention combines dense projections with pairwise interactions; and embedding lookup replaces an arithmetic transformation with an indexed read. Their parameter storage, operation counts, and transferred bytes must therefore be compared separately, as in table 6.9. Dense projections remain inside all these architectures, so improvements to their execution can transfer between families.

6.9.3.2 Gating, routing, and the transformer block

Gating generalizes beyond recurrence as the basic mechanism for data-dependent routing. Highway Networks (Srivastava et al. 2015) used gates to interpolate between a transformation and an identity bypass, a gated precursor of the residual shortcut. Encoder-decoder attention (Bahdanau et al. 2015) computes a dynamic routing distribution over input representations, and in transformers the softmax attention weights act as data-dependent routing coefficients that decide how features aggregate across tokens. Mixture-of-experts architectures extend the idea to dispatch each token to a subset of feedforward experts (Jacobs et al. 1991; Shazeer et al. 2017), which separates the weights a token reads, and so its FLOPs and bytes, from the model's total capacity. The hardware cost of gating is irregularity. Dense attention keeps static tensor shapes even though its weights vary per token, but sparse attention, expert routing, and dynamic graph execution introduce data-dependent control flow and runtime tensor sizes that defeat static memory allocation and balanced work dispatch.

↪ The irregular memory access that unstructured sparsity, embedding lookups, and dynamic routing impose on hardware is developed in section 11.5.2.1.

A transformer block is where all four building blocks meet. In the encoder tower of figure 6.11, residual paths bypass each multi-head attention and feed-forward sub-layer to preserve gradient flow



through deep stacks, dense GEMM projections carry the attention and feedforward transformations, LayerNorm or RMSNorm stabilizes activations around each sub-layer, and softmax attention weights gate information across positions. What the transformer changed was the dependency structure. Replacing recurrence with all-to-all attention cut the sequential depth for tokens to interact from $\mathcal{O}(S)$ steps to $\mathcal{O}(1)$, which let the other three blocks run at full width on parallel hardware. Vision Transformers[28] carry the same block set to images (Dosovitskiy et al. 2021).

This portability separates optimizations that transfer from those that do not. GEMM tiling and mixed-precision arithmetic help every row of table 6.9, residual memory management helps every deep network, and normalization kernel fusion helps CNNs and transformers alike. Attention-specific kernels remain tied to attention's memory pattern, but even they are built from the same GEMM and memory-access primitives. The profile and the building blocks describe what each family costs; choosing among families for a particular deployment requires turning those costs into a procedure.

28 **Vision transformers (ViTs)**: Google's 2020 ViT paper split 224×224 images into 16×16 patches (196 "tokens") and applied standard transformer attention. ViTs replace CNN's local convolutions with $\mathcal{O}(S^2)$ global attention over patch tokens. In the original study, large-scale pretraining improved ViT's competitiveness, illustrating how data and compute can compensate for weaker spatial inductive bias (Dosovitskiy et al. 2021).

6.9.4 Architecture selection framework

A wildlife monitoring sensor must classify camera-trap images within a watt-scale solar power budget, while an industrial recommendation service must retrieve terabyte-scale embeddings within a tail-latency budget of tens of milliseconds. Each constraint eliminates architectures that look competitive on unconstrained benchmarks, and a structural mismatch at this stage cannot be rescued later by compiler optimization or kernel tuning. Engineering teams nonetheless often default to architectures by popularity, deploying over-parameterized transformers where a lightweight CNN would suffice or selecting models that violate the inference latency budget. In D·A·M terms, architecture selection chooses the algorithm (A) that bridges the structure of the data (D) to the budgets of the machine (M): memory capacity, memory bandwidth, compute throughput, and thermal envelope.

Architecture selection turns on the algorithm axis, bridging data to machine.

Selection begins with data-to-architecture mapping, matching the symmetries of the input to an operator family. The useful strength of an inductive bias depends on the task (section 6.1). CNNs impose local connectivity, weight sharing, and translation equivariance, reducing parameter volume and exposing reuse for grid-like data. RNNs impose temporal recurrence, bounding inference state across sequence lengths at the cost of serialization. Transformers use content-based attention, gaining flexible interactions while paying for dense quadratic score computation. MLPs impose no specific spatial or temporal connectivity pattern, leaving those relationships to be learned. Ordered by the strength of their assumptions, the families therefore run from CNNs through RNNs and transformers to MLPs; the margin figure beside the inductive-bias definition draws the same ordering for CNNs, transformers, and MLPs. The stronger the prior, the fewer samples and the less computation a matching task needs, and the more a mismatched task loses, because a strong prior can exclude useful solutions as easily as it excludes useless ones. Model selection must test both predictive fit and the resulting machine costs, and the history of the Netflix Prize shows what happens when only the first test is run.

War Story 6.1: The ensemble Netflix did not ship (2009)

Context: Netflix awarded its $1M Grand Prize in 2009 for a 10 percent improvement in recommendation accuracy (Johnston 2012).

Mechanism: Bringing the winning improvement into production required substantial engineering effort just as Netflix's business was shifting from mailed DVDs to streaming. That shift also produced richer viewing signals and changed what personalization needed to optimize.

Impact: The additional accuracy did not justify the production effort, so Netflix did not deploy the Grand Prize code.

Fix: Netflix retained two algorithms from the earlier Progress Prize and redirected its recommendation work toward streaming-era personalization.

Systems lesson: An offline metric gain is only valuable when its integration cost and objective still match the production system.

Figure 6.16 formalizes this selection pipeline as a multi-stage triage tree: candidate architectures route first by input data structure (text, sequences, spatial grids, or tabular features) and then pass through sequential screening gates for memory capacity, compute budget, inference latency, accuracy targets, and hardware deployment readiness. High-cardinality recommendation workloads sit outside this dense flowchart and route to the sparse embedding family (section 6.8) before applying the same memory, compute, speed, accuracy, and deployment checks. If any constraint fails, the decision loop routes execution back to scale the model down, increase its capacity when accuracy falls short, or substitute an alternative architecture family.

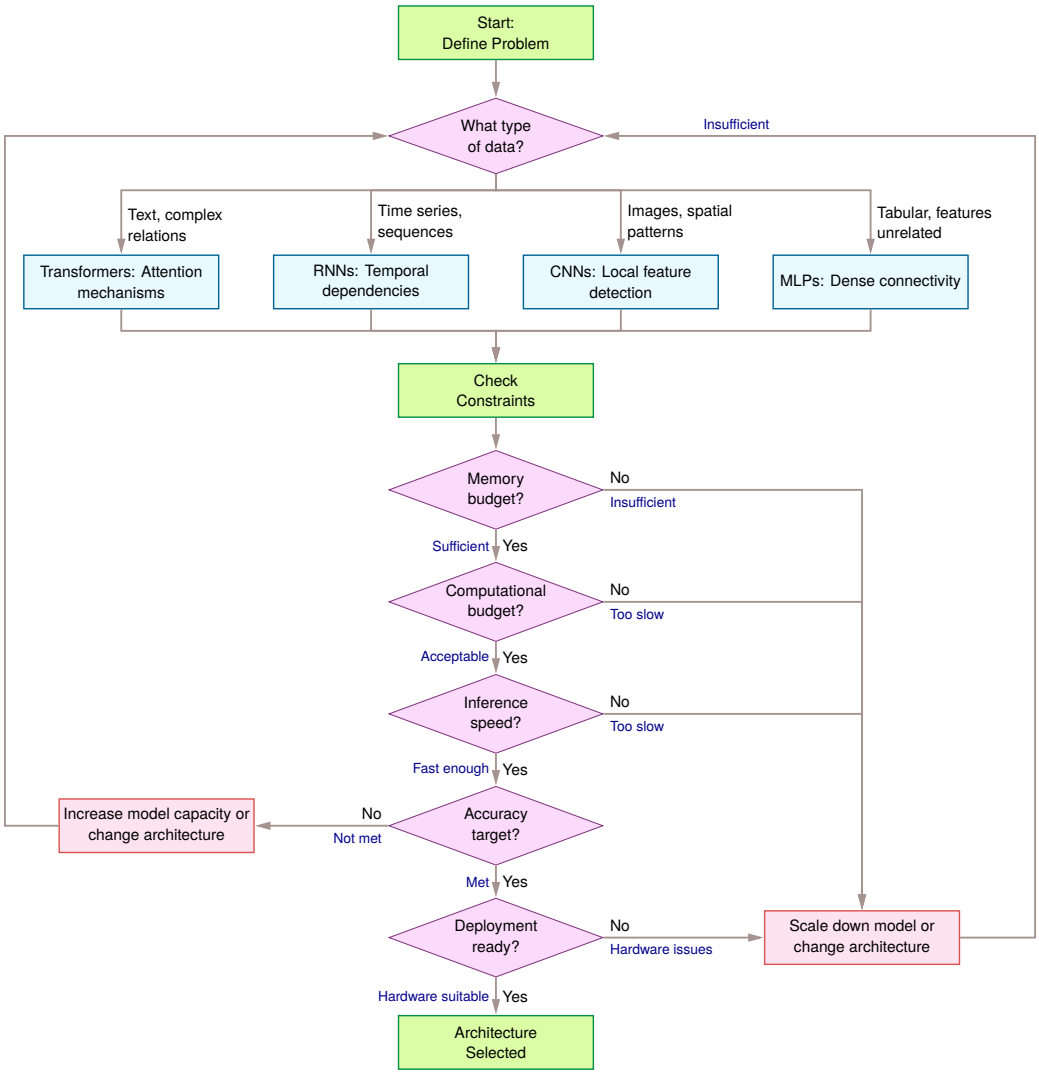


Figure 6.16: Architecture Selection Decision Framework: A systematic flowchart for choosing dense neural network architectures based on data characteristics and deployment constraints. The process begins by identifying the data type (text, sequences, images, or tabular features) to select initial candidates (transformers, RNNs, CNNs, or MLPs), then iteratively evaluates memory budget, computational cost, inference speed, accuracy targets, and hardware compatibility. High-cardinality recommendation workloads are handled separately by the sparse-embedding family, DLRM (section 6.8), then re-enter the same constraint checks.

The framework executes in three ordered phases, with model compression as the systematic way to scale a candidate down when it fails a budget:

1. **Data symmetry identification (D)**: Identify structural symmetries and invariances in the input data. Spatial locality routes candidates to CNNs; temporal sequence structure to RNNs; uncon-

strained cross-token dependency to transformers; tabular features without spatial geometry to MLPs; and high-cardinality categorical IDs to sparse embedding tables.

2. **Progressive physical constraint filtering (A × M)**: Filter candidate models against hardware budgets: static parameter storage in flash/DRAM, peak dynamic activation footprint in SRAM/HBM, arithmetic intensity against the hardware roofline, and tail latency deadlines. A violation requires scaling down model width or depth, applying quantization and compression, or switching to a lower-overhead architecture family.
3. **Empirical capacity and deployment validation**: Verify that candidate capacity meets target accuracy on representative evaluation distributions. If predictive accuracy falls short, scale model capacity and re-evaluate physical hardware constraints. If target accelerator hardware cannot sustain the required arithmetic throughput or memory bandwidth, select an alternative architecture rather than relying on marginal hyperparameter adjustments.

Kernel-level choices refine this decision. Im2col or direct convolution, fused normalization, and IO-aware tiled attention (section 8.6.4) change realized traffic and utilization, and can shift which iron-law term binds; chapter 7 and chapter 11 develop them. Architectural dependencies still matter. Batching independent recurrent sequences or fusing their operations reduces per-step cost, while the ordered state transitions remain. Candidate selection and kernel measurements therefore inform each other.

6.9.5 Architecture selection in practice

Every selection must first pass a feasibility check: whether the target hardware can sustain the required frame rate at all. A server-class vision pipeline on a mid-range GPU shows the throughput ceiling calculation in its simplest form. The wildlife monitoring deployment that follows applies the same checks under a watt-scale budget where GPUs are ruled out, which is where data structure, model capacity, and hardware budgets interact.

Napkin Math 6.3: The throughput ceiling

Problem: A real-time application must process 30 FPS of video with ResNet-50. What sustained compute throughput is required?

Math:

1. **Model cost**: ResNet-50 requires ~8.2 GFLOP per 224×224 image.
2. **Frame rate**: 30 FPS required.
3. **Sustained throughput**: 30 FPS × 8.2 GFLOP = 246 GFLOP/s.
4. **Effective throughput**: 10 TFLOP/s peak × 50–60 percent utilization = 5 TFLOP/s–6 TFLOP/s.
5. **ResNet-50 headroom**: 5 TFLOP/s ÷ 246 GFLOP/s = 20.3×.
6. **Detection-model check**: 30 FPS × 100 GFLOP = 3 TFLOP/s, leaving 1.7× headroom at the lower effective-throughput estimate.

Systems insight: A mid-range GPU delivering 10 TFLOP/s theoretical peak achieves 50–60 percent utilization in this planning scenario, yielding 5 TFLOP/s–6 TFLOP/s effective. For ResNet-50 at 30 FPS, the system has 20.3× headroom. Switching to an object detection model at 100 GFLOP per frame, however, requires 3 TFLOP/s sustained, leaving only 1.7× headroom. Batch size constraints or multi-stream processing quickly push the system toward the compute ceiling. The headroom assumes the GPU stays busy; a single 30 FPS stream runs at batch one, where kernel launches and small matrices usually hold utilization well below this planning figure.

The throughput ceiling converts an abstract compute requirement into a concrete hardware utilization percentage. A real-world deployment adds physical constraints the ceiling alone does not capture.

6.9.5.1 Worked example: Real-time wildlife monitoring

The design task is an embedded ML system that classifies wildlife species from camera trap images in an isolated national park. The deployment must execute inference entirely on-device with zero network connectivity, operate on solar-recharged battery power for six months, and achieve 90 percent accuracy across 50 target animal species. The walk-through applies the three-phase framework in five steps. Data characterization is the symmetry phase; deployment constraint profiling, candidate architecture evaluation, and hardware budget checks carry out the constraint-filtering phase; and operational risk assessment sets up the validation phase that only target-device measurement can complete.

The first step characterizes the data. The input consists of camera trap image frames (1920×1080 raw sensor resolution, downsampled to 224×224 for inference). Three properties favor a CNN candidate: spatial locality (fur textures or ear shapes occupy bounded neighborhoods), label invariance to translation (moving an animal within the frame should preserve its species label), and hierarchical composition (edges combine into textures, anatomical parts, and organisms). Convolution provides equivariant intermediate features that follow the animal's location; pooling can then support an invariant classification. Local weight sharing supplies a compact feature detector for these images.

The second step, constraint profiling, translates the deployment environment into hard hardware boundaries. Table 6.12 catalogs these physical constraints alongside the architectural requirements each imposes:

Table 6.12: Wildlife Monitoring Constraints: Five deployment constraints and their implications for the camera-trap scenario. No connectivity rules out cloud-only inference, while the power, latency, memory, and accuracy requirements must be validated on the target device.

Constraint	Requirement	Implication
Connectivity	None (offline)	All inference must run on-device
Power	~2 W average (solar + battery)	Rules out GPUs; needs a low-power SoC or edge NPU
Latency	<500 ms per detection	Allows batch size 1, no real-time streaming
Memory	512 MB RAM, 2 GB storage	Model, activations, and runtime buffers must fit locally
Accuracy	90%+ on 50 species	Requires sufficient model capacity

With physical constraints established, the third step evaluates candidate architectures against reference model baselines. The planning scenario reserves 100 MB of the available RAM for model weights, leaving the rest for activations, system software, and runtime buffers:

- **ResNet-50** (25.6M parameters, 8.2 GFLOP): A costly starting point for the 2 W envelope. Its weights fit once quantized (25.6 MB in INT8 against 102.4 MB in FP32), but its arithmetic does not: at the platform's 2 GOPS of sustained INT8 throughput assumed below, one frame takes about 4.1 seconds against a 500 ms target.
- **MobileNetV1** (4.2M parameters, 1138 MFLOP): A viable footprint and operation count. Its low arithmetic intensity, which can leave a data center GPU's matrix units idle, costs far less on a batch-one edge CPU whose much smaller compute peak is easier to keep busy. Storing weights in INT8 reduces model footprint to 4.2 MB (16.8 MB in FP32), and factorized depthwise separable convolutions drastically cut arithmetic operations.
- **KWS DS-CNN** (200K parameters, 20 MFLOP): An unmatched baseline. This model targets audio keyword spotting, so its reported size and task results do not establish accuracy on visual species classification. An adapted compact vision model would require training and evaluation on the camera-trap task.

While MobileNetV1 demonstrates the viability of depthwise separable convolutions, MobileNetV2 offers inverted residual blocks with linear bottlenecks as another compact candidate. Sizing the model with width multiplier 0.75× yields ~2.6M parameters (10.4 MB FP32, 2.6 MB with INT8 weights) and costs ~418 MFLOP at 224×224 input resolution. Its weight footprint fits the allocation; task evaluation must establish whether its capacity meets the accuracy target for the 50 species.

The fourth step, hardware sizing, checks the candidate against physical platform budgets. INT8 weights occupy 2.6 MB, the network's largest activation tensor, a $112\times112\times72$ expansion inside

its second bottleneck block, occupies 0.9 MB in INT8, and the scenario reserves 50 MB for OS and runtime buffers. Their 53.5 MB subtotal is only a single-tensor screen. Peak memory must instead include the weights, the maximum sum of simultaneously live tensor bytes, kernel workspace, and OS and runtime buffers. Inputs and outputs can coexist, and a residual path retains its input while the branch executes. The scenario has not yet established that live-tensor peak or the required workspace, so the small subtotal supports candidacy without confirming a fit in 512 MB of RAM.

For the candidate system-on-chip (SoC), an ARM Cortex-A53 at 1.2 GHz with NEON SIMD, this planning calculation assumes sustained throughput of ~2 GOPS INT8: $\frac{418\times10^{6}\ \text{INT8 ops}}{0.002\times10^{12}\ \text{INT8 ops/s}} = 209ms$ latency $\ll 500ms$ target ✓

Active power represents the final physical gate. At an estimated active inference draw of ~200 mW over 209 ms, each classification consumes 41.8 mJ. For a trigger-based rate of 100 inferences/day, model execution consumes 4.2 J/day. Full-system energy must also include image capture, sleep current, storage, and peripherals. Battery capacity, conversion losses, trigger frequency, and seasonal solar yield determine whether that daily budget supports six months of operation.

The fifth step assesses operational risks in the field. Table 6.13 pairs the primary accuracy, thermal, and coverage failure modes with corresponding systems engineering mitigations:

Table 6.13: Wildlife Camera Deployment Risks: Top accuracy, thermal, and species-coverage risks for the MobileNetV2 deployment, paired with the engineering mitigation chosen for each.

Risk	Mitigation
90% accuracy not achieved	Train on augmented dataset; consider EfficientNet-Lite if MobileNet insufficient
Thermal throttling in enclosure	Add passive heatsink; reduce inference frequency in high-temperature conditions
New species added postdeployment	Expand or retrain the output head; install the update during a physical service visit

The sizing exercise selects MobileNetV2 (0.75× width multiplier) quantized to INT8 as a candidate for an ARM Cortex-A53 SoC with 512 MB RAM. Under the assumed sustained throughput, the arithmetic estimate is approximately 209 ms per frame. Qualification now requires target-device measurements of end-to-end latency, peak memory, thermal behavior, and full-system energy, together with classification accuracy on representative camera distributions and seasonal battery tests. In production, this qualification phase regularly exposes counterintuitive trade-offs: models with fewer FLOPs can stall on bandwidth-limited hardware, expressive architectures can degrade on datasets lacking matched structure, and lab prototypes can fail against deployment memory hierarchies.

6.10 Fallacies and Pitfalls

Architecture choice is a systems decision, not a leaderboard selection. The common mistakes in architecture selection arise when teams treat architecture families as interchangeable accuracy tools while ignoring inductive bias, memory traffic, hardware mapping, and deployment state.

Fallacy: *More complex architectures always perform better than simpler ones.*

Engineers often assume that transformers outperform simpler architectures on all tasks. In production, the better choice is the simplest model that matches the data's structure and the machine's budget. Vision transformers matched CNN accuracy on ImageNet only after pretraining on far larger datasets (Dosovitskiy et al. 2021), or later with heavy augmentation and distillation; without that data or that training machinery, the CNN's locality bias wins at lower cost. The bitter lesson favors weak priors only once data and compute are large enough to pay for them, and a deployment that cannot supply that data and compute gets the cost of the weak prior without its benefit. Accuracy, training cost, and inference latency still require measurement for the specific implementation and task.

Pitfall: *Selecting architectures based solely on accuracy metrics without analyzing computational requirements.*

Practitioners choose architectures from papers reporting top-line accuracy, ignoring computational implications. RNNs expose a sequential critical path that limits parallelism, while transformers compute dense attention scores whose storage grows quadratically in naive implementations. Sequence

length 2,048 therefore requires 16× more materialized score memory than length 512. Systems that ignore these characteristics can miss latency targets, exceed memory budgets, and deliver much lower hardware utilization than expected.

Fallacy: *An architecture has one dominant bottleneck across training and inference.*

The same computation graph can occupy different systems regimes. Transformer training and prefill process many positions together and may bind on dense attention compute; small-batch autoregressive decoding repeatedly streams weights and KV-cache state and may bind on memory bandwidth. Batching, sequence length, precision, and cache layout can shift that boundary. A benchmark from one regime therefore cannot establish another's bottleneck; measure each against the iron law.

Pitfall: *Combining architectural patterns without analyzing interaction effects at the system level.*

Engineers add attention to CNNs or convolutions to transformers expecting additive benefits. Each pattern creates distinct memory access characteristics: CNNs exploit spatial locality through sliding windows, while dense attention introduces all-to-all score computation. Combining them can increase intermediate traffic and disrupt locality, so the hybrid's throughput cannot be inferred by adding the components' benefits. Adding recurrent connections to transformers likewise reintroduces sequential dependencies. Successful hybrids require profiling memory access and cache behavior before combining patterns.

Fallacy: *Architecture wins on training hardware transfer directly to deployment hardware.*

Teams design for high-end GPU clusters, then discover deployment failures on target hardware. An architecture exploiting 8× A100 GPUs (640 GB total memory) cannot deploy unchanged to a representative edge node such as the NVIDIA Jetson Orin NX (16 GB system memory). As section 6.9.4 emphasizes, architecture selection must analyze the full system stack because storage, latency, and power budgets vary by deployment target.

Pitfall: *Ignoring KV cache growth when estimating transformer serving costs.*

Teams budget transformer deployment based on model weight memory alone, overlooking the key-value (KV) cache used during autoregressive generation (Pope et al. 2023; Kwon et al. 2023). The cache grows linearly with concurrent sequences, layers, heads, and sequence length, so at long contexts or high concurrency it can become a binding serving constraint. The KV-cache footnote in section 6.7.4.2 works through the chapter's 32-layer, 32-head example. With 128-dimensional heads, 2,048-token sequences, and FP16 storage, each concurrent request holds $\approx$ 1 GB of KV cache. At 2–4 users, the cache alone consumes 2 GB–4 GB before allocator, activation, and workspace overhead. Those values consume part of the post-weight headroom of an 80 GB device and grow linearly with context and concurrency. Capacity planning must therefore budget weights, cache, and runtime buffers together, then reduce concurrency, context, or cache footprint, or add memory capacity, when the combined total approaches device memory.

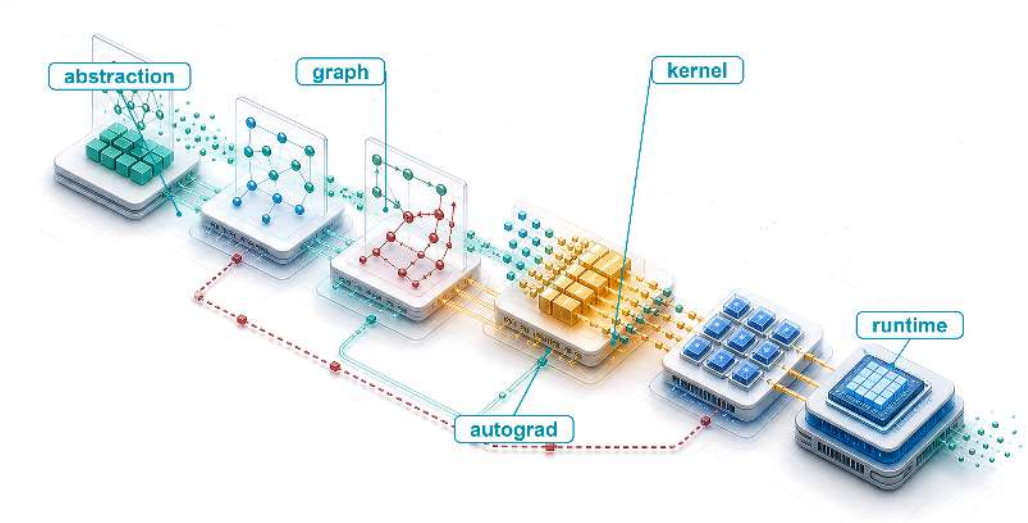
6.11 Summary

Architecture is infrastructure. Choosing among MLPs, CNNs, RNNs, transformers, and recommendation models (DLRM) shapes the physical terms in the serialized form of the iron law of ML systems ($T = D_{\text{vol}}/\text{BW} + O/(R_{\text{peak}} \cdot \eta_{\text{hw}}) + L_{\text{lat}}$). Examining each architecture through the four-part lens (pattern processing needs, algorithmic structure, computational mapping, and system implications) connects mathematical inductive bias to work, state, and dependencies. Execution conditions and the target machine then determine which term binds hardware performance.

The durable tool is arithmetic intensity read against the machine's balance. Reuse raises $I = O/D_{\text{vol}}$ and pushes a workload toward the compute term, as ResNet-50 does when batched; streamed weights lower it and expose the data term, as GPT-2 decoding does at small batch. Two families escape that single axis. A recurrent dependency chain sets a floor of S ordered updates that neither term removes, and an oversized embedding table imposes a capacity decision that fixes which bandwidth the data term pays before any arithmetic begins. Low FLOP counts, as MobileNetV2 and KWS show, help only when the resulting operation shapes still keep the hardware's functional units busy.

Key Takeaways: Architecture is infrastructure

- **Inductive bias is the unifying concept**: Every architecture encodes structural assumptions, such as locality for CNNs, sequence for RNNs, and global context for transformers. These biases trade generality for sample efficiency and determine which problems an architecture can solve efficiently.
- **Intensity against balance names the bottleneck**: A workload's arithmetic intensity, set against the machine's balance, predicts whether compute or bandwidth binds. One transformer sits on both sides: prefill reuses every weight across the prompt, while batch-one decode re-reads every weight and a growing KV cache for each token.
- **Quadratic costs are permanent constraints**: Dense transformer attention computes $\mathcal{O}(S^2)$ score interactions. Naive implementations also use quadratic score storage; tiled exact attention removes that storage cost but not the dense computation.
- **Lighthouse models isolate distinct bottlenecks**: ResNet-50 (compute), GPT-2 (bandwidth), DLRM (capacity), MobileNetV2 (compute-bound in its efficient regime, under an edge latency budget), KWS (power-bound). Each isolates one regime, and together they diagnose which physical constraint dominates a given system.
- **Depth benefits from architectural support**: Skip connections and normalization improve optimization in deep networks rather than acting as universal prerequisites beyond a fixed depth. These building blocks, illustrated here through CNNs, transfer to many deep architectures, including transformers.
- **FLOPs do not equal speed**: MobileNetV2 uses 13.7× fewer FLOPs than ResNet-50 but can gain far less than that on data center GPUs when its operation shapes and arithmetic intensity use the available compute units poorly. Architecture-hardware alignment, not operation count alone, determines throughput.
- **Architecture selection is deployment selection**: Choosing a transformer over a CNN determines memory requirements, latency floors, hardware utilization, and infrastructure costs. The architecture is the system constraint.



Architecture selection signs the silicon contract (principle 4) with hardware. A CNN commits to spatial locality and weight reuse; dense attention commits to $\mathcal{O}(S^2)$ score computation; and an RNN commits to serial time-step dependencies. These topological choices constrain operations O, opportunities for reducing transferred data D_{vol}, and dependency order. Realized memory footprint, bandwidth demand, and parallel efficiency also depend on the implementation. Pipelining consecutive stages across execution units overlaps work without removing the serial time-step path. Systems engineers can therefore anticipate likely bottleneck shifts before implementation by matching model inductive bias and data geometry to silicon physics.

What's Next: From blueprints to construction

Raw computational primitives (chapter 5) became concrete architectures in this chapter. Each architecture fixes *what* work must be performed, yet nothing in an architecture says when its operations run, how their gradients are computed, or which device executes them. A machine learning framework answers those three questions, acting as a compiler that lowers the architectural graph to the silicon. Chapter 7 examines how PyTorch, TensorFlow, and JAX solve these execution, differentiation, and hardware-abstraction problems, turning architectural graphs into computational graphs, autograd records, and optimized device kernels.

7.11 Summary

Purpose

Why does the framework silently constrain every decision that comes after it?

Model equations do not execute themselves. A framework translates an architecture into work that hardware can run, and that translation is not neutral. It decides when operations execute, what intermediate state training retains, how memory is allocated, and which deployment targets can use the resulting artifact. These choices shape more than speed. They also determine what can be debugged directly, what the compiler can optimize, and whether the same model survives the path from a research environment to a production runtime. The same model expressed through two execution paths can differ in speed or memory use by several times, a gap that no amount of model tuning recovers when the framework hides the structure a compiler needs. The abstractions that make experimentation convenient therefore create long-lived commitments. Once a project accumulates checkpoints, modules, data loaders, serving formats, and team expertise around a framework, changing it becomes a system migration rather than a library substitution, measured in engineer-months rather than afternoons. A framework well suited to rapid exploration can expose too little structure for efficient deployment, while a constrained execution path can sacrifice the flexibility needed during discovery. Because these choices meet in one software layer, a local convenience can become a downstream performance or portability constraint. The engineering question is not which framework is universally best, but which trade-offs the workload, team, and target machine can afford to make fixed. Understanding frameworks is therefore about reasoning through those system choices rather than learning transient API syntax, which changes with each release while the underlying trade-offs persist. In D·A·M terms, the framework mediates algorithm-machine co-design by turning algorithmic intent and data representation into executable work under machine constraints.

Learning Objectives

- Explain how frameworks mediate algorithm-machine co-design through execution, differentiation, and hardware abstraction
- Compare eager, graph, and just-in-time compiled execution using dispatch overhead, kernel fusion, compilation cost, and deployment constraints
- Analyze how reverse-mode differentiation computes every gradient in one backward pass and which forward state it must save or recompute
- Estimate host-to-device transfer time and explain how tensor layout, data type, and device placement determine which kernel runs and whether transfers overlap computation
- Implement module abstraction patterns for parameter discovery, mode behavior, serialization, and hooks
- Calculate training-step FLOPs, memory traffic, and dispatch overhead to identify whether a step is bound by dispatch, memory traffic, or arithmetic
- Select a development framework and deployment path based on model, hardware, team, and deployment requirements

7.1 Three Framework Problems

A few lines of Python can express one decoding step of a language model: embed the newest token, pass it through every transformer block, and project the result onto the vocabulary. The accelerator never sees those lines. It sees a stream of kernels,[1] the compiled routines it executes one launch at a time, together with memory allocations and copies, and the machine learning framework is the software that turns the first into the second. Chapter 6 fixed *what* work each architecture performs. It left open *when* each operation runs, *how* its gradients are computed, and *which* kernel on which device executes it.

GPT-2 XL, the book's bandwidth-bound lighthouse, shows what those open questions cost. One batch-one decoding step reads 3 GB of FP16 weights, which takes about 0.9 ms at the 3.35 TB/s memory bandwidth of an H100, the book's reference accelerator. Executed one operation at a time, the same step issues about 12 kernels in each of its 48 transformer blocks, 576 launches in all. At 5 µs of driver overhead per launch, launching alone takes 2.9 ms, about 3× the weight read. An eager Python framework adds 10 µs of dispatch to every operation, which raises the host's time to issue the step to 8.6 ms, about 10× the time the accelerator needs to read its weights. The accelerator spends most of the step waiting for its next instruction. Whether the step costs one millisecond or ten depends on what the framework does with those few lines of Python: run each operation as it is called, or capture the sequence, fuse it into fewer kernels, and launch it as a unit.

Every ML framework, regardless of API or design philosophy, must solve three core problems. The first is the *execution problem*: deciding when and how computation runs. A framework can execute operations immediately as written (eager execution[2]) or first construct a computational graph[3] (a record of operations and their data dependencies, developed in section 7.3.1) to optimize before launching device kernels (graph execution). The decoding step above is an execution problem, and this choice sets the trade-off between interactive debugging and whole-program compiler optimization.

With an execution strategy in place, the framework must solve the *differentiation problem*: computing gradients automatically. Because gradient-based training requires derivatives of a scalar loss with respect to millions or billions of parameters, manual calculus is impossible at scale. Frameworks implement automatic differentiation by registering derivative rules across supported operator compositions, chaining vector-Jacobian products while managing numerical precision and the memory overhead of intermediate activations retained for backward passes.

The third problem is *hardware abstraction*: targeting diverse hardware from a single interface. The same model definition should be expressible across CPUs, GPUs, Tensor Processing Units (TPUs), and mobile accelerators, even though each target presents distinct memory hierarchies, instruction sets, and interconnect bandwidths. For every operation the framework must choose which kernel runs on which device, with which memory layout and precision. Within the GPU

[1] **Kernel (GPU)**: In GPU programming, a kernel is the function dispatched to execute in parallel across thousands of threads. Each kernel launch costs about 5 µs of CPU-side overhead for parameter assembly and GPU signaling, and an eager framework's Python dispatch adds about 10 µs more before the launch, the split this chapter's overhead model uses. Small, unfused operations therefore spend more time on launch overhead (L_{lat}) than on useful arithmetic. Reducing kernel count through fusion is a direct attack on the overhead term of the iron law.

[2] **Eager execution**: This mode executes each operation immediately, which enables direct debugging with standard tools but sacrifices the global view needed for graph-level optimizations. Without capturing a larger region of computation, an eager runtime cannot fuse across that region or preplan its memory, leaving workload-dependent optimization opportunities for compilers such as `torch.compile`.

[3] **Computational graph**: Optimizing before executing is the design choice that separates graph execution from eager execution. Capturing the program as a data structure lets a framework fuse compatible operations into fewer GPU kernels before execution, reducing launch overhead and intermediate memory traffic. The engineering cost of this visibility is that the executed program differs from the source code, making debugging harder, a trade-off every graph-based framework must justify against the performance gain.

↩ Reverse-mode automatic differentiation and computational graph traversal for gradient computation are established in section 5.4.5.

domain, framework ecosystems increasingly expose custom-kernel languages such as Triton (Tillet et al. 2019), allowing developers to write high-performance, block-level kernels without hand-crafting low-level CUDA (NVIDIA's GPU programming platform (Nickolls et al. 2008)) or device assembly.

These three problems are tightly coupled: the execution model dictates when differentiation data structures are recorded, while the hardware abstraction layer determines which graph transformations can be lowered to the target. In the terms of the iron law of ML systems (principle 3), the model architecture fixes the operation count O, and the framework shapes the remaining terms. Execution strategy bears most directly on the fixed overhead L_{lat}, differentiation on the bytes moved D_{vol} (and on O, since the backward pass adds work), and abstraction on the hardware efficiency η_{hw}. These are emphases rather than exclusive assignments, since fusion, for example, cuts both launches and traffic, and the chapter uses this one mapping throughout. The framework plays the role for a model that a compiler plays for a C program, and the correspondence is literal: modern frameworks include optimizing compilers, such as Accelerated Linear Algebra (XLA) (Google 2025) and TorchInductor (Ansel et al. 2024), that lower a captured graph to machine code for the target accelerator. The formal definition below makes that role precise and separates frameworks from numerical libraries such as NumPy.

Definition 7.1: Machine learning frameworks

Machine learning frameworks are software systems that translate high-level mathematical model definitions into hardware-optimized execution plans by managing the computational graph, automatic differentiation, kernel dispatch, and memory allocation across the hardware hierarchy.

1. **Significance**: Frameworks shape every iron law term that the model itself does not fix: the bytes moved (D_{vol}), the hardware efficiency achieved (η_{hw}), and the fixed overhead paid (L_{lat}). Compiler-backed kernel fusion, for example, can eliminate writes and subsequent reads of intermediate values between compatible operations. Fusing a matrix multiplication, bias add, and rectified linear unit (ReLU) changes how the same mathematics reaches hardware without changing the model.
2. **Distinction**: Unlike a numerical library such as NumPy, which normally evaluates each operation as it is called, an ML framework can capture or defer execution to analyze a larger computational graph and apply cross-operation optimizations: kernel fusion, memory layout transformations, and parallel scheduling. Those optimizations require visibility beyond separately dispatched operations.
3. **Common pitfall**: A frequent misconception is that frameworks are interchangeable API wrappers. Framework choice determines which compiler paths are available. PyTorch can recover graph-level optimization from eager code through `torch.compile()`, while TensorFlow and JAX commonly rely on XLA-backed compilation paths that lower operations to target hardware. Moving from eager execution to a compiler path can change throughput materially, but the gain depends on model structure, shapes, operator support, and hardware.

An ML framework translates logical intent into physical execution under the constraints of the iron law, deciding how to partition computation across memory hierarchies, when to trade numerical precision for throughput, and how to schedule operations so that whichever term dominates (data movement D_{vol}, arithmetic computation, or launch latency L_{lat}) is minimized. The framework is where the governing physics developed throughout this book becomes executable code.

This chapter follows a model's graph downward, one level at a time (table 7.1): the decoding step above carries the execution level, and a two-layer MNIST training step, traced at the end, gathers every level. The execution section takes the graph to kernels and decides when each operation runs. The differentiation section builds the backward graph that training adds and accounts for the values it must keep. The abstraction section reaches the bottom of the descent, where tensors occupy device memory and kernels operate on them. Modules then assemble those pieces back into a model, and

the anatomy of one training step traces a single step through every level. The chapter closes with the major frameworks and how to choose among them.

Table 7.1: Chapter Map: Each section of the chapter lowers the model's computational graph one level closer to the hardware and names the iron law term that level most affects.

Section	Level of the graph	Question it answers	Iron law term most affected
Evolution of Framework Abstractions	Libraries, autodiff, compilers	How the levels of the stack came to exist	(context)
Execution: From Graphs to Kernels	Graph to kernels	When each operation runs, and how many launches it costs	Fixed overhead L_{lat}
Differentiation: Automatic Gradient Computation	Forward graph to backward graph	How gradients are computed, and which values must be kept	Bytes moved D_{vol}, and O
Abstraction: Tensors, Devices, and Operations	Tensors in device memory	Where each value lives and which kernel runs on it	Hardware efficiency η_{hw}
Modules: From Operations to Models	Operations to a model	How parameters and training state are organized	(organization)
Anatomy of a Training Step	Execution, differentiation, and abstraction in one step	Where one step's time and bytes go	All terms
Major Frameworks and **Choosing a Framework**	Complete systems	Which framework fits a given constraint	All terms

Automating this machinery (recording operation graphs, allocating gradient buffers, traversing dependencies in reverse, and dispatching hardware kernels) did not happen all at once. Execution, differentiation, and abstraction emerged sequentially as responses to scaling bottlenecks in earlier numerical tools, a four-decade progression from hand-tuned assembly routines to compiled graph runtimes.

7.2 Evolution of Framework Abstractions

In 1979, writing a matrix multiplication in Fortran that used the hardware efficiently required deep knowledge of cache lines, register scheduling, and vector units. By the late 2010s, a single line of Python (`torch.matmul(A, W)`) could dispatch to a tuned implementation without the programmer knowing the details of the hardware. Four decades of abstraction closed that gap, each layer removing a bottleneck that made the previous generation impractical at scale. Each layer automated a job the layer below left to the programmer. History built the layers from the bottom up, starting with tuned kernels and ending with graph compilers; the rest of this chapter walks them from the top down, starting from the graph a model defines.

The first layer established reusable hardware primitives. The Basic Linear Algebra Subprograms (BLAS)[4] standardized low-level linear-algebra operations (Lawson et al. 1979), and LAPACK (Anderson et al. 1999) built factorizations and eigensolvers on top of them. Naive nested loops saturate memory bandwidth long before the arithmetic units reach peak throughput; BLAS let numerical software delegate these operations to vendor libraries tuned for each processor's cache sizes, vector widths, and register files, and its Level 3 extension added the matrix-matrix routines, such as matrix multiplication (`C = A @ B`),[5] that dominate ML workloads (Dongarra et al. 1990). The second layer, NumPy[6] (Harris et al. 2020), wrapped those libraries in Python: the interpreter manages control flow and array metadata (shape, strides, and data type), while compiled code runs the inner loops over contiguous buffers. That division of labor, high-level intent in an interpreted language and inner loops in native code, became the template for every framework that followed.

The third layer automated gradient computation. NumPy users still derived and coded backpropagation by hand, an error-prone process that does not scale to deep networks. Deep learning frameworks such as Theano,[7] TensorFlow (Martín Abadi et al. 2016), and PyTorch (Paszke et al. 2019) made automatic differentiation a runtime primitive: by recording the forward computation as a graph, they construct the backward computation automatically. That automation let the bitter lesson operate at the pace of research. Once a new architecture no longer needed a hand-derived backward pass, general methods that scale with computation could be tried as quickly as their forward functions could be written.

[4] **BLAS (basic linear algebra subprograms)**: The 1979 API specification at the bottom layer of the stack; it fixed a set of Fortran-callable vector operations and separated the public routine names from the machine-specific implementation beneath them. Every framework above it inherits the same division: call a standard linear-algebra routine from any language and let a tuned vendor library target the processor. On NVIDIA GPUs, the tuned path for general matrix multiply (GEMM), a Level 3 routine added in 1990, is cuBLAS (NVIDIA 2024a).

[5] **GEMM**: The matrix-matrix primitive behind `C = A @ B`. Hardware vendors hand-tune GEMM for their specific chips because dense layers, attention projections, and convolution lowering all rely on matrix multiplication, making this one routine a performance floor for many frameworks above it in the stack. Its high arithmetic intensity makes GEMM the operation most able to approach peak compute throughput, while small or misaligned shapes often fall back to much lower utilization.

[6] **NumPy (numerical Python)**: In 2005, Travis Oliphant unified two competing Python array libraries (Numeric and Numarray) into a single BLAS-backed package. Its pattern of writing logic in Python and executing loops in compiled code became the design template for ML frameworks: PyTorch tensors and TensorFlow arrays extend the same n-dimensional array abstraction to GPUs.

Across that history (figure 7.1), the milestones run from BLAS and LAPACK routines through NumPy vectorization to symbolic graph capture in Theano and TensorFlow, dynamic graphs in PyTorch, and functional transformations in JAX. Each generation preserved the vendor-tuned kernel layer beneath it while raising the level of abstraction at which engineers express and differentiate models.

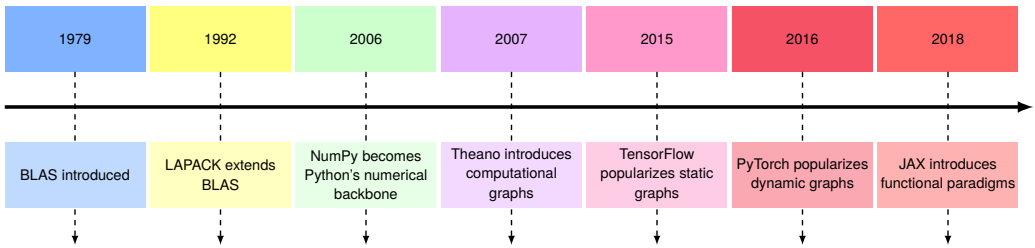

Figure 7.1: Computational Library Evolution: Numerical computing milestones from 1979 to 2018 show each era automating what the layer below exposed, from BLAS and LAPACK hardware routines to NumPy vectorized syntax and graph-based automatic differentiation in modern frameworks, trading low-level transparency for developer velocity.

Each generation hid details that consumed engineering effort in the previous one, and each introduced new trade-offs. BLAS hid assembly-level optimization but fixed the interface. NumPy hid memory management but left differentiation manual. Modern frameworks hide gradient computation but force a choice among execution models. Every layer also hides assumptions about the data it passes along: each operation expects its inputs to have a particular shape, data type, device, and, for physical quantities, unit. When nothing checks those expectations at the boundary, correct components can compose into a wrong system.

War Story 7.1: The interface that forgot its units (1999)

Context: NASA's Mars Climate Orbiter depended on ground software, spacecraft software, navigation teams, and contractor interfaces all agreeing on the physical meaning of exchanged values (Mars Climate Orbiter Mishap Investigation Board 1999).

Mechanism: Ground software supplied by Lockheed Martin computed thruster impulse in English units (pound-force seconds), while JPL navigation software consumed the values assuming SI units (newton-seconds), a 4.45× implicit unit mismatch.

Impact: On September 23, 1999, the spacecraft was lost after passing behind Mars (occultation). Its corrected 57 km periapsis, rather than the planned 226 km, was judged too low for survival.

Response: The board recommended unit-consistency checks, specification audits of transferred data, and stronger end-to-end verification of ground software.

Systems lesson: Two pieces of correct code can compose into a wrong system when the meaning of the values they exchange is implicit. ML frameworks meet the same failure whenever tensor memory layouts (such as channels-first NCHW [Batch × Channels × Height × Width] vs. channels-last NHWC [Batch × Height × Width × Channels]), quantization scale factors, or physical feature units differ across pipeline stages, producing plausible outputs that quietly corrupt downstream inference. Frameworks guard against the tensor cases by checking, at every operation, that its inputs have the expected shape, data type, and device.

A framework can run those checks as each operation executes, when the failing line and its intermediate values are directly visible, or before execution, when a captured graph can be validated and optimized as a whole. When checks and optimizations happen is the execution problem. It is the first framework design choice because runtime dispatch and graph capture determine both the debugging experience and what optimizations automatic differentiation and hardware mapping can later exploit.

7 **Theano**: Developed at the Montreal Institute for Learning Algorithms (MILA) under Yoshua Bengio starting in 2007, Theano was an early and influential Python framework that compiled symbolic mathematical expressions into optimized CPU and GPU code via computational graphs (Bergstra et al. 2010; Team et al. 2016). It demonstrated that a Python-defined computation graph could be compiled for GPU execution without requiring the researcher to write CUDA code. Mila ended active development of Theano in 2017 (Mila 2026).

↩ The bitter lesson, that general methods which exploit growing computation outlast hand-engineered approaches, is established in section 1.4.

7.3 Execution: From Graphs to Kernels

Consider two engineers writing the same neural network. The first debugs interactively, printing tensor shapes after each operation, inspecting intermediate values, and stepping through code with `pdb`. The second waits through a compilation step, then watches a model built from many small operations run faster while losing that direct, line-by-line view of intermediate state. Both are correct; they have made different choices about the **execution problem**, the question of whether operations should execute immediately as written or be recorded for later execution. It sets debugging workflow, deployment options, and peak hardware utilization. The GPT-2 XL decoding step that opened this chapter is the case in point: issued one operation at a time, it keeps the accelerator waiting on the host for most of the step.

7.3.1 Computational graphs

If a runtime sees only one Python operation at a time and forgets it as soon as the kernel returns, it cannot know which intermediate tensors later gradient rules will need or which adjacent operations could share registers on the accelerator. To plan across operations, a framework represents the program the same way chapter 6 represented model architectures, as a computational graph: a directed acyclic graph (DAG) where nodes represent operations and edges represent data dependencies. The rest of this chapter follows that graph down toward the hardware. It is the same structure that backpropagation traverses in reverse, here serving as the framework's internal model of the computation for scheduling and optimization as well.

A graph decouples the mathematical operations from the order in which hardware evaluates them. In the minimal case (figure 7.2), directed edges route input variables x and y into the central transformation operator $f(x, y)$, which emits the output variable z.

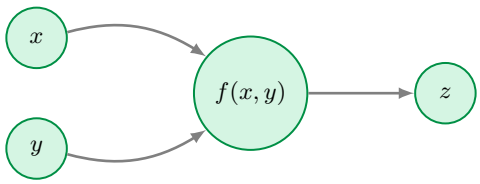

Figure 7.2: Simple Computational Graph: Representing $z = f(x, y)$ as a directed acyclic graph decouples mathematical dependencies from physical execution order, providing the structural blueprint frameworks require to track gradients and schedule operations across devices.

Real machine learning models require much more complex graph structures. Figure 7.3 partitions this system interaction into two coupled domains: the left container isolates a six-node neural network DAG with explicit dataflow edges, while the right container houses the runtime components (memory management and device placement) that interface with it.

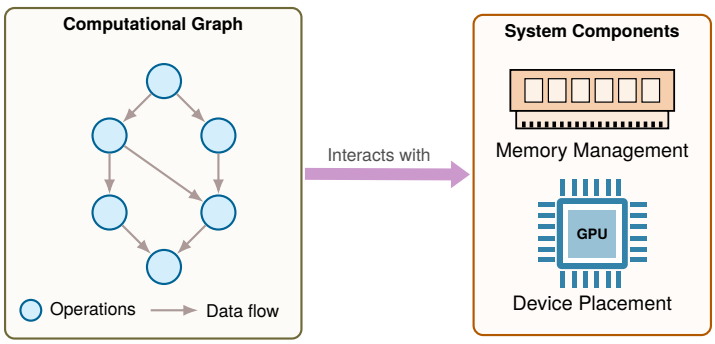

Figure 7.3: Computation Graph with System Interactions: A neural network DAG (left) interfaces with framework runtime components (right). By maintaining an explicit graph representation independent of execution, the framework can analyze tensor lifetimes for memory reuse and assign operations to target accelerators before issuing arithmetic.

This graph representation is more than a visualization; it is the data structure that enables both efficient execution and automatic differentiation. The timing of its construction forces a fundamental systems trade-off across debugging, optimization, deployment, and flexibility. Interactive debugging demands immediate execution so developers can inspect intermediate values and step through logic with standard tools. Global optimization requires observing large operator sequences at once to fuse kernels and plan memory reuse. Standalone deployment favors graphs that run without the host interpreter, while dynamic architectures require control flow that branches on computed tensor values. No single execution model serves all four demands at once.

7.3.2 The memory wall and kernel fusion

When an unoptimized runtime evaluates a sequence of three element-wise operations such as LayerNorm $\rightarrow$ Dropout $\rightarrow$ ReLU, it dispatches three separate GPU kernels: the first reads inputs from off-chip high-bandwidth memory (HBM) and writes intermediate results back to HBM, the second reads those results and writes back again, and the third reads them a final time. Shuttling intermediate tensors across the external memory bus three times dwarfs the arithmetic time and leaves compute units idle.

This bottleneck stems from the memory wall, the widening gap between compute growth and memory-bandwidth growth that equation 2.3 quantifies. An accelerator performs arithmetic far faster than it fetches operands from off-chip memory, so most individual operation types in a neural network (activations, normalizations, and other element-wise operations) are memory bound, limited by data movement, while the large matrix multiplications that dominate total arithmetic can be compute bound, limited by arithmetic throughput. Section 11.6 formalizes the boundary between the two regimes. On-chip storage (registers and SRAM scratchpads) runs at tens of terabytes per second but holds only tens of megabytes, whereas off-chip HBM or GDDR holds tens to a few hundred GB behind external buses with hundreds of cycles of latency.

Kernel fusion (also called operator fusion) fixes memory-bound chains by combining them into a single kernel that avoids intermediate HBM traffic. Instead of three round-trips to HBM, a fused kernel loads inputs from HBM once, evaluates normalization, dropout, and ReLU entirely within on-chip registers and SRAM, and writes only the final output tensor back to HBM, cutting memory traffic by roughly $3\times$. In general, for N elements of s_{elem} bytes each, fusing a chain of n_{ops} elementwise operations into one kernel reduces idealized read-and-write traffic from $2n_{\text{ops}}Ns_{\text{elem}}$ to $2Ns_{\text{elem}}$ bytes, a derivation worked in section C.3.4.2. Fusion also removes all but one of the chain's kernel launches. Attention kernels[8] use the same principle at larger scale: instead of materializing the full attention matrix in HBM, a fused implementation can keep tiles close to the compute units, cut HBM accesses by up to $9\times$, and produce workload-specific speedups from 15 percent to $3\times$ (Dao et al. 2022).

Framework compilers can fuse only operations that are visible to them simultaneously. When an eager runtime dispatches operations individually, each kernel launch executes in isolation, concealing cross-operation fusion and buffer-reuse opportunities. Capturing a broader region of computation into a deferred graph removes that isolation: the compiler can examine an entire sequence of dependencies, establish intermediate tensor lifetimes, and fuse compatible operations before dispatching work to the accelerator.

The computational graph enables global optimization, but it leaves a critical design choice unresolved: *when* the runtime constructs the graph. Consider an elementary expression such as `y = x * 2`. Evaluating the multiplication immediately yields a concrete tensor in `y`. This imperative flow is intuitive and directly debuggable, but the runtime sees only one operation at a time. Deferring execution records the operation symbolically into a dependency graph executed only upon request. That staging separates intent from evaluation, giving the compiler the end-to-end visibility required for kernel fusion and memory planning. Modern frameworks resolve this tension between *flexibility* and *optimization potential* with three execution strategies: eager execution with dynamic graphs, static computation graphs, and hybrid approaches that combine just-in-time (JIT) compilation with eager development.

↩ The memory wall and the growth-rate ratio behind it are established in section 2.2.

[8] **Fused attention kernel**: A fused attention kernel combines the $\mathbf{QK}^T$ product, softmax, and value-weighted output into a tiled implementation that keeps intermediate values in on-chip memory rather than materializing the full attention matrix in HBM. FlashAttention, introduced in section 6.6.4.1, is the canonical named example. The framework lesson is broader than the specific algorithm: fusion can shift an operation's position on the roofline model from bandwidth-limited toward throughput-limited execution by reducing round-trips through external memory.

↪ The on-chip limits that decide which intermediates a fused kernel can keep on a specific accelerator are developed in section 11.7.7.

7.3.3 Eager execution with dynamic graphs

When a tensor shape mismatches or an activation turns to `NaN` mid-layer, a deferred graph fails far from the Python line that created the operation, hiding the intermediate values that caused the fault. Eager execution, also called define-by-run, avoids that disconnect by evaluating each operation as soon as the program calls it and building the computation graph dynamically at runtime.

Example 7.1: Eager vs. graph execution code comparison

PyTorch (eager execution):

```
import torch

x = torch.tensor([1.0, 2.0])
y = x * 2
print(f"Intermediate value: {y}")  # Works immediately
z = y.sum()
```

TensorFlow 1.x (static graph):

```
import tensorflow as tf

x = tf.placeholder(tf.float32)
y = x * 2
# print(y) -> Prints Tensor("mul:0"...), not value!
z = tf.reduce_sum(y)

with tf.Session() as sess:
    result = sess.run(z, feed_dict={x: [1.0, 2.0]})
```

Systems insight: Eager execution exposes intermediate values as ordinary runtime state, which makes debugging direct. Static graphs stage computation before execution, which enables whole-graph optimization but changes the debugging model.

In this define-by-run model, when host code evaluates `y = x * 2`, the runtime dispatches the multiplication kernel to the device command queue and returns a tensor handle for subsequent operations. Device execution can continue asynchronously; dependent operations must wait for the result, and reading its value on the host can require synchronization.

Immediate evaluation gives eager code the flexibility of ordinary programming: developers can print intermediate values, use conditionals based on computed results, and debug with standard tools. The framework records operations as they happen, constructing a dynamic graph that reflects the actual execution path taken.

For gradient computation, the framework records a history of operations in what is called an autograd tape,[9] a transient data structure built during execution. Each tensor operation creates a node that records: the operation performed, references to input tensors, and how to compute gradients. These nodes form a DAG that records the actual path taken during forward-pass execution rather than a graph fixed in advance. Listing 7.1 shows how PyTorch records operations as they execute in its default eager mode.

[9] **Autograd tape**: The tape's own nodes are small; its memory cost comes from the tensors they reference. That footprint grows with model depth and sequence length as saved activations accumulate until backpropagation releases them, which is why deep models retain only selected activations and recompute the rest (activation checkpointing) to avoid out-of-memory failures.

Listing 7.1: Autograd Tape Construction: Each operation executes immediately while recording a backward node to the autograd tape for later gradient computation.

```
import torch

x = torch.tensor([1.0], requires_grad=True)
y = x * 2  # Executes immediately; records MulBackward node
z = y + 1  # Executes immediately; records AddBackward node
# The autograd tape exists NOW, built during execution
```

After these two operations, the framework has constructed an autograd tape with two nodes: one for the multiplication and one for the addition. The tape records that `z` depends on `y`, and `y` depends on `x`.

Calling `z.backward()` traverses this tape in reverse topological order, applying the chain rule at each node:

1. Compute $\frac{\partial z}{\partial z} = 1$ (seed gradient)
2. Call `AddBackward0.backward()` $\rightarrow \frac{\partial z}{\partial y_{\text{tape}}} = 1$
3. Call `MulBackward0.backward()` $\rightarrow \frac{\partial z}{\partial x} = 2$
4. Accumulate gradient in `x.grad`

After `backward()` completes, autograd normally releases the saved state needed by its backward rules. Other live references can still retain tensor storage and graph nodes. The next forward pass builds a new graph. Values needed for gradients are saved during the forward pass and remain available until backward consumes them, so their memory cost spans both phases rather than appearing only during backward.

Example 7.2: In-place operations can break gradients

Scenario: An engineer applies an in-place mutation (`x += 1`) within a custom PyTorch activation function to reduce memory allocations.

Diagnosis: In-place operations overwrite tensor memory containing forward-pass activations required by the autograd tape for backward-pass gradient computation, triggering a runtime version-counter error (PyTorch Contributors 2026a). PyTorch enforces this safety invariant by maintaining an integer version counter on each tensor that increments on every in-place write; if a saved tensor's version at backward execution differs from its version recorded during the forward pass, autograd throws an error because the activation required by the derivative rule was modified in place.

Systems lesson: Framework automatic differentiation depends on immutable forward-pass activation records. In-place writes to a saved tensor invalidate the autograd record, so PyTorch stops with an error rather than compute a wrong gradient.

In eager execution frameworks, operations evaluate imperatively as host code encounters them. The define-by-run cycle is therefore a loop of one operation at a time (figure 7.4). Python defines an operation, the runtime enqueues its device work, and control returns to Python for the next call while the device may execute asynchronously. When the runtime decides what to launch, it sees the current operation rather than a whole region of future calls.

The dynamic autograd tape expresses data-dependent behavior directly in the host language. Conditionals and loops can depend on tensor values computed during execution, enabling algorithms such as beam search, dynamic-length recurrent models, or adaptive compute paths that adjust their execution based on intermediate activations. Static graphs can also represent data-dependent control flow and dynamic dimensions through graph operations, but eager execution makes these patterns natural to write and debug in Python. Because operations are issued immediately, developers can print tensors, inspect values, and use standard debuggers (`pdb`, breakpoints) to diagnose errors much as they would in another Python program.

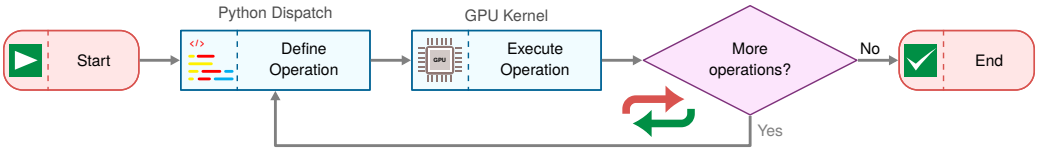

Figure 7.4: Dynamic Graph Execution Flow: In eager execution, each operation is issued as the program encounters it. Accelerator work may execute asynchronously after dispatch. This define-by-run model enables natural debugging and data-dependent control flow while limiting optimization across Python calls.

This flexibility imposes latency costs that map directly to the iron law. Each training step constructs an autograd tape dynamically, adding host-side Python dispatch latency and tape allocation to L_{lat}. Because every operation traverses the framework dispatcher before a device kernel launches, host overhead quickly dominates when individual kernels execute in single-digit microseconds. Eager execution also lacks a whole-graph view, preventing the framework from fusing element-wise chains into single GPU launches (which would cut D_{vol}) or pre-allocating a static memory arena for intermediate activations (which would cut allocation overhead in L_{lat}). The autograd tape must retain every tensor requested by registered backward rules, holding memory until backpropagation consumes it. Together, these costs impose a throughput ceiling on fine-grained workloads where dispatch latency overshadows device arithmetic.

7.3.4 Dispatch overhead in eager execution

Small op

Dispatch 94%

Large op

Compute

13%

Fixed dispatch dominates small ops and fades behind large ones.

Eager execution is slow on small operations because the host-side interpreter is slower than the device-side silicon. The **dispatch overhead ratio**, host software time T_{sw} divided by device hardware time T_{hw}, quantifies this mismatch in an additive model without host-device overlap. When the ratio exceeds 1, host dispatch takes more than half of each step. The dispatch overhead law of section 7.3.7.2 later expresses the same ratio through operation count and per-operation cost. Asynchronous execution can hide part of that host cost.

In the illustrative eager-execution model used here, every operation pays a fixed cost of approximately 15 µs for Python-side dispatch and driver launch combined, the same per-operation cost as the decoding step that opened the chapter. Actual overhead varies by framework, backend, and hardware, but its relative weight still depends on operation size. For a small operation such as a ReLU on a small vector, the kernel might execute in only 1 µs, so dispatch takes 94 percent of the modeled step time, the dispatch overhead ratio sits far above 1, and the GPU spends most of its time waiting for the next command. For a large operation such as a large matrix multiply, the kernel executes for 100 µs, dispatch drops to 13 percent of the modeled step time, and the dispatch overhead ratio falls well below 1. The operation is device-work dominated; distinguishing compute from memory limits still requires comparing its work and traffic.

Dispatch overhead explains why models with many small layers run significantly slower than their raw FLOP count predicts. Section A.5.3 places this symptom in the bottleneck taxonomy, classifying a dispatch-dominated workload as overhead-bound rather than compute-bound and showing which optimizations actually move it. Frameworks can move from *kernel-by-kernel dispatch* to *graph-level execution*, reducing repeated interpreter work and exposing operations that can be fused. A captured graph can still launch multiple kernels; fusion and runtime replay determine how much launch overhead remains. The hybrid JIT and compilation strategies in section 7.3.6 exist to address this overhead.

↩ The MNIST epoch estimate, in which this fixed per-operation cost decides training time on a CPU and an accelerator alike, is established in section 5.4.6.

7.3.5 Static computation graphs

The overhead costs of eager execution motivate the opposite design: capturing the entire computation before executing any of it. Because an eager runtime sees only one operation at a time, it cannot fuse a chain of small kernels or plan buffer reuse across a whole layer before launching work on the accelerator. Static graph execution solves this visibility problem by defining the complete computational graph as a symbolic representation first and executing it in a separate phase. This "define-then-run" execution model means the graph exists before any computation occurs, enabling ahead-of-time analysis, transformation, and global optimization that separate eager calls cannot support unless a compiler captures them.

Static graphs implement a clear separation between graph construction and execution. TensorFlow 1.x, which exemplified this approach, makes the two phases explicit in code (listing 7.2). It deliberately runs the same `x * 2` then `+ 1` computation shown under eager execution in listing 7.1, holding the arithmetic fixed so that the only thing that changes is *when* it executes: symbolic definition creates placeholders and operations without computation, while explicit execution triggers actual arithmetic.

Listing 7.2: Static Graph Two-Phase Execution: Graph construction (symbolic definition) is separated from execution (actual computation), enabling ahead-of-time optimization.

```
# Phase 1: Graph Construction (symbolic, no computation)
import tensorflow.compat.v1 as tf

tf.disable_v2_behavior()

# Define graph symbolically
x = tf.placeholder(tf.float32, shape=[1])  # Just a placeholder
y = x * 2  # Not executed, just recorded
z = y + 1  # Still no execution
# At this point, nothing has been computed

# Phase 2: Graph Execution (actual computation)
with tf.Session() as sess:
    result = sess.run(z, feed_dict={x: [1.0]})
    # Now computation happens: result = [3.0]
```

In the definition phase, the program declares operations and variables and builds the symbolic DAG without allocating any tensor memory. Only in the execution phase do data load, concrete buffers materialize on the accelerator, and the captured graph run (figure 7.5).

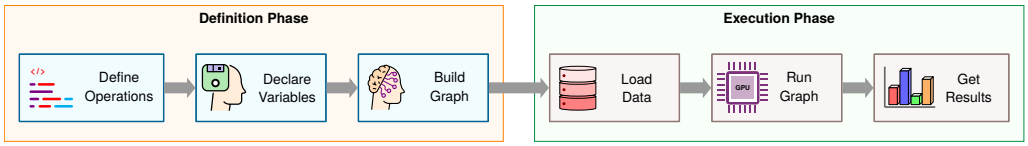

Figure 7.5: Static Graph Execution Lifecycle: Separating symbolic graph definition (left) from concrete execution (right) provides global visibility over the computation, allowing compilers to apply ahead-of-time optimizations (such as kernel fusion, buffer reuse, and layout transforms) before any tensors are materialized.

The key difference from eager execution is that during construction, `x`, `y`, and `z` are not tensors containing values but rather symbolic nodes in a graph. Operators such as `*` and `+` append transformation nodes to the graph definition without issuing arithmetic. Calling `print(y)` makes this distinction visible: it prints symbolic tensor metadata rather than numerical values. Only when the host invokes `sess.run()` does the runtime analyze, optimize, and execute the captured graph on device buffers.

Because the framework has the complete graph before execution, it can perform ahead-of-time optimization unavailable across uncaptured eager calls. The kernel fusion opportunity introduced in section 7.3.2 becomes actionable here: because the framework sees `y = x * 2` and `z = y + 1` together in the graph, it can fuse them into `z = x * 2 + 1`, eliminating the intermediate `y` and halving idealized memory traffic. When tensor shapes and lifetimes are known, the compiler can plan memory before execution and reuse buffers whose lifetimes do not overlap; dynamic dimensions may require bounds or runtime allocation. Tensor layouts can also be transformed globally (for example, NCHW to NHWC) to match hardware preferences, though physical layout conversions may still require copies. Dead-code elimination (DCE)[10] removes operations whose results are unused, and constant folding precomputes operations on constant values when their inputs are known. These optimizations map directly to iron law terms: kernel fusion can reduce D_{vol} by avoiding intermediate memory writes, constant folding reduces repeated work, planned allocation can reduce runtime overhead, and dead code elimination removes work and associated

[10] **Dead code elimination (DCE)**: Removes graph nodes whose results do not affect observable outputs or side effects. In ML graphs, dead code arises from unused branches or post-transform artifacts; side-effect analysis ensures safe removal to prevent execution of dead operations and reduce kernel launch overhead.

data movement when unused computations are present. Compilers such as **XLA**[11] (Google 2025) extend this approach, compiling captured subgraphs into fused machine code specialized for target hardware.

Static graphs can therefore approach high utilization when shapes, operators, and layouts match efficient backend paths. The cost of this performance is reduced flexibility. Standard Python control flow (`if`, `for`) cannot depend on computed tensor values in static graphs. TensorFlow provides graph-level control flow primitives (`tf.cond` and `tf.while_loop`) that support data-dependent conditions, but these require special syntax that diverges from standard Python, making code harder to write and reason about. Debugging is difficult because stack traces point to graph construction code, not execution code. Error messages often reference symbolic node names rather than the actual operations that failed.

7.3.6 Graph capture and JIT compilation

Staying in eager mode leaves small-operation workloads bound by host dispatch and unfused HBM traffic, while rewriting a research model into a static graph gives up interactive Python debugging and standard control flow. **JIT compilation** bridges that gap by letting developers write and debug ordinary eager code while capturing regions of the program at runtime for graph-level optimization. The core trade-off in graph capture is *fidelity vs. generality*. Tracing captures the execution path taken during a sample run, producing high fidelity to that path but missing branches not taken. Source-level compilation (scripting) analyzes supported program structure, preserving supported control flow but requiring a restricted language subset. Both approaches produce an intermediate representation (IR)[12] that enables graph optimizations such as kernel fusion, constant folding, dead code elimination, and buffer reuse.

The eager-vs.-compiled trade-off has a direct iron law consequence. JIT compilation amortizes the L_{lat} (dispatch overhead) across the compiled region. Longer compiled regions mean more overhead amortized per operation, which explains why graph breaks are performance-critical: each break forces a return to eager dispatch, resetting the amortization.

Graph-capture JIT systems follow the same architectural pattern across frameworks. The first execution observes tensor operations, records a graph region guarded by assumptions about shapes, dtypes, layouts, and control flow, lowers that region into an intermediate representation, applies fusion and layout optimizations, and caches executable code for later calls that satisfy the same guards. The compiled artifact is valid only while those assumptions hold, so a failed guard forces the runtime to recompile or fall back to eager execution. When eager fallback is enabled, unsupported Python code forms a graph boundary where execution returns to the eager runtime; a configuration requiring full-graph capture can instead report an error. PyTorch 2.0's `torch.compile` (Ansel et al. 2024) is a concrete instance of this pattern, but the systems idea is broader than the API: compilation pays only when captured regions are long enough and stable enough to amortize capture, lowering, code generation, and cache-management costs.

Lowering into an intermediate representation is far easier when the target vocabulary is small, and the eager frameworks a compiler starts from are not small. Figure 7.6 counts the operators that each framework defines at successive releases. PyTorch's native-function table grew from 1,064 schemas, overloads included, at version 1.0 in 2018 to 2,658 by version 2.9 in 2025 (PyTorch Contributors 2025), and TensorFlow's operator registry grew from 594 at version 1.0 in 2017 to 1,563 by version 2.20 in 2025 (TensorFlow Developers 2025). Every one of those entries is something a backend must implement, or that the framework must first functionalize and decompose.

Compiler-facing representations work from far smaller sets, which grew by tens of operators while the eager surfaces grew by thousands. The Core ATen IR, the operator set that PyTorch's compiler and export paths lower to, holds 192 operators (PyTorch Contributors 2025); the XLA compiler that TensorFlow and JAX both target defines 123 high-level optimizer (HLO) operations (OpenXLA Project 2025); and the Open Neural Network Exchange (ONNX) standard, which carries models between frameworks and runtimes, defines 203 (ONNX Project 2026). JAX starts on the compiler's side of this divide. Its user-facing operations reduce to about 135 `lax` primitives (JAX Developers 2025), a set the size of the compiler cores, so a JAX program reaches XLA with little decomposition left to do. The 13–14× gap between an eager surface and its compiler core (for TensorFlow, on its XLA path) is the work that decomposition performs. A new accelerator backend that implements a

[11] **XLA (accelerated linear algebra)**: XLA fuses subgraphs, specializes layouts, and lowers high-level operations into backend-specific code, so its fusion attacks both launch overhead (L_{lat}) and intermediate memory writes (D_{vol}). Its speedup is therefore not a fixed multiplier. Large GEMM-heavy regions may already be compute bound, while chains of small elementwise operations benefit more because fusion removes repeated trips through external memory, so gains depend on graph structure, backend support, and input-shape stability.

[12] **Intermediate representation (IR)**: The "intermediate" captures this format's architectural role: a language-independent layer that decouples the frontend (Python capture) from the backend (hardware code generation), exactly as LLVM IR decouples C/Rust/Swift frontends from x86/ARM backends. ML frameworks adopted this compiler pattern because it reduces the $\mathcal{O}(M \times N_{\text{backend}})$ cost of supporting M frontends and N_{backend} backends to $\mathcal{O}(M + N_{\text{backend}})$: a single graph capture mechanism (PyTorch's TorchDynamo, or TensorFlow's bridge into XLA) can target multiple hardware backends without rewriting the capture logic.

small core set can run models written against the full eager surface, which is why operator coverage, not peak throughput, often decides whether a model runs on a new device at all.

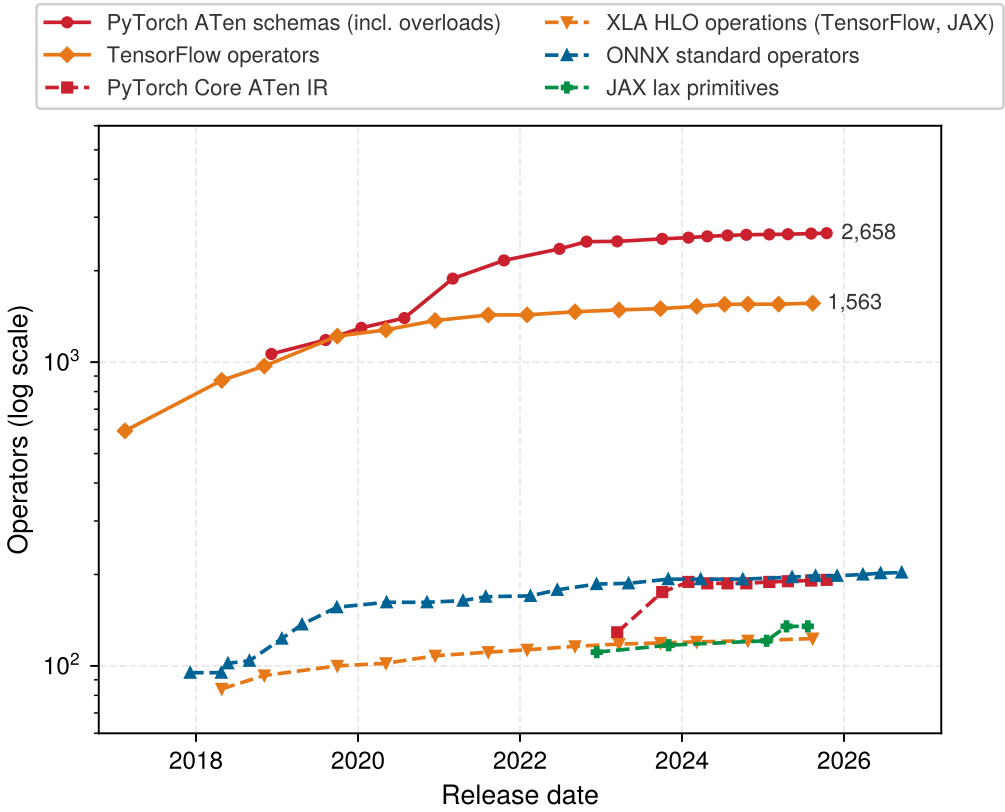

Figure 7.6: Eager Operator Surfaces versus Compiler Cores: Operators defined by the eager frameworks (PyTorch native-function schemas with overloads, and TensorFlow's registered operators) against the compiler-facing sets they lower to (PyTorch's Core ATen IR, XLA's HLO operations, the ONNX standard, and JAX's `lax` primitives) at each release, on a logarithmic axis. The eager surfaces grew past 1,500 and 2,600 entries while every compiler-facing set stayed between about 80 and 200. Counts mined from each project's repository at its release tags (PyTorch Contributors 2025; TensorFlow Developers 2025; OpenXLA Project 2025; ONNX Project 2026; JAX Developers 2025).

The two capture modes of PyTorch's TorchScript, now deprecated in favor of capture and export paths such as `torch.export` (PyTorch Contributors 2026d, 2026c), make the fidelity-generality trade-off concrete. Tracing executed a function with example inputs and recorded the tensor operations observed on that path. Scripting instead compiled a restricted, type-annotated subset of Python source, preserving supported branches in the graph at the cost of rejecting unsupported Python objects, library calls, and metaprogramming. Both produced an IR with static types in static single-assignment (SSA) form, where each variable is assigned exactly once, so fusion, constant folding, and dead code elimination could run without the Python interpreter.

The main limitation of tracing is that a trace records operations from an observed path rather than preserving arbitrary Python control flow. A data-dependent branch can therefore freeze into whichever side the example input took (listing 7.3).

Listing 7.3: Tracing a Data-Dependent Branch: Tracing records the path taken by the example input. PyTorch commonly emits a `TracerWarning` when a tensor value is converted to a Python condition because the resulting trace may not generalize.

```python
import torch

def conditional_forward(x):
    if x.sum() > 0:  # Data-dependent condition
        return x * 2
    else:
        return x * 3

traced = torch.jit.trace(conditional_forward, torch.tensor([1.0]))
# Tracing captures ONLY the x.sum() > 0 branch
# If input later has sum <= 0, traced version
# still executes x * 2 branch
```

In this example, converting the tensor condition to a Python Boolean commonly produces a `TracerWarning`; the resulting trace can still follow the captured branch for later inputs that require the other branch. Treating trace warnings as correctness failures is therefore essential when data-dependent Python control flow is present. The same hazard survives in modern graph-capture systems, which is why they guard each captured region with explicit assumptions about shapes and control flow.

Compilation therefore attacks the dispatch overhead of section 7.3.4 directly, and fusion adds a second saving in memory traffic. Notebook 7.1 quantifies both for a two-operation activation block.

Napkin Math 7.1: The physics of software overhead

Iron law connection: For small operations, the latency term (L_{lat}) in the iron law is dominated by software overhead: dispatching instructions from Python to the GPU. Each operation pays a Python dispatch cost of ~10 µs plus a kernel launch cost of ~5 µs, which together set the per-operation overhead applied in the two scenarios below. Python dispatch covers the framework call; driver launch covers submission to the device. A compiled region invoked from Python still pays an entry cost, whereas replay of a captured launch sequence removes repeated per-operation Python work and has its own submission cost.

Scenario one: Eager mode (the tiny-op trap) Consider a simple activation block, `y = relu(x + bias)`, in which the input and output each contain N elements of s_{elem} bytes each. Assume a scalar or broadcast bias remains in fast memory, so the traffic model counts the full input, intermediate, and output tensors.

- **Operations**: Two (Add, ReLU).
- Execution:
  1. Launch `Add` Kernel: 15 µs overhead.
  2. Read/Write Memory: $2Ns_{\text{elem}}$ bytes.
  3. Launch `ReLU` Kernel: 15 µs overhead.
  4. Read/Write Memory: $2Ns_{\text{elem}}$ bytes.
- **Total overhead**: 30 µs.
- **Total memory traffic**: $4Ns_{\text{elem}}$ bytes.

Scenario two: Compiled mode (fusion) The compiler fuses this into one kernel: `FusedAddRelu`. This scenario retains one ordinary Python entry and one driver launch, applying the same combined cost as eager mode to isolate the effect of reducing two calls to one. It does not model captured-graph replay.

- Execution:

1. Launch `Fused` Kernel: 15 µs overhead.
2. Read/Write Memory: $2Ns_{\text{elem}}$ bytes (the intermediate result stays on chip).

- **Total overhead**: 15 µs (2× less launch overhead).
- **Total memory traffic**: $2Ns_{\text{elem}}$ bytes (2× bandwidth efficiency).

Systems insight: Fusion saves on both terms at once: half the launches and, by the fused-chain traffic rule of section 7.3.2 with $n_{\text{ops}} = 2$, half the idealized traffic.

Scaling this arithmetic to a sequence of 5 small operations exposes the idle gaps on the accelerator timeline (figure 7.7). In eager execution, each 1 µs kernel waits on 10 µs of Python dispatch, leaving the accelerator idle for about 91 percent of the sequence; the figure isolates the Python share, and the per-kernel launch cost would widen each gap further. Compiling the sequence resolves both constraints simultaneously: the framework submits the work in a single launch of 5 µs, eliminating all intermediate host dispatch gaps, while operator fusion keeps intermediate activations in registers or cache to complete the entire sequence in 4 µs instead of the uncompiled 5 µs.

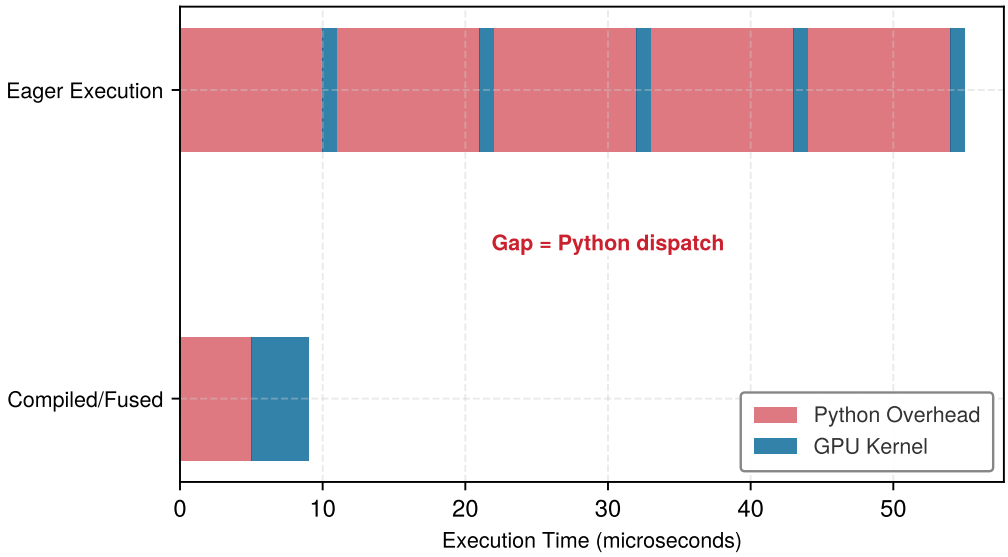

Figure 7.7: Python Dispatch Overhead: Execution timelines illustrate how host dispatch latency (L_{lat}) starves the accelerator during fine-grained operations. Eager execution incurs per-operation host overhead for each kernel, whereas compilation and fusion collapse the sequence into a single launch (drawn in the overhead color as one direct device submission), eliminating intermediate dispatch gaps and intermediate global memory round-trips.

Graph-capture compilers such as `torch.compile`[13] automate this fusion over captured regions without requiring engineers to write custom CUDA kernels.[14] However, compilation cannot span arbitrary Python code: graph breaks mark the boundary where compilation ceases to apply. Data-dependent Python control flow, unsupported library calls, I/O, custom Python objects, and highly variable shapes can shorten compiled regions. With eager fallback enabled, a break separates compiled subgraphs with standard Python execution, reintroducing interpreter dispatch and limiting fusion across the boundary. Tensor handles can pass between these regions while their storage remains on the device; host reads of device values can additionally require synchronization. This is why graph-break analysis belongs in performance engineering: the relevant metric is not whether compilation is enabled, but how much of the hot path remains inside long, stable compiled regions.

Backends occupy different points on the flexibility-performance spectrum. A **JIT** compiler traces model execution at runtime to generate optimized kernels dynamically, incurring initial warmup latency during the first pass. An **ahead-of-time (AOT)** compiler instead compiles captured computa-

[13] `torch.compile`: PyTorch's capture front end analyzes Python bytecode as each frame runs, rather than recording tensor operations alone. That vantage lets it keep capturing across Python control flow it can resolve from guarded values and insert a graph break where it cannot, which is why graph breaks rather than tracing errors are its characteristic failure mode.

[14] **CUDA (compute unified device architecture)**: NVIDIA's parallel computing platform, released in 2007, serving as the foundational layer between high-level Python operations and GPU silicon; when PyTorch executes `torch.matmul(A, W)`, the call traverses the framework's dispatcher, selects a cuBLAS kernel, and launches it on the GPU. Each launch adds the 5 µs kernel-launch share of the per-operation overhead on top of the framework's Python dispatch. For small operations, this dispatch overhead (L_{lat}) can exceed useful compute time. Fusing compatible groups of operations then reduces launch count as well as intermediate memory traffic; capturing the graph alone does not imply a single kernel.

tion before deployment, shifting compilation out of the hot path and enabling a standalone runtime when the export target supports one. A general JIT backend optimizes ordinary training and serving workloads with moderate compilation cost; a specialized inference backend can apply deeper fusion, precision lowering, and autotuning when the deployment target is fixed; an ahead-of-time mobile or embedded runtime removes even more flexibility to gain footprint and predictability. The same rule governs all of them: the narrower the target and the more stable the graph, the more optimization the compiler can safely perform.

Compilation shortens the list of kernels; a second mechanism removes the per-launch cost of whatever list remains. CUDA Graphs record a fixed sequence of kernel launches, with their arguments and memory addresses, once, and then replay the whole sequence with a single submission from the host (NVIDIA Corporation 2026a). Replay requires static shapes and fixed buffer addresses, which is why serving systems capture one graph per batch size. For the GPT-2 XL decoding step that opened the chapter, replay turns 576 separate launches into one submission, so the host's launch rate no longer sets the step time; what remains is the weight read of about 0.9 ms plus the device-side cost of running those kernels back to back, which fusion attacks. Every later decode floor in this book assumes this kind of capture.

The resulting workflow is a systems decision. Rapid prototyping favors eager execution because architecture changes and guard failures make recompilation cost visible. Long training runs and high-volume inference amortize compilation cost over many executions, provided the model has stable shapes and limited graph breaks. Debugging usually starts in eager mode because errors map directly to source code and standard debuggers such as `pdb` work mid-execution; compilation is reintroduced after the model behavior is correct and the performance bottleneck is measurable.

↩ The cost that slow experiment cycles impose on how many candidate models a team can test is established in section 3.3.

Set side by side across six dimensions (table 7.2), the three execution models differ most in when the graph is built and how much of it a compiler can see. Each row highlights how a design choice at graph construction time propagates into control flow, debugging, and runtime throughput.

Table 7.2: Execution Model Trade-Offs: Each execution model occupies a distinct position in the flexibility-optimization trade-off space. Eager execution maximizes debugging flexibility but limits cross-operation optimization; static graphs maximize optimization but require control flow to be represented in the graph; hybrid JIT compilation compiles captured regions while falling back to eager execution for unsupported patterns.

Aspect	Eager + Autograd Tape (PyTorch default)	Static graph (TensorFlow 1.x)	JIT Compilation (torch.compile)
Execution Model	Immediate	Deferred	Hybrid
Graph Construction	During forward pass	Before execution	First execution (cached)
Optimization	Per-operation kernels	Ahead-of-time	JIT compilation
Dynamic Control Flow	Python control flow	Graph control flow	Captured regions or breaks
Debugging	Easy (standard Python)	Difficult (symbolic)	Moderate (mixed)
Performance	Baseline	High (optimized)	High (compiled regions)

The same divide extends to memory planning, hardware specialization, research velocity, and integration with existing code (table 7.3). Where static capture invests upfront in planned buffer lifetimes and target-specific code generation, dynamic execution prioritizes rapid iteration and seamless composition with ordinary host code.

Table 7.3: Additional Graph Trade-Offs: Static graphs buy planned memory and hardware-specific code at the price of a define-then-run loop, while dynamic graphs buy iteration speed and natural integration with imperative code, complementing table 7.2. These trade-offs reappear when selecting frameworks in section 7.9.

Aspect	Static Graphs	Dynamic Graphs
Memory Management	Precise allocation planning, optimized memory usage	Flexible but potentially less efficient
Hardware Utilization	Can generate highly optimized hardware-specific code	May sacrifice hardware-specific optimizations
Research Velocity	Slower iteration due to define-then-run requirement	Faster prototyping and model experimentation

Aspect	Static Graphs	Dynamic Graphs
Integration with Legacy Code	More separation between definition and execution	Natural integration with imperative code

These trade-offs are not binary choices. Modern frameworks offer a spectrum of execution options, which raises the quantitative question of where on this spectrum a given project should operate.

7.3.7 Compilation and dispatch costs

Two quantitative principles make the choice of execution model measurable. The compilation continuum principle asks when compilation gains justify development cost by comparing production executions with development iterations. The dispatch overhead law writes the dispatch overhead ratio in terms of operation count and per-operation cost, giving a threshold that says when a whole workload is overhead-bound.

7.3.7.1 The compilation continuum principle

Equation 7.1 orders the execution models from maximum flexibility to maximum optimization in four positions, and each labeled arrow names the mechanism that carries a project one step rightward toward hardware:

$$\text{Eager} \xrightarrow{\text{capture}} \text{Graph JIT} \xrightarrow{\text{export}} \text{AOT Runtime} \xrightarrow{\text{specialize}} \text{Hardware} \tag{7.1}$$

Each step rightward sacrifices flexibility for performance. The practical question is *where* a given project should be placed on this continuum. The optimal compilation strategy depends on production executions, development recompilations, and their respective time costs, combined in equation 7.2:

$$\text{Compilation Benefit} = \frac{N_{\text{prod}} \cdot (T_{\text{eager}} - T_{\text{compiled}})}{T_{\text{compile}} + N_{\text{dev}} \cdot T_{\text{compile}}} \tag{7.2}$$

where:

- N_{prod} = number of production executions (dimensionless count: inference requests, training steps)
- N_{dev} = number of development iterations requiring recompilation (dimensionless count)
- T_{eager} = time per execution in eager mode (seconds)
- T_{compiled} = time per execution in compiled mode (seconds)
- T_{compile} = time per compilation or recompilation (seconds; assumed constant)

This model assumes that the compiled artifact remains valid between development changes and that the initial compilation and each recompilation have the same cost; under these assumptions, the decision rule is to compile when Compilation Benefit > 1. The ratio is dimensionless.

Table 7.4 applies that decision rule to hypothetical throughputs and compilation times across execution modes and model architectures:

Table 7.4: Illustrative Inference Throughput: The values are hypothetical inference throughputs on a data-center accelerator at batch size 32, assuming matching input shapes, precision, and numerical requirements across each row; they are assumptions, not benchmark measurements. Within this scenario, the table implies torch.compile speedups of 1.4–1.5× over eager mode and TensorRT (NVIDIA's ahead-of-time inference compiler, section 13.6) speedups of 2.3–2.7×. The setup column applies to torch.compile; TensorRT build costs require a separate measurement.

Model	Eager (examples/sec)	torch.compile (examples/sec)	TensorRT (examples/sec)	JIT Setup (seconds)
ResNet-50	1,450	2,150	3,800	15–30
BERT-Base	380	520	890	30–60
ViT-B/16	620	950	1,650	25–45
GPT-2 (124M)	180	260	420	45–90

Three cases illustrate how reuse changes the compilation decision. In research prototyping ($N_{\text{dev}} \gg N_{\text{prod}}$), teams should stay eager. If the architecture changes every few minutes, compilation

overhead can dominate. Under the scenario's 30 s compilation assumption, 10 compilations per hour consume 5 min.

For repeated execution ($N_{\text{prod}} \gg N_{\text{dev}}$), compilation can pay off because its one-time cost is amortized across many calls. In the hypothetical ResNet-50 inference scenario in table 7.4, torch.compile provides 48.3 percent higher throughput (2,150 img/s vs. 1,450 img/s). Using the scenario's 30 s compile cost, this pays off after the breakeven point in equation 7.3:

$$N_{\text{breakeven}} = \frac{T_{\text{compile}}}{T_{\text{eager}} - T_{\text{compiled}}} \tag{7.3}$$

Evaluating equation 7.3 with the hypothetical ResNet-50 values gives approximately 134,000 images. The same amortization principle applies to long training runs, using training throughput and compilation costs measured for that workload.

Long-lived production inference ($N_{\text{dev}} \approx 0$, $N_{\text{prod}} \to \infty$) extends this reuse further, providing more opportunity to amortize compilation. Aggressive autotuning can be worthwhile even when setup takes much longer, provided the model converts correctly, meets numerical requirements, and improves measured performance over the deployment lifetime.

The cases form a continuum of increasing reuse (figure 7.8). Each strategy's total time starts at its one-time compilation cost and grows at its per-execution cost, so eager wins at low execution counts, JIT wins once its compilation is amortized, and AOT wins only at the largest counts, where its higher upfront cost is fully repaid. The figure's crossovers (near 2×10^6 and 6.7×10^6 executions) come from an illustrative cost model in arbitrary units, not from the ResNet-50 scenario, whose eager-to-compiled breakeven sits near 134,000 images. What carries over is the order of the regions, not their positions.

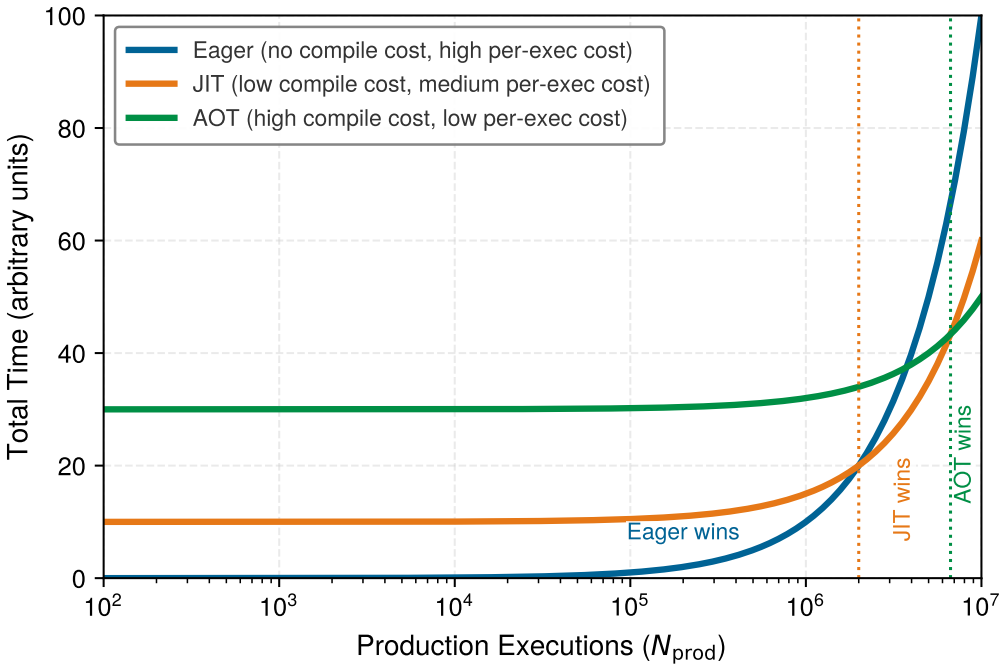

Figure 7.8: The Compilation Continuum: An illustrative cost model shows how one-time compilation cost and per-execution cost create eager, JIT, and AOT crossover regions as production executions increase. The crossover locations depend on the assumed compilation costs and per-execution rates.

These throughput differences are not uniform across workloads, so the execution strategy must align with the operational regime of each workload archetype. The appropriate strategy depends on the computational phase, the target backend, and the dominant iron law term. In batched prefill,

transformers have high arithmetic intensity that benefits from dense matrix compilation; in small-batch autoregressive decoding, however, the workload shifts into a bandwidth-bound regime where memory transfers dominate. Table 7.5 maps each recurring archetype to a candidate execution strategy based on these primary physical constraints.

↩ The workload archetypes and the iron law term that dominates each are established in section 2.3.2.

Table 7.5: Framework Execution Strategy by Workload: Each workload archetype pairs with a candidate execution strategy aligned to its dominant iron law term. Fusion cannot lift the bandwidth-bound row's weight-streaming limit; only larger batches or lower precision move it. For the power-bound row, memory capacity is a feasibility gate that must be met before any iron law term matters. For the capacity-bound row, the bandwidth and latency are those of irregular embedding gathers and the network exchange that follows them, not the streaming peak.

Archetype	Dominant Iron Law Term	Candidate Framework Strategy	Rationale
ResNet-50 (compute-bound)	$\frac{O}{R_{\text{peak}} \cdot \eta_{\text{hw}}}$ (Compute)	Compiled dense kernels	Regular dense kernels benefit from layout selection, precision lowering, and backend specialization; fusion helps most in surrounding memory- or launch-bound regions
GPT-2 (bandwidth-bound)	$\frac{D_{\text{vol}}}{\text{BW}}$ (Memory Bandwidth)	Fused attention + graph compilation	Fused attention eliminates intermediate activation round-trips, while compilation removes kernel launch overhead; streaming parameter and KV-cache traffic remain bandwidth-limited
DLRM (capacity-bound)	Capacity first, then $\frac{D_{\text{vol}}}{\text{BW}} + L_{\text{lat}}$ (gathers)	Specialized lookup kernels and measured capture	Irregular gathers limit some optimizations; measure compilation benefits in dense regions and surrounding dispatch
DS-CNN (power-bound)	Energy and memory capacity (feasibility gates)	Static-arena microcontroller runtime	Fixed memory and a small native runtime must fit the target before latency can be optimized

The rows differ in what a compiler can reach. Dense convolution exposes most of its work to fusion and layout selection, while embedding gathers and a microcontroller's fixed memory sit largely outside the graph a compiler optimizes.

Lighthouse 7.1: Framework strategy by archetype

The four recurring archetypes in table 7.5 trace one principle across the framework: compilation benefits scale with how much of the workload is optimizable.

Systems insight: In the illustrative scenario, compute-bound workloads such as the ResNet-50 row in table 7.4 benefit because their dense kernels expose substantial surface for layout selection, precision lowering, and fusion. Bandwidth-bound workloads such as small-batch GPT-2 generation require distinguishing intermediate activation traffic from parameter streaming: fusing attention kernels eliminates round-trips for transient activation tensors and removes dispatch latency, but memory bandwidth continues to bind on streaming model weights and key-value caches unless batching increases arithmetic intensity. Capacity-bound workloads such as DLRM can gain less when irregular embedding lookups leave limited compiler scope.

7.3.7.2 The dispatch overhead law

A second principle, the dispatch overhead law, emerges from equation 7.4, which identifies the regime in which framework overhead, rather than compute or memory, dominates execution time. Let N_{ops} be the number of operations (count), t_{dispatch} the per-operation dispatch overhead (seconds), and T_{compute} and T_{memory} the total compute and memory times (seconds). The ratio uses the additive, no-overlap approximation $T_{\text{hw}} \approx T_{\text{compute}} + T_{\text{memory}}$; when execution overlaps those costs, measured hardware time should replace their sum. Framework overhead dominates when operations are small relative to dispatch cost:

$$\text{Overhead Ratio} = \frac{N_{\text{ops}} \cdot t_{\text{dispatch}}}{T_{\text{compute}} + T_{\text{memory}}} \tag{7.4}$$

When Overhead Ratio > 1, the model is overhead-bound. This is the dispatch overhead ratio $T_{\text{sw}}/T_{\text{hw}}$ of section 7.3.4, written with $T_{\text{sw}} = N_{\text{ops}} \cdot t_{\text{dispatch}}$ so that operation count and per-operation cost appear explicitly. The fraction of step time spent in dispatch is Overhead Ratio$/(1+$ Overhead Ratio$)$, so a ratio above 1 means dispatch takes more than half of the step. Compilation can provide its largest gains for overhead-bound workloads because fusion reduces the number of dispatches. The training-step trace in section 7.7 works this effect through end to end, previewed by the numbers that follow.

Applying equation 7.4 means comparing the software overhead $T_{\text{sw}} = N_{\text{ops}} \cdot t_{\text{dispatch}}$ with the hardware execution time T_{hw} (both in seconds). The regime depends on the size of individual operations rather than on the model's parameter count. Notebook 7.2 contrasts a small multilayer perceptron with a large transformer layer to quantify when host overhead or device arithmetic bounds the system.

Napkin Math 7.2: Dispatch overhead at two scales

Problem: Determine the threshold where host-side Python interpreter dispatch overhead bounds end-to-end execution time relative to accelerator hardware execution.

Scenario one: Small multilayer perceptron (overhead bound)

- **Compute**: 6 ops across small matrix/element-wise operations.
- **Hardware time**: $T_{\text{hw}} \approx 2.6$ µs (mostly memory latency).
- **Software overhead**: $T_{\text{sw}} \approx 6$ ops $\times$ 15 µs/op = 90 µs.
- **Ratio**: 90 µs/2.6 µs ≈ 34.6.
- **Small-model outcome**: The system spends 97 percent of time in host-side dispatch and kernel-launch overhead. Eliminating all modeled dispatch overhead would give an upper-bound speedup of 35.6×.

Scenario two: GPT-3 layer (device bound)

- **Compute**: Huge matrix multiplications.
- **Assumptions**: Both times below are illustrative round values for one GPT-3-scale layer over a large batch, not derived from a specific accelerator. The conclusion does not hinge on them, because at the chapter's 15 µs/op the ratio would reach 1 only if the layer issued thousands of separately dispatched kernels.
- **Hardware time**: $T_{\text{hw}} \approx 100$ ms = 100000 µs.
- **Software overhead**: $T_{\text{sw}} \approx 180$ µs, one transformer block's 12 eager kernels at 15 µs/op.
- **Ratio**: 180 µs/100000 µs ≈ 0.0018.
- **Large-model outcome**: Modeled Python overhead is negligible. Compilation may still improve fusion, layout, or backend specialization; dispatch elimination contributes little.

Systems insight: Dispatch overhead is regime-dependent. Compilation can reduce host-side overhead for small-operation workloads by fusing operations into fewer launches, while large models benefit mainly from fused kernels and memory movement reductions.

7.3.8 Static runtimes for microcontrollers

The compilation continuum ends at the far edge, where the binding cost on a microcontroller is not each dispatch but the runtime itself, whose memory and latency footprint exceeds the device. While cloud frameworks such as PyTorch and TensorFlow 2.x prioritize flexibility through eager execution, TinyML[15] systems operating on microcontrollers (MCUs) with kilobytes of memory cannot afford the overhead of a Python interpreter or a fully dynamic runtime.

[15] **TinyML**: Systems designed for MCUs cannot afford a Python interpreter. Micro-runtimes instead use small C/C++ runtimes, fixed memory planning, and model-specific operators. TensorFlow Lite Micro remains interpreter-based: the application supplies a tensor arena whose buffers are planned and reused without heap allocation after setup. Predictable memory is mandatory because exceeding a 256 KB device budget can prevent initialization or inference.

Lighthouse 7.2: Lighthouse example: KWS on TinyML

Scenario: Deploying the keyword spotting (KWS) lighthouse, a DS-CNN and the book's power-bound workload, to an Nordic nRF52840 (Cortex-M4F) microcontroller with 256 KB RAM and 1 MB Flash. This is a smaller target than the ESP32-S3 of the earlier smart-doorbell scenario, chosen to show the runtime at its tightest.

Constraint: A full PyTorch and Python runtime exceeds the device's memory budget by orders of magnitude.

Framework solution: Micro-frameworks such as **TensorFlow Lite Micro (TFLM)** (David et al. 2021) solve this through a tiny interpreter-based runtime with a fixed memory discipline:

1. **Fixed memory arena**: The application supplies a contiguous tensor arena, and the framework plans and reuses buffers from that arena rather than relying on dynamic allocation during inference.
2. **Kernel selection**: Only the specific kernels used by the model (for example, Conv2D, DepthwiseConv) need to be linked or registered with the runtime.
3. **Compact interpreter execution**: The MCU runs a small C/C++ interpreter over a flat model representation, with the model and arena bound at initialization rather than assembled dynamically at runtime.

Binding constraint: The power budget makes keyword spotting a power-bound workload, but the first gate the framework must pass is memory capacity, not bandwidth or dispatch overhead, which is why table 7.5 treats it as a feasibility gate. The framework's primary job is to ensure the model's intermediate activations (the "working set") fit within the MCU's tiny SRAM.

These micro-runtimes sacrifice dynamic flexibility to reduce footprint and make memory predictable. With compact models, low-power hardware, and duty cycling, that discipline enables milliwatt-scale inference with mostly on-chip data movement. Across the full spectrum from dynamic eager execution to static graph compilation and specialized micro-runtimes, developers must therefore match the execution strategy to the binding constraint of the target.

Checkpoint 7.1: Execution models

The choice of execution mode determines both developer velocity and model performance.

Debuggability vs. speed

- ☐ **Eager mode (Python-first)**: why does executing ops one-by-one make debugging easy but optimization hard?
- ☐ **Graph mode (compiler-first)**: why does building a static graph enable kernel fusion?

Modern compromise

- ☐ **JIT compilation**: how does `torch.compile` bridge the gap?
- ☐ **Dispatch-overhead estimate**: if 6 ops each incur the chapter's 15 µs/op dispatch overhead while hardware work takes 2.6 µs, which term dominates?

The execution problem determines when computation happens and what optimizations are possible. Neural network training, however, requires a capability that no amount of clever scheduling can provide: the ability to compute gradients automatically.

7.4 Differentiation: Automatic Gradient Computation

Training requires determining how an incremental change in each of millions of parameters alters the scalar loss. Doing this manually for even a simple three-layer network requires deriving and implementing dozens of partial derivatives; for a modern transformer with billions of parameters,

manual differentiation is intractable. A framework that executes efficiently but cannot differentiate can run inference but cannot learn.

The **differentiation problem** is the task of computing gradients[16] automatically. Training requires the derivative of a scalar loss $\mathcal{L}$ with respect to every parameter. When executing the forward pass, the runtime records an execution tape and saves intermediate activation buffers for subsequent derivative evaluations. Backpropagation already showed why reverse-mode automatic differentiation (AD)[17] suits this shape of problem, since one reverse traversal from a single scalar loss yields every parameter gradient, a claim the forward-versus-reverse comparison below makes precise. Major ML frameworks therefore use reverse-mode AD for ordinary scalar-loss training (Baydin et al. 2018).

Building on the backpropagation algorithm, the systems engineering of differentiation addresses how frameworks represent computation graphs, manage memory for intermediate values, and orchestrate the backward pass efficiently across accelerators. The framework mechanizes the chain rule as large-scale systems bookkeeping: tracking operator dependencies, staging activation buffers, and dispatching backward kernels. The function in listing 7.4 reduces the core idea to three elementary operations.

Listing 7.4: Automatic Differentiation: The function $f(x) = x^2 \sin(x)$ breaks into a square, a sine, and a product, each with a known local derivative.

```
def f(x):
    a = x * x  # Square
    b = sin(x)  # Sine
    c = a * b  # Product
    return c
```

Frameworks decompose this function into elementary operations, each with a known local derivative, and then combine these local derivatives via the chain rule to compute gradients through supported compositions. The systems challenge is executing this transformation under physical hardware constraints: the framework must represent the computation graph, make necessary forward values available, and schedule backward kernels without exhausting accelerator HBM. Production runtimes address these challenges through structured graph recording, caching allocators, and reverse-mode traversal.

7.4.1 Forward and reverse mode

Computing the gradient of a scalar loss across millions of model weights one weight at a time would require millions of separate passes through the network, whereas sweeping backward from the single scalar loss recovers every weight gradient in one reverse pass. Automatic differentiation operates in these two traversal directions: forward mode, whose cost scales with the number of inputs, and reverse mode, whose cost scales with the number of outputs. Because deep learning objectives reduce a very large parameter set to a single scalar loss, this asymmetry dictates both the memory footprint and the execution schedule of the underlying framework.

7.4.1.1 Forward mode

Forward mode automatic differentiation computes directional derivatives alongside the forward calculation itself. For each intermediate variable v_i, the runtime evaluates both the value v_i and its directional derivative (tangent) $\dot{v}_i = \sum_j \frac{\partial v_i}{\partial x_j} \dot{x}_j$. Because tangents flow forward alongside the values, forward mode requires no execution tape and never retains forward activations for a later backward pass.

To see the mechanism concretely, consider computing both the value and derivative of $f(x) = x^2 \sin(x)$. Listing 7.5 shows how forward mode evaluates local derivative rules alongside each elementary operation, applying the chain and product rules at every step:

16 | **Gradients**: A gradient holds one value for every parameter it differentiates, so each weight tensor acquires a gradient tensor of the same shape. Computing gradients automatically therefore doubles the parameter-sized state before any optimizer runs, which is why training-memory accounts, such as the one in section 5.4.5.5, list gradients as a full copy of the weights.

17 | **Reverse-mode AD**: Reverse mode's single backward pass has a concrete memory cost, because the operation-dependent values that derivative rules read must be retained until the backward traversal reaches them. Activation checkpointing changes this saved set by omitting selected values and recomputing them during the backward pass.

↪ The optimization algorithms that consume these gradients are developed in section 8.3.2.

Listing 7.5: Forward Mode AD: Forward mode propagates derivatives forward through the computation graph, computing one directional derivative per seeded forward pass.

```
def f(x):  # Computing both value and derivative
    # Step 1: x -> x²
    a = x * x  # Value: x²
    da = 2 * x  # Derivative: 2x

    # Step 2: x -> sin(x)
    b = sin(x)  # Value: sin(x)
    db = cos(x)  # Derivative: cos(x)

    # Step 3: Combine using product rule
    result = a * b  # Value: x² * sin(x)
    dresult = a * db + b * da  # Derivative: x²*cos(x) + sin(x)*2x

    return result, dresult
```

Forward mode mechanizes this paired tracking through dual numbers, values of the form $v + \dot{v}\epsilon$ where $\epsilon^2 = 0$, so each operator updates the value and its tangent together without retaining a graph. Seeding $\dot{x} = 1.0$ carries the derivative through the trace (listing 7.6).

Listing 7.6: Dual-Number Trace: Evaluating the forward-mode function of listing 7.5 at $x = 2.0$ keeps a value and its derivative on every line, so one pass yields both $f(2.0) \approx 3.637$ and $f'(2.0) \approx 1.973$.

```
x, dx = 2.0, 1.0  # seed: track the derivative with respect to x

a = x * x  # value:      4.0
da = 2 * x  # derivative: 4.0
b = sin(x)  # value:      0.9093
db = cos(x)  # derivative: -0.4161
c = a * b  # value:      3.637
dc = a * db + b * da  # derivative: 1.973
```

A single forward pass with a seeded tangent vector $\dot{\mathbf{x}}$ evaluates a Jacobian-vector product (JVP), $\mathbf{J}\dot{\mathbf{x}}$, where $\mathbf{J} \in \mathbb{R}^{M \times P}$ is the Jacobian matrix. When an objective maps P parameter inputs to a single scalar loss ($M = 1$), recovering the full gradient $\nabla_\theta \mathcal{L} \in \mathbb{R}^P$ requires setting $\dot{\mathbf{x}}$ to each of the P standard basis vectors in turn. Recovering gradients with forward mode therefore requires P distinct forward evaluations (or propagating P-wide tangent bundles), scaling compute and memory traffic as $\mathcal{O}(P)$ with parameter count. For networks with millions or billions of parameters, this scaling makes forward-mode gradient calculation intractable, although forward JVPs remain effective when input dimensions are small or when evaluating directional derivatives and Hessian-vector products.

7.4.1.2 Reverse mode

An intermediate layer that maps an input vector $\mathbf{x} \in \mathbb{R}^N$ to an output $\mathbf{y} \in \mathbb{R}^M$ of width $N = M = 100{,}000$ has a full Jacobian $\mathbf{J} \in \mathbb{R}^{M \times N}$ of 10^{10} elements, which would require 40 GB of memory in FP32 just to store one layer's derivatives. Reverse-mode automatic differentiation avoids materializing this matrix and matches the many-parameters-to-one-loss shape of neural network training. Instead of propagating tangents forward from inputs, reverse mode propagates adjoints $\bar{v}_i = \partial \mathcal{L} / \partial v_i$ backward from the single scalar loss $\mathcal{L}$ to all parameters.

While forward mode computes Jacobian-vector products ($\mathbf{J}\dot{\mathbf{x}}$), reverse mode evaluates vector-Jacobian products (VJPs), $\mathbf{v}^T\mathbf{J} = \sum_{j=1}^{M} \bar{y}_j \, \partial y_j / \partial \mathbf{x}$, where $\bar{y}_j = \partial \mathcal{L} / \partial y_j$ is one element of the upstream gradient vector $\mathbf{v} = \frac{\partial \mathcal{L}}{\partial \mathbf{y}} \in \mathbb{R}^M$. Because training optimizes a single scalar loss $\mathcal{L}$, the backward pass only ever needs to multiply this upstream gradient vector by each local operation's derivative rule, never the 40 GB full Jacobian matrix.

To see how VJPs sidestep the full matrix, consider a simple element-wise operation such as $\mathbf{y} = \text{ReLU}(\mathbf{x})$ with an input vector $\mathbf{x} = [-1.0, 2.0, 3.0]$ and an upstream gradient $\mathbf{v} = [0.5, 0.5, 0.5]$

flowing backward from the loss. Because the derivative of ReLU is 1 when $x > 0$ and 0 otherwise, the local gradient vector is $\frac{\partial \mathbf{y}}{\partial \mathbf{x}} = [0, 1, 1]$. Instead of building a 3×3 diagonal matrix and executing a matrix multiplication, the VJP computes the element-wise product $\mathbf{v} \odot \frac{\partial \mathbf{y}}{\partial \mathbf{x}} = [0.0, 0.5, 0.5]$ directly, streaming vectors without ever materializing the massive $M \times N$ matrix in memory. Seeding the reverse sweep with $\bar{\mathcal{L}} = 1$ yields the complete parameter gradient vector $\nabla_\theta \mathcal{L}$ in a single backward pass, regardless of whether the model contains ten parameters or ten billion.

Reverse mode operates on the same three-operation function $f(x) = x^2 \sin(x)$ from listing 7.4, where x reaches the output through two distinct computational paths: the square and the sine. Algorithm 7.1 defines the reverse-mode traversal algorithm over a directed acyclic graph before tracing this concrete evaluation.

Algorithm 7.1 Reverse-mode automatic differentiation

Require: directed acyclic graph with scalar output y; nodes $v_1, \ldots, v_n$ in topological order; a local derivative rule for each node
Ensure: adjoints $\bar{v}_i = \partial y / \partial v_i$ for the requested input or parameter nodes

for $i = 1$ to n **do**
  compute v_i, record dependencies, and save values requested by its derivative rule ▷ *forward pass*
end for
$\bar{v}_i \leftarrow 0$ for all i; $\bar{y} \leftarrow 1$
for $i = n$ down to 1 **do**
  for each parent u of v_i **do**
    $\bar{u} \leftarrow \bar{u} + \bar{v}_i \, \partial v_i / \partial u$ ▷ *accumulate via the chain rule*
  end for
  release stored values once every rule that needs them has run
end for
return the adjoints for the requested nodes

The algorithmic structure of algorithm 7.1 reveals its systems cost. The forward pass records operator dependencies and buffers intermediate values required by backward derivative rules until the reverse sweep consumes them. Reverse mode trades activation storage and graph bookkeeping for a single backward pass, whose cost is a small constant multiple of the forward pass regardless of parameter count (Baur and Strassen 1983; Griewank and Walther 2008).

For the concrete function in listing 7.4 evaluated at $x = 2.0$, the forward pass records $a = x^2 = 4.0$, $b = \sin(x) \approx 0.9093$, and $c = ab \approx 3.637$. Seeding $\bar{c} = 1.0$, the product rule yields adjoints $\bar{a} = 0.9093$ and $\bar{b} = 4.0$. The square branch contributes $0.9093 \cdot 4.0 \approx 3.6372$ to $\bar{x}$, while the sine branch contributes $4.0 \cos(2.0) \approx -1.6646$. Accumulating both paths gives the exact derivative $\partial c / \partial x = \bar{x} \approx 1.973$.

This single backward traversal computes $\partial c / \partial x$ regardless of how many fan-out paths connect x to c. In a deep neural network, every weight tensor influences the scalar loss through thousands of divergent paths across successive layers; reverse mode aggregates all incoming adjoints in one reverse sweep. That one sweep, rather than one pass per parameter, is what keeps training a 175B-parameter model such as GPT-3 computationally tractable.

Executing this traversal in hardware exposes a physical constraint: evaluating local derivatives during the backward pass requires the operating point established during forward execution. The framework must therefore determine which forward tensors to persist in device memory, when to allocate them, and when to free them. The recorded graph answers the "when to free" question, because each saved tensor can be released as soon as the last backward rule that reads it has run. The peak itself is bounded separately, by splitting a large batch into micro-batches whose saved activations are freed before the next one starts while their gradients sum into the same buffers (gradient accumulation).[18]

A two-layer network makes these requirements concrete (listing 7.7). Tracing both passes explicitly shows which forward activations must survive until the reverse sweep consumes them.

[18] **Gradient accumulation**: The framework processes a large logical batch as smaller micro-batches, freeing each micro-batch's saved activations after backward while accumulating parameter-sized gradients. Processing 4,096 samples in 64-sample micro-batches can reduce the batch-dependent activation peak by up to 64× when activation memory scales linearly with batch size; weights, gradients, optimizer state, and other fixed costs do not shrink. The trade-off is more sequential work before each optimizer update.

Listing 7.7: Reverse Mode in a Neural Network: The forward pass computes and stores intermediate values; the backward pass walks the computation in reverse to produce gradients for every parameter.

```
def simple_network(x, w1, w2):
    hidden = x * w1  # First layer
    activated = max(0, hidden)  # ReLU activation
    output = activated * w2  # Second layer
    return output

# --- Forward pass stores intermediates ---
x, w1, w2 = 1.0, 2.0, 3.0
hidden = x * w1
activated = max(0, hidden)
output = activated * w2

# --- Backward pass consumes them ---
d_output = 1.0  # Seed gradient
d_w2 = activated  # = 2.0
d_activated = w2  # = 3.0
d_hidden = d_activated * (1 if hidden > 0 else 0)  # ReLU gate: 3.0
d_w1 = x * d_hidden  # = 3.0
d_x = w1 * d_hidden  # = 6.0
```

Three implementation requirements emerge from this example. First, the framework must track dependencies between operations to determine the correct reverse traversal order. Second, the information needed by each backward rule must be available, either saved during the forward pass or regenerated. The chain rule evaluates local derivatives at the forward operating point. For example, evaluating $\frac{\partial}{\partial z}\text{ReLU}(z) = \mathbb{I}(z > 0)$ requires the sign of the pre-activation z, which can be recovered from a saved value or mask, and computing a dense layer's weight gradient $\frac{\partial \mathcal{L}}{\partial \mathbf{W}} = \mathbf{X}^T \frac{\partial \mathcal{L}}{\partial \mathbf{Z}}$, where $\mathbf{Z}$ is the layer's pre-activation output, requires the forward input activation tensor $\mathbf{X}$. Third, every differentiated operation needs both a forward implementation and a corresponding backward rule. These requirements define the engineering surface of automatic differentiation, where retaining forward values can consume much of the training memory budget.

7.4.2 Activation memory

A 175B-parameter model in FP16 requires 350 GB just for weights, exceeding the physical memory of any single accelerator. Reverse-mode AD compounds this memory pressure by retaining operation-dependent forward activations for backward derivative rules. Saved activations weigh just as heavily on models whose weights fit easily. In a batch-64 ResNet-50 (worked below in section 7.4.3.2), saved activations exceed the FP32 weights by roughly two orders of magnitude, on top of weights, gradients, and optimizer states. Memory capacity, rather than raw floating-point throughput, frequently establishes the feasibility boundary of training.

This saved-activation footprint accumulates across successive layers, because each forward layer adds tensors that must persist until the backward sweep unwinds to that layer (listing 7.8). For a batch of B sequences of length S passing through N_L layers of width d, each saving n_{saved} tensors of s_{elem} bytes per element, the saved state is approximately

$$M_{\text{activations}} \approx B \times N_L \times S \times d \times n_{\text{saved}} \times s_{\text{elem}}$$

This total grows linearly in both batch size and network depth. Consequently, the batch size that fits on an accelerator during training is far smaller than the batch size that fits during inference, where intermediate activations can be discarded as soon as the next layer consumes them.

Listing 7.8: Activation Persistence Across Layers: The marked intermediates represent values retained for backward; peak saved-activation memory depends on their number and sizes.

```
def deep_network(x, w1, w2, w3):
    # Forward pass - must store intermediates
    hidden1 = x * w1
    activated1 = max(0, hidden1)  # Store for backward
    hidden2 = activated1 * w2
    activated2 = max(0, hidden2)  # Store for backward
    output = activated2 * w3
    return output
```

This is a capacity limit rather than the bandwidth gap of the memory wall, and frameworks relieve it through two primary architectural strategies. The first is activation checkpointing (or gradient checkpointing), a reverse-mode technique (Griewank and Walther 2000) that deep learning frameworks adopted to train deep networks in sublinear memory (T. Chen et al. 2016). Rather than buffering every intermediate activation, the runtime stores only selected segment boundary tensors and recomputes dropped intermediates on demand during the backward pass. In listing 7.9, the backward pass re-executes each forward segment to regenerate its activations rather than loading them from global memory.

↪ Activation checkpointing schedules and their recomputation cost are developed in section 8.6.5.2.

Listing 7.9: Activation Checkpointing: The forward pass stores only segment boundaries; the backward pass re-runs each segment to regenerate the dropped activations, trading recomputation for memory.

```
# Standard backward: every forward activation stays resident
h1 = layer1(x)  # kept for backward
h2 = layer2(h1)  # kept for backward
out = layer3(h2)  # kept for backward

# Checkpointed: keep only the boundary h1 and drop h2. The
# backward pass re-runs the wrapped segment to regenerate
# h2 on demand instead of holding it in memory.
h1 = layer1(x)  # boundary: kept
out = checkpoint(
    lambda a: layer3(layer2(a)), h1
)  # h2 recomputed in backward
```

The second strategy is the kernel fusion that the memory wall motivated in section 7.3.2, applied here to the body of a layer. Its capacity benefit is narrower than its traffic benefit. Temporaries that pass only between the fused operators are never allocated in HBM, so they add nothing to peak memory, while any value a backward rule reads must still be stored.[19] Rather than executing matrix multiplication, bias addition, and activation functions as separate kernels that serialize intermediate tensors to accelerator global memory (HBM), compilers fuse compatible operators into a single kernel that passes intermediate values through registers or on-chip shared memory.

The backward pass itself relies on specialized hardware-optimized kernels. Rather than synthesizing backward passes from naive elementary operations, frameworks invoke tuned backward kernels (such as cuDNN primitives) that optimize memory access strides and register usage on accelerator hardware (Chetlur et al. 2014). Combining checkpointing, kernel fusion, and specialized backward kernels enables large architectures to train within physical accelerator memory limits without incurring out-of-memory faults.

[19] **Fusion and saved state**: Fusion removes the forward round-trip of an intermediate through HBM, but it does not remove the backward pass's need for that value. If a derivative rule reads a fused intermediate, such as the pre-activation whose sign forms the ReLU mask, the fused kernel must still write that value (or a compact mask) to memory, or the backward pass must recompute it. Fusion and checkpointing therefore interact, because the compiler decides which intermediates to materialize from what the backward graph will read.

7.4.3 Autograd internals

Checkpointing, fusion, and specialized kernels address the physical bottlenecks of automatic differentiation, but production frameworks hide these mechanisms beneath a training loop of four calls that clear the gradients, run the forward pass, call backward on the loss, and step the optimizer. Behind those calls, the runtime builds and traverses a dynamic computation graph, allocates and frees intermediate buffers, schedules backward kernels on device streams, and applies a numerical-precision policy.

7.4.3.1 Recording the backward graph

If a forward operation discards its inputs and leaves no record of what function produced its output, calling `loss.backward()` has no path back to the model weights and no saved activations to plug into the chain rule. To make reverse traversal possible without ahead-of-time graph compilation, the autograd system dynamically constructs a directed acyclic graph of `Node` (or `Function`) objects during the forward pass. Each node stores an operator's backward differentiation rule and holds references to the tensors needed to evaluate its vector-Jacobian products. Because edges point backward from outputs toward inputs, the engine can walk the graph in reverse topological order as soon as it receives the initial gradient from the scalar loss; the memory that those node references keep alive is examined in section 7.4.3.2.

When gradient recording is enabled and an operation has inputs requiring gradients, its output carries a `grad_fn` referencing the backward `Function`. Each `Function` links to antecedent nodes through its `next_functions` list, forming a chain from the scalar loss back to leaf parameter tensors. Listing 7.10 inspects this pointer chain for a simple composite computation:

Listing 7.10: Reverse-Linked Graph Structure: Recorded outputs link through `grad_fn` to backward functions, forming a reverse chain from output to leaf parameters. One backward traversal computes the scalar loss gradient; its work grows with the graph.

```
import torch

x = torch.tensor([2.0], requires_grad=True)
y = x * 3
z = y.pow(2)

# Traverse the reverse-linked graph
print(z.grad_fn)  # PowBackward0
print(z.grad_fn.next_functions)  # -> MulBackward0
print(
    z.grad_fn.next_functions[0][0].next_functions
)  # -> AccumulateGrad (leaf)
```

The inspection exposes the traversal path: `PowBackward0` (from `z = y.pow(2)`) links to `MulBackward0` (from `y = x * 3`), which terminates at `AccumulateGrad` on the leaf parameter tensor `x`. Leaf tensors are graph sinks where accumulated gradients write directly into the `.grad` buffer rather than propagating further. The tuple format `(Function, index)` tracks the specific output index for multi-output operations.

This reverse-linked graph imposes a lifetime constraint: the topology and the forward information required by each backward rule must remain available until that rule executes. Host-side graph metadata (pointers and node descriptors) is distinct from the device tensor buffers it references. Retaining those buffers can consume gigabytes of accelerator capacity as model depth and batch size grow; recomputation or offloading changes where and how the required values are made available.

Production training also needs control over gradient propagation beyond a standard backward sweep, in three forms: selective gradient computation for freezing layers during transfer learning via `requires_grad=False` or `.detach()`; gradient inspection and modification for clipping, debugging, or logging intermediate adjoints via runtime hooks; and custom differentiation rules for non-standard operations such as specialized CUDA kernels or novel activation functions. These extension points operate via callbacks invoked during graph construction and reverse traversal, preserving the core engine's execution path. In PyTorch, these capabilities map to five runtime mechanisms, each with its own memory or correctness hazard (table 7.6).

Table 7.6: Autograd Control Mechanisms: Each extension point that the autograd engine exposes during graph traversal trades a specific control for a memory or correctness cost.

Mechanism	What it controls	Cost or hazard
`retain_graph=True`	Keeps saved graph state available for another backward traversal	Retains memory that would otherwise be released; the amount depends on the graph and saved values
Gradient accumulation	Successive backward passes sum into `.grad` until `zero_grad()` resets them, enabling large effective batches	Forgetting the reset silently mixes gradients across optimization steps
Custom `autograd.Function`	User-defined forward and backward rules for operations outside the built-in library	Makes the implementer decide what to save and how to differentiate
Gradient hooks	Inspecting or modifying gradients mid-traversal (clipping, logging, debugging)	Runs arbitrary Python per registered tensor on every backward pass
`.detach()`	Cuts gradient flow at a chosen boundary (frozen layers, inference outputs)	The legacy `.data` attribute bypasses autograd and silently corrupts gradients; clone before in-place mutation

Custom autograd functions move two decisions from the engine to the programmer, what to save and how to differentiate: the implementation explicitly defines which forward tensors to preserve in `ctx.save_for_backward()` and evaluates the corresponding vector-Jacobian products in `backward()`. Listing 7.11 demonstrates this interface for a custom multiply-add operation:

Listing 7.11: Custom Autograd Function: A custom multiply-add defines its own forward and backward rules and names the tensors that backward needs through `ctx.save_for_backward()`.

```python
import torch

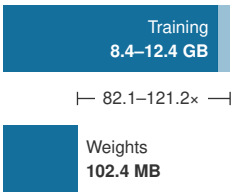
class MultiplyAdd(torch.autograd.Function):
    @staticmethod
    def forward(ctx, x, y, z):
        # Save tensors needed for backward
        ctx.save_for_backward(x, y)
        return x * y + z

    @staticmethod
    def backward(ctx, grad_output):
        # Retrieve saved tensors
        x, y = ctx.saved_tensors

        # Compute gradients using chain rule
        grad_x = grad_output * y  # dL/dx = dL/dout * dout/dx
        grad_y = grad_output * x  # dL/dy = dL/dout * dout/dy
        grad_z = grad_output  # dL/dz = dL/dout * 1

        return grad_x, grad_y, grad_z

# Usage
x = torch.tensor([2.0], requires_grad=True)
y = torch.tensor([3.0], requires_grad=True)
z = torch.tensor([1.0], requires_grad=True)



output = MultiplyAdd.apply(x, y, z)
output.backward()

print(
    x.grad, y.grad, z.grad
)  # tensor([3.]), tensor([2.]), tensor([1.])
```

7.4.3.2 Saved tensors and the memory-compute trade-off

In a retained-activation implementation, saved device tensors remain live until their backward consumers finish. These retained activations represent a primary driver of training memory overhead, compounding the footprint of weights, gradients, and optimizer states. Because different operations require different forward information (a matrix multiplication weight gradient requires input activations, while elementwise ReLU needs only the pre-activation sign), the exact memory profile depends on operator semantics and how the implementation stores that information.

Consider an illustrative ResNet-50 training scenario with 25.6M parameters (~102.4 MB of FP32 weights), batch size 64, and 224×224 images. With 8 GB–12 GB of saved activations, gradients add ~102.4 MB, and two Adaptive Moment Estimation (Adam) FP32 moment buffers add ~204.8 MB. Summing those four components gives an 8.4 GB–12.4 GB training scenario, roughly 82.1–121.2× the FP32 weight storage alone. This is a capacity-planning sum; actual peak memory depends on which components are live together. Inference requires no optimizer states, gradients, or saved backward buffers, but still has live activations and runtime workspace.

The training memory sum dwarfs FP32 weight storage alone.

Parameter count alone therefore does not tell an engineer whether training fits. Total training memory obeys the four-component formulation ($M_{\text{total}} = M_{\text{weights}} + M_{\text{gradients}} + M_{\text{optimizer}} + M_{\text{activations}}$) plus allocator overhead, as stated in section C.3.3.

Frameworks provide three graph-level controls to manage this trade-off. Activation checkpointing, whose mechanism listing 7.9 showed, alters what the graph retains: the engine stores selected segment boundaries and regenerates intermediate activations during the backward pass. In iron law terms, checkpointing increases the arithmetic operation count (O) to reduce peak activation storage; its effect on transfer volume (D_{vol}) depends on the recomputation path. Tensor detachment sets a gradient boundary: calling `.detach()` makes subsequent operations treat that tensor as independent of its prior computation. It does not retroactively free all previously saved state, and cutting a path changes which gradients are computed. Transfer learning shows the payoff. When a frozen feature extractor runs with gradient recording disabled and its output enters the trainable head as a constant, autograd saves none of the extractor's activations, so only the head pays the activation-storage cost. Mixed-precision training provides a third lever: representing eligible activations and weights in 16-bit formats halves their bytes relative to FP32, reducing tensor volume (D_{vol}) and enabling higher arithmetic throughput on supported Tensor Cores (R_{peak}).

The recorded graph fixes which backward kernels the device must execute (the O term), and the saved-tensor policy fixes how many bytes stay resident and move through the memory hierarchy (the D_{vol} term). Mixed precision acts on the second directly, because it shrinks every saved value and every operand a kernel reads.

↪ The decision of when these single-machine levers stop being enough and training must scale beyond one machine is developed in section 8.7.3.

7.4.3.3 Mixed-precision training support

Mixed precision (Micikevicius et al. 2018) improves two iron law terms at once. Tensor Cores run 16-bit matrix multiplications faster than FP32 units, raising R_{peak}, and eligible 16-bit activations halve the bytes stored and moved, reducing D_{vol}.

Automatic mixed-precision APIs implement this as a dispatch policy rather than a change to model code. Inside an `autocast` region, the dispatcher consults a per-operator precision list before selecting a kernel. Compute-intensive operations such as convolutions and linear projections run in FP16 or BF16, while numerically sensitive operations such as softmax, reductions, and loss calculations run in FP32. The second framework component, `GradScaler`, compensates for FP16's narrow exponent range (5 bits, with normal values bounded below by $\approx 6.10 \times 10^{-5}$). It multiplies the scalar loss by a loss-scale factor s_{loss} before backward traversal so that small gradients remain representable, divides the parameter gradients by s_{loss} before the optimizer update, and skips any step whose gradients overflow. BF16 keeps FP32's 8-bit exponent, so BF16 recipes usually run under `autocast` with the scaler disabled. The framework therefore supplies the dispatch and scaling machinery, while the choice among FP16, BF16, TF32 (an Ampere-class matrix-multiply format pairing FP32's exponent with FP16's mantissa), and FP8 and the way the loss scale adapts during training are policy decisions that section 8.6.3 develops, with the scaling mechanism itself in section 8.6.3.1. Listing 7.12 shows the two framework components working together in the FP16 path.

Listing 7.12: Mixed-Precision API: Modern frameworks provide automatic mixed-precision support through context managers that handle precision selection and numerical stability.

```
import torch
from torch.amp import autocast, GradScaler

model = MyModel().cuda()
optimizer = torch.optim.Adam(model.parameters())
scaler = GradScaler("cuda")

for inputs, targets in dataloader:
    inputs, targets = inputs.cuda(), targets.cuda()
    optimizer.zero_grad()

    # Framework automatically selects precision per operation
    with autocast(device_type="cuda", dtype=torch.float16):
        outputs = model(inputs)
        loss = criterion(outputs, targets)

    # GradScaler handles gradient scaling for numerical stability
    scaler.scale(loss).backward()
    scaler.step(optimizer)
    scaler.update()
```

Operation precision and weight storage are separate choices, so mixed precision also changes how many copies of each parameter training keeps. Under autocast the parameters stay in FP32 and are cast to 16 bits per operation, while recipes that store 16-bit working weights also keep an FP32 master copy for the update; either way the optimizer's FP32 moment buffers sit on top of gradients and saved activations. The per-parameter accounting, and the gap it opens between a model's weight file and its training footprint, is worked in section 5.4.5.5; budgeting and reducing optimizer memory is developed in section 8.3.2.5, and the training checkpoints that write this state to storage so a run can resume after a failure in section 8.4.5.

7.4.3.4 Tensor lifetimes and the caching allocator

Checkpointing and fusion (section 7.4.2) decide which values exist during a training step. The runtime still has to decide when each value's memory is reclaimed and how fresh memory is obtained. Where tensors live and how they move between host and device are the subject of section 7.5.2; the question here is narrower, namely when a value saved for the backward pass can be freed. In the retained-activation scheme of listing 7.8, forward layers add saved tensors that remain live until backward traversal consumes them. This saved-activation footprint peaks at the onset of backpropagation and recedes as intermediate buffers are released. Total training memory can peak later as gradients and temporary workspaces become live. Modern runtimes reclaim saved tensors once their backward consumers and other references no longer need them.

Allocation itself is also slow. Invoking device memory allocation and release (`cudaMalloc` and `cudaFree`) incurs substantial driver overhead, and `cudaFree` can block the host until all previously queued device work completes, draining accelerator command queues (Paszke et al. 2019). To eliminate this latency, modern frameworks intercept allocations with **caching allocators** that maintain pools of pre-reserved device memory blocks across training iterations. Suballocating from these pools amortizes device allocation costs and avoids the synchronizations that these calls can force, though varying tensor lifetimes can still induce memory fragmentation.

> Systems Perspective 7.1: Caching allocator and utilization
>
> Caching allocators primarily reduce allocation overhead and improve block reuse. Two considerations remain:
>
> 1. Allocation latency: Reusing a cached block avoids repeated device-allocation calls, whose cost and synchronization behavior depend on the allocator and runtime.

2. Fragmentation: Size classes and block splitting improve reuse but can leave free capacity in blocks that do not satisfy a request. Because each tensor requires a contiguous address range, external fragmentation occurs when variable tensor lifetimes leave small, non-contiguous free blocks in the pool; a large allocation can trigger an out-of-memory (OOM) error even when the total aggregate free memory across all blocks exceeds the requested size.

An out-of-memory error can reflect live allocations, allocator-reserved blocks, fragmentation, or another process. `nvidia-smi` reports device-level usage and is not sufficient by itself to diagnose the framework allocator; allocator-specific memory statistics are needed.

7.4.4 Tape-based and transform-based differentiation

A training iteration can run more slowly in production than in an isolated profile because the full step coordinates the allocator, the device manager, the scheduler, the data pipeline, and the optimizer, work that an operator microbenchmark does not measure. How heavy that coordination is depends on how the AD system records computation in the first place. A framework that builds a dynamic trace at runtime pays per-operation bookkeeping on every forward pass, and its caching allocator must accommodate allocation patterns that can vary with execution. A framework that captures a stable computation, by contrast, may pre-plan buffers and reuse storage across the forward and backward graphs because it can reason about lifetimes before execution. The gain depends on capture coverage, tensor lifetimes, shapes, and backend support.

The execution models of section 7.3 dictate these designs. PyTorch (Paszke et al. 2019) builds its tape during forward execution, which grants unconstrained Python control flow and direct debugging but retains tape metadata and saved tensors until backward traversal completes. Early TensorFlow (Martín Abadi et al. 2016) differentiated symbolically during graph construction, producing a fixed backward graph amenable to whole-graph dead-code elimination and memory reuse before execution; TensorFlow 2.x executes eagerly by default and compiles differentiation graphs through `tf.function` when throughput requires it (TensorFlow Developers 2024a). JAX[20] (Frostig et al. 2018) treats differentiation as a transformation that turns one function into its derivative function, which composes with vectorization (`jax.vmap()`) and compilation (`jax.jit()`) at the cost of requiring pure functions.

These implementation differences determine how much debugging visibility, compiler optimization, and deployment portability a team can expect from each framework. Each design also resolves a tension common to all of them. Backward rules need forward information, while device memory limits how much of it can be kept, so every framework must choose which activations to save, which operations to fuse, and how much recomputation to accept. Those choices decide which models can train on a given accelerator.

Checkpoint 7.2: The systems cost of gradients

Training is inherently more expensive than inference because of automatic differentiation.

Computational reality

- ☐ **Reverse mode AD**: why is it efficient for a scalar loss with many parameters?
- ☐ **Saved activations**: can you explain how saved-value memory depends on graph depth, tensor shapes, and checkpointing?

Optimization mechanics

- ☐ **Activation checkpointing**: how does recomputing activations save memory?

The execution and differentiation problems together enable the training loop: the execution model determines when computation happens, while automatic differentiation computes the gradients that drive learning. Both problems, however, assume that the same code can run across diverse hardware, and that assumption cannot be taken for granted. A model trained on an NVIDIA H100

[20] **JAX**: JAX exposes `grad`, `jit`, and `vmap` as transformations on functions; they can be composed when one transformation's outputs match what the next expects as inputs, but order matters: vectorizing gradients is not generally the same operation as differentiating a vector-valued result. Compilation can produce fused regions, library calls, and multiple kernels rather than one universal kernel. Transformed functions should be pure; Python side effects may occur during tracing but are not represented in the compiled program, while supported callbacks express intentional runtime effects.

must serve inference on a mobile phone's ARM CPU, a Google TPU, or a microcontroller with kilobytes of memory. The same `torch.matmul` call must dispatch to cuBLAS on one device and a hand-tuned ARM NEON kernel on another. This hardware diversity creates the third problem.

7.5 Abstraction: Tensors, Devices, and Operations

The preceding sections end at the level where values occupy memory and kernels run on a particular device. Modern machine learning applications demand portability across dissimilar execution targets. A model trained on data-center GPUs with tens of gigabytes of high-bandwidth memory each must deploy on an Apple neural engine, an edge TPU, or an ARM microcontroller with 256 kilobytes of SRAM. The **abstraction problem** requires frameworks to hide this underlying hardware diversity behind a uniform programming interface without sacrificing the specialized instruction sets, memory layouts, and compute pipelines of each target. GPUs expose abundant throughput-oriented parallelism but have different memory and execution semantics from CPUs. TPUs favor regular tensor programs and compiler-visible shapes. A microcontroller has kilobytes where a server has gigabytes. Frameworks must therefore balance unified developer ergonomics against target-specific performance tuning.

The problem decomposes into two interacting dimensions. The first is *data representation*: how frameworks encode tensors, parameters, and computational state in forms that work across hardware. The second is *execution mapping*: how high-level operations translate into hardware-specific implementations. These dimensions are not independent concerns. The way data is represented (memory layout, precision, device placement) directly affects *what* execution strategies are possible. A tensor stored in row-major format on a GPU requires different kernels than one in column-major format on a CPU. A model quantized to INT8 enables entirely different execution paths than FP32.

Solving the abstraction problem requires tensor representations that encode both mathematical semantics and hardware constraints, intermediate representations that enable hardware-specific compilation, and runtime systems that manage data movement across the memory hierarchy. To make this concrete, trace what must happen when a programmer writes `model(input)`. The framework must resolve four decisions in rapid succession, and the rest of this section takes them in order: data representation (tensor shape, memory layout, numeric precision), device placement and movement (the bandwidth hierarchy connecting host memory, accelerator memory, and other accelerators), input delivery (data pipelines that keep the accelerator fed), and kernel execution (dispatch, scheduling, and resource management). Organizing thousands of tensors back into one model follows in section 7.6.

7.5.1 Tensors

A ResNet-50 forward pass touches 25.6M parameters, produces intermediate activations at every layer, and must coordinate memory across CPU and GPU address spaces. Frameworks organize all of this data so that a single `model(input)` call executes millions of operations without the programmer managing a single pointer. Computational graphs specify the *logical* flow of those operations, while data structures determine how they access and manipulate data in *physical* memory, a distinction that can change throughput by an order of magnitude depending on whether data is contiguous in cache, pinned for direct memory access (DMA) transfer, or scattered across pages. To sustain terabytes per second of memory bandwidth across architectures from 1D sequences to 5D video while hiding device management behind a uniform API, frameworks build on a single data container: the tensor.

7.5.1.1 What a tensor carries

Every framework represents data with a single abstraction, the tensor, an n-dimensional array that pairs numerical values with the information needed to interpret and place them. Alongside the raw data pointer, the tensor header tracks shape, stride, element type, target device, and differentiation state so that operators can dispatch the right kernel without copying the underlying buffer.

Every computation in a neural network operates on tensors.[21] Training batches, activation maps, parameter gradients, and optimizer states are all tensors. This unified representation lets frameworks optimize a single data structure for hardware rather than managing separate containers for each role.

[21] **Tensor**: In mathematics, tensors obey coordinate-transformation laws; ML frameworks use the term more broadly for multidimensional arrays carrying shape, dtype, strides, device placement, and often automatic-differentiation metadata. A transpose commonly creates a strided view, while reshape may return either a view or a copy depending on the layout. These storage semantics make layout relevant to kernel selection and data movement.

Definition 7.2: Tensor

Tensors are n-dimensional arrays with shape, data type, stride, and device metadata. Framework runtimes use this information to select compatible operations and hardware kernels.

1. **Significance**: A contiguous FP32 tensor of shape $[1024, 1024]$ occupies $1024 \times 1024 \times 4$ = 4,194,304 bytes (about 4.2 MB). A noncontiguous view may be accepted directly by a strided kernel or may require materialization when an operation demands a supported contiguous layout.
2. **Distinction**: NumPy arrays also carry shape, dtype, and stride metadata. Framework tensors additionally integrate device placement, automatic differentiation, and accelerator dispatch.
3. **Common pitfall**: Tensor operations may return a new allocation, a view sharing existing storage, or an in-place update, depending on the operation and API variant. Memory accounting must distinguish these cases.

Because weights, gradients, master copies, optimizer moments, and saved activations are all tensors, they draw on the same device allocator and differ only in shape, dtype, device, and lifetime. That uniformity lets one caching allocator and one placement mechanism serve every role. It is also why a parameter count underestimates memory, since each weight tensor brings several companion tensors with it, as the training-versus-inference accounting of section 5.4.5.5 showed.

7.5.1.2 Rank, layout, and data type

Physical computer memory is a 1D array of linear byte addresses, whereas model inputs are 2D matrices, 3D RGB images, or 4D image batches. Tensors bridge this mismatch by pairing linear storage with coordinate axes whose count is the tensor's rank. Figure 7.9 traces this rank expansion from left to right, progressing from a Rank 0 scalar cell and Rank 1 column vector $(1, 3, 5, \ldots, 3)$ to a Rank 2 matrix grid and Rank 3 isometric volume tensor.

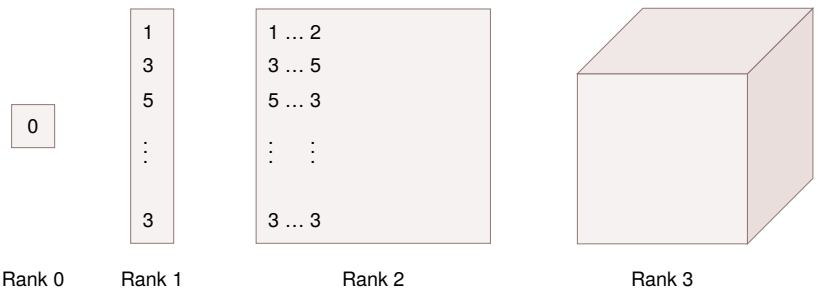


Figure 7.9: Tensor Rank Hierarchy: Ascending tensor ranks (0 to 3) generalize multi-dimensional indexing from scalars to volume tensors. Each additional rank adds an organizational axis that the framework must linearize into physical memory addresses via strides.

In vision applications, raw pixel arrays map directly onto multi-dimensional tensor layouts. For a 3×3 pixel patch (figure 7.10), planar grids for height (3 pixels vertically) and width (3 pixels horizontally) stack along depth into three color channels (red, green, and blue), forming a rank-3 coordinate space.

Framework tensors carry more than raw numbers. Each tensor stores **tensor metadata**, runtime information used to validate operations and select fast execution paths: a *shape* tuple (for example, `[64, 3, 224, 224]` for a batch of images), a *dtype* (framework literals such as `float32`, `float16`, or `int8`), and a *device* tag (CPU, cuda:0). A matrix multiplication, for instance, checks shape compatibility at dispatch time and uses the dtype to route to the correct hardware kernel, whether a standard FP32 GEMM or a Tensor Core FP16 path.

Memory layout implementation introduces distinct challenges in tensor design. While tensors provide an abstraction of multi-dimensional data, physical computer memory remains linear. Stride

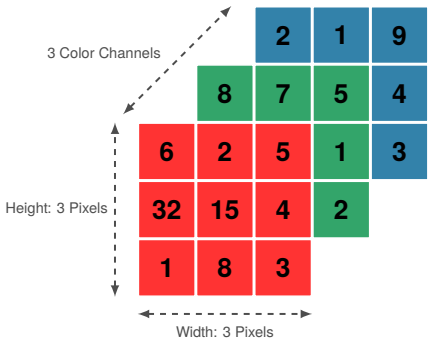

Figure 7.10: Image as an RGB Tensor: Decomposing a 2D color image into stacked height, width, and channel dimensions forms a rank-3 tensor. In ML systems, the ordering of these dimensions (such as channel-first vs. channel-last) determines memory access locality and cache efficiency during convolution operations.

patterns address this disparity by creating mappings between multi-dimensional tensor indices and linear memory addresses. Strides therefore fix the memory access pattern of every tensor operation and, with it, much of the operation's performance. Figure 7.11 contrasts how a 2×3 logical matrix maps into contiguous physical memory: row-major ordering (top right, pink) packs elements sequentially along rows ($[1.0, 2.0, 3.0, 4.0, 5.0, 6.0]$) using strides $[3, 1]$, whereas column-major ordering (bottom right, green) serializes along columns ($[1, 4, 2, 5, 3, 6]$) using strides $[1, 2]$. In both schemes, the framework computes element offsets via $i \times \text{stride}[0] + j \times \text{stride}[1]$.

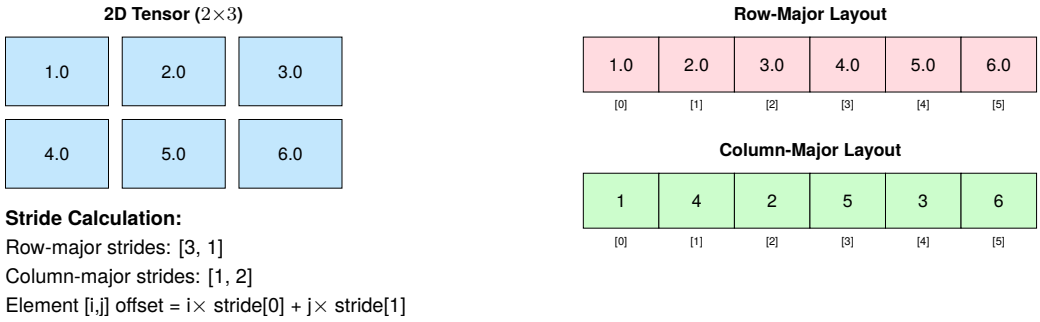

Figure 7.11: Tensor Memory Layout: A 2×3 tensor can be stored in linear memory using either row-major (C-style) or column-major (Fortran-style) ordering. Strides count elements skipped in each dimension, so i × stride[0] + j × stride[1] gives an element offset. Multiplying by the element size gives the byte offset from the storage origin. The choice of layout affects which traversals access neighboring elements efficiently.

Stride choices become performance choices. Row-major layout (used by NumPy, PyTorch) stores elements row by row, making row-wise operations more cache-friendly. Column-major layout (used by some BLAS libraries) stores elements column by column, optimizing column-wise access patterns. The stride values encode this layout information: in row-major layout for a 2×3 tensor, moving to the next row requires skipping three elements (stride[0] = 3), while moving to the next column requires skipping one element (stride[1] = 1).

These memory layout details have direct performance implications, but no ordering is universally superior. Efficient access depends on which dimension an operation traverses, the kernel's supported layouts, vectorization, and the target memory hierarchy. A mismatched layout may require strided access or a conversion, while a kernel designed for that layout can access it efficiently. PyTorch's `.transpose()` creates a view by changing stride metadata while sharing storage. A later reshape can reuse that storage only when the strides permit the requested view. Calling `.contiguous()` copies elements into a new buffer when the requested contiguous layout is not already present.

The dtype is the tensor-level lever that trades numerical range against data movement. The standard choice in machine learning has been FP32 precision, exposed in frameworks through dtype literals such as `float32`, offering a balance of precision and efficiency. Modern frameworks

extend this with specialized numeric types: integers for indexing and embedding lookups, reduced-precision floating point such as FP16 for memory-efficient training and deployment, and narrow integers such as INT8 for high-throughput inference on specialized hardware. The choice of numeric type affects both model behavior and computational efficiency. Neural network training typically requires FP32 precision for critical accumulations to maintain stable gradient computations, while inference tasks can often use lower precision (framework dtype literals such as `int8` or even `int4`, corresponding to INT8 and INT4), reducing memory usage and increasing processing speed. The autocast policy of section 7.4.3.3 combines these benefits per operation, running most computations at 16-bit precision while keeping accumulations and numerically sensitive operations in FP32. When operations mix tensors of different types, explicit casting rules must preserve numerical correctness without hiding the memory traffic and precision loss that each conversion introduces.

Tensors answer the data-representation problem by encoding shape, layout, and precision into a single abstraction. A perfectly shaped tensor on the wrong device, however, or one that must cross the PCIe-to-HBM bandwidth gap to reach the GPU, can erase every layout optimization. The next problem is placement: where data lives and how it moves.

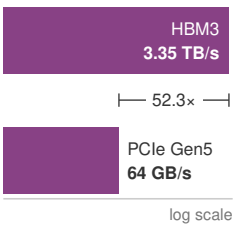
7.5.2 Devices and memory

On an H100, the PCIe Gen5 x16 host link delivers 64 GB/s between CPU and GPU while on-package HBM3 provides 3.35 TB/s inside the GPU, a 52.3× bandwidth gap that lets a single misplaced tensor copy erase the entire speedup of GPU acceleration. Where tensor data physically resides, and how it moves between host and accelerator memory, therefore determines whether computation runs at HBM speed or stalls on the host interconnect.

7.5.2.1 Frameworks as the operating system interface

While the high-level API focuses on math, the framework backend plays the role that an operating system plays for a single machine. It schedules compute and moves data, building on the CUDA runtime's primitives for launching kernels and managing device memory.

On the data-movement side, the framework coordinates with this runtime to implement **DMA** over the PCIe bus. The bandwidth gap between the host (CPU) and device (GPU) is the first bottleneck a data-loading pipeline meets, and section D.3.2 models this transfer, separating the two constraints, $T = L_{\text{lat}} + D_{\text{vol}}/\text{BW}$, that determine whether a given data-loading strategy is limited by per-transfer latency or by sustained bandwidth. Frameworks mitigate this through pinned memory (page-locked host memory), which enables DMA transfers without pageable-memory staging. This host-device interface is what makes high-throughput training loops possible on a single machine.



Because cross-device operations cross that 52.3× gap, the framework tracks where every tensor lives and requires that operations combine only tensors on the same device. When data must move, the framework must decide whether to block execution or overlap the transfer with other work. These decisions, invisible to most users, can move a training loop from transfer-bound execution toward substantially higher hardware utilization.

Three principles govern device and memory management: respect the bandwidth hierarchy, overlap unavoidable transfers with computation, and synchronize only where correctness requires it. The bandwidth hierarchy comes first, because the cost of moving data between devices varies by orders of magnitude with the interconnect.[22] For a 1000×1000 float32 tensor (4 MB), roughly the size of an activation tensor in a moderately sized model, the transfer times in table 7.7 separate the on-device path from every host link by more than an order of magnitude.

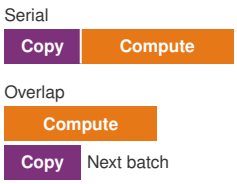
Table 7.7: Device Transfer Overhead: A 4 MB tensor takes far longer to cross a host link than to move within device memory. PCIe bandwidth shown is unidirectional (typical for GPU transfers), with full-duplex operation providing 2× total bandwidth; the NVLink row lists both its per-direction and bidirectional rates. These transfer costs can dominate lightweight operations, making device placement critical.

Interconnect	Bandwidth	Transfer Time	Path
PCIe Gen5 x16	64 GB/s	62.5 µs	Host to device
NVLink 4.0	450 GB/s per direction (900 GB/s bidirectional)	8.9 µs	GPU to GPU

↩ The single-node stack, in which the operating system moves data between host memory and accelerator memory, is established in section 2.4.1.

On the H100, on-device HBM3 outruns the host PCIe link by 52.3×.

[22] **NVLink**: NVIDIA's high-bandwidth GPU-to-GPU interconnect, providing 900 GB/s bidirectional bandwidth (NVLink 4.0 on the H100) compared to 128 GB/s for its PCIe Gen5 x16 host link. This 7.0× bandwidth advantage determines whether tensor parallelism, splitting one large tensor computation across multiple GPUs, is practical for a given model size: GPUs connected only by PCIe can make the D_{vol}/BW communication term dominate total training time, erasing the benefit of additional compute.



Interconnect	Bandwidth	Transfer Time	Path
HBM3	3,350 GB/s	1.2 µs	On device

These numbers connect directly to the iron law of ML systems. Every cross-device transfer contributes to $(D_{\text{vol}}/\text{BW})$ at a fraction of on-device bandwidth. Dividing 1 GB by the stated PCIe Gen5 x16 peak gives 15.6 ms, a bandwidth-only lower bound that omits protocol, launch, synchronization, topology, and contention overhead. Transfers can dominate lightweight or small-batch workloads, so deployed latency must be measured rather than inferred from peak bandwidth alone.

Device placement discipline protects the bandwidth hierarchy from accidental PCIe traffic. Every tensor carries a device attribute, and frameworks enforce a strict invariant: operations can only combine tensors on the same device, raising a `RuntimeError` when `cuda:0` and `cuda:1` tensors mix so that cross-device transfers remain explicit. Calling `.to()` on a tensor returns the original tensor when its data type and device already match the request (unless `copy=True` forces a copy) and otherwise returns a converted copy; in contrast, `nn.Module.to()` modifies registered parameters and buffers in place and returns the module.

The performance discipline follows directly from this bandwidth gap: allocate tensors on the target device from the start rather than creating them on the host and transferring them, reuse GPU memory across iterations rather than reallocating it, and colocate inputs, labels, and model parameters on the same device to eliminate implicit transfers. At 64 GB/s, violating any of these principles inserts PCIe transfers into the critical path that can dominate a training iteration that otherwise runs at 3.35 TB/s on-device.

When transfers are unavoidable, the next optimization is to hide their latency by executing them concurrently with computation. GPUs contain separate hardware units for computation (streaming multiprocessors) and data transfer (copy engines), and the framework exposes them through the CUDA stream, an execution queue whose operations run in order within the stream but concurrently with other streams. When copies and computation share one stream, they execute serially. Placing the next batch's transfer on one stream while the current batch computes on another can make the steady-state batch interval approach $\max(T_{\text{compute}}, T_{\text{transfer}})$, the larger stage time rather than their sum. Each batch still requires its own transfer to finish before its consumer runs. With sufficient independent work and hardware resources, stream-based overlap can hide much of the D_{vol}/BW penalty when computation is the longer stage (see listing 7.13).

Overlap pays the longer stage, not the sum.

The `non_blocking=True` flag requests a copy that is asynchronous with respect to the host, but real overlap also requires pinned memory. Ordinary host memory is pageable: the operating system may relocate or swap its pages at any time, and a DMA engine, which copies across PCIe without involving CPU cores, cannot handle a page fault. A copy from pageable memory therefore first stages the data synchronously into a temporary pinned buffer. Tensors placed in pinned (page-locked) host memory skip that staging, so their transfers can overlap accelerator computation. In listing 7.13 the two streams are separate; a complete pipeline must also hand each transferred batch to its consumer only after the copy completes, using the synchronization mechanisms that follow.

Listing 7.13: Overlapping Computation and Transfer: Separate streams can overlap eligible copies and computation when dependencies are synchronized correctly. Pinned host memory generally enables host-to-device copies to overlap with other device work.

```
compute_stream = torch.cuda.Stream()
transfer_stream = torch.cuda.Stream()

# Transfer next batch while computing
# current batch
with torch.cuda.stream(transfer_stream):
    next_batch = next_batch_cpu.to("cuda", non_blocking=True)

with torch.cuda.stream(compute_stream):
    output = model(current_batch)
    loss = criterion(output, labels)

# Pinned host memory can enable transfer overlap
x_pinned = torch.randn(1000, 1000).pin_memory()
x_gpu = x_pinned.to("cuda", non_blocking=True)  # Asynchronous

# A pageable source may require staging and
# should not be assumed to overlap
y_regular = torch.randn(1000, 1000)
y_gpu = y_regular.to("cuda", non_blocking=True)
```

Concurrent execution introduces ordering constraints: when one stream's output becomes another stream's input, the system must enforce a happens-before relationship without unnecessarily serializing independent work. Two synchronization mechanisms exist, and their performance consequences differ sharply. Full device synchronization (`torch.cuda.synchronize()`) blocks all streams and the CPU until every queued operation completes, creating a global serialization point that eliminates overlap. CUDA events provide the alternative: fine-grained synchronization that blocks only the dependent stream, allowing other streams and the CPU to continue execution (see listing 7.14).

Listing 7.14: CUDA Events for Synchronization: Events enable fine-grained producer-consumer patterns between streams without blocking the entire device.

```
# Create streams and event
stream1 = torch.cuda.Stream()
stream2 = torch.cuda.Stream()
event = torch.cuda.Event()

# Stream 1: producer
with torch.cuda.stream(stream1):
    result1 = expensive_computation(data1)
    event.record()  # Mark completion point

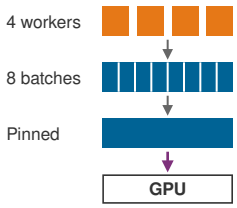
# Stream 2: consumer (waits only for stream1's event)
with torch.cuda.stream(stream2):
    event.wait()  # Block stream2 until event is recorded
    result2 = dependent_computation(result1)  # Safe to use result1
```

Full synchronization after every operation converts a concurrent pipeline into a sequential one, negating the hardware parallelism that streams expose, whereas event-based synchronization enforces only the dependencies that correctness requires. That difference creates a common operational trap: debug code left with `torch.cuda.synchronize()` in the hot path turns an overlapped pipeline into a serialized one. A timeline profiler shows the resulting gaps between kernels, while the kernel profilers and hardware counters that explain why an individual kernel underperforms belong to the profiling method of section 8.5.

7.5.2.2 Placement across accelerators

The same placement machinery extends to the one to eight accelerators of a single machine. Each device can hold a complete replica of the model and process a different slice of the batch, which requires summing every replica's gradients after the backward pass (an AllReduce), or the devices can hold different groups of layers and pass activations between them. Frameworks express these arrangements through named device groups, such as `ProcessGroup` in PyTorch or `Mesh` in JAX, and preserve the model's semantics while the hardware path underneath changes: NVLink delivers 900 GB/s of bidirectional bandwidth per H100 inside one node (table 7.7), while devices joined only by PCIe pay the slower path for every exchange. Parameter state multiplies with each arrangement, because every weight brings a gradient, optimizer moments, and often a second copy at another precision, and each replica or partition must own its share. Which arrangement to choose, and what its communication costs, is developed in section 8.7.

↪ The AllReduce collective and its communication cost are developed in section 8.7.1.1.



At the framework level, the central requirement is placement expressiveness on one machine with one to eight accelerators. The first arrangement is data parallelism; the second is pipeline parallelism. A third arrangement, tensor parallelism, splits individual tensor operations across devices. These are alternative placement choices, not a requirement to combine every strategy. The framework must express device ownership, transfers, and synchronization while preserving the model's semantics.

7.5.3 Data loading

Streams and events hide transfers behind computation, but scheduling cannot help if input data arrives too slowly in the first place. The data pipeline must sustain the accelerator's consumption rate. An accelerator processing 1,000 images per second at 224 by 224 resolution needs about 150.5 MB/s of sustained raw uint8 image throughput, and any shortfall idles the accelerator and lowers the effective utilization term in the iron law. The framework's contribution to this feeding problem is an abstraction that separates what a sample is from how samples reach the device. A *Dataset* defines access to individual samples, and a *DataLoader* (Paszke et al. 2019) turns that definition into a pipeline built from parallel worker processes, prefetching, and pinned staging memory.

↩ The feeding problem, in which data delivery must keep pace with accelerator consumption, is established in section 4.9.3.

Worker processes come first. With `num_workers > 0`, the DataLoader spawns CPU processes that load and preprocess samples independently, distributes sample indices to them through a shared queue, and assembles their completed samples into batches in the main process. Multiple workers overlap I/O wait with decoding and augmentation when one process is too slow to feed the accelerator; once the pipeline meets demand, extra workers add overhead rather than throughput.

Four workers fill eight prefetched batches, which drain through pinned memory to the GPU.

Prefetching sets pipeline depth. The `prefetch_factor` parameter controls how many batches each worker prepares in advance, so four workers with `prefetch_factor=2` keep up to eight batches in flight, at a cost in host memory proportional to the queued data. Prefetching raises the chance that input work overlaps accelerator computation but cannot prevent stalls when storage, decoding, or contention makes production slower than consumption.

Pinned memory completes the path to the device. The `pin_memory=True` option places batches in the page-locked host memory of section 7.5.2, so their host-to-device copies skip pageable-memory staging and can overlap device work. For a batch of 64 FP32 images at $224\times224\times3$ (38.5 MB), dividing by the H100's PCIe Gen5 x16 peak gives 0.6 ms; this is a bandwidth-only lower bound, not a measured pinned-transfer latency. The realized benefit over pageable memory depends on the platform, batch size, pipeline, and overlap. Pinned pages also reduce pageable system memory.

The DataLoader configuration in listing 7.15 is useful only when each parameter is tied to a bottleneck: `num_workers` sets loading parallelism, `prefetch_factor` sets pipeline depth, and `pin_memory` enables DMA transfers. Each worker also holds its own copy of the Dataset object and its own Python state, so the worker count trades throughput against host memory, and changes one worker makes to that state do not reach the others or the main process unless the state lives in explicitly shared or memory-mapped storage. PyTorch seeds each worker's own generator separately, but augmentation code that draws from NumPy or Python's `random` module still needs a `worker_init_fn` such as `seed_worker`.

Listing 7.15: DataLoader Throughput Configuration: Four workers with a prefetch depth of two keep up to eight batches in flight through pinned memory, and a per-worker seed function makes NumPy and Python augmentation reproducible.

```
import random

import numpy as np
import torch
from torch.utils.data import DataLoader

def seed_worker(worker_id):
    worker_seed = torch.initial_seed() % 2**32
    np.random.seed(worker_seed)
    random.seed(worker_seed)

loader = DataLoader(
    dataset,
    batch_size=64,
    shuffle=True,
    num_workers=4,  # Parallel worker processes (mechanism 1)
    prefetch_factor=2,  # Batches prepared ahead per worker (mechanism 2)
    pin_memory=True,  # Page-locked memory for DMA (mechanism 3)
    worker_init_fn=seed_worker,  # Reproducible augmentation per worker
)

# Pipeline effect: while GPU processes batch N,
# 4 workers load batches N+1..N+8 into pinned memory,
# ready for DMA transfer when the GPU finishes.
```

The Dataset interface decides how samples can be scheduled. A *map-style* dataset implements `__len__` and `__getitem__`, so a sampler can shuffle by index, which suits data that fits in memory or supports efficient random access on disk. An *iterable-style* dataset implements `__iter__` and yields samples sequentially from a stream where random access is impractical, so any shuffling must be buffered inside the iterator. Batch collation through the `collate_fn` parameter then combines samples into a batch. The default stacks tensors along a new batch dimension, which requires identical shapes; variable-length data such as text needs custom collation that pads, sorts by length, or builds attention masks, and those choices change both memory use and throughput.

↪ Sizing worker count and prefetch depth against measured throughput and memory is developed in section 8.6.2.2.

With input delivered at the rate the accelerator consumes it, the remaining abstraction problem is execution, the translation of each operation into work that runs on the target hardware.

7.5.4 Core operations

Calling `y = torch.matmul(x, w)` without selecting a kernel matched to `x` and `w`'s device, data type, stride layout, and tile dimensions either fails at runtime or leaves Tensor Cores idle while a generic loop crawls through memory. Bridging that single Python call to thousands of parallel accelerator threads traverses three coordinated functional tiers. From left to right in figure 7.12, system-level operations (scheduling, memory management, and resource optimization) organize graph execution; basic numerical operations (GEMM, BLAS, and element-wise kernels) execute algebraic routines; and hardware operations (compute kernel management, memory abstraction, and execution control) bind the workload directly to device streams and physical silicon. The discussion that follows traces this hierarchy from the hardware kernel primitives upward to system orchestration.

7.5.4.1 Hardware abstraction operations

The hardware abstraction layer isolates framework code from platform-specific details. It solves three concrete problems: selecting the right compute kernel, moving data through the memory hierarchy, and coordinating execution across processing units.

The kernel manager dispatches each supported operation to an implementation for the current backend. For matrix multiplication, this may be a CPU BLAS backend such as Intel oneMKL or OpenBLAS (Intel Corporation 2026a; OpenBLAS Project 2026), cuBLAS on NVIDIA GPUs (NVIDIA

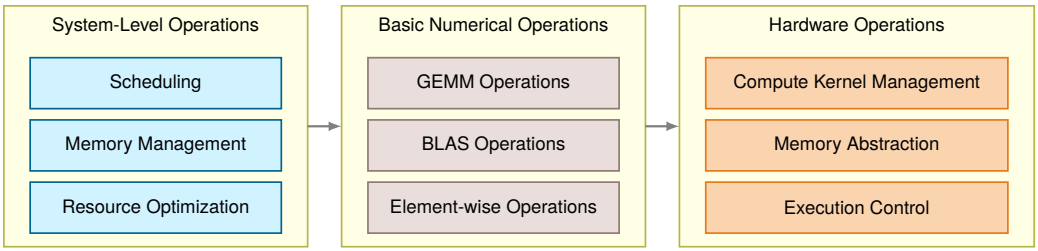


Figure 7.12: Core Operations Stack: Three functional tiers bridge high-level Python code to physical execution. Hardware operations manage low-level kernel dispatch and memory transfers, basic numerical operations execute dense GEMM and element-wise routines, and system-level operations coordinate graph scheduling and memory lifetimes across accelerators.

2024a), or accelerator-specific tensor instructions. Selection depends on dimensions, dtype, layout, backend, and library heuristics. A 4096×4096 FP16 GEMM on an H100 may use a Tensor Core path whose published dense peak is 989 TFLOP/s (Choquette 2023; NVIDIA Corporation 2022). If the backend has no implementation for an operator, execution may fall back, be partitioned, or fail, depending on the framework and runtime.

The memory abstraction layer moves tensors among pageable or pinned host memory, device memory, and unified memory, and transforms data layouts to match hardware preferences. In physical silicon, tensors do not exist as multi-dimensional matrices; they are stored as one-dimensional arrays of linear byte addresses. Layout formats dictate how dimensions map to that 1D sequence: *channels-first* NCHW places all spatial pixels of one channel contiguously before storing the next channel, whereas *channels-last* NHWC groups all channel values for a single spatial coordinate consecutively. Accelerator matrix units often prefer NHWC because loading all channels for a pixel aligns with a single, contiguous 128-byte memory transaction (a coalesced access). A framework may therefore execute kernels in NHWC for peak hardware utilization while preserving NCHW for user-facing APIs. Alignment requirements vary from 4 bytes on CPUs to 128 bytes on high-bandwidth accelerators; misaligned or strided accesses split requests across multiple memory transactions and can cut effective bandwidth substantially. The runtime also preserves dependency ordering when multiple execution units access the same tensor, preventing races during concurrent operations.

The execution controller coordinates work across multiple processing units and memory spaces. On a modern GPU, graph runtimes or explicit stream use can overlap independent kernels when dependency analysis proves they are ready and the kernels leave enough resources unused to run concurrently. Eager default-stream execution often serializes this work instead. The controller inserts synchronization barriers where data dependencies require them, tracks event completions to trigger dependent operations, and routes hardware errors (ECC failures, timeout watchdogs) to the framework's error handling path.

7.5.4.2 Basic numerical operations

With hardware abstraction managing the platform-specific details, frameworks build a layer of mathematical operations on top. GEMM dominates ML computation. The operation $\mathbf{C} = \alpha\mathbf{AW} + \beta\mathbf{C}$ accounts for the vast majority of arithmetic in neural networks: a single ResNet-50 forward pass performs approximately 8.2 GFLOP, nearly all of which reduce to GEMM. Section C.1.3 derives how GEMM arithmetic intensity scales with matrix dimension, predicting whether a given layer is compute bound or memory bound before any profiler runs. Frameworks optimize GEMM through cache-aware tiling (splitting matrices into blocks that fit in L1/L2 cache), loop unrolling for instruction-level parallelism, and shape-specific kernels. Fully connected layers use standard dense GEMM, while convolutional layers use im2col transformations that reshape input patches into matrix columns, converting convolution into GEMM.

↪ Tiling on an accelerator, where on-chip storage and the compute array fix the tile size and a dimension one element past a tile boundary can halve utilization, is developed in section 11.7.5.

Beyond GEMM, frameworks implement BLAS operations (AXPY for vector addition, GEMV for matrix-vector products) and element-wise operations (activation functions, normalization). Element-wise operations are individually cheap but collectively expensive, because each one reads and writes its full tensor; they are the fusion targets of section 7.3.2.

Training in FP32 uses 4 bytes per parameter; quantizing to INT8 reduces this to 1 byte, cutting memory by 4× and enabling 2–4× throughput improvements on hardware with INT8 acceleration.

Training typically keeps numerically sensitive accumulations in higher precision, while inference can often run many operations in FP16 or INT8 with little quality loss. Frameworks maintain separate kernel implementations for each precision format and handle workflows where different layers operate at different bit widths within a single forward pass.

7.5.4.3 System-level operations

Hardware abstraction and numerical operations provide the building blocks; system-level operations orchestrate them. The scheduler orders operations by their graph dependencies and overlaps independent work through the streams and events of section 7.5.2. The memory manager reuses freed blocks through the caching allocator of section 7.4.3.4 and, when a model exceeds device memory, executes the activation-checkpointing policy of section 7.4.2. The resource optimizer ties these decisions to the kernel selection described earlier. Its failures are the ones those mechanisms predict, since a poor schedule leaves resources idle and fragmentation or excessive live state can cause an out-of-memory error even when aggregate device capacity appears sufficient.

Checkpoint 7.3: Hardware abstraction

The abstraction problem is the bridge between *portable code* and *efficient execution*.

- ☐ **Two dimensions**: can you distinguish data representation (layout, dtype, placement) from execution mapping (kernel selection, scheduling), and explain how they constrain each other?
- ☐ **Kernel dispatch**: can you explain why the same high-level operation (for example, GEMM) needs multiple implementations (CPU vector path vs. GPU Tensor Core path) and how shapes/dtypes affect the choice?
- ☐ **Memory abstraction**: can you explain why frameworks use caching allocators and layout transforms (NCHW↔NHWC) rather than calling device allocators on every tensor?
- ☐ **Execution control**: can you describe what the runtime is doing when it overlaps independent work (streams) and inserts synchronization only where dependencies require it?

Tensors, streams, and kernel dispatch complete the descent to the hardware, but they operate at the granularity of individual buffers and operations. Model development needs the opposite direction, composing thousands of low-level operations, together with the parameters that automatic differentiation tracks, into reusable, nestable building blocks called *modules*.

7.6 Modules: From Operations to Models

A network such as ResNet-50, containing 25.6M parameters across fifty layers, requires extensive coordination: registering weights with optimizers, tracking device placement, toggling training and evaluation modes, and serializing checkpoints. Managing this manually would drown model development in error-prone tensor plumbing. The organizational layer of the framework resolves this through hierarchical composition.

Every major framework implements this through a module abstraction that binds parameter tensors, forward computation, and lifecycle hooks into a unified interface. PyTorch's `nn.Module`[23] provides an instructive case study because its design patterns recur across frameworks: Keras uses similar layer abstractions (Chollet 2018), JAX's Flax employs analogous module structures, and TensorFlow's functional API shares conceptual parallels. Three enduring design principles recur regardless of syntax or programming paradigm.

7.6.1 Automatic parameter discovery

A modern neural network may contain millions of trainable parameters spread across dozens of layers. Without automation, a programmer would need to enumerate every parameter tensor and pass it to the optimizer manually, an error-prone process that scales poorly with model complexity. Frameworks solve this through **automatic parameter discovery**: the system walks the module tree, collecting every parameter tensor so the optimizer can update them in a single call.

[23] **nn.Module**: The pattern recurs across frameworks because the organizational problem is universal. `nn.Module` automatically registers any assigned submodule or parameter into a hierarchical tree, enabling a single `.to('cuda')` call to recursively place millions of parameters onto a GPU. Keras layers, JAX Flax modules, and TensorFlow's `tf.Module` all implement the same tree-walking pattern. Without it, managing model state would require manual bookkeeping that scales linearly with architectural depth, a cost that grows prohibitive for models with hundreds of layers.

This is a tree traversal problem at its core. PyTorch's `Module.__setattr__` registers an assigned `nn.Parameter` or child `nn.Module` in the module's internal mappings. A call to `.parameters()` recursively traverses registered submodules and yields registered parameters. Other frameworks expose analogous parameter trees or collections, though their mechanisms differ.

Automatic parameter discovery gives the optimizer a complete parameter set or parameter groups, enabling grouped or fused multi-tensor update kernels when the framework and backend support them. The immediate win is correctness and composability: newly attached submodules participate in device moves, serialization, and optimizer construction without a separate manual registry. It also lets optimized update paths operate over parameter collections without per-parameter user code. Listing 7.16 demonstrates the core mechanism: attribute assignment triggers registration, and `.parameters()` returns all discovered tensors.

The distinction between *parameters* and *buffers* illustrates a subtlety of discovery. Registered parameters appear in `.parameters()` whether trainable or frozen; `requires_grad` separately controls whether autograd accumulates a gradient for them. Registered buffers move with the module and can appear in its state dictionary but are excluded from `.parameters()` and ordinary optimizer discovery. Batch-normalization running statistics are a common buffer use case.

Listing 7.16: Parameter Registration: Automatic parameter tracking through attribute assignment enables optimizer access to all trainable weights without manual enumeration.

```
import torch
import torch.nn as nn

class CustomLayer(nn.Module):
    def __init__(self, input_size, output_size):
        super().__init__()
        self.weight = nn.Parameter(
            torch.randn(output_size, input_size)
        )
        self.bias = nn.Parameter(torch.randn(output_size))
        self.register_buffer("running_mean", torch.zeros(output_size))

    def forward(self, x):
        return torch.matmul(x, self.weight.t()) + self.bias

layer = CustomLayer(10, 20)
# Framework discovers both parameters automatically:
for name, param in layer.named_parameters():
    print(f"{name}: shape {param.shape}")
```

The other major frameworks draw the same line between trainable parameters and nontrainable state through different accessors (table 7.8). Regardless of syntax, each API separates tensors that the optimizer should update from persistent buffers that merely ride along in checkpoints and device transfers.

Table 7.8: Parameter Discovery APIs Across Frameworks: Each framework exposes a different surface for distinguishing trainable parameters from nontrainable buffers, but all four solve the same underlying problem of letting optimizers find weights to update while preserving state (running statistics, frozen tensors) across forward passes. The shared pattern is structured access to parameters and persistent state. Accessor semantics differ: PyTorch also yields frozen registered parameters, so trainability remains a separate property.

Framework	Parameter Access	Nontrainable State
PyTorch	`model.parameters()`	`register_buffer()`
Keras	`layer.trainable_weights`	`layer.non_trainable_weights`
JAX/Flax	`variables["params"]` after `variables = model.init(key, x)`	Separate variable collections (for example, `batch_stats`)

Framework	Parameter Access	Nontrainable State
TensorFlow	`module.trainable_variables`	`module.non_trainable_variables`

7.6.2 Mode-dependent behavior

Training and inference require different computational behavior from the same model graph. During training, dropout layers randomly zero elements with probability $p_{\text{drop}} = \Pr(\text{drop})$ to regularize the network, while during inference those same layers must perform identity mapping to produce deterministic outputs. Batch normalization uses per-batch statistics during training but switches to accumulated running statistics during inference. If these behavioral changes are left to the programmer, forgetting a single mode switch produces silently incorrect predictions in production.

Frameworks solve this with a *state flag* that propagates through the module hierarchy. A single call to `.eval()` on the root module recursively sets `self.training = False` on every descendant, and each layer queries this flag to select its behavior. This is an instance of a broader systems principle: the same computation graph must produce different execution behavior depending on context. Compilers face the same challenge when the same source code must produce debug builds (with bounds checking and symbol tables) vs. release builds (with aggressive optimization). The flag-propagation pattern ensures correctness by centralizing the mode decision at the root rather than requiring per-layer coordination.

Evaluation mode and gradient recording are separate controls. Calling `.eval()` changes mode-dependent layer behavior but leaves autograd recording enabled. For inference that needs no gradients, `torch.no_grad()` disables that recording, avoiding the associated saved backward state while `.eval()` selects the appropriate layer behavior.

This principle extends to parameter freezing for transfer learning. Setting `requires_grad=False` prevents autograd from accumulating gradients in those parameters and removes their gradient storage. It does not necessarily remove the layer's backward computation because gradients may still need to pass through its operations to reach trainable inputs or earlier parameters. Savings therefore depend on where the frozen region lies and which tensors require gradients.

7.6.3 Hierarchical composition and serialization

Complex models compose from reusable submodules, creating a tree structure. A ResNet is not implemented as a monolithic block of operations but as a hierarchy: the root module contains a sequence of residual blocks, each block contains convolution layers and normalization layers, and each layer contains parameter tensors. This hierarchical composition must support two operations, made concrete in listing 7.17: recursive parameter collection for training and **state serialization** for checkpointing and deployment.

Listing 7.17: Nested Module Composition: Hierarchical module composition enables recursive parameter collection and a flat state mapping across the module tree.

```
import torch
import torch.nn as nn

class ResidualBlock(nn.Module):
    def __init__(self, channels):
        super().__init__()
        self.conv1 = nn.Conv2d(channels, channels, 3, padding=1)
        self.bn1 = nn.BatchNorm2d(channels)
        self.conv2 = nn.Conv2d(channels, channels, 3, padding=1)
        self.bn2 = nn.BatchNorm2d(channels)

    def forward(self, x):
        residual = x
        x = torch.relu(self.bn1(self.conv1(x)))
        x = self.bn2(self.conv2(x))
        return torch.relu(x + residual)

class ResNet(nn.Module):
    def __init__(self, num_blocks, channels=64):
        super().__init__()
        self.conv_in = nn.Conv2d(3, channels, 7, padding=3)
        self.blocks = nn.ModuleList(
            [ResidualBlock(channels) for _ in range(num_blocks)]
        )
        self.fc = nn.Linear(channels, 10)

    def forward(self, x):
        x = self.conv_in(x)
        for block in self.blocks:
            x = block(x)
        x = x.mean(dim=[2, 3])  # Global average pooling
        return self.fc(x)

model = ResNet(num_blocks=4)
total = sum(p.numel() for p in model.parameters())
print(f"Total parameters: {total}")
# state_dict() flattens the tree: 'blocks.0.conv1.weight', etc.
print(list(model.state_dict().keys())[:4])
```

Hierarchical composition mirrors the hardware memory hierarchy in a systems-relevant way: each submodule's parameters can be loaded independently, enabling placement across devices. When a model is too large for a single GPU, the framework can assign different subtrees of the module hierarchy to different devices, with the tree structure providing natural partition boundaries.

The `state_dict()` method produces an ordered mapping whose dotted keys (for example, `blocks.0.conv1.weight`) encode locations in the module hierarchy. A checkpoint for 7 billion FP16 parameters contains approximately 14 GB of weight payload before metadata or additional state, but the file format and storage path determine how those bytes are serialized. Resuming training needs more than the model's state: optimizers expose their moment buffers and step counts through their own `state_dict()`, and a training checkpoint saves both so that the run continues with the same optimizer state. `load_state_dict()` copies matching parameter and buffer values into an already-constructed module and reports missing or unexpected keys according to its strictness setting; it does not reconstruct the module hierarchy. Cross-framework exchange requires a compatible graph and operator representation in addition to weights.

The hierarchical structure also enables module-level traversal for systematic operations. Methods such as `.named_modules()` iterate the entire tree, supporting bulk transformations such as replacing all BatchNorm layers with GroupNorm or applying Xavier initialization to every Linear layer. These

traversal operations depend on the same tree structure that enables parameter discovery, illustrating how a single design decision propagates benefits across multiple use cases.

None of these three principles is specific to PyTorch. Keras layers, Flax modules, and functional approaches address the same problems of parameter management, state tracking, and composition, and differ in how they prioritize among competing solutions rather than in which problems they solve. Two practical patterns show how the principles become system controls: selective parameter freezing reduces unnecessary gradient work for transfer learning (listing 7.18), and module hooks provide noninvasive inspection (listing 7.19).

Listing 7.18: Parameter Freezing: Setting `requires_grad=False` on a pretrained backbone keeps it fixed while a newly attached head trains, and the optimizer receives only the trainable parameters.

```
import torch
import torch.nn as nn
from torchvision.models import ResNet18_Weights, resnet18

# Freeze all parameters in a pretrained
# model
pretrained_model = resnet18(weights=ResNet18_Weights.DEFAULT)

for param in pretrained_model.parameters():
    param.requires_grad = False

# Replace final layer with trainable parameters
pretrained_model.fc = nn.Linear(512, 10)  # New layer is trainable

# Only fc.parameters() will receive
# gradients during training
optimizer = torch.optim.Adam(
    filter(lambda p: p.requires_grad, pretrained_model.parameters()),
    lr=0.001,
)
```

Module hooks are the inspection counterpart to parameter freezing. They intercept intermediate computations without modifying model code, enabling gradient flow diagnosis and activation monitoring (listing 7.19).

Listing 7.19: Module Hooks: Forward hooks capture activations and backward hooks capture gradients during training without modifying the model's code.

```
import torch
import torch.nn as nn

model = nn.Sequential(nn.Linear(10, 20), nn.ReLU(), nn.Linear(20, 5))

# Forward hook to inspect activations
def forward_hook(module, input, output):
    print(
        f"Layer: {module.__class__.__name__}, "
        f"Output shape: {output.shape}, "
        f"mean={output.mean():.3f}, "
        f"std={output.std():.3f}"
    )

# Backward hook to inspect gradients
def backward_hook(module, grad_input, grad_output):
    print(f"Gradient norm: {grad_output[0].norm():.3f}")

# Register hooks on specific layer
handle_fwd = model[0].register_forward_hook(forward_hook)
handle_bwd = model[0].register_full_backward_hook(backward_hook)

# Execute forward and backward pass
x = torch.randn(32, 10)
y = model(x)
loss = y.sum()
loss.backward()

# Remove hooks when done
handle_fwd.remove()
handle_bwd.remove()
```

Parameter discovery, freezing, and hooks are how the module abstraction turns thousands of tensors, each with its own shape, dtype, device, and lifetime, into one object that an optimizer can update, a serializer can save, and a profiler can inspect. With execution, differentiation, and abstraction each examined on its own, the remaining step is to watch them operate together: a single training step exercises every mechanism of this chapter at once.

7.7 Anatomy of a Training Step

In every iteration of a training loop, millions of floating-point operations, dynamic memory allocations, and hardware kernel launches must complete within a step that lasts anywhere from microseconds to seconds; for the small network below, as the analysis shows, host dispatch takes most of that time. Execution, differentiation, and hardware abstraction operate simultaneously during model training. In listing 7.20, a minimal two-layer multilayer perceptron illustrates this convergence across eight executable statements. Tracing each statement through the runtime stack connects the quantitative principles developed in section 7.3.7 to physical execution.

The network is a two-layer version of the MNIST digit classifier from chapter 5, with 784 inputs, 128 hidden units, and 10 outputs, trained at batch size 32. The example assumes trainable CUDA tensors `W1` and `W2` with shapes `(784, 128)` and `(128, 10)`, matching bias vectors `b1` and `b2`, and an optimizer already constructed over these parameters. The listing shows one iteration after that setup.

Listing 7.20: Training Step Anatomy: One minimal training iteration of a two-layer MLP exercises tensor allocation, kernel dispatch, autograd recording, gradient computation, and parameter updates.

```
# Single training step for a 2-layer MLP
x = torch.randn(32, 784, device="cuda")  # Input batch
y = torch.randint(0, 10, (32,), device="cuda")  # Labels

# Forward pass
optimizer.zero_grad()
h = torch.relu(x @ W1 + b1)  # Hidden layer
logits = h @ W2 + b2  # Output layer
loss = F.cross_entropy(logits, y)

# Backward pass
loss.backward()

# Parameter update
optimizer.step()
```

7.7.1 Forward pass

During the forward pass, executing `h = torch.relu(x @ W1 + b1)` triggers an eager execution sequence:

1. Python dispatch: The Python interpreter invokes `torch.matmul`, which routes through PyTorch's C++ dispatcher to select the CUDA backend, incurring the Python-dispatch share of the per-operation overhead (about 10 µs in this chapter's model) before issuing work to the device.
2. Kernel selection: cuBLAS selects a GEMM kernel configured for dimensions $32 \times 784 \times 128$, partitioning the computation into thread blocks sized to fit the streaming multiprocessor shared memory and L2 cache tiles.
3. Kernel launch: The host thread enqueues the launch descriptor into the GPU command stream, consuming driver launch latency while asynchronous execution allows host execution to proceed without blocking on completion.
4. GPU execution: The streaming multiprocessors stream `W1` from HBM[24] through L2 cache into registers and the FP32 arithmetic units (Tensor Cores engage only when TF32 or a 16-bit data type is enabled), evaluate the matrix product, and write the output activations back to HBM.
5. Autograd recording: Concurrently on the host, PyTorch's autograd engine instantiates an `MmBackward` node on the dynamic tape, saving references to the device tensors needed for the requested gradients. Here the weight gradient requires `x`; no input gradient is requested.

The subsequent bias addition (`+ b1`) and activation (`torch.relu`) follow an identical eager path, with each operation dispatching a separate kernel, executing round-trips to HBM, and appending a node to the tape. By the time the forward pass reaches the loss function, the autograd graph holds a complete chain of backward functions and saved activation pointers ready for reverse traversal.

7.7.2 Backward pass

Calling `loss.backward()` executes reverse-mode automatic differentiation in four stages:

1. Tape traversal: The autograd engine traverses the recorded computational graph in reverse topological order, starting from the scalar loss node.
2. Gradient computation: The engine executes the backward kernel registered to each node. Traversing backward, `CrossEntropyBackward` evaluates $\frac{\partial \mathcal{L}}{\partial \text{logits}}$ using the combined softmax-cross-entropy derivative; `MmBackward` for $\mathbf{W}_2$ computes $\frac{\partial \mathcal{L}}{\partial \mathbf{W}_2} = \mathbf{H}^T \cdot \frac{\partial \mathcal{L}}{\partial \text{logits}}$ and $\frac{\partial \mathcal{L}}{\partial \mathbf{H}}$, where $\mathbf{H}$ is the batch of hidden activations (`h`); `ReluBackward` evaluates the activation mask, zeroing gradients where forward activations satisfy $\mathbf{H} \leq 0$; and `MmBackward` for $\mathbf{W}_1$ computes $\frac{\partial \mathcal{L}}{\partial \mathbf{W}_1} = \mathbf{X}^T \cdot \frac{\partial \mathcal{L}}{\partial \mathbf{Z}_1}$, where $\mathbf{Z}_1 = \mathbf{X}\mathbf{W}_1 + \mathbf{b}_1$ is the pre-activation. Because the input batch $\mathbf{X}$ (`x`) does not set `requires_grad=True`, traversal terminates without evaluating $\frac{\partial \mathcal{L}}{\partial \mathbf{X}}$.

[24] **HBM (high bandwidth memory)**: Provides 3.35 TB/s on the H100, making it the memory tier that most directly feeds accelerator arithmetic; HBM bandwidth determines whether operations are memory bound or compute bound, and its 80 GB capacity sets the hard ceiling on total live training state. Weights, activations, gradients, optimizer state, and temporary workspace must fit during execution. When they do not, the framework must resort to offloading, selective recomputation, or placement across devices, each adding complexity to what the programmer perceives as a single `loss.backward()` call.

3. Gradient accumulation: Computed parameter gradients accumulate in-place into the `.grad` fields of leaf tensors ($\mathbf{W}_1$, $\mathbf{b}_1$, $\mathbf{W}_2$, $\mathbf{b}_2$).
4. Saved-state release: As each backward node completes, the framework releases the saved tensor references that it no longer needs. Storage becomes reusable only when no other live reference retains it; in this listing, Python variables such as `h` can keep tensors alive after backward. The caching allocator can reuse released regions for subsequent operations without returning them immediately to the device.

After backward fills the parameter `.grad` buffers, `optimizer.step()` reads those gradients, updates the parameters, and advances any optimizer state. Backward itself computes gradients without applying that update, and the optimizer state the update reads is part of training memory, not of the backward pass.

7.7.3 Memory traffic

The operation counts below follow the products required by the backward traversal above. The count excludes input generation, bias additions and reductions, optimizer updates, and allocator bookkeeping. Within that boundary, each matrix multiplication reads two operands and writes one result. Counting these buffers and the corresponding arithmetic connects the graph to an execution-time estimate; loss and activation kernels receive the simpler operation-equivalent models stated below.

The traffic model assumes FP32 values occupying 4 bytes each. For `x @ W1`, it counts one read of the input matrix with shape `(32, 784)`, one read of the weight matrix with shape `(784, 128)`, and one write of the result with shape `(32, 128)`. Multiplying each shape's dimensions, summing the three element counts, and multiplying by the element width gives the table's 0.52 MB. The second matrix multiplication uses the same operand rule with its own shapes.

ReLU instead reads and writes each element of its `(32, 128)` tensor once, so its modeled traffic is twice that tensor's element count times 4 bytes, yielding 32.8 KB. These counts describe the modeled operator-buffer boundary. They assume full operand reuse within each matrix multiplication and exclude extra layout copies, workspace, and repeated tile loads; cached operands can also reduce actual HBM reads. Saving a reference for backward does not itself copy a tensor. A physical layout conversion, when required, adds its own read and write traffic to these counts.

The backward products use the same read/read/write rule. The weight gradient `h.T @ dlogits` multiplies `(128, 32)` by `(32, 10)`; the hidden gradient `dlogits @ W2.T` multiplies `(32, 10)` by `(10, 128)`; and `x.T @ dz1` multiplies `(784, 32)` by `(32, 128)`. The first two each cost as much arithmetic as the second forward GEMM, while the third matches the first forward GEMM. No `(32, 128)` by `(128, 784)` product is needed because the raw input requests no gradient. The total dense matrix work is therefore 2.013× the forward dense work. This applies the input-gradient exception derived in section 5.4.5.4 to this two-layer network.

The forward cross-entropy model assigns one operation-equivalent each to exponentiation, accumulation, and normalization per logit, and counts the logit read and saved-score write. For the nonlinear backward work, the ReLU model reads the saved activation and upstream gradient and writes a masked gradient. The simplified combined cross-entropy model reads saved probabilities and integer labels, then subtracts the target and scales by the batch mean to write the logit gradient. Actual loss implementations may split these operations across kernels. The resulting estimates, collected in table 7.9, make the arithmetic-intensity comparison reproducible without substituting for a measured memory-traffic profile.

Table 7.9: Per-Operation Roofline Analysis: Analytical work and buffer-traffic estimates separate the two-layer MLP's matrix multiplications from its low-intensity elementwise and loss operations. Each GEMM counts two operand reads and one result write; backward includes only the requested gradients. Cross-entropy and pointwise derivative work use the simplified models stated in the text. These are operator-level estimates rather than measured device instruction or HBM-transaction counts.

Component	Modeled Work	Memory Traffic	Arithmetic Intensity
MatMul (x @ W1)	$2 \times 32 \times 784 \times 128 = 6.42$ MFLOP	0.52 MB	12.4 FLOP/byte
ReLU	$32 \times 128 = 4.1$ KFLOP	32.8 KB	0.125 FLOP/byte

Component	Modeled Work	Memory Traffic	Arithmetic Intensity
MatMul (h @ W2)	$2 \times 32 \times 128 \times 10 = 81.9$ KFLOP	22.8 KB	3.6 FLOP/byte
Cross-entropy (simplified)	~0.96 KFLOP	2.6 KB	0.375 FLOP/byte
Backward `dW2`	81.9 KFLOP	22.8 KB	3.6 FLOP/byte
Backward `dh`	81.9 KFLOP	22.8 KB	3.6 FLOP/byte
Backward `dW1`	6.42 MFLOP	0.52 MB	12.4 FLOP/byte
Backward nonlinear (simplified)	4.7 KFLOP	52.0 KB	0.091 FLOP/byte

The arithmetic-intensity column helps predict each layer's regime when compared with the target machine's compute-to-bandwidth ratio. Matrix multiplications reuse operands far more than element-wise operations, but their shapes still determine whether they reach the compute roofline. Conversely, the forward ReLU and cross-entropy estimates perform negligible compute per byte transferred (0.125 FLOP/byte and 0.375 FLOP/byte), making them sensitive to memory bandwidth and, at small sizes, launch latency. In un-fused eager execution, each element-wise operation incurs a separate kernel dispatch and writes intermediate tensors to global-memory buffers between kernels; actual HBM traffic depends on caching.

The analytical model yields ~13.1 MFLOP of arithmetic work and ~1.2 MB of memory traffic for the operations included in the table. Dividing these quantities by peak H100 hardware rates determines the idealized lower bounds:

- $T_{\text{compute}} \approx 13.1$ MFLOP/67 TFLOP/s FP32 ≈ 0.2 µs
- $T_{\text{memory}} \approx 1.2$ MB/3.35 TB/s ≈ 0.4 µs
- Under a one-kernel-per-modeled-operator assumption, the 4 selected forward operators and 5 backward operators require 9 driver launches. Python enters each forward operation and calls `backward()` once, giving 5 entries. The illustrative host cost is therefore 5×10 µs plus 9×5 µs, or 95 µs.
- The excluded optimizer step is not small. An FP32 Adam update reads each parameter, its gradient, and two moments and writes three of them, 28 bytes per parameter, so the 101,770 parameters of this network move about 2.85 MB, more than the whole modeled forward and backward traffic. Counting its launches and the omitted Python calls only raises the host cost above this lower bound.

This dispatch model excludes autograd traversal overhead, allocation, and the operations omitted from the table. The backward engine launches its internal kernels without a separate Python call for each one; a profile must establish the actual launch count, particularly for loss kernels. Host costs are added without overlap here. In this model, T_{sw} exceeds the ideal lower bounds T_{compute} and T_{memory} by more than an order of magnitude, so the overhead ratio of equation 7.4 sits far above 1 and the step is overhead-bound under these assumptions. This is the small multilayer perceptron (MLP) regime of notebook 7.2, now reached from a real training loop. Profiling has a specific job here, which is to confirm that measured kernel times, achieved bandwidth, and host-device overlap match the model before acting on it. When dispatch dominates, three mechanisms attack the launch overhead from different angles: kernel fusion via `torch.compile` merges consecutive memory-bound operations into a single kernel to avoid intermediate round-trips to HBM and collapse launch boundaries; batch size scaling grows the arithmetic payload linearly while keeping dispatch overhead constant to amortize fixed launch latency across more compute work; and graph capture removes repeated Python work in captured regions while allowing CUDA Graph replay to submit a captured launch sequence with less host overhead, without requiring the entire step to become one fused kernel.

7.7.4 Dispatch to hardware

The tensor operations in this training step map to heterogeneous hardware architectures through backend abstraction layers, as table 7.10 summarizes. The displayed script uses CUDA; another target requires matching device placement and a supported backend execution path. Each backend maps common tensor semantics to silicon-specific primitives, so a single `loss.backward()` invocation

routes to different execution pipelines depending on device placement. Because differences in floating-point summation order, reduction trees, and non-deterministic atomic operations introduce numerical variation across backends, equivalence must be validated against explicit numerical tolerances rather than bitwise identity.

Table 7.10: Hardware Backends Behind a Single Code Path: Each backend implements the same tensor operations through a different library and execution mechanism, so identical Python maps onto distinct silicon.

Hardware	Backend library	Execution mechanism
CUDA GPU	cuBLAS (NVIDIA 2024a; Choquette et al. 2021)	GEMM kernels and CUDA streams for async execution
CPU	Intel oneMKL or OpenBLAS (Intel Corporation 2026a; OpenBLAS Project 2026)	Thread-level parallelism around optimized kernels
TPU	XLA (Google 2025)	Compilation to TPU-specific HLO operations
Apple Silicon	Metal Performance Shaders	MPS backend

Implementation decisions such as device placement, batch size, and compilation mode cascade through execution, differentiation, and abstraction layers simultaneously. Treating the framework as an opaque mathematical interpreter rather than a hardware-aware scheduler hides these interactions until they surface as an idle accelerator or an out-of-memory failure.

Systems Perspective 7.2: The three problems in action

In D·A·M terms, the single training step exposes how the framework balances algorithm and machine:

- Execution: Eager mode preserves imperative line-by-line debugging at the cost of per-kernel launch and dispatch latency.
- Differentiation: Reverse-mode automatic differentiation retains intermediate forward activations in HBM to compute exact vector-Jacobian products in reverse topological order.
- Abstraction: Unified tensor APIs decouple model code from heterogeneous silicon, dispatching identical operations to cuBLAS, oneMKL, or XLA-compiled HLO programs.

Resolving the friction among these dimensions requires matching operator granularity to hardware rooflines: fusing operations to eliminate memory round-trips, scaling batches to amortize launch latency, and structuring tensors to saturate accelerator execution pipelines.

The step's costs reduce to a handful of counting rules derived earlier in the chapter and collected in the chapter summary, so a training or inference step can be estimated on paper before it is profiled: count dispatched operations and compare their overhead with device time, count the passes an unfused elementwise chain makes over memory, check whether a compiled artifact will run often enough to repay its compilation, size the activations that backward must keep, and time every host-to-device copy. Applied to the two-layer MLP, the dispatch rule gives the overhead-bound verdict reached above, the elementwise-traffic rule explains why fusing its bias and ReLU kernels removes a round trip, and the saved-activation rule bounds what activation checkpointing could save. Every one of these costs exists whichever framework runs the step; frameworks differ in which of them they make easy to see and to reduce. TensorFlow, PyTorch, and JAX each answer the three framework problems in a different way.

7.8 Major Frameworks: TensorFlow, PyTorch, and JAX

A team that prototypes quickly but cannot deploy the resulting model, or deploys reliably but cannot debug training failures, has run into a framework design trade-off rather than a missing API

call. Each major framework solves all three core problems but emphasizes a different path through them. TensorFlow couples eager development to graph capture and a broad deployment ecosystem; PyTorch begins with eager execution and adds capture, compilation, and export paths; JAX organizes differentiation, vectorization, and compilation as composable function transformations. These are architectural emphases, not exclusive capabilities, and their value depends on the workload and deployment target.

7.8.1 TensorFlow

TensorFlow's architecture spans eager development and graph-based optimization across hardware from cloud TPUs to microcontrollers. TensorFlow 2 executes eagerly by default. Performance-sensitive functions can be captured with `tf.function`, and deployment formats route captured computation to server, mobile, and browser runtimes. This dual path preserves the production graph capabilities inherited from TensorFlow 1.x without requiring every TensorFlow 2 program to build a complete graph before it runs.

Within a captured `tf.function`, TensorFlow can apply graph optimizations such as constant folding, kernel fusion, and layout planning. The SavedModel serialization format is the boundary that separates training from deployment (figure 7.13). Training workflows on the left, including `tf.data` preprocessing, the Keras modeling API, and distribution strategies across CPUs, GPUs, and TPUs, serialize into one SavedModel artifact. From this central interface, graph definitions pass through supported serving or target-specific conversion paths into deployment runtimes on the right (TensorFlow Serving, TensorFlow Lite, TensorFlow.js, and native language bindings) without retaining Python runtime dependencies.

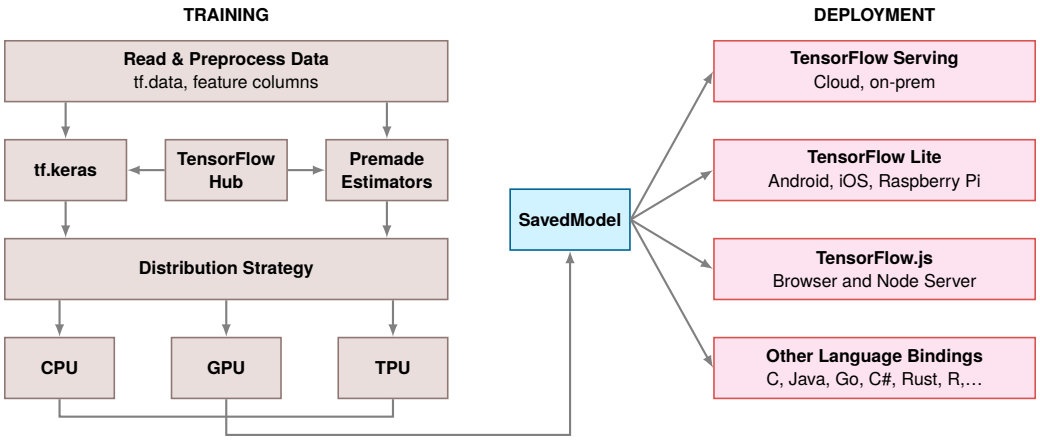

Figure 7.13: TensorFlow Training-to-Deployment Pipeline: The SavedModel format provides a boundary between training and deployment by capturing graph structure, weights, and signatures. The right-hand paths include direct serving and target-specific conversion for Lite and JavaScript runtimes. Supported operators and conversion determine whether each path can run without Python in production.

TensorFlow's answer to the execution problem is therefore two-sided: eager by default for development, with `tf.function` as the graph-conversion path for performance-sensitive code (TensorFlow Developers 2024a). Its strength is the compiled path from a captured graph to many deployment runtimes.

7.8.2 PyTorch

Where TensorFlow's design centers the path from captured graph to deployment runtime, PyTorch centers *developer experience*. PyTorch was built from the start on dynamic graphs (or "Define-by-Run"). Instead of building a graph before execution, PyTorch builds the computational graph as the code runs, because researchers need immediate feedback when experimenting with novel architectures and a define-then-run cycle slows that loop. Python loops, conditionals, and debuggers work directly inside a model's forward pass, with no special syntax and no separate compilation step, which matters most while architectures and training objectives are still changing.

PyTorch's answer to the differentiation problem is tape-based autograd (section 7.4.3.1): flexible and debuggable, but harder to optimize globally because the tape is rebuilt each iteration. Its answer to the abstraction problem is more pragmatic than comprehensive: strong GPU support through cuBLAS and cuDNN, with deployment paths including `torch.export`, edge-targeted ExecuTorch, ONNX, and specialized runtimes.

The trade-off is therefore a more fragmented deployment path. Because the graph is dynamic, the framework cannot easily perform global optimizations before execution. A model that works perfectly in development may hit performance walls in production when dispatch overhead dominates small operations. To bridge this research-to-production gap, PyTorch added graph-capture and compilation paths (`torch.compile` and export workflows) that capture a dynamic model and turn it into an optimized representation for deployment. This evolution shows how an eager framework can move toward the production end of the compilation continuum while preserving the interactive experience that motivated the design.

7.8.3 JAX

PyTorch's eager execution and TensorFlow's graph compilation represent two points on a spectrum, yet both share an imperative programming heritage where computation proceeds as a sequence of stateful operations. JAX takes a different user-facing approach, built on functional programming principles and composable program transformations rather than object-level tapes or user-authored graph APIs (Bradbury et al. 2018). Developed at Google, JAX is especially useful for work requiring custom differentiation, advanced optimization research, and large-scale distributed training.

JAX's architecture treats differentiation, vectorization, and compilation as transformations on functions. The `jax.grad` function returns a function that computes gradients, which can then be transformed again when the interfaces are compatible. For example, `vmap(grad(f))` can compute per-example gradients and `jit(vmap(grad(f)))` can compile that batched computation. Transformation order is semantically meaningful rather than arbitrary.

The programming model shifts from tracking state through objects to transforming pure functions. Where PyTorch and TensorFlow expose autograd through dynamic tapes or graph-compilation paths, JAX asks users to write pure Python functions, and automatic differentiation, vectorization, and JIT compilation all become *program transformations* that compose (listing 7.21).

Listing 7.21: JAX Function Transformations: Wrapping an ordinary loss function in `grad`, then `vmap`, then `jit` yields per-example gradients compiled through XLA.

```
import jax
import jax.numpy as jnp

def loss_fn(params, x, y):
    pred = jnp.dot(x, params["w"]) + params["b"]
    return jnp.mean((pred - y) ** 2)

# Transform: compute gradients
grad_fn = jax.grad(loss_fn)

# Transform: vectorize over batch dimension
batched_grad = jax.vmap(grad_fn, in_axes=(None, 0, 0))

# Transform: compile to XLA
fast_batched_grad = jax.jit(batched_grad)

# Compose all three: fast, batched gradient computation
```

This functional approach requires **pure functions** (no side effects) and **immutable data** (arrays cannot be modified in place). These constraints are stricter than PyTorch's mutable object model, and they are what make the transformations safe. Because function outputs depend only on in-

puts, the compiler can reorder, fuse, and parallelize operations without changing results, and one transformation can be applied to the output of another.

Each transformation does one job. `jax.grad` returns a gradient function; `jax.vmap` can vectorize a compatible function over mapped axes; and `jax.jit` can trace and compile a stable transformed function for a particular argument signature. Unlike an iterative Python loop that issues individual operations sequentially with repeated dispatch overhead, `jax.vmap` pushes the batch dimension directly into the underlying primitives, allowing compatible per-sample matrix-vector operations to become batched matrix-matrix multiplications (GEMM). The compiled program can contain multiple kernels and library calls. Across devices, JAX shards arrays over a device `Mesh` and compiles with `jax.jit`, or maps explicitly with `jax.shard_map` (the successor to the older `jax.pmap`); gradient aggregation is expressed with collectives such as `lax.psum` or `lax.pmean`. These transformations compose according to their types and semantics, and different orders can compute different quantities.

The same minimalist core delegates neural network abstractions to companion libraries (Flax and Equinox) and optimization to Optax. This separation reflects the functional philosophy: the core provides transformations, while libraries build conventional abstractions on top. The trade-off is that production readiness depends on both the transformation model and the maturity of the surrounding libraries, export paths, and operational tooling for the target environment.

The functional constraints pay off where gradient computation is itself the object of study. Custom differentiation, including higher-order gradients and custom vector-Jacobian product (VJP) and Jacobian-vector product (JVP) rules, composes cleanly because pure functions make differentiation rules predictable, which serves optimization research and scientific computing with AD. Compilation-heavy accelerator workloads gain utilization from XLA when the program fits the functional style. In exchange, JAX demands more upfront investment than PyTorch, with explicit state management, a learning curve for the functional paradigm, and compiled code that is harder to debug than eager execution. It fits teams whose requirements match these strengths rather than serving as a default.

7.8.4 Design trade-offs compared

The preceding sections described each framework's design philosophy in qualitative terms: graph-first vs. eager-first, stateful vs. functional. The useful comparison is not which framework is fastest in the abstract, because that answer changes with model shape, batch size, hardware backend, and compiler configuration. The useful comparison is what each design lets the system see and optimize. Table 7.11 therefore maps TensorFlow, PyTorch, and JAX back to the three framework problems: execution visibility, differentiation model, and hardware abstraction path.

Table 7.11: Framework Design Trade-Offs: Each column reflects a distinct answer to the three core problems. TensorFlow makes deployment and graph capture central, PyTorch makes eager execution and debugging central, and JAX makes functional transformation and compiler visibility central. The table is a diagnostic map, not a benchmark ranking.

Aspect	TensorFlow	PyTorch	JAX
Graph Type	Static roots, dynamic front end in 2.x	Dynamic	Functional transformations
Programming Model	Imperative front end, graph capture path	Imperative	Functional
Core Data Structure	Tensor with framework-managed state	Tensor with framework-managed state	Immutable array
Execution Mode	Eager by default, graph for optimization	Eager by default	Trace and just-in-time compilation
Automatic Differentiation	Reverse mode over captured computation	Reverse mode over an eager tape	Forward and reverse transformations
Hardware Abstraction	Broad deployment runtimes and XLA paths	Native GPU path plus export/compile runtimes	XLA-centered accelerator compilation
Optimization Risk	Graph capture and operator coverage	Graph breaks after eager development	Purity, shape stability, and tracing

The comparison therefore tells an engineer which constraint to profile first. In PyTorch, check whether eager dispatch or graph breaks dominate. In TensorFlow, check whether the captured graph covers the operators and deployment target. In JAX, check whether shapes and purity let XLA compile the program actually executed. A framework-level comparison or leaderboard can orient a decision, but it cannot replace profiling the specific workload on the target hardware.

The same simple network exposes how each design philosophy shapes the code. Listing 7.22 implements one neural network, a single linear layer mapping ten inputs to one output, across all three frameworks.

Listing 7.22: Hello World in Three Frameworks: One single-layer network is written three ways, in PyTorch (object-oriented), TensorFlow/Keras (declarative), and JAX (functional).

```
# PyTorch - Dynamic, Pythonic
import torch.nn as nn

class SimpleNet(nn.Module):
    def __init__(self):
        super().__init__()
        self.fc = nn.Linear(10, 1)

    def forward(self, x):
        return self.fc(x)

# TensorFlow/Keras - High-level API
import tensorflow as tf

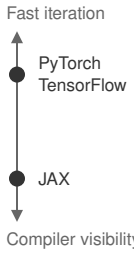
model = tf.keras.Sequential(
    [tf.keras.layers.Dense(1, input_shape=(10,))]
)

# JAX - Functional approach
import jax.numpy as jnp
from jax import random

def simple_net(params, x):
    return jnp.dot(x, params["w"]) + params["b"]

key = random.PRNGKey(0)
key_w, key_b = random.split(key)
params = {
    "w": random.normal(key_w, (10, 1)),
    "b": random.normal(key_b, (1,)),
}
```

These three implementations solve the same mathematical problem, yet each reveals where its framework keeps state and when its computation graph comes into existence. PyTorch binds state and computation together through class inheritance (`nn.Module`) and evaluates eagerly, building the graph as Python runs so that standard debuggers and control flow work naturally, at the cost of hiding the full computation from an optimizer unless a graph-capture pass is invoked. TensorFlow and Keras also execute eagerly by default in TensorFlow 2, whereas structured models can be captured with `tf.function` and exported to supported deployment runtimes whenever operator coverage and target conversion allow. By contrast, JAX treats the model as a pure function[25] over immutable arrays with no internal object state, turning `grad`, `vmap` (automatic vectorization), and `jit` (just-in-time compilation[26]) into composable transformations on stateless functions in exchange for explicit parameter passing.



No framework maximizes all three goals simultaneously, and the ten-line program makes the trade visible in source code rather than buried in compiler internals: where state lives, when the

[25] **Pure function**: Returns outputs determined by its inputs without relying on untracked side effects; JAX transformations are designed for pure functions. Ordinary Python effects may run during tracing but are not represented in the compiled computation, and impure code can fail or behave unexpectedly. Runtime printing or external effects require supported mechanisms such as `jax.debug.print` or callbacks; random draws require explicitly managed keys.

[26] **Just-in-time (JIT) compilation**: Traces a function for an argument signature and lowers it to backend-specific executable code; the first call pays tracing and compilation costs; compatible later calls can reuse the cached executable. New shapes, dtypes, devices, or static arguments may trigger another compilation. Both compilation time and cached-call overhead depend on the program, backend, and hardware.

graph exists, and what the compiler is allowed to see. Each design trades what the compiler can see against how quickly a person can iterate. Graph capture and ahead-of-time compilation can reduce runtime overhead and intermediate data movement; eager evaluation shortens the human iteration loop, outside the iron-law runtime equation, at the cost of compiler visibility until a graph-capture path is used; functional purity gives XLA more freedom to transform a stable traced program. Each philosophy also shapes code syntax, team workflows, debugging practices, and deployment pipelines, so migration costs grow with project-specific integrations and assumptions.

7.9 Choosing a Framework

Eager defaults favor iteration; JAX's traced functions favor the compiler.

Those differences in where state lives and what the compiler sees become concrete obligations once a team commits to one framework for a project that must ship to a particular device. Framework selection decides which framework a team develops in, given the model it must express, the team that must maintain it, and the targets it must eventually run on. Development framework and deployment runtime need not be the same system: a model can be developed in PyTorch or TensorFlow and exported to a compact runtime for the device. The choice of that inference runtime is a serving decision, developed in section 13.6. The development framework still has to reach it, so the deployment target acts as a filter on which frameworks are viable.

Suppose a team deploys a fixed-shape vision model to a CPU-only embedded Linux device, with a 20 ms p99 (99th-percentile, section 12.6.2.1) inference-latency target under a specified load and a 256 MB model-and-runtime memory budget. Assume target-device trials with matching inputs, batch size, precision, and numerical tolerances establish two viable paths: PyTorch development with ONNX Runtime has 18 ms p99 latency and 140 MB peak memory use, while TensorFlow development with TensorFlow Lite has 15 ms p99 latency and 90 MB peak memory use. A path that depends on a GPU-only runtime fails the hardware filter even if its latency elsewhere is lower. These are hypothetical project measurements, not general performance rankings. The selection must now distinguish a feasible path from a worthwhile migration.

The embedded project has already fixed the deployment target, but it leaves two choices open: which development environment the team can maintain and which compatible export path meets its budget. Eager development and compiled deployment can coexist along either path, so the team need not trade away its debugging workflow to obtain a compact inference runtime.

> **Systems Perspective 7.3: Framework selection constraints**
>
> Rather than seeking the "best" framework, effective selection first eliminates candidates that cannot satisfy hard constraints: deployment target, required operations, compiler path, and team expertise. Only then should soft preferences such as performance, development speed, and ecosystem rank the survivors.

7.9.1 Framework selection criteria

The two hypothetical measurements establish latency and memory feasibility only for the tested model and inputs. A defensible choice also checks operator semantics, software dependencies, and hardware coverage. The three TensorFlow variants in table 7.12 make those filters visible within one ecosystem; the same questions apply to the PyTorch-to-ONNX path.

Table 7.12: TensorFlow Variants Across Deployment Tiers: The rows group what each variant can express (first four), what it requires of the platform (middle three), and what hardware and footprint it targets (last three). Training capability disappears across the tiers while inference and lower-precision tooling survive, which leaves operator coverage as the discriminating capability: broad in TensorFlow, inference-focused in TensorFlow Lite, and reduced to the operators one model selects in TensorFlow Lite Micro. Binary size and memory footprint depend on the build, selected operators, delegates, model, and runtime configuration rather than on the variant alone.

	TensorFlow	**TensorFlow Lite**	**TensorFlow Lite for Microcontrollers**
Training	Yes	Limited	No
Inference	Yes	Yes	Yes

	TensorFlow	**TensorFlow Lite**	**TensorFlow Lite for Microcontrollers**
Operator Coverage	Broad	Inference-focused	Model-selected subset
Native Lower-Precision Tooling	Yes	Yes	Yes
Needs an OS	Yes	Yes	No
Model Access	Filesystem or service	Platform-specific storage mapping	Platform-specific compiled or mapped storage
Accelerator Support	Yes	Delegates	Optimized kernels and integrations
Base Binary Size	Build- and package-dependent	Build- and delegate-dependent	Model- and operator-selection-dependent
Base Memory Footprint	Model-, runtime-, and allocator-dependent	Model-, delegate-, and allocator-dependent	Fixed arena plus runtime state
Optimized Architectures	x86, TPUs, GPUs	Arm Cortex-A, x86	Arm Cortex-M, DSPs, MCUs

7.9.1.1 Model requirements

For the fixed-shape vision model, the first filter is successful conversion of every required operation with acceptable numerical results. Training support is needed in the development framework but not in the deployed runtime. TensorFlow, TensorFlow Lite, and TensorFlow Lite Micro expose different operator and training capabilities. A missing inference operator, by contrast, can invalidate the deployment path even when the rest of the graph fits, which is why operator coverage is the discriminating row among the capabilities in table 7.12.

> Systems Perspective 7.4: Dynamic vs. static computational graphs
>
> The static-vs.-dynamic graph distinction (examined in section 7.3) has direct implications for model requirements analysis. Static graphs require control flow and dynamic behavior to be represented in forms understood by the graph runtime, which enables ahead-of-time optimization for deployment. Eager execution follows ordinary Python control flow directly, while graph-capture paths such as `torch.compile` and `tf.function` recover optimization opportunities when they can represent the executed program.

7.9.1.2 Software dependencies

Embedded Linux supplies operating-system services, so an OS dependency does not eliminate either candidate in this project. A bare-metal microcontroller would impose a different filter. The platform rows of table 7.12 separate that requirement from model access and accelerator integration; availability of a runtime on one tier does not imply availability on another.

The CPU-only project needs a supported CPU implementation of every required operator; it cannot count on a mobile NPU delegate or a server GPU backend. TensorFlow Lite Micro instead links a selected operator set into a small C/C++ application and can read a model FlatBuffer compiled into flash. That design removes the need for a POSIX filesystem or heap allocation during inference, but those savings do not by themselves justify selecting a microcontroller runtime for a Linux device.

7.9.1.3 Hardware constraints

A runtime that supports the operating system still has to fit alongside the model, working buffers, and application. The hardware rows of table 7.12 separate supported processor families from footprint, which depends on the actual build. The project must compare peak memory for the deployed configuration, not the size of its weight file or an empty runtime package.

The supplied trials already include model-and-runtime peak memory, so both candidates pass the project's capacity filter. That conclusion must be revisited when input shapes, selected operators, delegates, or runtime versions change. On a fixed-arena target, the analogous check is whether the planned tensor and scratch buffers fit with the rest of the application.

7.9.1.4 Production-ready evaluation factors

Satisfying model requirements, software dependencies, and hardware constraints establishes technical feasibility; production viability also depends on what the development framework's toolchain supports. If the deployment uses reduced precision, the framework must support the chosen path: post-training quantization (PTQ), which converts an already-trained model using a small representative calibration dataset to set value ranges, or quantization-aware training (QAT), which simulates low-precision arithmetic during training to recover accuracy before deployment. Toolchain stability matters as much: whether saved models remain loadable across framework and runtime updates, and whether the framework exposes the profiling hooks needed to confirm that the deployed model still meets its latency target.

↪ Post-training quantization, its calibration, and quantization-aware training are developed in section 10.3.3.

7.9.2 Development support and long-term viability assessment

Once both paths pass the technical filters, the remaining decision concerns the team's ability to maintain them. The project already has PyTorch models and an ONNX export pipeline. Adopting another development stack would add conversion validation, new debugging practices, and another set of runtime dependencies even though both candidates meet the deployment limits.

Custom C++ or CUDA operators, specialized serialization, and vendor compiler passes increase the cost of later migration. Preserving an exit path means isolating framework-specific ingestion and operator code and testing the intended export format throughout development. These commitments belong in the selection decision because the shortest inference time does not account for the work needed to keep the model deployable.

Both surviving paths meet the stated runtime limits. The team already maintains PyTorch models and an ONNX export pipeline, so it selects PyTorch with ONNX Runtime. The measured path satisfies deployment requirements without introducing a second development stack. The faster TensorFlow Lite path remains viable, but its unused latency and memory advantage does not by itself justify migration. The decision depends on retaining that headroom as the model changes. Before committing, the team must check export coverage and numerical tolerances across representative inputs and repeat the latency check under expected contention; a later operator change or tighter latency target can invalidate the choice. The choice follows the project's constraints and maintenance costs; a different team or deployment envelope can favor the other viable path.

The worked selection turned on constraints that no benchmark table records: export coverage, numerical tolerance, the team's existing pipeline, and the cost of a second stack. Engineers who reason from benchmark headlines or general-purpose programming habits fall into predictable traps.

7.10 Fallacies and Pitfalls

Framework selection involves subtle trade-offs where intuitions from conventional software engineering fail. The memory wall, kernel fusion constraints, and deployment target diversity create pitfalls that waste engineering effort and cause production systems to miss latency targets.

Fallacy: *All frameworks provide equivalent performance for the same model architecture.*

Engineers assume that a model performs the same in every framework because the mathematics is the same. The GPT-2 XL decoding step that opened this chapter refutes this: the identical step spends about 8.6 ms on the host when an eager framework issues its 576 kernels one at a time, against a weight read of about 0.9 ms once the launches are captured and replayed. In the hypothetical ResNet-50 scenario of table 7.4, compilation raises throughput by 48.3 percent and a specialized inference engine by 2.6× over eager mode. Fusion depth, graph capture, and backend libraries differ between frameworks, so organizations that assume equivalence can miss latency targets and face late framework migrations.

Pitfall: *Choosing frameworks based on popularity rather than project requirements.*

Engineers assume the most popular framework works for any project. In reality, deployment constraints dominate. A mobile runtime such as ExecuTorch or TensorFlow Lite and a microcontroller runtime such as TensorFlow Lite Micro make different assumptions about memory allocation, operator coverage, and hardware delegates; the former targets phones with GB-scale memory, while

the latter often targets devices with hundreds of KB of RAM, commonly below 256 KB for small TinyML deployments. Teams that prototype edge applications without checking the final runtime can face memory bloat that exceeds device capacity or a late framework migration after development completes. Check the deployment runtime (section 13.6) before selecting a training framework.

Fallacy: *Framework abstractions eliminate the need for systems knowledge.*

Engineers assume high-level APIs handle all optimization automatically. The training step of section 7.7 shows otherwise. Its ReLU has an arithmetic intensity of 0.125 FLOP/byte, about 160× below the H100's FP32 ridge of roughly 20 FLOP/byte, and the whole step spends about 95 µs in host dispatch against well under a microsecond of ideal device time. No API call reveals either fact. Engineers must identify the limiting resource before choosing fusion, batching, layout, or precision optimizations.

Pitfall: *Ignoring vendor lock-in from framework-specific formats.*

Engineers assume framework migration is straightforward since models are "just math." Converting TensorFlow SavedModel to PyTorch can require rewriting custom operations, validating numerical equivalence across large test suites, and retraining when operations lack exact equivalents. The ONNX interchange format (section 13.6) improves portability, but custom operators, dynamic shapes, and backend-specific optimizations can still require manual work. Organizations that ignore this during initial framework selection face costly migrations when deployment requirements change or better frameworks emerge.

Pitfall: *Increasing batch size without modeling activation memory.*

Engineers assume that if memory is available, larger batches always improve throughput. Larger mini-batches amortize fixed dispatch overhead, but they also scale the activation memory that must stay live until the backward pass consumes it. In the illustrative ResNet-50 scenario of section 7.4.3.2, batch 64 already holds 8 GB–12 GB of saved activations. Batch 256 holds 32 GB–48 GB, and batch 512 holds 64 GB–96 GB, which on an 80 GB H100 forces activation checkpointing. Recomputation then adds roughly one extra forward pass per step, which can cost more throughput than the larger batch gained, and materialized attention scores make the effect sharper for transformers because they grow with the square of sequence length. Teams that blindly maximize batch size can achieve lower throughput than smaller batches that avoid recomputation.

↪ How activation memory grows linearly with batch size and caps the batch that fits in accelerator memory is developed in section 8.3.2.1.

Fallacy: *Compilation overhead is negligible.*

Engineers assume compilation overhead is a one-time cost that pays off quickly. The hypothetical values in table 7.4 assign ResNet-50 higher compiled throughput and a compile window of 15 s to 30 s per graph change. Under those assumptions, timed with the table's inference throughputs (a training loop would add backward work but pay the same recompilation cost), a 10,000-image experiment with 10 code changes completes in 6.9 s in eager mode and 304.7 s in compiled mode, including recompilation overhead. The compiled workflow is therefore about 44.2× slower in this illustrative rapid-prototyping scenario. Teams that enable compilation during rapid prototyping can waste time waiting for recompilations that negate throughput gains.

Pitfall: *Using one execution policy for exploration and production.*

The right framework mode depends on the loop. During exploration, eager execution and small tests shorten feedback by avoiding repeated graph captures and recompilations. During production serving or long training runs, compilation can amortize setup across many requests or samples. The deciding factors are workload duration and stability: compilation pays when graph structure and shapes recur, whereas changing control flow or input shapes can invalidate cached artifacts and restart the amortization. In the hypothetical ResNet-50 scenario, one 30 s compilation pays for itself only after about 134,000 images. A prototyping loop that recompiles every few minutes never reaches that point, while a serving system passes it within minutes of steady traffic. One policy for both phases either slows research iteration or leaves production throughput unused.

7.11 Summary

Machine learning frameworks solve three core systems challenges that make deep learning tractable on modern hardware. The first is execution: deciding when and how operations run. Frameworks

balance the trade-off between eager evaluation for interactive debugging and graph execution for whole-program compilation, while modern hybrid approaches such as `torch.compile` capture graphs dynamically without sacrificing the Python control loop. The second is differentiation: computing gradients automatically. Frameworks implement reverse-mode automatic differentiation that applies the chain rule across compositions of operations, constructing an autograd tape or backward graph of vector-Jacobian products while making the required forward values available through retention or recomputation. This primitive makes training large models feasible through a single `loss.backward()` call. The third is abstraction: targeting heterogeneous hardware from a unified interface. Frameworks provide multi-dimensional tensor abstractions, intermediate representations, and runtime dispatch systems that bridge high-level model definitions to optimized device kernels across CPUs, GPUs, TPUs, and custom accelerators.

These challenges are linked through the iron law of ML systems (section 1.7): execution strategy affects dispatch latency (L_{lat}), differentiation adds arithmetic and memory traffic (D_{vol}), and abstraction influences hardware utilization efficiency (η_{hw}). These are diagnostic emphases, not exclusive assignments, since fusion changes both launches and traffic while differentiation changes both work and live storage. Workloads with little reuse are frequently memory-bandwidth bound (D_{vol}/BW). Frameworks mitigate this memory wall through kernel fusion, which merges compatible elementwise operations to keep intermediates in registers or on-chip SRAM instead of round-tripping through global memory. The separate capacity limit yields to selective recomputation, which trades additional floating-point operations (O) for lower peak activation memory.

The counting rules developed across the chapter fit on one page (table 7.13). Together they let an engineer estimate, before profiling, whether a step is bound by dispatch, by memory traffic, or by arithmetic.

Table 7.13: Key Equations: Each counting rule appears in the notation of the section that derives it, so that a step can be estimated before it is profiled. The elementwise rule assumes each of n_{ops} unfused operations reads and writes all N elements of s_{elem} bytes once; the activation rule is written for a transformer layer stack, and an MLP drops the sequence length.

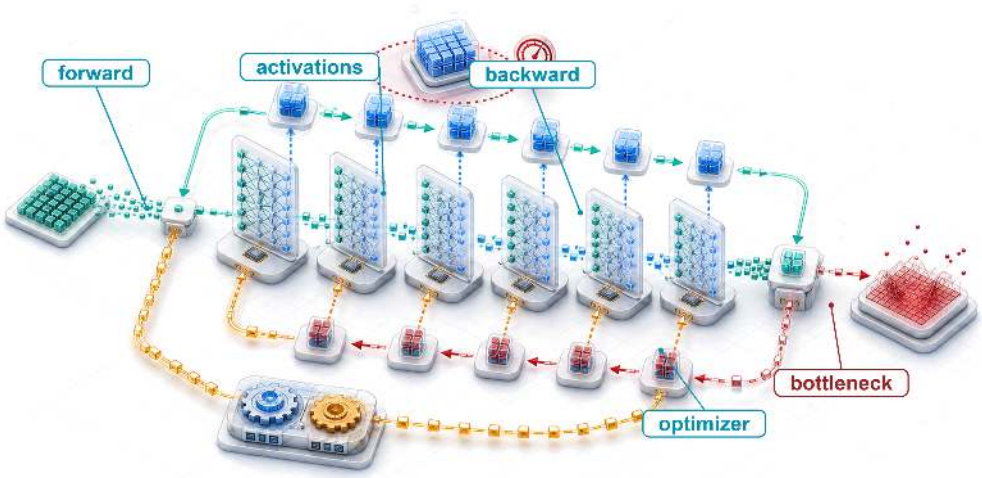
Cost	Formula	Where derived
Dispatch overhead ratio	$\frac{N_{\text{ops}} \cdot t_{\text{dispatch}}}{T_{\text{compute}} + T_{\text{memory}}}$; overhead-bound above 1	equation 7.4
Elementwise chain traffic	$2n_{\text{ops}}Ns_{\text{elem}}$ bytes unfused; $2Ns_{\text{elem}}$ bytes fused	section 7.3.2
Compilation breakeven	$N_{\text{breakeven}} = \frac{T_{\text{compile}}}{T_{\text{eager}} - T_{\text{compiled}}}$ executions	equation 7.3
Saved activation bytes	$M_{\text{activations}} \approx B \times N_L \times S \times d \times n_{\text{saved}} \times s_{\text{elem}}$	section 7.4.2
Host-to-device transfer time	$T = L_{\text{lat}} + D_{\text{vol}}/\text{BW}$	section 7.5.2

Key Takeaways: The layer between math and hardware

- **Every framework solves three problems**: Execution dictates runtime dispatch, differentiation computes gradients, and abstraction targets heterogeneous hardware. TensorFlow, PyTorch, and JAX give different answers on each axis, from graph capture to eager tapes to functional transformations, and those answers fix what a team can debug, compile, and deploy long after the API syntax has changed.
- **The memory wall drives optimization**: Accelerator compute capacity has outpaced memory bandwidth, making off-chip data movement a recurring bottleneck. Kernel fusion and lower-precision formats can reduce the memory traffic term (D_{vol}/BW), while selective recomputation primarily reduces peak activation storage by adding work.
- **Compilation must amortize setup cost**: The compilation continuum principle in equation 7.2 quantifies when runtime speedup offsets compilation overhead. While dynamic workloads favor eager execution, repeatedly executed graphs benefit from JIT or ahead-of-time compilation, where the dispatch overhead law (equation 7.4) demonstrates that small operations gain disproportionately when host launch overhead (L_{lat}) is reduced.

- **Gradients cost memory as well as arithmetic**: Reverse-mode differentiation keeps the forward values that backward rules read, so saved activations grow with batch size and depth and often dominate training memory; activation checkpointing trades recomputation for that storage.
- **Where a tensor lives sets what it costs**: A host-to-device copy runs at a small fraction of on-device bandwidth, so placement, pinned memory, and stream overlap decide whether transfers hide behind computation, while layout and data type decide which kernel runs.
- **Module abstractions automate state management**: Automatic parameter registration, mode flags that propagate from the root, hierarchical serialization, and hooks let one object be updated, saved, switched between training and evaluation, and inspected without per-tensor bookkeeping.
- **A step can be estimated before it is profiled**: The chapter's cost formulas (dispatch overhead ratio, fused traffic, compilation breakeven, saved activations, transfer time) show that a small MLP training step is overhead-bound on a data-center accelerator before any profiler runs.
- **Deployment targets filter the development framework**: A framework is viable only if it can export every required operator to a runtime that fits the target device; among the viable paths, team expertise and migration cost decide.

A framework presents itself as an ergonomic programming interface, yet its true role is translating mathematical graphs into physical hardware operations. That translation determines the work, traffic, and overhead paid under the iron law of ML systems (principle 3). Eager execution prioritizes developer iteration at the cost of host dispatch latency (L_{lat}), while graph compilation trades upfront optimization time to reduce avoidable global memory traffic (D_{vol}/BW) through fused kernels. Automatic differentiation adds backward work and traffic (D_{vol}), with checkpointing trading retained activation storage against recomputed arithmetic (O). What appears to be an API convenience therefore decides, for as long as a project uses it, how much avoidable work and data movement the implementation performs within physical limits that no framework can remove.



What's Next: From one training step to a training run

Frameworks translate architectures into executable kernels, and their computational graphs, autograd tapes, and dispatch pipelines are what let engineers see and control each step of training. This chapter traced a single training step through that machinery. A training run repeats that step many thousands or millions of times, and every budget decision the machinery exposes is still unmade, including which activations to checkpoint when memory runs short, how large a batch the hardware allows, and at what point a single device stops being enough. Chapter 8 makes those decisions. It opens with why training costs orders of magnitude more than inference, then budgets memory, time, and cost for real training runs and shows how far one machine can go before scaling out.

Purpose

Why can training a model cost orders of magnitude more than one inference?

Inference computes a forward pass as data flows through the network and a prediction emerges. Training adds a backward pass and an optimizer step, retains intermediate state, and repeats that work across many examples and optimization steps. Optimizers may also maintain momentum and variance estimates whose storage exceeds the model weights, so memory rather than arithmetic often decides what fits on a device. The ratio depends on the model, workload, training duration, and inference volume, but one training run commonly costs orders of magnitude more than one inference. A lab that trains in three days can explore many more designs than one that takes a month. Over a year, that difference is more than a hundred iterations against about a dozen, and each result informs the next design while the slower lab waits weeks for every answer. A faster step is not faster training if it delays convergence, so throughput matters only relative to time to target quality. Across repeated experiments, even modest changes in convergence or utilization compound into substantial schedule and cost differences. The central systems challenge is to keep accelerators supplied with data and useful arithmetic without exhausting memory or losing time to synchronization. Which intervention helps depends on the binding compute, memory, data, or communication constraint, so profiling must precede scaling or optimization. Batch size, numerical precision, checkpointing, data loading, and parallelism must therefore be treated as coupled decisions rather than independent tuning knobs. For the systems engineer, training is where hardware and parallelism determine whether a run fits within memory, schedule, and budget, and whether the repeated optimization loop accelerates or stalls. In D·A·M terms, each precision and parallelism decision trades the mathematics of optimization against the physics of execution.

Learning Objectives

- Explain training cost asymmetry using forward, backward, optimizer-state, data, and iteration costs
- Calculate FLOPs, run time, energy, activation memory, optimizer state, and dollar cost for full training and fine-tuning
- Compare SGD, Adam, and AdamW by convergence behavior, memory overhead, and compute cost
- Design single-machine training pipelines with prefetching, overlap, batching, and checkpointed training state
- Diagnose compute-, memory-, and data-bound training bottlenecks with profiling evidence and model FLOPs utilization
- Apply mixed precision, FlashAttention, gradient accumulation, and activation checkpointing to fit accelerator memory and throughput limits
- Evaluate single-machine multi-accelerator configurations using memory, duration, communication, energy, and cost constraints, and recognize when a workload exceeds the node boundary

8.1 From One Step to a Training Run

A training run is one training step repeated millions of times, so every byte a step holds and every millisecond it spends is multiplied by the length of the run. Each step reads a batch of examples, computes a forward pass and a loss, propagates gradients backward, and updates every parameter, and the run repeats that sequence until the model reaches its quality target. The anatomy of a training step in section 7.7 traced one such step for a two-layer MNIST classifier, a smaller sibling of the three-layer network of chapter 5: 101,770 parameters, about 19.5 MFLOP per batch of 32 images by the dense-training rule (somewhat less in that chapter's exact trace, which skips the gradient of the raw input), and 1.6 MB of weights, gradients, and optimizer state. One step of GPT-2 XL over 32 sequences of 1,024 tokens costs about 295 TFLOP, roughly 15 million times the classifier's arithmetic, and its weights, gradients, and optimizer state occupy 24 GB before a single activation is stored. The framework mechanisms that made the small step possible leave every decision about the large run open: which intermediate activations to keep when high-bandwidth memory (HBM) runs out, how large a batch the memory permits, how to keep the accelerator supplied with data, and when one accelerator stops being enough. Running a model once and training it from scratch sit at opposite ends of the operational spectrum, and the size of that gap defines the discipline of training systems.

In 2019, training a GPT-2-scale model required approximately $50,000 in compute resources, whereas pretraining a frontier architecture such as GPT-4 reached an estimated $100M.[1] Although neither figure represents an audited financial disclosure, the more than three-order-of-magnitude gulf between them highlights the economic reality of deep learning. This **training cost asymmetry** reflects the gap between running a trained model on a single query and repeating the forward-backward-update loop across an entire corpus.

For GPT-2, a single forward token evaluation consumes roughly 3.00×10^9 floating-point operations, derived from standard transformer architectural accounting (Radford et al. 2019). Pretraining the full model across its WebText corpus required a cumulative budget of 1.50×10^{21} FLOPs, equivalent to approximately 167 billion token evaluations when forward and backward passes are evaluated together.

Definition 8.1: Training systems

Machine learning training systems are software-hardware systems that execute the iterative optimization loop (forward pass, loss computation, backward pass, and parameter update) to minimize a loss function over a training dataset.

[1] **Training cost scaling**: The roughly 2,000× ratio between this chapter's two cost anchors illustrates how parameter counts, training-token budgets, hardware generations, and accelerator fleets can compound; it is not a controlled comparison of disclosed training bills. OpenAI's GPT-2 report documents the model and training setup but does not disclose training cost (Radford et al. 2019). Exact GPT-4 training details were also not disclosed, so the GPT-4-class figure is explicitly an industry estimate supported by public reporting and independent infrastructure analysis (Knight 2023; Patel and Wong 2023).

1. Significance: Training holds far more state per parameter than inference. In the common mixed-precision recipe with the Adaptive Moment Estimation (Adam) optimizer, gradients and optimizer state raise the per-parameter footprint to 8× the FP16 weights an inference server stores, before any activation is counted (section 8.3.2.3 derives the multiplier). This multiplier is a major reason a model that serves on one accelerator needs several for training.
2. Distinction: Unlike inference systems, which execute a single forward pass and discard intermediate activations, standard backpropagation stores the tensors needed by the backward pass, creating a footprint that grows with model depth and batch size.
3. Common pitfall: A frequent misconception is that training failures are compute problems. A common failure is an out-of-memory (OOM) error, a memory-management problem: tensors saved for backpropagation accumulate during the forward pass and can exhaust memory before the first gradient is computed.

Three characteristics distinguish training workloads from general-purpose computing, and each demands a targeted systems intervention. First, computational intensity dominates the schedule: spreading the 1.50×10^{21} FLOPs budget over days of wall-clock time requires sustained PFLOP/s-scale throughput from hardware whose realized large-model throughput is often far below theoretical peak (Narayanan et al. 2021; Chowdhery et al. 2022), pushing the system toward higher arithmetic utilization and lower-precision numeric formats. Second, memory pressure compounds across four state tensors: storing 1.5B weights requires 6 GB in FP32, the Adam optimizer adds two state tensors per parameter that consume another 12 GB, and activation memory adds a workload-dependent footprint governed by architecture, sequence length, batch size, precision, and checkpointing. Because the combined state can exceed a single accelerator's capacity, training systems rely on gradient checkpointing,[2] which trades redundant arithmetic for reduced activation storage, and mixed-precision training,[3] which halves activation storage by casting activations to 16-bit formats while retaining FP32 master weights and optimizer moments for numerical stability.

Third, sequential data dependencies tie each gradient update to the result of the previous one, limiting how much parallelism the system can exploit across steps. Hiding the non-compute work inside each step therefore requires pipeline architectures that overlap I/O and communication with computation so that execution units do not stall waiting for input. The analysis here establishes the execution baseline on single-machine and single-node multi-GPU topologies; scaling across distributed network boundaries introduces multi-node communication fabrics and fault-tolerance protocols treated in advanced distributed systems texts.

8.1.1 Running cases: GPT-2 XL and ResNet-50

GPT-2 is the book's bandwidth-bound lighthouse. Generating one token at a time reads every weight for little arithmetic, so in inference its home regime is the bandwidth-bound one. Training changes that profile. A batch of long sequences reuses each weight across thousands of token positions, so the same model now presses on arithmetic throughput and, through activations and optimizer state, on memory capacity. The chapter uses it to test each training cost and optimization.

Lighthouse 8.1: Lighthouse example: Training GPT-2

Context: GPT-2 (1.5 billion parameters) serves as the primary case study because it is large enough to expose meaningful compute, activation, and optimizer-state constraints while remaining easier to analyze than frontier-scale models. Whether it requires distributed training depends on precision, optimizer state, activation memory, hardware capacity, and the target training time. Table 8.1 maps each model property to the systems constraint it creates:

[2] **Gradient checkpointing (activation checkpointing)**: Backpropagation retains the forward values required by each backward rule. Checkpointing saves selected values and recomputes others during backward, trading additional work for lower activation memory. The $\sqrt{N_L}$ checkpoint placement and its associated recomputation cost describe the classical schedule analyzed by T. Chen et al. (2016) rather than every checkpointing implementation. Section 8.6.5.2 works through that schedule for GPT-2's layer count.

[3] **Mixed-precision training**: Uses lower precision for selected computation and storage while retaining higher precision where accumulation or numerical range requires it. A common FP16 recipe maintains FP32 master weights and uses loss scaling to reduce gradient underflow (Micikevicius et al. 2018). BF16 ("Brain Floating Point," from Google Brain (Wang and Kanwar 2019)) matches FP32's 8-bit exponent range and therefore usually avoids dynamic loss scaling, though the exact state and accumulation precision depend on the optimizer and implementation.

↩ The feeding problem, in which data delivery must keep pace with accelerator consumption, is established in section 4.9.3.

↩ GPT-2's home regime in inference, bandwidth-bound because each generated token rereads every weight, is established in section 2.3.2.

Table 8.1: GPT-2 (1.5 Billion Parameters) Lighthouse Model Specifications: Parameter count, architecture depth, dataset size, and total training compute mapped to their systems implications. Each row pairs a model property with the engineering constraint it creates: memory footprint for weights, activation pressure from pipeline depth, I/O throughput requirements, and parallelization demand.

Property	Specification	Systems Implication
Parameters	1.5B (XL)	Requires ~3 GB (FP16) or ~6 GB (FP32) for weights alone.
Architecture	48 Layers, 1600 Dim	Deep pipeline creates heavy activation memory pressure.
Dataset	WebText (40 GB)	Preprocessing, shuffling, and delivery must sustain the selected training configuration.
Compute	~ 1.50 × 10^{21} FLOPs	Training duration depends on achieved throughput and accelerator count.

Mechanism: In dense transformer models, the arithmetic work per token is directly proportional to parameter count P. In the forward pass, each parameter participates in one multiply-accumulate operation (1 MAC = 2 FLOPs), consuming $2P$ FLOPs/token. Backpropagation computes two matrix products per parameter: one to propagate gradients backward with respect to activations ($2P$ FLOPs), and another to calculate weight gradients for the optimizer ($2P$ FLOPs). The backward pass therefore requires twice the compute of the forward pass ($4P$ FLOPs/token), yielding a total work factor of $2P + 4P = 6P$ FLOPs/token. Across a dataset of D tokens, total training work is $O \approx 6 \cdot P \cdot D$, or 1.50 × 10^{21} FLOPs.

Training GPT-2 couples this operation count with the four-term training-memory budget of equation 5.29, $M_{\text{total}} = M_{\text{weights}} + M_{\text{gradients}} + M_{\text{optimizer}} + M_{\text{activations}}$. Balancing execution time $T_{\text{train}} = \frac{O}{R_{\text{peak}} \times \eta_{\text{hw}}}$ requires orchestrating data ingestion, activation memory, and compute throughput within accelerator HBM capacity.

ResNet-50, the book's compute-bound lighthouse, carries the chapter's input pipeline. Its home regime is compute-bound because a convolution reuses each weight at every spatial position, so one 224×224 image costs about 8.2 GFLOP in the forward pass and about 24.6 GFLOP once the backward pass is added, for only 25.6 million parameters. Training it on a current data-center accelerator moves the binding term upstream. Each image must be read, decoded, and augmented on the host before the accelerator sees it, and the data pipeline (section 8.4.2) shows the accelerator consuming images faster than the host processors can prepare them. The two cases therefore cross regimes in opposite directions. GPT-2 leaves its bandwidth-bound home for arithmetic and memory capacity, while ResNet-50 leaves its compute-bound home for an input-bound one.

Every number in the chapter uses one reference machine, an NVIDIA H100 with 80 GB of HBM delivering 3.35 TB/s and a dense 16-bit arithmetic peak of 989 TFLOP/s. The H100 is a point-in-time instance of the data-center accelerator class whose design chapter 11 develops; its successors change the constants, not the reasoning.

The chapter follows GPT-2 XL's run from estimate to execution (table 8.2). The first half converts the run's operation count into time and energy, accounts for the arithmetic and bytes of one step, and assembles the pipeline that executes it, including the checkpoints that let a long run survive failure. The second half diagnoses a measured step, removes its binding term one technique at a time until GPT-2 XL trains on a single accelerator, and closes with when and how to add accelerators.

Table 8.2: Chapter Map: Each section answers one question about the training run and names the term of the training-time law, or the memory constraint, that its techniques move. Memory does not appear in the law; it decides whether a configuration runs at all.

Section	Question it answers	Law term or constraint it moves	Running case
Training-Time Law	How long, and how much energy, a run takes	All terms of $T_{\text{train}} = O/(R_{\text{peak}} \times \eta_{\text{hw}})$	GPT-2 XL run on one H100
Computation and Memory Costs of Training	What one step costs in FLOPs and in bytes	O per step; the memory constraint	GPT-2 XL step; Llama 3 8B fine-tuning

Section	Question it answers	Law term or constraint it moves	Running case
Pipeline Architecture	How data, compute, updates, and saved state flow through a step	η_{hw} lost between stages	ResNet-50 input feed; GPT-2 XL step
Identifying Bottlenecks	Which stage limits a measured step	η_{hw}, diagnosed	GPT-2 XL profile
Pipeline Optimizations	Which technique removes the binding term	R_{peak} (precision), η_{hw} (overlap, IO), memory (accumulation, checkpointing)	GPT-2 XL on one H100
Scaling Training Systems	When to add accelerators, and what synchronization costs	$R_{peak} \times \eta_{hw}$ across devices, less communication	GPT-2 XL on an eight-H100 node

8.2 Training-Time Law

Every later estimate in the chapter starts from how long the run takes, and the training-time law fixes that first. GPT-2 XL's run needs about 1.50×10^{21} FLOPs. Converting that operation count into days on an accelerator, and every loss of time into a factor engineering can recover, requires a decomposition of training time into its physical constituents in which wasted time appears as a lower utilization factor.

The iron law of ML systems (principle 3) supplies that decomposition directly once specialized to training. In its multiplicative D·A·M form, a training run processes D tokens (Data) at roughly $6P$ forward-and-backward FLOPs per token (Algorithm), for $O = 6 \cdot P \cdot D$ total operations, at a realized machine pace of $1/(R_{peak} \times \eta_{hw})$ seconds per FLOP (Machine). This training-time form of the iron law, which this chapter shortens to the training-time law, keeps that macroscopic product as the organizing equation so that every optimization technique maps to one of its factors.

Definition 8.2: The training-time law

The training-time law expresses training time through the workload's operation count and its effective achieved throughput:

$$T_{train} = \frac{O}{R_{peak} \times \eta_{hw}} \tag{8.1}$$

Here O counts useful model forward-and-backward FLOPs, excluding rematerialization. Additional execution work is reflected in effective throughput. The factor η_{hw} is an effective end-to-end utilization factor, the achieved model-operation rate divided by the relevant hardware peak. Data stalls, communication, synchronization, launch overhead, and inefficient kernels all reduce this factor. Prefetching and overlap can hide part of those costs but do not guarantee their removal.

1. Significance: In the D·A·M taxonomy, these terms map directly to the three multiplicative factors. The numerator $O = (\text{Samples/Task}) \times (\text{FLOPs/Sample})$ is governed by Data (training token count D) and Algorithm (model architecture or compression methods such as pruning and distillation), while the Machine factor $\text{Seconds/FLOP} = 1/(R_{peak} \times \eta_{hw})$ combines hardware execution units at the chosen numerical precision (R_{peak}) with effective systems utilization (η_{hw}, the primary engineering target, where Narayanan et al. (2021) measured 44 to 52 percent of theoretical peak throughput across GPT models trained on A100 clusters). Chapter 10 defines the compression techniques; here they serve only to show where such methods enter the accounting.
2. Distinction: The training-time law (equation 8.1) is the macroscopic D·A·M product form of the iron law, folding every non-arithmetic delay into η_{hw}. When η_{hw} is low, the unpacked three-term iron law exposes data movement (D_{vol}/BW), kernel computation, and fixed latency (L_{lat}) separately to diagnose which underlying bottleneck is responsible.

3. Common pitfall: A frequent misconception is that η_{hw} is fixed by hardware. It is a pipeline property, so diagnosing which factor dominates requires profiling rather than reading hardware specs.

Equation 8.1 reveals three levers for improvement: reduce total operations through data curation or algorithmic innovation, increase peak throughput through hardware selection and precision formats, or improve utilization through pipeline orchestration. Memory does not appear in the law at all. It acts as a feasibility constraint, because a configuration whose state does not fit runs at no speed. The chapter map (table 8.2) shows which section works on which factor, and table 8.8 places each optimization technique against the factor it moves, with its memory effect listed separately.

The training-time law focuses on execution efficiency, how fast the hardware processes a given workload. It does not predict how data quality, dataset size, or curriculum design determines the total operations O needed to reach a target accuracy; that workload must be supplied or estimated separately. A cleaner dataset or a better data mix can reduce the number of epochs required, shrinking O without touching hardware at all. Holding the workload fixed, the question is how to execute it as fast as possible.

↪ Data selection, which shrinks total operations (O) by keeping the examples that return the most learning per unit of compute, is developed in section 9.1.

Actual training throughput remains below the arithmetic peak whenever kernels, data delivery, or communication leave resources idle. Scaling to multiple accelerators introduces additional communication overhead, a trade-off quantified in section 8.7.

For GPT-2 XL on the reference H100, the law becomes a schedule. At the accelerator's 989 TFLOP/s dense 16-bit peak and a utilization η_{hw} of 50 percent, the high end of what large training runs sustain (Narayanan et al. 2021), the run takes about 35 days on one accelerator, about 5.1 million steps of 0.60 s each over 32 sequences of 1,024 tokens. Time converts directly into energy. Energy is power integrated over time, $E_{total} = P_{device} \times T_{train}$ at constant power, so at the H100's 700 W thermal design power the run draws about 590 kWh at the accelerator alone, about 417 J per step. Every technique that shortens the run at constant power removes energy in the same proportion, which is why the utilization factor matters to an energy budget as much as to a schedule.

↩ The iron law's first estimate of a training run, the same operation-count-to-days conversion applied to a GPT-3-class model on an accelerator cluster, is established in section 1.7.

The same conversion scales to runs far larger than GPT-2. A 70B-parameter Llama 2 model trained on 2T tokens across a 1,024-accelerator H100 cluster at the same utilization takes about 19.2 days and $1.89M of rented accelerator time, while buying that cluster costs as much as about 16.3 such runs before networking, facilities, power, and staff are counted (section 15.4.2 develops the full cost model).

Not every training workload is bound by arithmetic. DLRM, the book's capacity-bound lighthouse, holds 100B to 10T parameters, mostly in embedding tables, so its first training problem is fitting those tables in memory at all, whereas dense models such as GPT-2 meet arithmetic and activation-memory limits first.

Checkpoint 8.1: The physics of training

Training speed is governed by the utilization of hardware peaks.

Utilization gap

- ☐ **Peak vs. real**: why does sustained end-to-end utilization remain below the arithmetic peak?
- ☐ **Utilization losses**: which sources of lost time does the definition of η_{hw} fold in, and which of them can overlap hide rather than remove?
- ☐ **Order of magnitude**: a frontier run needs on the order of 10^{23} FLOPs at a utilization η_{hw} well below 1. Estimate which lever shortens wall-clock time more, doubling R_{peak} or doubling η_{hw}, and why, in practice, the two levers differ in cost and reachability even though the training-time law treats them symmetrically.

Each milestone in the history of deep learning moved the binding constraint from one factor of this law to another. Backpropagation, popularized for multilayer networks in 1986 (Rumelhart et al. 1986), made the operation count O of a deep network computable at all. AlexNet's five-to-six-day

ImageNet run on two GPUs in 2012 (Krizhevsky et al. 2012) showed that this arithmetic mapped onto the far higher R_{peak} of graphics hardware. Transformers from 2017 onward (Vaswani et al. 2017) concentrated the work into large dense matrix multiplications with large activation footprints. GPT-3's roughly 3.14×10^{23} FLOPs in 2020 (Brown et al. 2020) made utilization (η_{hw}) the difference between an affordable run and an unaffordable one, and IO-aware kernels such as FlashAttention later raised η_{hw} by attacking attention's memory traffic.

The history follows the bitter lesson. Backpropagation supplied a general recipe, and each later step let that recipe absorb more computation, more parameters, and more data. If capability tracks the computation a general method can absorb, then every point of η_{hw} lost to stalls, and every gigabyte of memory that forces a smaller model or batch, is capability forgone at a fixed budget. The first obligation of a training system is therefore to convert its compute budget into useful operations as completely as the hardware allows.

↩ The bitter lesson, that general methods which absorb more computation outperform encoded human expertise, is established in section 1.4.

The law takes a run's operation count and its achieved rate as given, and both come from the costs of individual operations. Every bottleneck traces back to specific mathematical operations: compute-intensive matrix multiplications governed by peak throughput (Goto and Geijn 2008), low-intensity normalization layers governed by memory bandwidth, and optimizer state tensors that inflate the static memory footprint. Modern accelerators have compute-to-bandwidth ratios (roofline ridge points) that far exceed the arithmetic intensity of many neural network layers, leaving memory-bound kernels starved for operands (Hennessy and Patterson 2017). Software frameworks expose these physical boundaries as configurable switches, such as mixed-precision autocasting contexts or activation checkpointing flags, and each switch must be set against the machine's measured limits rather than tuned blindly. Optimizing a training system therefore begins with what each operation costs in FLOPs and bytes.

8.3 Computation and Memory Costs of Training

In a model such as GPT-2, the tensors participating in a single training step far exceed the 30 to 50 MB of on-chip SRAM available on a modern accelerator, so executing a layer's matrix multiplication $\mathbf{Z} = \mathbf{AW}$ requires staging matrix tiles continuously across two levels of the physical memory hierarchy. Off-chip global device memory (HBM or GDDR) offers large storage capacity (typically 16 to 96 GB) to hold weights, optimizer states, and large activation tensors, whereas on-chip SRAM (registers and shared memory) sits directly on the processor die adjacent to the arithmetic execution units. Because the external memory bus bounds HBM traffic to roughly 1.5–3.5 TB/s while on-chip SRAM delivers roughly 15–20 TB/s across its 30 to 50 MB capacity, performance depends on how much work a kernel performs for every byte it fetches from HBM.

Dense matrix multiplications have high arithmetic intensity, amortizing the cost of moving bytes from HBM into SRAM over many operations and enabling specialized execution units such as Tensor Cores[4] to achieve high compute utilization. In contrast, surrounding elementwise operations (activations, normalizations, and residual additions) have low arithmetic intensity and remain bounded by memory bandwidth, creating opportunities for kernel fusion to eliminate redundant round-trips to HBM. Chapter 5 established *what* neural network operations compute and *why* they enable learning; the systems question is *what* they cost in FLOPs, memory, and bandwidth when those operations execute at scale.

4 | **Tensor Core**: A specialized matrix-multiply-accumulate unit that supports reduced-precision inputs and higher-precision accumulation. Supported tile shapes, alignment constraints, and peak-throughput ratios vary by architecture, dtype, sparsity mode, and library kernel.

Four dimensions structure this cost analysis: the FLOP counts of the matrix operations that dominate dense neural-network training, the optimizer state (the fixed bytes per parameter that every update reads and writes), the activation memory (the batch-dependent bytes that backpropagation must keep), and the arithmetic intensity that classifies each operation as compute-bound or memory-bound against the hardware's ridge point. Together, these four dimensions provide the vocabulary for analyzing the computational intensity, memory pressure, and data dependencies introduced in section 8.1.

8.3.1 Forward and backward computation

Every forward matrix multiplication in a training step must be followed by two backward matrix multiplications (one to propagate error gradients to the preceding layer and one to compute weight gradients) while intermediate activations sit in device memory waiting for their backward consumer. Although each layer applies only a linear transformation and a nonlinear activation, repeating

that forward-and-backward pair across dozens of layers and millions of steps dominates modern training infrastructure. The introduction of backpropagation[5] by Rumelhart et al. (1986) and the development of efficient matrix computation libraries such as Basic Linear Algebra Subprograms (BLAS)[6] (Dongarra et al. 1988) laid the groundwork for modern training architectures.

Forward propagation, in its simplest case, involves two operations: matrix multiplication and activation function application. Matrix multiplication implements the linear transformation at each layer. At layer ℓ, the computation can be written in row-vector form, with one example per row:

$$\mathbf{A}^{(\ell)} = f\left(\mathbf{A}^{(\ell-1)}\mathbf{W}^{(\ell)} + \mathbf{b}^{(\ell)}\right)$$

where:

- $\mathbf{A}^{(\ell-1)}$ represents the activations from the previous layer (or the input layer for the first layer), with each row being a sample in the batch,
- $\mathbf{W}^{(\ell)} \in \mathbb{R}^{n_{\ell-1} \times n_\ell}$ is the weight matrix at layer ℓ, which contains the parameters learned by the network,
- $\mathbf{b}^{(\ell)}$ is the bias vector for layer ℓ,
- $f(\cdot)$ is the activation function applied elementwise (for example, ReLU, sigmoid) to introduce nonlinearity.

8.3.1.1 Matrix operations

Section 5.4.2.2 established that forward propagation reduces to chains of matrix multiplications. Every architecture also shares a small set of building blocks, from dense projections and residual paths to normalization, each with its own cost to the machine. Training amplifies these patterns: each operation executes not once but billions of times, and each forward pass is paired with a backward pass that costs roughly twice the forward pass, tripling the work per step. Understanding which matrix operations dominate, and how their shapes change between forward and backward passes, reveals *why* specific system designs and optimizations emerged for training.

The predominance of matrix multiplication has shaped both linear algebra software and accelerator architecture. Early implementations relied on general-purpose CPU libraries, but modern training scale requires tiled, accelerator-native libraries such as cuBLAS (NVIDIA 2024a) and oneDNN that partition operands to fit cache hierarchies and feed systolic arrays.

This dense computational workload motivates blocked algorithms that parallelize across thousands of execution cores while aligning with the memory access patterns of forward and backward passes. Because backpropagation requires simultaneous access to weight matrices, incoming gradients, and stored activations, hardware architects have prioritized high memory bandwidth alongside raw arithmetic throughput. Evaluating one layer of the GPT-2 lighthouse model illustrates the scale and distribution of these operations.

Napkin Math 8.1: GPT-2 attention layer computation

Each GPT-2 layer performs attention computations that exemplify dense matrix multiplication demands. For one GPT-2 transformer layer (all heads combined) with batch size $B = 32$, sequence length $S = 1024$, and hidden dimension $d = 1600$:

Query, Key, Value Projections (the three linear transformations that create attention inputs, 3 separate matrix multiplications):

$$O_{\text{QKV}} = 2 \times 3 \times (B \times S \times d \times d)$$
$$= 2 \times 3 \times (32 \times 1024 \times 1600 \times 1600) \approx 503 \text{ billion FLOPs}$$

Attention matmuls ($\mathbf{QK}^T$ and the product of the attention probabilities with $\mathbf{V}$):

$$O_{\text{QK}} = 2 \times B \times N_{\text{heads}} \times S \times S \times d_{\text{head}} = 107.4 \text{ billion FLOPs}$$
$$O_{\text{AV}} = O_{\text{QK}}; \quad \text{pair total} \approx 214.8 \text{ billion FLOPs}$$

Output projection (attention output $\rightarrow$ hidden):

$$O_{\text{out}} = 2 \times B \times S \times d \times d \approx 168 \text{ billion FLOPs}$$

[5] **Backpropagation provenance**: The algorithm was independently derived by Linnainmaa (1970) for automatic differentiation of computer programs and by Werbos (1974) in a Harvard PhD thesis on economic modeling, over a decade before Rumelhart et al. (1986) popularized it for neural networks. A framework's backward pass traverses the computational graph in reverse topological order and applies the chain rule; independent subgraphs may expose parallel work during that traversal.

[6] **BLAS (basic linear algebra subprograms)**: The original BLAS specification standardized reusable Fortran-callable vector operations (Lawson et al. 1979); later BLAS extensions added matrix-vector and matrix-matrix routines, giving the familiar Level 1, Level 2, and Level 3 hierarchy (Dongarra et al. 1988). Training is dominated by Level 3 operations precisely because their high arithmetic intensity, $\mathcal{O}(N)$ FLOP/byte, can sustain high compute utilization. Frameworks commonly dispatch dense matrix multiplication to optimized libraries such as cuBLAS and oneDNN or to compiler-generated kernels.

↩ The building blocks every architecture shares, and what each costs the machine, are established in section 6.9.3.

Feed-Forward Network (Two linear transformations with expansion factor 4):

$$O_{\text{FFN}} \approx 16 \times B \times S \times d^2$$

Computation Scale

- Per-layer forward total (QKV 503 + attention 214.8 + output proj 168 + FFN 1,342 billion): ~2,228 GFLOP
- With 48 layers in GPT-2: ~320.8 TFLOP per training step, forward and backward. This exceeds the 295 TFLOP of the six-FLOPs-per-parameter rule used elsewhere in the chapter mostly because it adds the attention score and weighted-sum products, about 31 TFLOP per step, which grow with the square of sequence length and which that rule leaves out; the rule's parameter count also includes embedding weights that this per-layer tally omits
- Across this illustrative 50,000 steps scenario: ~16,042 PFLOP

Systems insight: The reference H100 (989 TFLOP/s dense peak with Tensor Cores, 67 TFLOP/s without) would require 0.32 s for the modeled attention-plus-FFN training step at 100 percent utilization. If the target is a step of about 200 ms, ideal arithmetic alone needs about two accelerators, and at the 30 to 50 percent utilization large runs sustain the requirement grows to 4 to 6 before communication and pipeline overhead are counted.

These FLOP counts are the compute term of the iron law made concrete, and they explain why training cost scales as a predictable function of model architecture and sequence length rather than as an unpredictable emergent property.

8.3.1.2 Matrix-vector and batched operations

Not all neural network layers execute as dense matrix-matrix multiplications. Normalization layers, bias additions, and autoregressive recurrent updates execute matrix-vector operations, which use each loaded weight once and leave a massively parallel accelerator waiting on memory. Batching turns those matrix-vector products (GEMV) into general matrix multiplications (GEMM) that reuse each loaded weight across B examples, the same conversion that raised the running dense network's arithmetic intensity at batch 32 in section 5.4.2.4. For training, the trade-off is an immediate expansion of working memory: every additional sample in the batch scales the intermediate activation volume that must reside in device memory during backpropagation. Hardware design directly mirrors this progression. Google's first Tensor Processing Unit (TPU) integrated dedicated two-dimensional systolic matrix units that required batched execution to achieve efficiency (Jouppi et al. 2017), while large-scale models such as GPT-3 use distributed clusters specifically to execute the massive GEMM patterns exposed by large global batches (Brown et al. 2020).

Matrix multiplication's dominance also explains the shape of training hardware. Its independent output elements map onto thousands of parallel arithmetic lanes, dedicated matrix units such as Tensor Cores run lower-precision matrix products several times faster than scalar arithmetic, and blocked computation keeps reused operands in on-chip memories rather than refetching them from HBM. Mixed-precision training (section 8.6.3) exploits the second property, and the realized gain of any of them still depends on the nonmatrix work, memory traffic, and input and communication costs around the matrix products.

Matrix multiplications dominate training compute, but neural networks require more than linear transformations. Between each layer's matrix operations, activation functions introduce the nonlinearity that enables networks to learn complex patterns. These functions appear computationally trivial compared to matrix multiplication, yet their implementation characteristics affect training efficiency in ways that matter at scale.

↪ Why accelerators devote their silicon to dense matrix units, and how those units are fed, is developed in section 11.4.

8.3.1.3 Activation functions

Section 5.3.2.2 established what sigmoid, tanh, ReLU, and softmax compute, why the S-curves saturate, and why a ReLU comparison costs far less silicon than an exponential. At training scale, what matters is that their arithmetic rarely sets throughput. A standalone elementwise activation performs only 1 to 4 FLOPs per element while moving 8 bytes (an FP32 read and write), roughly

0.125–0.5 FLOP/byte, so its latency is set by memory bandwidth rather than by which function it computes. GPT-2's activation, the Gaussian Error Linear Unit (GELU), shows what remains of the arithmetic choice, an exact form against a cheaper approximation.

> **Systems Perspective 8.1: The GELU activation choice**
>
> Beyond the foundational activation functions (Sigmoid, Tanh, ReLU), modern architectures increasingly adopt smoother alternatives. GPT-2 uses a GELU activation (Radford et al. 2019), the Gaussian Error Linear Unit introduced by Hendrycks and Gimpel (2016) and often implemented with the common tanh-based approximation from that formulation. Its exact definition is:
>
> $$\text{GELU}(x) = x \cdot \Phi(x) = x \cdot \frac{1}{2}\left[1 + \text{erf}\left(\frac{x}{\sqrt{2}}\right)\right]$$
>
> where $\Phi(x)$ is the cumulative distribution function of the standard normal distribution.
>
> GELU applies a smooth, input-dependent scaling rather than ReLU's hard threshold. It is deterministic despite its formulation in terms of a Gaussian cumulative distribution. Whether it improves model quality relative to another activation is an empirical property of the architecture and training recipe, not a universal guarantee.
>
> Exact GELU uses `erf`, while common implementations use a tanh-based approximation such as listing 8.1. The approximation changes arithmetic cost and introduces a small numerical difference from the exact function. Its end-to-end cost depends mainly on whether the compiler fuses the activation into the preceding matrix multiplication, which removes the memory round-trip that dominates a standalone activation kernel.

Listing 8.1: GELU Approximation: Fast approximation avoids expensive erf() computation while preserving activation properties.

```
# Fast GELU approximation used in production systems
# Avoids expensive erf() computation while
# preserving activation properties
gelu_approx = (
    0.5 * x * (1 + tanh(sqrt(2 / pi) * (x + 0.044715 * x**3)))
)
```

Forward-pass matrix multiplications dominate floating-point operations, while activation functions stress memory bandwidth. Transforming these forward activations into model convergence requires propagating error gradients backward through the graph to update parameter tensors. That optimization step introduces state storage, update scheduling, and numerical stability constraints that govern training efficiency.

↩ The memory wall that bounds elementwise activation kernels, and kernel fusion as the framework's response to it, are established in section 7.3.2.

8.3.2 Optimizers and their memory

Every parameter update reads gradients, mutates persistent state tensors in High Bandwidth Memory (HBM), and writes updated weights back across the memory bus. Because modern optimizers keep one or two auxiliary state values per parameter, optimizer state often consumes more HBM capacity than the weights themselves while executing as a bandwidth-bound elementwise pass. In the D·A·M taxonomy, the choice of optimization algorithm couples the mathematical trajectory (Algorithm) directly to the working-set footprint and memory traffic (Machine).

8.3.2.1 Gradient-based optimization methods

At hardware scale, updating parameters along the steepest-descent direction collides with two physical limits: HBM capacity restricts how many activations and optimizer states remain resident, and memory bandwidth restricts how rapidly parameters update once gradients arrive. The mathematical formulation of gradient descent assumes modest networks on a single device, where neither limit binds.

↩ Gradient descent and its parameter-update rule are established in section 5.4.4.

Gradient descent In a training system, each gradient descent iteration is a chain of dependent operations (forward pass, loss, backward pass, parameter update), none of which can start before its predecessor finishes. Full-batch gradient descent, which computes each update from the entire training set, need not hold the dataset in memory at once, because examples can stream through the accelerator in micro-batches; its cost is time rather than memory. With one million training examples, every update waits for a million examples of forward and backward work, and the parameters stay frozen throughout, reducing the rate at which the model can learn from data.

Mini-batch processing Mini-batch gradient descent (definition 5.2) sits between full-batch and single-example updates, computing each update over a batch small enough to fit in memory and large enough to keep the accelerator busy (Dean et al. 2012). Single-example updates (stochastic gradient descent with a batch of one) return dense layers to the bandwidth-limited matrix-vector regime of section 8.3.1.2 and rewrite every parameter once per example. Averaging over B independent examples shrinks the standard deviation of the gradient estimate approximately as $1/\sqrt{B}$, and the batch size becomes a key system parameter, influencing both computational efficiency and memory requirements.

The choice of batch size B directly governs accelerator memory allocation. The partial decomposition in equation 8.2 separates fixed parameter and gradient storage from the batch-dependent activation working set; optimizer states, any master weights, and runtime workspaces must also enter the full budget:

$$\text{Memory Required} = M_{\text{weights}} + M_{\text{gradients}} + M_{\text{activations}}, \qquad M_{\text{activations}} \propto B \tag{8.2}$$

Because the activation term scales with B while parameter and gradient memory stay fixed, doubling the batch doubles the activation working set, and a model that fits comfortably at a small batch can exhaust the 80 GB of HBM on the reference H100 once the batch grows. Section 8.4.3.2 works through an illustrative ResNet-50 budget.

Sharing each loaded weight across the batch lets a larger batch move dense feedforward and attention projections toward the compute-bound regime; shape and the hardware ridge point determine whether compute throughput becomes limiting. Throughput and convergence follow separate curves, however. Goyal et al. (2017) trained ResNet-50 on ImageNet at $B = 8{,}192$ by scaling the learning rate linearly with batch size and adding a warmup period, a configuration-specific recipe rather than evidence of a universal critical batch size; its useful range depends on the model, data, optimizer, and target accuracy.

When the batch size necessary to saturate execution units or ensure stable convergence exceeds physical memory capacity, systems decouple the physical micro-batch size (B_{micro}) from the algorithmic batch size by accumulating gradients over several micro-batches before invoking the optimizer, which keeps peak activation storage to that of one micro-batch. Section 8.6.5 develops this gradient accumulation and the conditions under which it reproduces the large-batch gradient.

⇄ **Contrast:** Training packs large batches to amortize weight transfers and saturate arithmetic units, whereas online serving inverts the priority to per-request latency under stochastic arrivals, as analyzed in section 13.1.

8.3.2.2 Adaptive and momentum-based optimizers

Basic mini-batch stochastic gradient descent (SGD) applies a uniform scalar learning rate to every parameter tensor, which can stall training when loss curvature differs by orders of magnitude across dimensions. Momentum smooths updates using directional gradient history, RMSprop adapts individual step sizes using squared-gradient magnitudes, and Adam combines first-moment tracking with adaptive second-moment scaling (Kingma and Ba 2015). While these algorithmic enhancements can reduce the total optimization steps required to converge, they do so by introducing persistent auxiliary state that directly increases accelerator memory pressure and memory-bus traffic.

Momentum-based methods Momentum methods[7] (Polyak 1964) address SGD's oscillation problem by accumulating a velocity vector across iterations, damping high-frequency oscillations along steep ravines. In hardware, this smoothing requires allocating and maintaining a persistent velocity tensor matching the exact shape and precision of the model parameters. Parameters and this auxiliary state together occupy $2\times$ the parameter footprint before gradients and activations are counted.

Adaptive learning rate methods While momentum smooths gradient direction, it does not address the different scales of gradients across parameters. RMSprop[8] solves this by maintaining a moving average of squared gradients for each parameter, automatically reducing step sizes for parameters

7 | **Momentum**: Borrowed from physics, where momentum (mass × velocity) describes an object's tendency to continue moving. The metaphor explains the design because accumulated velocity smooths noisy gradients and can reduce the iterations needed for convergence. The systems cost is one additional velocity value per parameter, while Adam maintains two moment values per parameter.

8 | **RMSprop**: Proposed by Geoffrey Hinton in Lecture 6e of his 2012 Coursera course and never published in a peer-reviewed paper. Its per-parameter squared-gradient average is what Adam inherits as its second moment v_t, directly contributing to Adam's $3\times$ memory overhead described in section 8.3.2.3.

with historically large gradients. Adapting step sizes per parameter requires maintaining a running average of squared gradients s_t, imposing a $2\times$ static memory overhead equivalent to momentum. Furthermore, computing this running average introduces elementwise square and square-root kernels during each parameter update.

Adam optimization Adam[9] combines the benefits of both momentum and RMSprop: momentum's gradient smoothing addresses noisy updates, while RMSprop's adaptive scaling handles parameter-specific step sizes. This combination maintains two moving averages for each parameter. Here m_t and v_t are the first- and second-moment buffers, β_1 and β_2 are their decay factors, η is the learning rate, and ϵ is the numerical-stability constant in the denominator:

$$m_t = \beta_1 m_{t-1} + (1-\beta_1)\nabla\mathcal{L}(\theta_t)$$

$$v_t = \beta_2 v_{t-1} + (1-\beta_2)(\nabla\mathcal{L}(\theta_t))^2$$

$$\hat{m}_t = \frac{m_t}{1-\beta_1^t}, \qquad \hat{v}_t = \frac{v_t}{1-\beta_2^t}$$

$$\theta_{t+1} = \theta_t - \eta\frac{\hat{m}_t}{\sqrt{\hat{v}_t}+\epsilon}$$

Maintaining both moment buffers triples the parameter-plus-optimizer-state footprint: the training system must allocate two persistent state tensors (m_t and v_t) alongside the parameter tensors. For a 100M-parameter model, those auxiliary vectors alone add 800 MB beyond weight storage.

[9] **Adam (adaptive moment estimation)**: The two moving averages are the first moment (momentum) and second moment (uncentered variance) of the gradients, stored for every model parameter. For a 7B model, Adam's FP32 moment tensors alone consume 56 GB; the full standard mixed-precision training state before activations is 112 GB once FP16 weights, FP16 gradients, FP32 master weights, and Adam moments are counted together.

8.3.2.3 System cost of optimizer state

Auxiliary state memory increases progressively from SGD (zero auxiliary state) through Momentum and RMSprop (one state vector per parameter) to Adam (two state vectors per parameter), as quantified in table 8.3. These memory footprints establish a trade-off against convergence rate.[10] Adam often achieves target loss in fewer optimization steps, but its static memory footprint restricts the batch size that fits in accelerator HBM and increases memory-bus traffic on every update. At GPT-2 scale, this overhead becomes a first-order memory constraint.

[10] **Convergence**: A run reaches its stopping criterion when the selected training or validation metric no longer improves enough to justify additional work. The required steps depend on the model, data, optimizer, schedule, batch size, and target quality. Fewer steps can reduce wall-clock time and cost, but adaptive optimizers add state whose memory and traffic must be included in the system budget.

Table 8.3: Optimizer Memory Footprint: Different optimization algorithms impose varying auxiliary-state costs due to the storage of intermediate values like velocities and squared gradients. The multiplier row counts parameters plus optimizer auxiliary state and excludes gradients and activations; full training memory must add those terms explicitly. These trade-offs govern resource-constrained deployments and large-scale model training.

Property	SGD	Momentum	RMSprop	Adam
Memory Overhead	None	Velocity terms	Squared gradients	Both velocity and squared gradients
Parameter + optimizer state	$1\times$	$2\times$	$2\times$	$3\times$
Dense State Access	Parameters and gradients	Adds velocity	Adds squared-gradient state	Adds first- and second-moment state
Update Work	Lowest auxiliary work	Adds momentum update	Adds adaptive scaling	Adds moment updates and bias correction
Hardware Efficiency	Varies	Varies	Varies	Varies
Convergence Behavior	Varies	Varies	Varies	Varies

Three multipliers for Adam's memory appear in this chapter, and they differ only in what they count and what they divide by. The table's $3\times$ counts FP32 weights plus two FP32 moments against the FP32 weights alone, 12 bytes per parameter against 4. Adding FP32 gradients gives the 16 bytes per parameter of plain FP32 Adam. The standard mixed-precision recipe also lands at 16 bytes (2 for FP16 weights, 2 for FP16 gradients, 4 for FP32 master weights, 8 for the moments), and it is that same 16 bytes, measured against the 2 bytes of FP16 inference weights, that the definition of training systems reports as 8×.

The costs quantified in table 8.3 create a design tension. Adam's two moment buffers may improve optimization for a given workload, but their memory can reduce the model size or batch size that fits on an accelerator. AdamW[11] (Loshchilov and Hutter 2019) decouples weight decay from Adam's

[11] **AdamW (Adam with decoupled weight decay)**: Standard ℓ_2 regularization enters the gradient and is therefore rescaled by Adam's adaptive update. AdamW applies weight decay as a separate parameter update, restoring the intended distinction between adaptive gradient scaling and decay (Loshchilov and Hutter 2019). It uses the same moment-buffer structure as Adam, though its effect on model quality remains workload dependent.

adaptive gradient update without adding another per-parameter state tensor.

Napkin Math 8.2: GPT-2 optimizer memory requirements

A representative GPT-2 XL training configuration uses the Adam optimizer with five hyperparameters:

- $\beta_1 = 0.9$ (momentum decay)
- $\beta_2 = 0.999$ (second moment decay)
- Learning rate: Warmed up from 0 to 2.5e-4 over first 500 steps, then cosine decay
- Weight decay: 0.01
- Gradient clipping: Global norm clipping at 1.0

Math:
For GPT-2's 1.5B parameters in FP32 (4 bytes each), the memory breaks down across four components:

- Parameters: 1.5B $\times$ 4 bytes = 6 GB
- Gradients: 1.5B $\times$ 4 bytes = 6 GB
- Adam State (m_t, v_t): 1.5B $\times$ 8 bytes = 12 GB
- Total static memory: 24 GB

This static training state alone, 24 GB for GPT-2, takes about 28 percent of an H100's 80 GB before any activation is stored, and how much room the activations need depends on batch size and sequence length. The activation notebook below adds the batch-dependent term at batch 32, and the pipeline optimizations then remove it piece by piece until the walkthrough (section 8.6.6) fits the step on one accelerator.

System Decisions Driven by Optimizer

1. Mixed precision training (FP16) reduces operation precision but requires keeping FP32 master weights, so the static footprint stays at ~24 GB, the same 16 bytes per parameter as FP32 Adam.
2. Gradient accumulation (section 8.6.5) builds an effective batch of $B = 512$ from micro-batches that fit in memory.

Systems insight: This illustrative configuration shows how Adam's moment buffers constrain capacity. Any convergence benefit relative to SGD or momentum must be measured under a matched model, data, schedule, batch size, and stopping criterion.

8.3.2.4 The optimizer step

Optimizer memory, once quantified, fixes what each update must read and write. In the training loop, `optimizer.zero_grad()` and `optimizer.step()` bracket each update. Gradients accumulate across `backward()` calls until they are cleared, and `step()` consumes them and mutates the optimizer's persistent state (section 7.7 traces both calls through the framework). The accumulation behavior later becomes useful for building large effective batches, but only when the loop manages that boundary deliberately. For Adam optimization, `step()` performs momentum estimation, squared-gradient tracking, bias correction, and the parameter update, and algorithm 8.1 makes that hidden state explicit so the memory cost remains visible rather than disappearing behind an API call.

Parameters (P) and gradients (G) take one share each, and Adam's moment buffers m and v add two more in this simplified static-state view.

Algorithm 8.1 Adam parameter update (one optimizer step)

Require: gradient $g_t = \nabla \mathcal{L}(\theta_t)$; step t; rate η; decays β_1, β_2; constant ϵ
Ensure: updated parameter θ_{t+1}; moment buffers m_t, v_t carried to the next step
1: $m_t \leftarrow \beta_1 m_{t-1} + (1-\beta_1)\, g_t$ ▷ *first moment (momentum)*
2: $v_t \leftarrow \beta_2 v_{t-1} + (1-\beta_2)\, g_t^2$ ▷ *uncentered second moment*
3: $\hat{m}_t \leftarrow m_t/(1-\beta_1^t)$; $\hat{v}_t \leftarrow v_t/(1-\beta_2^t)$ ▷ *bias correction*
4: $\theta_{t+1} \leftarrow \theta_t - \eta\, \hat{m}_t/(\sqrt{\hat{v}_t} + \epsilon)$ ▷ *parameter update*

Steps 1 and 2 keep two persistent moment buffers per parameter, so parameters plus optimizer state reach roughly $3\times$ the parameter memory before gradients, activations, and FP32 master weights are counted. Beyond capacity, the optimizer step imposes a severe memory-bandwidth bottleneck. The update consists of elementwise operations with an arithmetic intensity below 1 FLOP/byte. In FP32, updating each parameter requires reading four tensors ($g_t, \theta_t, m_{t-1}, v_{t-1}$) and writing three ($m_t, v_t, \theta_{t+1}$), streaming 28 bytes across the memory bus for roughly a dozen arithmetic operations. Because matrix execution units (such as Tensor Cores) sit idle during this memory-bound phase, high-performance training systems use fused optimizer kernels to combine moment updates, bias correction, and weight writes into a single kernel launch per parameter group, minimizing round-trips through device memory.

8.3.2.5 Reducing optimizer memory

Because optimizer tensors remain resident between updates, reducing their footprint can make a larger micro-batch feasible even when the optimizer is not the longest phase of the step. At billion-parameter scale, optimizer state becomes a first-order, batch-independent term in the memory budget. As quantified in the GPT-2 worked example (section 8.3.2.3), a 1.5B model requires 12 GB for Adam optimizer state alone in FP32, in addition to parameters and gradients, before accounting for activations. This challenge has motivated memory-efficient optimizer variants: Adafactor factorizes second-moment state (Shazeer and Stern 2018), 8-bit optimizers quantize optimizer statistics (Dettmers et al. 2022), and GaLore computes updates in a low-rank space (Zhao et al. 2024).

To attribute a memory saving to the optimizer, hold the model, batch size, precision, and activation policy fixed and compare the complete memory budget. Low-rank projection buffers and other temporary state belong in that budget. A smaller optimizer-state term does not guarantee that the full training recipe fits, nor that it reaches the same validation quality in less time.

8.3.2.6 Learning rate schedules

The framework's learning rate scheduling hook changes the optimizer's trajectory without adding per-parameter state. It adjusts the learning rate η during training, letting the system shape convergence behavior while leaving the underlying optimizer equations intact.

Schedules such as cosine annealing (Loshchilov and Hutter 2017), exponential decay, or step-wise reductions implement that trajectory by changing the step size over time. A scheduler tracks lightweight scalar state (current step, epoch, warmup phase) that must be serialized into checkpoints alongside optimizer states to resume the schedule (section 8.4.5). Reproducing the training trajectory also requires the relevant random-number and data-position state and compatible execution settings. This separation lets the systems engineer combine base optimization algorithms (SGD, Adam) with scheduling strategies (cosine annealing, linear warmup) without modifying the underlying tensor update rules.

8.3.2.7 Time to target quality

A faster update is valuable only if the recipe reaches the required validation quality sooner. Optimizer state and numerical precision affect the price of each update, while the optimizer and schedule affect how many updates the run needs. Both quantities enter a time-to-target decision.

Consider two precision-and-optimizer recipes for the same model, dataset, effective batch, machine, and validation target. Both fit in memory. Table 8.4 supplies hypothetical observations for their first accepted checkpoint and calculates the total elapsed time from them.

Table 8.4: Illustrative Time-to-Quality Comparison: Step durations, target-reaching update counts, and evaluation/checkpoint overhead are supplied observations for a hypothetical workload, not benchmark results. Totals multiply updates by end-to-end step time and add overhead excluded from that step time.

Quantity	Recipe A	Recipe B
End-to-end update time	2 s	1.5 s
Updates to the same validation target	6,000	10,000
Update time × update count	200 min	250 min
Separate evaluation and checkpoint time	10 min	10 min
Total time to accepted checkpoint	210 min	260 min

Recipe A reaches the target sooner. At its shorter step duration, Recipe B would tie A's total time if it reached the target at 8,000 updates under the stated overhead. Its assumed 10,000 updates exceed that budget. On the same allocated machine, shorter total time also means fewer billed accelerator-hours.

A profile measures the cost of an update; validation measures how many updates the required quality takes. Comparing optimizers, precision, or batch schedules requires both measurements under a common acceptance criterion. A real experiment must also account for run-to-run variation and any change in evaluation frequency; an apparent crossing of the target is not evidence that a recipe reliably meets it.

Optimizer rules specify how parameters move once gradient vectors are in hand, yet computing those gradients dominates both arithmetic and memory in a billion-parameter network. The mechanics of gradient generation, rather than the optimizer update itself, therefore govern the training memory budget and step time.

8.3.3 Backpropagation and activation memory

Backpropagation evaluates parameter gradients by traversing the network's computational graph in reverse topological order, applying the chain rule layer by layer (section 5.4.5). Each backward rule reads values from the forward pass, either saved or recomputed, so tensors that inference would release after their last forward consumer stay alive until the backward pass reaches them (section 7.4.3.2). Computing $\frac{\partial \mathcal{L}}{\partial \mathbf{W}^{(\ell)}}$ requires the layer's forward input, and the retention of those inputs creates the training memory equation that gradient checkpointing later exploits. At the scale of GPT-2 XL, the question is what that retention costs in memory capacity and arithmetic throughput, because retained activations in HBM can become the binding memory constraint of the run.

The arithmetic side of that cost follows from the derivative equations of section 5.4.5.4. Backpropagation through a linear layer $\mathbf{Z} = \mathbf{AW}$ evaluates two matrix products, the activation gradient $\nabla_{\mathbf{A}} \mathcal{L} = (\nabla_{\mathbf{Z}} \mathcal{L})\mathbf{W}^T$ that carries the error signal upstream and the parameter gradient $\nabla_{\mathbf{W}} \mathcal{L} = \mathbf{A}^T (\nabla_{\mathbf{Z}} \mathcal{L})$ that the optimizer consumes. Each permutes the forward matrix dimensions while keeping the forward product's leading FLOP count, so backward costs about twice forward and a complete step about three times the forward FLOPs. At the scale of a transformer, that same factor of three turns the $2P$ forward FLOPs per token into the $6P$ per token behind the lighthouse budget. The memory side of the cost has no such fixed ratio, because it depends on which forward values the backward rules must read.

The three-layer MNIST classifier ($784 \to 128 \to 64 \to 10$) of chapter 5 needed only kilobytes of activation storage. GPT-2 processing a single batch of 32 sequences of 1024 tokens requires approximately 286.9 GB of saved activations. Adding parameters, gradients, master weights, and optimizer state raises the estimated training footprint to 310.9 GB, about 3.6× the H100's 80 GB before temporary workspace is counted. Section C.3.3 puts a number on each term of the full training memory equation ($M_{\text{total}} = M_{\text{weights}} + M_{\text{gradients}} + M_{\text{optimizer}} + M_{\text{activations}}$) for GPT-2. Modern ML frameworks automate gradient evaluation through automatic differentiation, but managing the resulting memory footprint and arithmetic schedule remains an unavoidable systems engineering responsibility.

8.3.3.1 Activation memory requirements

The four-term training-memory budget of equation 5.29 partitions training state into saved forward activations required by backward derivative rules, model parameters, parameter gradients, and optimizer state (including any higher-precision master weights), and only the first category grows with the batch. Consider a batch of training examples passing through a network. The forward pass computes and stores:

$$\mathbf{Z}^{(\ell)} = \mathbf{A}^{(\ell-1)}\mathbf{W}^{(\ell)} + \mathbf{b}^{(\ell)}$$
$$\mathbf{A}^{(\ell)} = f(\mathbf{Z}^{(\ell)})$$

To compute the parameter gradient $\nabla_{\mathbf{W}^{(\ell)}}\mathcal{L} = (\mathbf{A}^{(\ell-1)})^T(\nabla_{\mathbf{Z}^{(\ell)}}\mathcal{L})$, the backward rule must read the layer's input activations $\mathbf{A}^{(\ell-1)}$. To propagate the error signal upstream through the nonlinear activation function via $\nabla_{\mathbf{Z}^{(\ell)}}\mathcal{L} = (\nabla_{\mathbf{A}^{(\ell)}}\mathcal{L}) \odot f'(\mathbf{Z}^{(\ell)})$, the kernel requires either the pre-activation tensor $\mathbf{Z}^{(\ell)}$ (as in GELU) or the post-activation output $\mathbf{A}^{(\ell)}$ (when f' can be computed from the output, as in sigmoid, or via a 1-bit boolean mask in ReLU). Fused kernels and selective recomputation can compress this saved footprint. Nevertheless, because activations scale with batch size B and sequence length S, their storage demands grow with the data dimension, whereas parameter and optimizer memory remain fixed by the model architecture. The GPT-2 calculation in notebook 8.3 decomposes this memory pressure across attention blocks, feed-forward sublayers, and optimizer states.

Napkin Math 8.3: GPT-2 activation memory breakdown

For GPT-2 with batch size B = 32, sequence length S = 1024, hidden dimension d = 1600, and 48 layers:

Math:

- Attention activations: $B \times S \times d \times 4$ (Q, K, V, output) = 32 × 1024 × 1600 × 4 × 2 bytes (FP16) = 419.4 MB
- FFN activations: $B \times S \times (4d)$ (intermediate expansion) = 32 × 1024 × 6400 × 2 bytes = 419.4 MB
- Attention scores: $5 \times N_{\text{heads}} \times S^2 \times B$ bytes, because each element of a head's $S \times S$ attention matrix is saved three times for backward: 2 bytes for the FP16 softmax probabilities, 1 byte for the dropout mask, and 2 bytes for the probabilities after dropout. With 25 heads, this term reaches 4194.3 MB per layer. It is the dominant term, quadratic in sequence length, and exactly what selective recomputation discards
- Layer norm states: Minimal (~10 MB per layer)
- Total per layer: ~5043.2 MB (attention + FFN + attention scores + layer norm states)

Result:

- Line items across all layers: 5043.2 MB × 48 layers ≈ 242.1 GB
- Total activation memory (library estimate): 286.9 GB, about 44.8 GB more than the line items because it also counts saved tensors the list omits, such as the inputs to each linear and normalization layer, the GELU output, and the dropout masks
- Parameters (FP16): 3 GB
- Gradients: 3 GB
- Master weights (FP32): 6 GB
- Adam moment state (FP32): 12 GB
- Peak memory during training: ~310.9 GB

This exceeds a single H100's 80 GB capacity.

Solutions:

1. Selective activation recomputation: Discard attention intermediates and recompute them during backward, reducing this modeled activation term by 70.2 percent to ~85.6 GB; the additional work depends on the implementation
2. Activation CPU offloading: Store some activations in CPU RAM, transfer during backward pass
3. Mixed precision: FP16 activations (already applied) vs. FP32 (would be 573.8 GB)
4. Reduced micro-batch size and gradient accumulation: Build a larger effective batch from multiple memory-feasible forward/backward passes

Systems insight: Even after selective recomputation, the modeled activations plus static state total about 109.6 GB, still above the H100's 80 GB before workspace and allocator overhead. Selective recomputation removes 70.2 percent of the activations, the same quadratic attention term that FlashAttention never stores; the segment schedule in notebook 8.8 goes further by retaining only segment inputs between passes, and the walkthrough composes these techniques until the batch-32 step fits.

This breakdown illustrates the practical engineering decisions required when accelerator memory falls short. The same trade-off between stored activations, recomputation, and batch size drives the memory-computation analysis that follows.

8.3.3.2 Memory-computation trade-offs

Training systems must balance memory usage against computational efficiency. Each forward pass generates values that backward rules may request. For a simplified network model with N_L layers, let s_ℓ denote the bytes of saved intermediate state per example at layer ℓ and $M_{\text{activations}}^{(\ell)}$ the bytes of saved activation outputs per example. Under this per-example convention, their storage scales linearly with batch size and is approximated by equation 8.3:

$$M_{\text{activations}} = B \times \sum_{\ell=1}^{N_L} \left(s_\ell + M_{\text{activations}}^{(\ell)} \right) \tag{8.3}$$

This memory requirement compounds with the weights, gradients, and optimizer memory discussed in section 8.3.2.3. Together they form the same four-term budget that equation 5.29 established and the lighthouse callout applied to GPT-2, labeled here once as equation 8.4 so that later sections can point to it:

$$M_{\text{total}} = M_{\text{weights}} + M_{\text{gradients}} + M_{\text{optimizer}} + M_{\text{activations}} \tag{8.4}$$

The runtime peak can exceed this sum because temporary workspaces, communication buffers, allocator behavior, and framework bookkeeping also occupy memory. To reduce the activation term, training systems can recompute intermediate values during backward rather than storing them. This increases computational work but can enable deeper networks or larger batches on memory-constrained hardware (T. Chen et al. 2016). Activation checkpointing, which keeps activations only at selected layers and rebuilds the rest during the backward pass, is developed in section 8.6.5.1, with its optimal spacing and its cost for GPT-2 in section 8.6.5.2.

Capacity is only one of two physical constraints imposed by memory; the other is bandwidth. Accelerators provide high matrix compute throughput, but shuttling intermediate activation tensors between off-chip High Bandwidth Memory (HBM) and on-chip SRAM frequently saturates the memory bus (Jouppi et al. 2017). Even when activations fit comfortably within HBM capacity, the time required to read and write them can dwarf the arithmetic execution time. To relieve this memory bus pressure, modern training engines fuse elementwise operations directly into preceding matrix multiplications and stage gradient computations through on-chip SRAM tiles rather than global memory. At the runtime level, framework caching allocators track tensor lifetimes across the computation graph, recycling memory blocks as soon as an activation's final backward consumer completes (Paszke et al. 2019).

8.3.3.3 Fine-tuning memory on one accelerator

GPT-2 XL's static state leaves most of an H100 for activations. One size class up, the memory constraint changes the training recipe itself. Llama 3 8B (Dubey et al. 2024), the larger member of the book's bandwidth-bound language-model family, is usually adapted to a new task rather than trained from scratch, and whether that adaptation fits on one accelerator depends on which parameters it trains.

Training scope changes which terms of the memory budget are populated. Let P count all resident model parameters, including any added head or adapters. Inference retains their weights but has $M_{\text{gradients}} = M_{\text{optimizer}} = 0$, because it neither computes parameter gradients nor updates weights. Full fine-tuning allocates gradients and optimizer state for all P parameters, following the chosen precision recipe. Head-only adaptation keeps the frozen backbone resident but allocates gradients, master weights when used, and optimizer moments only for the trainable head. Adapters, small trainable modules inserted into a frozen network, similarly restrict these update buffers to the added parameters. Their weight-memory term still includes both the frozen base and the adapters; storing fewer trainable parameters does not remove the base weights.

Saved activation memory follows the backward path rather than the trainable parameter count. When a frozen feature extractor runs without gradient recording and supplies its output as a constant to a trainable head, the head retains that boundary input and its own required backward values; the backbone has no saved backward activations. Inference also avoids saved backward state, although live forward intermediates and workspaces still consume memory. Adapters distributed through the network create a different topology. Gradients must traverse intervening frozen operations to reach earlier adapters, so those operations may still require saved tensors or recomputation. Setting `requires_grad=False` on base weights suppresses their parameter gradients, but disabling recording across that path would also cut the gradients the adapters need.

↩ Gradient-recording and detachment controls for frozen feature extractors are established in section 7.4.3.2.

The comparison therefore separates a residency decision from a differentiation decision. Subtracting $M_{\text{weights}} + M_{\text{gradients}} + M_{\text{optimizer}}$ from device capacity gives the space available for activations and runtime overhead. A head-only configuration may fit where full fine-tuning does not, provided it meets the task's quality target; an adapter configuration must still budget the activations on its backward path. If those activations exceed the remaining space, checkpointing or a smaller micro-batch may still be necessary despite the small optimizer state. For a fixed training scope, only activation memory scales approximately linearly with batch size (equation 8.3); model parameters and optimizer state remain fixed. The Llama 3 8B case puts numbers on both decisions.

Napkin Math 8.4: Fine-tuning Llama 3 8B on one H100

Problem: Can a 8.0B-parameter Llama 3 model be fine-tuned on one H100 with 80 GB (85.9 GB in decimal units) of HBM, first with every parameter trained and then with low-rank adapters?

Given: The mixed-precision Adam recipe of section 8.3.2, a batch of 4 sequences of 2,048 tokens, and attention that never stores the quadratic score matrix.

Math:

1. **Full fine-tuning, static state**: FP16 weights 16 GB + FP16 gradients 16 GB + FP32 master weights 32 GB + Adam moments 64 GB = 128 GB, already beyond one accelerator before any activation is stored.
2. **Activations**: The per-layer estimate of section 8.3.3.1, without the quadratic attention term, gives 36.5 GB at this batch, so full fine-tuning needs about 165 GB in all.
3. **Low-rank adapters**: Low-rank adaptation (LoRA) (Hu et al. 2021) freezes the base weights and trains a pair of small matrices beside each adapted projection. Rank-16 adapters on every query and value projection add 6.8 million trainable parameters, 0.08 percent of the model, whose gradients, master copies, and moments occupy 0.11 GB.
4. **Adapter total**: Frozen BF16 weights 16 GB + adapter state 0.11 GB + activations 36.5 GB ≈ 53 GB, leaving about 33 GB for workspaces and allocator overhead.

Systems insight: Full-parameter training of this model does not fit one accelerator; it requires partitioning its state across devices with fully sharded data parallelism (FSDP) or ZeRO, which section 8.7.1.1 develops, or offloading state to host memory. Adapters change which terms of the memory budget are populated: the frozen weights stay resident, but gradients and optimizer state shrink to the adapters, and activations still follow the backward path through every frozen layer. Storing the frozen base weights in a 4-bit format shrinks the largest remaining term further (Dettmers et al. 2023), a recipe distinct from the full-parameter mixed-precision training above.

Forward propagation, gradient computation, and parameter updates define *what* training systems must compute. An operation's name alone, however, does not reveal *where* the system stalls. Matrix shape, kernel fusion, numerical precision, and the memory hierarchy determine whether arithmetic throughput or data movement binds execution. Arithmetic intensity provides the analytical tool to quantify that balance.

8.3.4 Arithmetic intensity

During a single training step on the reference H100, a large dense matrix multiplication runs near the chip's Tensor Core peak while a standalone softmax or LayerNorm kernel stalls waiting for bytes from HBM. Arithmetic intensity explains that split by comparing the operations a kernel performs to the bytes it moves across the memory bus:

$$I = \frac{O}{D_{\text{vol}}}$$

Within the roofline model, operations above the hardware ridge point have a compute-throughput ceiling, while those below it have a memory-bandwidth ceiling. Launch overhead, limited parallelism, and imperfect execution can keep measured performance below either ceiling. Section 11.6 develops the roofline model and the hardware ridge point, and section D.2.1 works through the derivation.[12]

Table 8.5 summarizes common tendencies rather than fixed measurements. Dense matrix multiplication can reuse operands enough to reach high arithmetic intensity, while standalone elementwise and reduction kernels often perform less work per byte moved. The target hardware's ridge point determines the resulting regime.

Table 8.5: Training Operation Classification Conditions: Operation families follow common arithmetic-intensity tendencies, but classification requires comparing the measured implementation with the target hardware's ridge point. Memory-sensitive kernels may benefit from reducing traffic or increasing fusion, while compute-bound kernels benefit from additional arithmetic throughput.

Operation	Arithmetic-intensity tendency	Classification condition
Dense MatMul (large)	High when shapes and tiling provide substantial operand reuse	Compute-bound only when intensity exceeds the ridge
Activation functions	Usually low as standalone elementwise kernels	Often memory-sensitive unless fusion removes traffic
LayerNorm/BatchNorm	Reduction and elementwise work with multiple tensor passes	Depends on fusion, shape, and target ridge point
Attention softmax	Reduction and normalization over the attention axis	Depends on materialization, tiling, and fusion

Hardware efficiency during model training depends directly on kernel arithmetic intensity. Figure 8.1 bounds attainable throughput across training kernels on the H100's roofline, contrasting memory-bandwidth-bound operators (softmax, LayerNorm) along the sloped ceiling against compute-bound operators (dense MatMul) on the flat 989 TFLOP/s peak.

On the reference machine the ridge in figure 8.1 sits at 295.2 FLOP/byte, the H100's 989 TFLOP/s peak divided by its 3.35 TB/s of HBM bandwidth. The operation points in this diagram are illustrative placements that show how to interpret the model, not measured GPT-2 coordinates.

[12] **Ridge point and precision**: The roofline ridge point, the arithmetic intensity threshold separating memory-bound from compute-bound operations, shifts with numerical precision. On the same accelerator, a lower-precision Tensor Core path can expose much more arithmetic throughput at roughly the same memory bandwidth, raising the ridge point substantially. Switching from TF32-style execution to BF16 mixed precision can therefore change which optimization technique yields returns, making precision selection inseparable from roofline analysis.

↩ Arithmetic intensity, the ridge point, and the memory-bound and compute-bound regimes they separate are established informally in section 2.4.2.

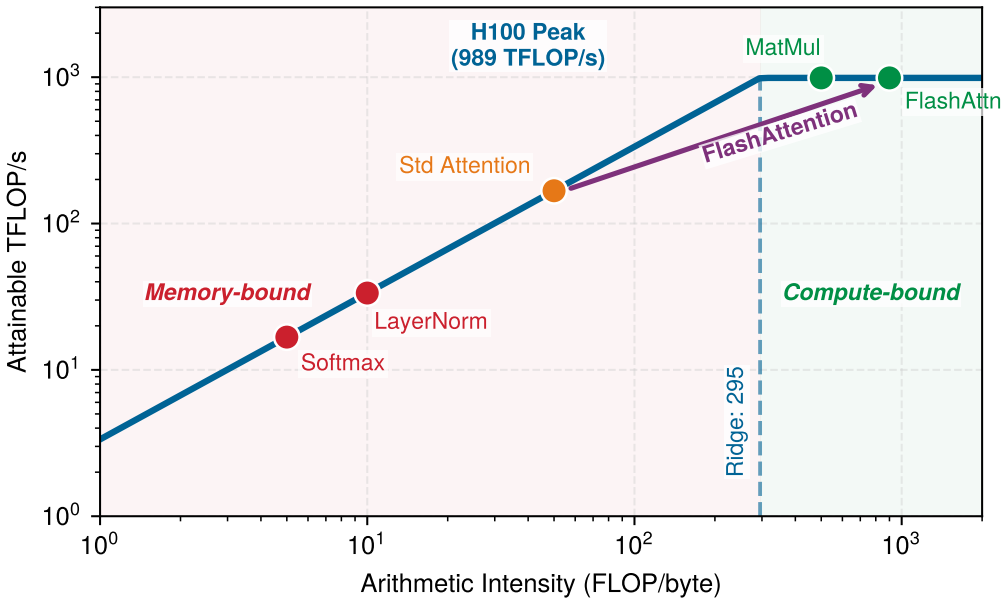

Figure 8.1: Illustrative Training Roofline: An H100 roofline with assumed operation coordinates illustrates how arithmetic intensity changes the attainable-performance ceiling. The points are not a profile of one GPT-2 execution. FlashAttention is shown moving right because it reduces HBM traffic; whether a real attention kernel crosses the ridge depends on shape, precision, hardware, and implementation.

Consider a GPT-2 attention layer that materializes the $S \times S$ attention-score matrix. For each head, the $\mathbf{QK}^T$ product costs approximately $2S^2 d_{\text{head}}$ FLOPs, while writing the FP16 score matrix and reading it back moves about $4S^2$ bytes. Counting only that score-matrix traffic gives the approximation $d_{\text{head}}/2$. For GPT-2 Small ($d = 768$ across 12 heads, so $d_{\text{head}} = 64$), this restricted accounting yields 32 FLOP/byte. The lighthouse GPT-2 XL gives the same answer, because its head dimension is also 64 and the ratio depends only on d_{head}. A complete kernel analysis must also count Q and K traffic, softmax work, additional reads and writes, cache reuse, and fusion. The $\mathcal{O}(S^2)$ materialized score traffic remains the term that FlashAttention targets.

At 295.2 FLOP/byte, the H100's ridge sits far to the right of the 32 FLOP/byte materialized attention estimate, so low-intensity operations such as attention softmax remain memory bound even when large matrix multiplications on the same device are compute bound.

> Systems Perspective 8.2: Peak FLOP/s vs. sustained performance
>
> Peak TFLOP/s is an arithmetic ceiling rather than a prediction of sustained application performance. For an implementation that is strictly bandwidth bound, raising only the arithmetic ceiling does not improve the roofline bound. Mixed-precision training can both enable faster arithmetic paths and reduce traffic for tensors actually stored and transferred at lower precision. The realized gain depends on kernel support, conversion overhead, numerical requirements, and which resource is binding. Roofline-guided optimization therefore measures the implementation before choosing fusion, precision changes, or additional compute.

Batch size also moves an operation along the intensity axis, because a larger batch spreads each weight load over more examples. Where the transition from memory-bound to compute-bound execution falls depends on the operation's shape, its precision, and the hardware.

This analysis guides optimization strategy selection. For memory-bound operations, reducing data movement through kernel fusion, reduced precision, or algorithmic improvements like FlashAttention provides the largest gains. For compute-bound operations, increasing throughput through

Tensor Cores and parallel execution matters more. The first case asks how to move fewer bytes, and the second asks how to keep more arithmetic units busy.

The trajectory vector in figure 8.1 illustrates how FlashAttention[13] can shift transformer attention toward, and for favorable shapes across, the 295.2 FLOP/byte ridge line onto the compute ceiling. By never materializing the full $S \times S$ attention matrix in HBM and instead processing tiles that fit in fast SRAM (tiling, the general technique developed in section 11.7.5), FlashAttention reduces auxiliary attention memory from $\mathcal{O}(S^2)$ to $\mathcal{O}(S)$ and sharply reduces HBM traffic. The original work reports up to 3× speedups on evaluated workloads (Dao et al. 2022), with gains depending on tensor shape, hardware, and baseline. The algorithm and the conditions under which it applies are examined in detail in section 8.6.4.

[13] **FlashAttention**: The core mechanism processes attention in small tiles that fit within the accelerator's fast on-chip SRAM, avoiding writes of the full intermediate $S \times S$ matrix to slower HBM. The exact HBM IO bound depends on tile size and SRAM capacity, but the practical effect is a large reduction in memory traffic and auxiliary activation storage.

Arithmetic-intensity analysis is how the silicon contract (principle 4) is checked in training. The silicon contract names the resource a workload is built to exploit; the analysis determines which physical resource actually constrains a particular implementation. Dense matrix multiplication reaches the compute-bound regime when tensor shapes provide sufficient data reuse, while standalone normalization and elementwise activation kernels remain memory bandwidth bound.

Optimizing individual operations is necessary but insufficient. A perfectly tuned matrix multiplication achieves nothing if the accelerator sits idle waiting for the next batch of data. Isolated operation costs (dense matrix multiplication FLOPs, memory-bound activations, and optimizer state allocations) compound within the execution loop. Sustained throughput requires orchestrating these discrete operations into a balanced pipeline where upstream data delivery and downstream parameter updates prevent accelerator starvation.

8.4 Pipeline Architecture

A training step is not a single operation but a sequence of dependent stages: data must be loaded before computation can begin, forward passes must complete before backward passes start, and gradients must be computed before parameters can update. The speed of the slowest stage determines the speed of the entire system. Without pipelining, these stages serialize, idling the accelerator while the host prepares data or transfers batches across the bus.

While model execution graphs govern arithmetic on the accelerator, sustained training requires feeding those kernels across physical machine boundaries. Host CPUs ingest raw records from storage and apply preprocessing in host DRAM, while accelerators execute matrix multiplications in HBM. Data must cross the interconnect, typically a PCIe link whose bandwidth is an order of magnitude lower than device memory bandwidth. When upstream data preparation or bus transfer exceeds the duration of the forward and backward passes, the accelerator compute engines starve, reducing the hardware utilization factor η_{hw} in the training-time law.

The training system divides into three subsystems. The data pipeline handles ingestion, transformation, and batching on the host; the training loop coordinates forward passes, backward passes, and parameter updates on the accelerator; and the evaluation pipeline periodically assesses model quality on held-out data. The three subsystems decouple across the training lifecycle (figure 8.2): processed batches flow into the core forward/backward training loop while metrics stream to an asynchronous evaluation pipeline. The interfaces between them form critical synchronization boundaries where I/O latency, interconnect transfers, or synchronous validation pauses can throttle accelerator utilization. The data pipeline supplies two of the three terms of the pipeline bottleneck model defined later (equation 8.6), host preprocessing and host-to-accelerator transfer, the accelerator training loop supplies the third through matrix compute, and periodic evaluation claims shared execution time from that loop.

8.4.1 Pipeline stages and accelerator bubbles

A training step passes through four stages, a **staged system pipeline** rather than a monolithic loop. If one stage is slower than the rest, the others wait:

1. **Data Loading & Preprocessing** (CPU/Storage): Fetching raw bytes from Non-Volatile Memory Express (NVMe) storage, decoding samples, and executing transformations on CPU cores.
2. **Host-to-Device Transfer** (PCIe): Moving the preprocessed batch across the PCIe bus into GPU memory via direct memory access (DMA).

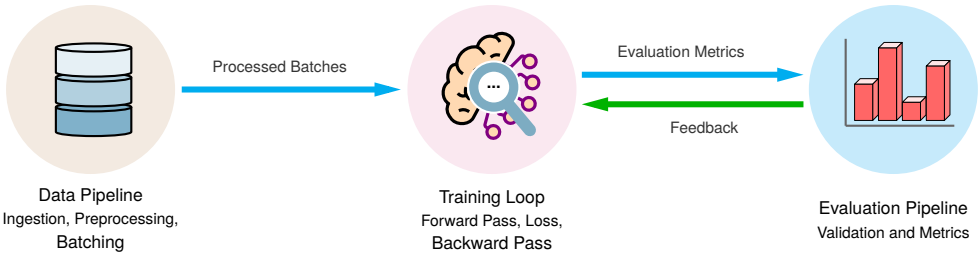

Figure 8.2: Training System Overview: The training lifecycle coordinates data preparation, core forward/backward computation, and validation evaluation. The interfaces between these three pipelines represent critical synchronization boundaries where I/O delays or evaluation pauses can throttle accelerator utilization.

3. **Forward/Backward Pass** (Accelerator): Propagating activations forward and gradients backward through layer kernels on the GPU.
4. **Parameter Synchronization** (Interconnect, present only when multiple accelerators train the model): Exchanging gradients between accelerators across the available interconnect fabric. NVLink provides up to 900 GB/s in the H100 configuration examined later, while alternative architectures rely on PCIe switches or scale-out network fabrics.

Any throughput mismatch among these stages creates **accelerator bubbles**, idle windows during which compute units stall while waiting for upstream dependencies. These bubbles stem from imbalances within the per-step pipeline. A systems engineer eliminates them through asynchronous prefetching and pipeline overlapping, staging the next batch into high-bandwidth memory before the active step completes. The first three stages form the analytical basis for the pipeline execution model in equation 8.6, where the slowest stage dictates end-to-end iteration throughput, and section 8.5 provides the profiling methods required to isolate that bottleneck.

Across the three decoupled subsystems of figure 8.2, each stage occupies a distinct hardware domain: host storage and CPU cores ingest and preprocess data, accelerator compute engines execute the model loop, and evaluation pipelines periodically preempt execution to calculate validation metrics. Any latency imbalance among them therefore becomes idle accelerator cycles. At the ingestion boundary, the data pipeline stages raw records from persistent storage into host memory, applies transformations such as augmentation and normalization (LeCun et al. 2012), and packs tensors into dense batches. These batches transfer over the host-accelerator interconnect (such as PCIe) into accelerator memory. At the validation boundary, the evaluation pipeline periodically runs held-out data through the model without computing gradients. Because validation occupies the same accelerator cores needed for training, its invocation frequency represents a direct trade-off between monitoring resolution and overall training throughput.

Within the accelerator, the training iteration forms a closed feedback loop governed by strict data and memory dependencies. Figure 8.3 traces this cyclic sequence across three stages (predict, gradients, and update), showing how predictions, the loss, and parameter gradients feed the optimizer before returning updated weights to the next iteration.

While section 8.3 counted the FLOPs and bytes of each operator in this cycle, memory residency and data dependencies govern how the hardware executes them. During the forward pass, intermediate activation tensors must remain resident in accelerator HBM because the backward pass requires them to evaluate chain-rule derivatives. Once gradients are computed, the optimizer reads both the parameters and accumulated gradients to apply the update rule, producing new weights for the subsequent iteration. The memory capacity required to hold activations, weights, and optimizer states establishes the memory floor for the entire training step.

This execution loop repeats across batches and epochs until the optimization converges. Maximizing accelerator arithmetic efficiency requires overlapping these pipeline stages across the system hierarchy. Host CPU threads prefetch and stage batch $k+1$ into page-locked (*pinned*) host memory while the accelerator executes batch k, so the DMA engine can stream it across PCIe asynchronously (section 7.5.2 explains why pinning is required). This concurrent staging hides storage latency and bus transfer time behind matrix-multiplication compute kernels. When this concurrency breaks

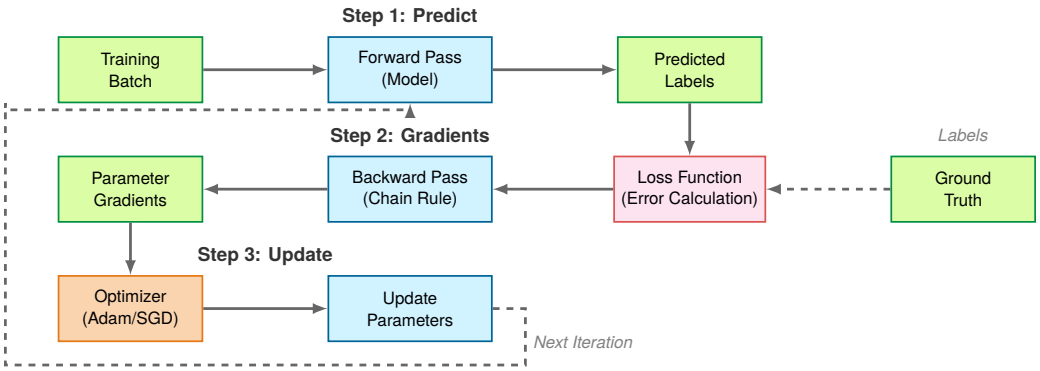

Figure 8.3: The Iterative Training Loop: Each iteration sequences forward prediction, gradient computation by backpropagation, and an optimizer update. Updated parameters return to the next forward pass while the next batch remains a separate input. Data dependencies and memory residency set the step's minimum execution time and memory floor.

down, because an I/O-bound data pipeline starves the device of input tensors or frequent evaluation stalls the update loop, the accelerator idles, degrading effective throughput.

8.4.2 Data pipeline

Keeping an accelerator's arithmetic units saturated requires streaming training examples from persistent storage into device memory at or above the model's consumption rate. Data engineering posed this as the feeding problem (section 4.9.3) and measured the throughput lost when a slow storage path cannot keep up; training is where that loss is paid on every step. ResNet-50 is the chapter's input-pipeline case, because its images are far heavier for the host to prepare than GPT-2's token IDs. The stage trace below starts with GPT-2 XL under a scenario assumption, on-the-fly single-core tokenization (production runs usually pre-tokenize), and the system implications then turn to ResNet-50. Upstream data engineering prepares and partitions datasets on storage media, while the runtime data pipeline executes concurrently with model computation on the host CPU.

The data pipeline bridges raw storage and accelerator execution across the machine boundary. Figure 8.4 partitions this data movement across three physical zones: staging raw files from persistent storage into host memory, formatting and augmenting tensors across CPU worker threads, and streaming batched inputs over the interconnect to parallel GPU accelerators.

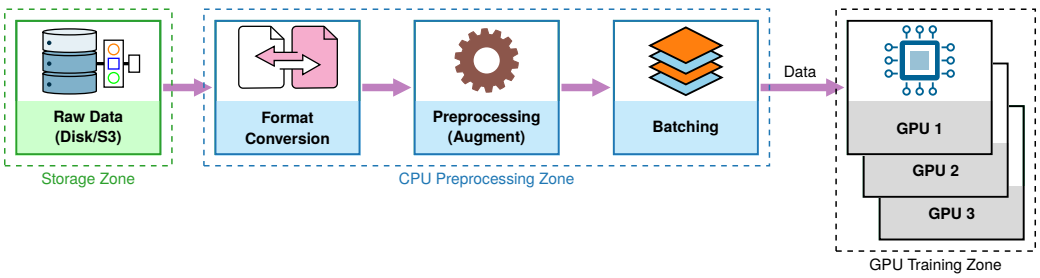

Figure 8.4: CPU-to-GPU Data Flow: Training data transitions through storage, CPU preprocessing, and GPU execution zones. Each stage represents a potential throughput gate; disk read bandwidth, transformation latency, and PCIe host-to-device transfers must collectively sustain the GPU consumption rate to keep accelerators at peak utilization.

In the storage zone, raw records reside on local NVMe drives or networked storage systems. In the CPU preprocessing zone, host worker threads decode raw bytes, apply transformations such as tokenization or data augmentation, and collate individual records into dense mini-batch tensors. In the GPU training zone, accelerators transfer those tensors across the PCIe bus and execute forward and backward passes. Because these three zones form a strict pipeline, the slowest stage dictates end-to-end training throughput. In the pipeline model developed below, the storage and CPU zones

together set the preprocessing term, the PCIe crossing sets the transfer term, and the GPU zone sets the compute term.

8.4.2.1 Core components

Data pipeline throughput originates at the storage subsystem. Upstream layout decisions, such as sequential chunking in columnar or container formats (Parquet, TFRecord, Arrow), dictate the physical I/O patterns presented to the operating system.

↩ How file format and storage layout set the data term of the iron law is established in section 4.10.2.

Storage throughput is bounded by the slower of two hardware constraints, $R_{\text{storage}} = \min(\text{BW}_{\text{disk}}, \text{BW}_{\text{network}})$, where BW_{disk} is the physical disk bandwidth and $\text{BW}_{\text{network}}$ represents the network bandwidth for distributed storage systems. In practice, training workloads rarely achieve this theoretical maximum because data shuffling can turn large sequential reads into smaller, less efficient accesses. Effective storage throughput can be modeled as $R_{\text{storage,eff}} = R_{\text{storage}} \times F_{\text{access}}$, where F_{access} depends on record size, file layout, caching, and storage hardware. When unbuffered random reads degrade F_{access}, storage bandwidth drops by an order of magnitude, transforming an I/O system that appears sufficient on paper into a primary training bottleneck.

GPT-2's 40 GB WebText corpus fits in the host memory of a single training server, so once cached it can be served from system RAM without repeated storage reads, although preprocessing and transfer costs remain. A corpus that exceeds local memory must instead be streamed, and the system must orchestrate storage reads, preprocessing, caching, and delivery throughout training. Whether multiple workers, prefetching, local caches, or distributed storage pay off then depends on which of those stages limits throughput.

8.4.2.2 Preprocessing

Once retrieved from storage, raw bytes require CPU transformation into model-ready tensors. While static feature extraction can run offline, dynamic transformations such as on-the-fly tokenization and image augmentation execute during training. Under ideal independent-worker scaling, the CPU worker pool delivers transformation capacity according to equation 8.5:

$$R_{\text{preprocessing}} = \frac{N_{\text{workers}}}{T_{\text{transform}}} \tag{8.5}$$

where N_{workers} parallel processing threads each perform transformations requiring $T_{\text{transform}}$ seconds per batch. Training architectures employ multiple workers to ensure transformation keeps pace with accelerator consumption rates.

However, transforming records assumes that storage delivers raw bytes fast enough to keep worker queues filled. Under overlapped host staging, the achieved host preparation rate cannot exceed the slower of storage retrieval and CPU transformation. Dividing effective storage throughput $R_{\text{storage,eff}}$ by the raw bytes retrieved per batch yields the storage delivery rate in batches per second. When storage delivery lags behind worker demand, additional CPU threads sit idle waiting on disk I/O, capping host throughput regardless of N_{workers}. The complete host preparation rate is therefore bounded by the lesser of the storage delivery rate and the worker transformation capacity $N_{\text{workers}}/T_{\text{transform}}$.

Preprocessed data must then transfer across the host-accelerator interconnect before computation can begin. End-to-end training throughput is consequently constrained by the slowest of three sequential stages, as formalized in equation 8.6. In this three-stage pipeline model, the host preparation rate $R_{\text{preprocessing}}$ captures the joint bound of storage delivery and CPU worker transformation, while the remaining terms capture host-to-device bus transfer and device execution:

$$R_{\text{training}} = \min\left(R_{\text{preprocessing}}, \frac{\text{BW}_{\text{host}}}{D_{\text{vol}}^{(\text{batch})}}, \frac{R_{\text{sustained}}}{O_{\text{batch}}}\right) \tag{8.6}$$

where BW_{host} is the host-to-accelerator transfer bandwidth, $D_{\text{vol}}^{(\text{batch})}$ is the input bytes per batch transferred to the device, and O_{batch} is the forward-backward work per batch in FLOPs. Every term is therefore expressed in batches per second before the minimum is taken.

Example 8.1: GPT-2 language model data pipeline

Scenario: Quantifying storage access, CPU tokenization, and PCIe host-to-device transfers supplying one H100 training GPT-2 XL at batch 32. The device service interval is the step time the training-time law gives at the chapter's utilization, about 596 ms per batch; fitting that batch in memory requires the techniques of section 8.6, but the input path does not depend on which ones are used.

Stage trace:

1. **Raw text storage**: The WebText corpus contributes about 40 GB of raw text. Sequential reads from NVMe SSD storage reach 7 GB/s. Under document sampling with access factor 0.1, random-access storage bandwidth drops to 0.70 GB/s, giving $T_{\text{read}} = D_{\text{vol}}/R_{\text{storage,eff}} \approx 0.1$ ms.
2. **Tokenization**: A BPE tokenizer (50,257 vocabulary) converts text into token IDs. For batch size $B = 32$ and sequence length $S = 1024$ (32.8K tokens total), a single CPU core processing 50K tokens/s takes $T_{\text{tokenize}} \approx 655.4$ ms per batch.
3. **Batching and padding**: Padding and packing generate an int64 tensor of shape 32 sequences $\times$ 1,024 tokens, producing 262.1 KB per batch.
4. **PCIe transfer**: Transferring the tensor across the H100's PCIe Gen5 x16 link (64 GB/s bandwidth) takes $T_{\text{transfer}} = 0.004$ ms, making bus transfer negligible.

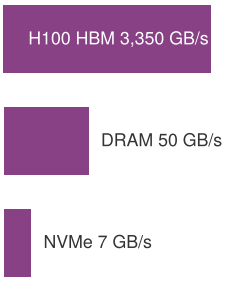
Systems insight: Single-core CPU preparation ($T_{\text{prep}} \approx 655.4$ ms) exceeds the accelerator service interval ($T_{\text{GPU}} \approx 596$ ms), so a serial pipeline pays both costs on every step and the device service stage occupies only about 48 percent of the serial step. Slower preparation increases the exposed input wait. Scaling to 8 parallel worker processes reduces the ideal average interval between prepared batches to $T_{\text{tokenize}}/N_{\text{workers}} \approx 81.9$ ms, while prefetching overlaps T_{prep} with T_{GPU} to keep the device stage supplied throughout ideal steady-state execution, delivering 54 sequences per second on one H100. The service interval is a modeled step time, not a measurement of hardware busy time. Keeping inputs available does not establish useful FLOP utilization, which requires a separate useful-work count and measured step time. Parallel workers need not shorten the latency of an individual batch, and contention or imperfect overlap can reduce the modeled throughput.

This min-of-three relationship governs training pipeline design because system throughput equals bottleneck throughput. An accelerator with 989 TFLOP/s of compute capacity delivers zero useful work while waiting for data. Conversely, a perfectly optimized data pipeline provides no benefit if the accelerator is already compute-saturated. Balanced pipeline design aligns preprocessing capacity, transfer bandwidth, and compute throughput so that no single stage dominates iteration time. Under that scenario, the GPT-2 workload shows CPU tokenization, rather than storage retrieval or bus transfer, forming the primary throughput barrier unless parallel workers and prefetching conceal host preparation latency.

Data pipeline throughput is not the only flow that can starve the accelerator. Multi-GPU training adds a second stream of traffic: the gradient synchronization required after every step. Once synchronization time exceeds compute time, communication becomes the limiting factor. Section 8.7.2 quantifies that network wall at the point where training crosses the node boundary.

8.4.2.3 System implications

Comparing supply with demand requires both in the same unit. Grouping the two host-side terms of equation 8.6 into a single pipeline rate R_{pipeline}, in batches per second, and writing the accelerator's consumption rate as $R_{\text{accel}} = R_{\text{sustained}}/O_{\text{batch}}$, also in batches per second (where $R_{\text{sustained}}$ stays in FLOP/s), leaves a coupled system whose throughput is $\min(R_{\text{pipeline}}, R_{\text{accel}})$. When $R_{\text{pipeline}} < R_{\text{accel}}$, the accelerator sits idle waiting for data, and its busy-time fraction drops proportionally in this ideal



supply model, as equation 8.7 shows. Busy time counts every moment the accelerator is executing, so it is an upper bound on, and distinct from, the model-FLOP utilization defined later in the chapter:

$$\text{Accelerator Utilization} = \min\left(1, \frac{R_{\text{pipeline}}}{R_{\text{accel}}}\right) \times 100\% \tag{8.7}$$

ResNet-50 shows how quickly that drop arrives on current hardware. One training image costs about 24.6 GFLOP, so the H100's dense 16-bit peak could consume about 40,200 images/s. A well-tuned training step sustains only part of that ceiling; at the 25 percent fraction implied by the 3,200 images/s that section 4.9.3 assumed for the previous-generation A100, the H100 consumes about 10,100 images/s. A host worker that decodes and augments 375 images/s would need 28 workers per accelerator to keep up, but an eight-accelerator H100 server provides 112 host cores, 14 per accelerator. Those workers supply about 5,250 images/s, so by equation 8.7 the accelerator is busy only about 52 percent of the time. The same host fed an A100 with 9 workers and cores to spare. Upgrading the accelerator raised its appetite 3× without changing the host, which moves ResNet-50 from its home compute-bound regime into an input-bound one. Faster arithmetic adds nothing until the input pipeline is rebalanced, with more host cores per accelerator, decoding on the accelerator, or cached decoded data, and section 8.6.2 takes up the overlap that hides what remains.

8.4.2.4 Data flows

Training data traverses three memory tiers on its way from disk to accelerator, and the bandwidth gap between these tiers, spanning roughly two orders of magnitude, is the central challenge of data pipeline design. For equal byte volumes at each tier, the effective transfer rate is bounded by $\min(\text{BW}_{\text{storage}}, \text{BW}_{\text{system}}, \text{BW}_{\text{accelerator}})$, the same minimum as equation 8.6 applied to bandwidth tiers. When decoding, tokenization, or reuse changes the bytes handled per batch, each bandwidth must first be divided by its own per-batch byte volume so that the rates are comparable.

Bandwidth steps up the storage to DRAM to HBM hierarchy.

Local NVMe storage provides 7 GB/s, system memory delivers 50 GB/s, and the H100's HBM delivers 3350 GB/s. Each tier is roughly an order of magnitude or more faster than the one below it, which means data that flows freely within accelerator memory creates a severe bottleneck when it must be fetched from disk. Stated in time rather than rate, the pipeline model says that when stages overlap correctly (fetching the next batch from storage while preprocessing the current one and transferring the previous one to the accelerator), the steady-state input service interval, denoted here by iteration time, is governed by the *maximum* of the stage times, $T_{\text{iteration}} = \max(T_{\text{fetch}}, T_{\text{process}}, T_{\text{transfer}})$, rather than their *sum*. This overlap is what prefetching seeks to achieve, with each tier operating concurrently on different batches. End-to-end training must also include accelerator compute and any exposed synchronization or evaluation time.

8.4.2.5 Practical architectures

An NVMe device rated at 7 GB/s would sustain 3.50 GB/s if a workload achieved half of peak. Small random reads and shuffling can reduce throughput further; the penalty depends on access size, queue depth, file layout, and caching.

To keep accelerators fed despite this bandwidth reduction, pipeline architectures maintain multiple data buffers simultaneously: prefetch buffers loading future batches, processing buffers holding data under transformation, and transfer buffers staging data for accelerator consumption. The total host memory required scales with the per-batch memory footprint M_{batch} according to equation 8.8:

$$M_{\text{required}} = (N_{\text{prefetch}} + N_{\text{processing}} + N_{\text{transfer}}) \times M_{\text{batch}} \tag{8.8}$$

To avoid starving the accelerator, the average preprocessing service time per batch across all workers must not exceed the compute time per batch ($T_{\text{preprocessing}} \leq T_{\text{compute}}$), which restates the preprocessing term of equation 8.6 in time. If preprocessing takes 40 ms per batch on one worker while the accelerator consumes a batch every 10 ms, ideal scaling requires at least four workers; actual worker requirements depend on storage throughput, CPU contention, and transformation cost, which section 8.6.2 examines through prefetching and parallel workers.

8.4.3 Forward and backward pass

The operation counts in section 8.3.1.1 become a scheduling problem once a prepared batch reaches the forward pass: the runtime must launch kernels with enough parallel work, stage their operands, and keep the values required by backward execution.

8.4.3.1 Compute operations

A dense layer's FLOP count is already fixed by its input width, output width, and batch size. Its execution time also depends on how that work fills the accelerator. A layer with dimensions of 512×1024 at batch 64 supplies 33.6 million MACs, or 67.1 MFLOP; the kernel must divide this work among execution units without leaving a long, mostly empty final wave.

Accelerators execute these parallel workloads by grouping execution threads into fixed-size units: warps[14] of 32 threads on NVIDIA architectures, or wavefronts of 64 threads on AMD architectures. Hardware execution efficiency depends on aligning tensor dimensions and tile shapes with the thread-block geometry and the operand matrix dimensions required by specialized units like Tensor Cores.

[14] **Warp**: From textile weaving, where a "warp" is the set of threads held taut on a loom while a shuttle weaves across them. NVIDIA adopted the term because GPU threads within a warp execute the same instruction in lockstep, analogous to parallel threads moving together on the loom. An NVIDIA warp contains 32 threads.

Systems Perspective 8.3: Wave quantization and tail effects

A common mistake in ML systems is ignoring the fixed execution granularity of GPU kernels. GPU execution is quantized into waves of work, but the relevant unit is the kernel's thread or tile mapping, not necessarily one sample per thread.

Warps make the granularity concrete. In the illustrative special case where one independent work item maps to one thread, 32 items fill one warp while 33 items require a second, mostly empty warp. Neural-network kernels usually map each sample to many threads, so batch size alone does not determine this utilization.

On a large GPU such as the NVIDIA H100 with 132 Streaming Multiprocessors (SMs), where each SM schedules groups of warps, the hardware processes thousands of threads in a single wave. If the total workload slightly exceeds a wave boundary (for example, 1.01 waves), the hardware must execute a second, nearly empty wave to completion before the next task begins.

Table 8.6 quantifies that one-item-per-thread illustration. It is not a general batch-size performance model.

Table 8.6: Illustrative Warp-Tail Arithmetic: Under a one-work-item-per-thread mapping, counts just above a 32-thread boundary launch a partially filled warp, so 33 items use two warps while 64 fill the same two warps. Actual training kernels map tensors to threads and tiles in implementation-specific ways, often assigning many threads to each sample, so these values cannot be inferred from batch size alone. Profiling must identify the kernel's real mapping and wave boundaries.

Independent Work Items	Warps Needed	Lane Utilization	Relative Time
32	1	100%	1×
33	2	51.6%	~2×
64	2	100%	1×
65	3	67.7%	~1.5×

Systems insight: The table teaches the shape of the penalty, not its size for any real kernel. The actionable rule is to choose batch, sequence, and hidden dimensions that are multiples of the kernel's tile size and that divide into whole waves across the SMs, then benchmark the neighboring candidates. Profiling reveals partially filled warps or waves; batch size alone cannot.

Beyond dense matrix multiplication, distinct neural architectures introduce specialized computational patterns. Convolutional networks, for instance, slide spatial filters across multichannel input tensors. Consider an input tensor of dimensions $64 \times 224 \times 224 \times 3$ (batch size $\times$ height $\times$ width $\times$ channels) processed by 7×7 kernels. Each position requires 147 multiply-accumulate operations, and with 64 filters operating across 218×218 spatial dimensions, the arithmetic work reaches hundreds of millions of multiply-accumulate operations per image. Accelerators execute

these spatial convolutions by either lowering them into dense GEMMs through column unfolding (`im2col`) or applying Winograd minimal filtering, which reduces multiplications at the cost of extra additions and transform workspace.

The other operator families impose different scheduling constraints. Attention alternates batched matrix products with row-wise reductions, while normalization requires statistics before normalized outputs can be produced. The arithmetic-intensity analysis in section 8.3.4 explains their traffic cost; the runtime must additionally respect these reduction dependencies and choose which intermediates can remain inside a fused kernel.

Optimized operator libraries such as cuDNN (Chetlur et al. 2014) implement multiple computational algorithms for each layer type, dynamically selecting among them based on tensor dimensions, scratchpad memory limits, and hardware capabilities. For example, cuDNN chooses between direct convolution, GEMM-based lowering, fast Fourier transform (FFT) convolution, and Winograd transforms by evaluating the trade-off between workspace memory overhead and arithmetic operations (NVIDIA Corporation 2023a). These hardware utilization patterns reinforce the coupling between batch size and hardware efficiency established in section 8.3.2.1: larger batch sizes saturate accelerator compute units and amortize memory transfers, but increase intermediate activation storage.

8.4.3.2 Memory management

Memory management binds during the forward pass, when intermediate activations must be retained in high-bandwidth memory for gradient computation during backpropagation. How quickly that retained state grows depends on the architecture, as a convolutional network shows.

Consider ResNet-50 processing images at 224×224 resolution with a batch size of 32. The initial convolutional layer produces activation maps of dimension $112 \times 112 \times 64$; per image at single-precision (4 bytes), this requires approximately 3.2 MB. For an illustrative capacity budget, assume retained forward activations total 8 GB, the backward pass adds another 4 GB of activation working set (a supplied scenario assumption, distinct from stored parameter gradients), and model parameters consume 102.4 MB. This 12.1 GB subtotal excludes parameter gradients, optimizer state, and additional runtime workspace; those terms must be added before deciding whether training fits.

Under the same linear-scaling assumption, doubling the batch size to 64 doubles activation storage: forward activations reach 16 GB and the backward activation working set reaches 8 GB, raising this subtotal to 24.1 GB. In vision models with large spatial resolutions, activations dominate the memory footprint while parameter storage (102.4 MB) is negligible. For large language models, the balance inverts: GPT-3 (175B parameters) requires approximately 700 GB just for parameters in FP32 (350 GB in FP16), exceeding single-accelerator capacity before allocating any activation memory or optimizer state.

Because accelerator memory (80 GB on the reference H100) must hold activations, parameters, gradients, and optimizer states simultaneously, memory capacity rather than compute throughput frequently caps the feasible batch size. Two system-level techniques relieve this capacity bottleneck: activation checkpointing discards intermediate activations during the forward pass and recomputes them during the backward pass, trading redundant arithmetic for reduced storage; and mixed-precision training halves storage per value for tensors represented in 16-bit formats instead of FP32. Master weights and optimizer state may remain in FP32, so the saving must be calculated for each term of the memory budget. Both techniques are analyzed in detail in section 8.6.

During backpropagation (section 8.3.3), the backward pass traverses the network in reverse order, consuming retained forward activations to compute parameter and activation gradients at roughly twice the arithmetic cost of the forward pass. Memory requirements shift dynamically across layers. In ResNet-50, mid-network layers expand to 256 filters from the initial 64, where reduced spatial map dimensions partly compensate for higher channel depth. Peak memory footprint reflects retained forward activations, active gradient buffers, temporary workspaces, and the runtime allocation schedule rather than the width of a single layer alone.

8.4.4 Parameter updates

Once backward execution populates the gradient buffers, the optimizer consumes them and updates the persistent state defined in algorithm 8.1. The important pipeline boundary is the weight mutation: the next forward pass must observe the completed update. Listing 8.2 shows that boundary at the framework interface.

Listing 8.2: Parameter Update: Computes gradients and applies an optimizer step to model parameters. Repeating this cycle seeks to minimize the training objective, although improvement is not guaranteed on every step or epoch.

```
loss.backward()  # Compute gradients
optimizer.step()  # Update parameters
```

The optimizer's memory traffic is exposed on this dependency path. The FP32 Adam update, which moves 28 bytes per parameter in section 8.3.2.4, must finish before the next forward pass reads those weights. Fusing moment updates and weight writes can shorten this interval by reducing passes over HBM, even when the forward and backward matrix products already use the arithmetic units efficiently.

8.4.4.1 Batch size and parameter updates

Increasing batch size improves accelerator utilization by raising the arithmetic intensity of matrix multiplications and reducing synchronization frequency, but it also alters optimization dynamics. Scaling batch size without retuning the learning-rate schedule can degrade convergence, creating an optimization gap where hardware efficiency comes at the expense of model quality. Figure 8.5 isolates this dynamic across synthetic loss trajectories: holding the learning rate fixed while expanding from batch 32 to batch 256 leaves an acute optimization gap (dashed silver curve), whereas linearly scaling the learning rate brings convergence close to the baseline path (green curve).

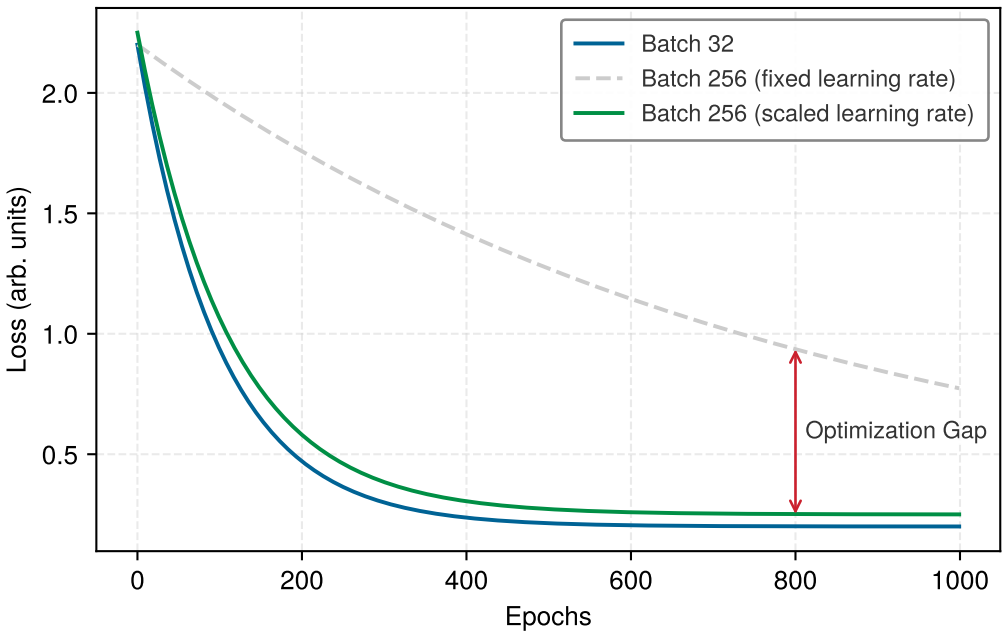


Figure 8.5: Illustrative Linear-Scaling Scenario: Synthetic training-loss curves (arbitrary units) compare a batch-32 baseline with batch 256 under a fixed or linearly scaled learning rate. The curves illustrate why increasing batch size may require retuning; they are not measured traces or a guarantee that linear scaling preserves convergence.

For a fixed token budget, doubling the global batch size halves the number of parameter updates per epoch. To traverse a comparable distance in parameter space with fewer updates, the linear scaling rule of the large-batch ResNet-50 recipe in section 8.3.2.1 scales the learning rate proportionally

with batch size ($\eta_{\text{new}} = \eta_{\text{base}} \times B_{\text{new}}/B_{\text{base}}$). Although effective across moderate batch ranges when combined with learning-rate warmup, linear scaling does not guarantee equivalent convergence or generalization. Beyond a critical batch size, gradient noise is largely eliminated, and further batch expansion yields diminishing returns per training sample while escalating memory pressure.

Beyond convergence dynamics, batch size dictates communication frequency in distributed systems. A larger global batch reduces the number of optimizer steps and gradient synchronizations per epoch. Because the communication payload of dense all-reduce synchronizations depends on parameter count rather than batch size, larger batches amortize interconnect latency over more compute FLOPs. In distributed settings, local micro-batch size and global batch size jointly determine the maximum degree of data parallelism. When memory capacity constrains the local micro-batch, gradient accumulation (section 8.6.5) decouples the effective batch size from per-device activation memory, accumulating gradients across multiple forward-backward passes before triggering an optimizer step.

8.4.5 Training state and checkpoints

A run that takes 35 days on one accelerator does not run uninterrupted. Hardware fails, jobs are preempted, and numerical instabilities corrupt weights, so a training system must save the run's state to storage at intervals and restore it exactly. That saved state is a different mechanism from the activation checkpointing of section 8.6.5.1, which recomputes values inside one step; a training checkpoint is a file that carries the run across steps.

Resuming requires restoring model weights and optimizer state in lockstep: first-moment vectors, second-moment variance estimates, and step counters. In the mixed-precision Adam recipe of section 8.3.2.3, a checkpoint holds the FP16 working weights (2 bytes per parameter), the FP32 master weights (4 bytes), and the two FP32 moments (8 bytes), 14 bytes per parameter. The FP16 gradients, which every step recomputes, are left out of the 16 bytes per parameter that training holds in device memory. For GPT-2 XL the checkpoint payload is therefore about 21 GB (3 GB + 6 GB + 12 GB), 7× the FP16 weights alone, and writing it to a local NVMe drive at 7 GB/s takes about 3 s. Checkpoint volume governs how long a save stalls the run and how long recovery takes, connecting fault tolerance to the iron law's D_{vol} term.

At the framework level, optimizers expose internal state dictionaries via `state_dict()` for serialization. Listing 8.3 demonstrates accessing optimizer state dictionaries, and listing 8.4 shows saving and restoring model parameters and optimizer states. Reproducing the training trajectory also requires the relevant random-number state, data position, learning-rate scheduler, and gradient-scaler state.

Listing 8.3: State Dictionary Interface: Optimizers expose internal state through state_dict(), enabling serialization of momentum buffers and adaptive learning rate estimates for checkpointing.

```
import torch
import torch.nn as nn
import torch.optim as optim

model = nn.Linear(10, 5)
optimizer = optim.Adam(model.parameters(), lr=0.001)

# After training steps, optimizer accumulates state
loss = model(torch.randn(3, 10)).sum()
loss.backward()
optimizer.step()

# Access state for checkpointing
state = optimizer.state_dict()
# Contains: {'state': {...}, 'param_groups': [{'lr': 0.001, ...}]}
```

Listing 8.4: Checkpoint Save and Load: Save both model parameters and optimizer state to properly resume training with correct momentum and adaptive learning rate values.

```
# Saving checkpoint
checkpoint = {
    "epoch": epoch,
    "model_state_dict": model.state_dict(),
    "optimizer_state_dict": optimizer.state_dict(),
}
torch.save(checkpoint, "checkpoint.pt")

# Resuming training
checkpoint = torch.load("checkpoint.pt")
model.load_state_dict(checkpoint["model_state_dict"])
optimizer.load_state_dict(checkpoint["optimizer_state_dict"])
```

A checkpoint holds only persistent state. During a training step, the FP16 gradients rejoin that state in device memory and the saved activations from reverse-mode automatic differentiation sit on top of it, so device memory must hold more than the checkpoint file suggests. Notebook 8.5 works through the full comparison for a billion-parameter model.

Napkin Math 8.5: Training memory beyond the checkpoint

The frameworks chapter's ResNet-50 breakdown (section 7.4.3.1) already showed training memory several times the size of the stored weights. The following scenario extends the comparison to gradients, optimizer state, and saved activations at billion-parameter scale.

Problem: Calculate the memory that gradients, optimizer states, and forward activations add beyond raw model weights in this billion-parameter training scenario.

Math:

1. Model weights (FP16): 2 GB.
2. Gradients (FP16): 2 GB (same size as weights).
3. Master weights (FP32): 4 GB, the full-precision copy that mixed-precision training updates.
4. Optimizer states (Adam): 8 GB (momentum and variance in FP32, 4× the FP16 weight memory).
5. Activations: For a batch size of 32 and a 100-layer network, reverse-mode automatic differentiation retains the operation-dependent values required by derivative rules; activation checkpointing can omit selected values and recompute them during the backward pass.

$$M_{\text{activations}} \approx B \times N_L \times S \times d \times n_{\text{saved}} \times s_{\text{elem}}$$

For a 1024-token sequence, 1024-wide hidden state, 1 saved tensor per layer, and $s_{\text{elem}} = 2$ bytes for FP16: $32 \times 100 \times 1024 \times 1024 \times 1 \times 2 \approx$ **6.7**GB. Materialized attention terms can add a separate $B \times N_{\text{heads}} \times S^2$ component, which is why memory-efficient attention kernels matter.

Systems insight: A 2 GB model carries 16 GB of steady-state training state once gradients and optimizer buffers have been allocated, 8× its FP16 weights (16 bytes per parameter in the mixed-precision Adam recipe), while its checkpoint file holds 14 bytes per parameter. During a training step, batch-dependent activations add another 6.7 GB, raising the peak to about 20.7 GB beyond the weights. During training, data movement includes saving and retrieving these activations.

Checkpoint cadence decides how much work a failure discards. Because every update depends on the one before it, a single unmitigated numerical explosion does not cost one step; it can invali-

date every step taken since the last good checkpoint, which at frontier scale means thousands of accelerator-hours.

War Story 8.1: The PaLM loss spikes (2022)

Context: PaLM's 540-billion-parameter run used 6,144 TPU v4 chips across two 3,072-chip Pods connected through Google's data-center network and suffered severe training-instability spikes absent from smaller runs (Chowdhery et al. 2022).

Failure mode: The training loss spiked roughly 20 times despite gradient clipping. The spikes occurred at highly irregular intervals, sometimes late in training, never appeared in smaller models, and had no identified principled mitigation.

Impact: Each recovery discarded recent progress on an expensive 6,144-chip run, so reproducible checkpoints and repeatable data order were prerequisites for replay.

Response: Engineers restarted training from an uncorrupted checkpoint roughly 100 steps prior to each spike and skipped approximately 200–500 data batches around the failure window.

Systems lesson: Every step discarded in a recovery is paid for again in cluster time, so operational fault tolerance decides how much of the hardware's time turns into lasting progress. Automated loss-spike detection, checkpoint cadence, and batch skipping are core system mechanisms for keeping that lost fraction small.

PaLM's recoveries kept 6,144 chips busy on steps that were later thrown away, so the cluster's time was spent without the run advancing. In the training-time law that discarded work appears as a lower utilization factor η_{hw}, which makes checkpoint cadence a throughput decision as well as a reliability one. Frequent saves stall the run for the write time above, while sparse saves lengthen the replay after each failure.

Decomposing the training pipeline exposes the mechanics of data loading, forward and backward execution, parameter updates, and saved training state, while the computation and memory costs in section 8.3 quantify the FLOPs, memory footprint, and bandwidth each phase demands. Yet knowing how stages execute does not reveal where a specific training workload stalls. A pipeline is only as fast as its slowest stage. In an overlapped pipeline where data loading takes 120 ms and computation takes 100 ms, a 20 percent faster kernel saves nothing, because the step still takes 120 ms. Before applying optimization techniques, systems engineers must profile the execution timeline to determine whether compute, memory bandwidth, storage I/O, or network synchronization binds performance.

Checkpoint 8.2: Costing a step and building its pipeline

The first half of the chapter costed one training step and assembled the pipeline that runs it. Check that each piece can be computed before moving on to diagnosis and optimization.

Cost of a step

- ☐ **Run time and energy**: Using the training-time law, estimate how many days one accelerator needs for a run of 10^{21} FLOPs at a given peak rate and utilization, and how much energy it draws at a given device power.
- ☐ **Static state**: Explain why the common mixed-precision Adam recipe holds 16 bytes per parameter, and why switching to 16-bit arithmetic does not shrink that number.
- ☐ **Memory estimate**: For GPT-2 XL in mixed precision at batch 32 and sequence length 1,024, estimate weights, gradients, master weights, optimizer state, and activations, identify the largest term, and decide whether the total fits on an 80 GB accelerator.
- ☐ **Fine-tuning scope**: Explain why full fine-tuning of an 8-billion-parameter model overflows one 80 GB accelerator while low-rank adapters fit, and which memory terms each choice populates.

Pipeline

- ☐ **Slowest stage**: Given host preparation, transfer, and compute rates in batches per second, identify the stage that sets training throughput and compute the accelerator's busy-time fraction.
- ☐ **Training state**: Explain why a training checkpoint file is smaller than the training state in device memory, and what else must be saved to resume a run exactly.

8.5 Identifying Bottlenecks

An accelerator can report near-100 percent activity in `nvidia-smi` while spending half its cycles stalled on memory traffic, padding, or recomputing discarded activations. Knowing what each operation costs on paper does not show which resource actually saturates during a run, and raw device busy-time percentages cannot separate useful training arithmetic from overhead. Model FLOPs utilization (MFU)[15] supplies that comparison by measuring achieved model arithmetic against the hardware's peak rate.

[15] **Model FLOPs utilization (MFU)**: The PaLM paper (Chowdhery et al. 2022) defined MFU as observed throughput divided by the theoretical maximum throughput at peak FLOPs. Its 540-billion-parameter run reported 46.2 percent MFU on 6,144 TPU v4 chips. The remainder is not credited by the model-FLOP numerator, and MFU alone does not identify how much came from memory traffic, communication, pipeline bubbles, recomputation, or other work.

Definition 8.3: Model FLOPs utilization (MFU)

Model FLOPs utilization (MFU) is the efficiency metric $\text{MFU} = O_{\text{model}}/(R_{\text{peak}} \cdot T_{\text{step}})$, where O_{model} is the useful per-step model FLOP count (forward plus backward, excluding rematerialization) and T_{step} is the measured wall-clock time per training step, expressing what fraction of peak hardware throughput is doing useful model computation.

1. Significance: MFU makes the effective-throughput term in the iron law concrete. For GPT-2 XL (1.5B parameters) processing 32,768 tokens per step on an H100 (989 TFLOP/s dense FP16/BF16 Tensor Core peak), a 0.60 s step gives model FLOPs divided by the available peak-rate FLOP budget of approximately 0.50 (50 percent). The remaining 50 percent is not credited as model FLOPs and can reflect memory traffic, communication, bubbles, non-model operations, or idle time. Diagnosing that gap requires a profile rather than a universal threshold.
2. Distinction: Hardware utilization reports whether device engines are active, whereas MFU credits the analytical model-FLOP estimate used in its numerator. It can therefore exclude recomputation and padding even when those operations keep the device busy. Comparisons across accelerators remain sensitive to the selected peak-throughput specification and FLOP-counting convention.
3. Common pitfall: A frequent misconception is that 100 percent MFU is a realistic sustained target. Memory traffic, communication, and non-matrix work keep end-to-end runs below peak. Reported values depend on the model, precision, batch shape, hardware, and MFU definition, and can improve with FlashAttention and careful tuning.

Three distinct metrics are commonly referred to as "utilization" in training systems, and each addresses a different operational question. The hardware efficiency factor η_{hw} in the training-time law (equation 8.1) represents the end-to-end fraction of theoretical peak compute converted into useful model arithmetic across an entire run, whereas MFU measures this same ratio over an individual training step as the direct empirical estimator for η_{hw}. In contrast, the accelerator busy-time fraction of equation 8.7, the metric reported by standard operating-system and vendor monitoring utilities such as `nvidia-smi`, indicates only whether execution cores are active, without distinguishing useful matrix products from memory-stall cycles, padding overhead, or rematerialization. Consequently, busy-time utilization serves only as an upper bound on MFU: a data-starved pipeline has a low busy-time fraction, whereas a well-fed but memory-stalled workload shows near-100 percent busy-time utilization alongside low MFU.

Training bottlenecks can be investigated through three categories aligned with the D·A·M taxonomy (Data, Algorithm, Machine). Table 8.7 connects each axis to a common training bottleneck, its observable symptoms, and relevant optimization techniques. The axis names where the remedy usually lives rather than what the bottleneck is. Compute-bound and memory-bound execution are both

mismatches between an algorithm and a machine, as the ridge point showed, but a compute-bound kernel is most often relieved by asking for less or cheaper arithmetic (Algorithm), a memory-bound kernel by changing how the machine stages and moves bytes (Machine), and an input stall by repairing the data path (Data). These are diagnostic starting points, not exclusive mappings.

↪ The full D·A·M diagnostic framework, with its troubleshooting matrix and scorecard, is collected for reference in Appendix A.

Table 8.7: D·A·M Taxonomy Applied to Training Bottlenecks: Each row associates a D·A·M axis with one common bottleneck and its characteristic symptoms. Profiling reveals the workload's limiting constraint and guides practitioners to an appropriate optimization technique.

D·A·M Axis	Bottleneck	Symptoms	Primary Solutions
Algorithm	Compute-bound	High arithmetic-unit activity; additional bandwidth does not improve throughput; arithmetic throughput is limiting	Reduced precision, more efficient algorithms, faster compute hardware
Machine	Memory-bound	High memory-bandwidth use relative to arithmetic throughput; kernels stall on data movement	Kernel fusion, memory-efficient attention, reduced precision formats
Data	Data-bound	Periodic accelerator utilization drops to near-zero; CPU fully busy during gaps; pipeline cannot feed GPU fast enough	Prefetching, pipeline overlap, faster storage, DataLoader parallelism

Among these three regimes, data-bound stalls are the most frequently misdiagnosed because they manifest on the accelerator as idle gaps rather than saturated execution units. When host-side ingestion, decoding, or preprocessing cannot sustain the throughput demanded by device memory buses, the accelerator starves.

Example 8.2: The GIL-locked GPU

Scenario: An engineering team builds a PyTorch data-loading pipeline using standard Python `threading` for CPU-bound image preprocessing that holds the global interpreter lock (GIL).

Diagnosis: The GIL serializes these Python-level preprocessing threads, making host preparation time ($T_{\text{prep}} \approx 250$ ms) far exceed GPU execution time ($T_{\text{GPU}} \approx 12$ ms), reducing the accelerator busy-time fraction to about 4.6 percent in this serial preparation-and-compute model. Here the fraction measures time spent computing, not arithmetic efficiency relative to peak throughput.

Systems lesson: Python CPU work that holds the GIL can serialize threads and starve GPUs; native operations may release it. Process workers (`num_workers > 0`) avoid interpreter serialization, while the NVIDIA Data Loading Library (DALI) can move eligible work off the host.

In the execution timeline captured by figure 8.6, wide white intervals separate brief GPU stream activity bursts, marking periods where accelerator compute engines idle while CPU-side Python threads assemble the next batch.

Two classes of tools expose these signatures. Framework-level profilers record a timeline of operations, memory allocations, and input-pipeline stalls, which locates idle gaps and attributes them to host work. System- and kernel-level GPU profilers record kernel execution, memory transfers, synchronization points, and per-kernel counters such as achieved memory throughput and arithmetic-unit occupancy, which explains why a kernel that runs is slow. The method below uses the first class to find where time goes and the second to explain it.

↪ How profilers and benchmark harnesses turn these measurements into reproducible results is developed in section 12.5.

A disciplined profiling workflow proceeds top-down from system timelines to kernel-level performance counters, mapping observable profiler traces to the D·A·M taxonomy in table 8.7. First, timeline visualization locates idle intervals between kernel invocations. Correlating these gaps with batch preparation, transfers, host dispatch, and synchronization establishes what prevents the next kernel from running. When input starvation is confirmed, remedies include asynchronous prefetching, multi-process workers, or offloading preprocessing to the accelerator to overlap data movement with compute. Second, when kernels execute contiguously without host-induced gaps, memory throughput relative to peak bandwidth distinguishes memory-bound from compute-bound

Figure 8.6: Data-Bound Profiler Trace: In this timeline trace, isolated GPU compute blocks are separated by prominent white intervals. These idle gaps mark periods where accelerator streams stall waiting for CPU-side batch preparation and host-to-device transfers, providing a characteristic signature of an input-bound pipeline.

execution. If HBM traffic saturates while arithmetic units idle, the workload is memory-bound; kernel fusion and memory-efficient attention relieve this constraint by retaining intermediate tensors in on-chip SRAM rather than writing them back to global memory. Finally, if tensor cores operate near theoretical capacity and memory buses have spare bandwidth, the workload is compute-bound, where throughput gains require lower numerical precision, such as BF16 or FP8, to increase peak arithmetic throughput.

Applied to the chapter's two running cases, the method gives two different first moves. Before profiling anything, the FP32 GPT-2 XL step at batch 32 does not fit in an H100's memory, a capacity limit that the memory techniques below must address first. Once it fits, the timeline shows the input gaps. With single-core tokenization, host preparation takes about 655.4 ms per batch against a device step of about 596 ms (example 8.1), so a serial pipeline keeps the device stage busy only about 48 percent of each step, a Data-axis diagnosis that no kernel optimization can fix. ResNet-50 on the H100 reaches the same axis by a different route: the host cores available per accelerator supply too few decoded images, leaving the accelerator busy only about 52 percent of the time. A diagnosis names the binding resource; it does not remove it. These two profiles, read against the training-time law and the memory constraint, determine which intervention to apply first and which ones would change nothing.

8.6 Pipeline Optimizations

Even well-designed training pipelines rarely approach hardware peak throughput without targeted optimization: at a typical model-FLOP utilization of 30 percent to 50 percent, an H100 rated at 989 TFLOP/s delivers only 296.7 TFLOP/s–494.5 TFLOP/s of useful model arithmetic. These derived scenario values reflect the gaps between peak and realized throughput reported across published large-model systems (Narayanan et al. 2021; Chowdhery et al. 2022). Systems such as SuperNeurons show one version of this problem, in which memory-management bottlenecks prevent larger networks from training efficiently unless the runtime actively optimizes activation storage and transfer (L. Wang et al. 2018). Closing that utilization gap requires matching a targeted systems intervention to the specific resource that profiling shows is saturated: data movement, arithmetic throughput, or memory capacity. Table 8.8 extends the D·A·M bottleneck classification of table 8.7 by matching each bottleneck to the technique that removes it, the term of the training-time law that the technique moves, and its effect on memory, which decides feasibility rather than appearing in the law.

Table 8.8: Matching Optimizations to Bottlenecks: Each technique removes one profiled bottleneck by moving one factor of the training-time law, equation 8.1, and changes memory, which decides whether a configuration runs at all. Kernel fusion is developed with the frameworks that apply it.

Bottleneck the profile shows	Technique	Law term moved	Memory effect	Developed in
Accelerator idle while input is prepared	Prefetching and overlap	$\eta_{\text{hw}} \uparrow$	Prefetch buffers ↑ in host or device memory	section 8.6.2
Arithmetic rate at FP32	Mixed precision (FP16/BF16)	$R_{\text{peak}} \uparrow$; bytes moved ↓	Activations ↓; static state unchanged	section 8.6.3
Attention's quadratic HBM traffic	FlashAttention (IO-aware tiling)	$\eta_{\text{hw}} \uparrow$; same model FLOPs	Attention scores ↓ from quadratic to linear	section 8.6.4
Batch too large for memory	Gradient accumulation	η_{hw} may ↓ at smaller micro-batches	Activations ↓ to one micro-batch	section 8.6.5.1
Activations exceed memory	Activation checkpointing	$\eta_{\text{hw}} \downarrow$ (recomputation adds work)	Activations ↓ to segment boundaries	section 8.6.5.1
Kernel launches and intermediate traffic	Kernel fusion	$\eta_{\text{hw}} \uparrow$	Intermediates ↓	section 7.3.2

Because training throughput is governed by the system's binding constraint, applying an optimization to a nonbinding subsystem yields no end-to-end speedup. Accelerating tensor arithmetic with lower precision or FlashAttention cannot reduce step time if compute pipelines remain stalled waiting for batches from the host. Conversely, expanding prefetch buffers provides no benefit when execution is bound by HBM capacity or backward-pass recomputation. Profiling must therefore identify whether the workload is bound by input supply, memory capacity, memory bandwidth, or arithmetic throughput before an intervention is selected.

Although the governing constraint shifts with system scale (a 100 GB model faces capacity and interconnect limits that never bind a 1 GB model), identifying and mitigating each bottleneck follows consistent physical principles. Data movement latency emerges when host storage I/O and PCIe transfers cannot stage batches fast enough to keep accelerator compute units saturated. Computational throughput falls below peak hardware rates when operations execute in FP32 instead of using lower-precision Tensor Cores, or when non-fused kernels repeatedly transfer intermediate activations across the memory bus. Memory capacity constraints bind execution because accelerator HBM must simultaneously hold model parameters, optimizer states, gradients, and forward activations. Exhausting this memory caps both model depth and per-device batch size.

Because system resources are tightly coupled, relieving one constraint often exposes another. This is the conservation-of-complexity heuristic from the opening of Part I, which holds that complexity tends to move among Data, Algorithm, and Machine rather than disappear. For example, resolving host I/O stalls by aggressively prefetching batches consumes host memory; separately staged device queues also consume accelerator memory. Conversely, shrinking per-device batch sizes to fit within HBM limits lowers the arithmetic intensity of matrix multiplications, shifting execution from compute-bound matrix math into memory-bandwidth stalls. For GPT-2 XL, the profile above already ranks the first moves. If counters confirm that attention is bandwidth limited, IO-aware attention tiling (FlashAttention) targets that constraint; asynchronous prefetching hides data ingestion behind computation, and mixed precision accelerates eligible tensor operations while reducing storage for activations retained in the lower-precision format. The optimization challenge is to diagnose the governing bottleneck from execution profiles and apply targeted interventions without creating a more severe constraint elsewhere.

8.6.1 Systematic optimization framework

Tuning a training pipeline without a profile wastes work on resources that are not limiting step time or shifts the bottleneck to a neighbor. A disciplined optimization pass therefore proceeds in three steps: profile the step to locate the binding constraint, pick an intervention that relieves that specific limit, and check how combined interventions compete for shared memory and bandwidth.

First, profiling tools such as PyTorch Profiler, TensorFlow Profiler, or NVIDIA Nsight Systems record timestamps and hardware counters across each iteration. Traces capture kernel execution times on accelerator execution units, DMA transfers across PCIe or NVLink buses, and host CPU thread scheduling. Comparing elapsed time across these lanes isolates which subsystem sets the critical path. When data-loading intervals lie on the critical path and coincide with accelerator input waits, as in the GPT-2 XL profile above, the run is data-starved; speeding up matrix multiply kernels yields almost no wall-clock gain until input delivery keeps up.

Second, each diagnosed bottleneck points to a specific remedy. When the accelerator idles waiting for batches, asynchronous prefetching and double-buffering over PCIe overlap host data preparation with device compute. When kernel runtimes are bound by HBM bandwidth rather than arithmetic, kernel fusion and tiled algorithms such as FlashAttention keep intermediate activations in on-chip SRAM. When HBM capacity runs out, activation checkpointing discards and recomputes activations during the backward pass, or gradient accumulation splits each batch across sequential micro-batches to cap peak allocation. Finally, when streaming multiprocessors saturate with dense matrix math, 16-bit formats (FP16 or BF16) move eligible operations onto Tensor Cores, multiplying peak matrix throughput several-fold over FP32 CUDA cores (table 8.9) while halving the bytes moved per operand.

Third, combining interventions requires checking their side effects on shared hardware resources. Asynchronous prefetching hides data movement latency behind computation, but double-buffered batch queues consume pinned host memory and device HBM. Other pairs reinforce one another: combining 16-bit mixed precision with activation checkpointing cuts activation memory enough to admit a larger per-device batch size, raising the arithmetic intensity of matrix multiplications on underfed Tensor Cores. After each change, a fresh profile verifies that the secondary resource cost has not created a new bottleneck.

Figure 8.7 formalizes this diagnostic playbook into a triage flowchart, using low accelerator activity and high memory allocation as signals for further investigation. Idle gaps require tracing input preparation, host work, and synchronization; capacity pressure motivates memory-saving techniques. When neither signal explains a missed target, kernel profiling distinguishes bandwidth, arithmetic, and launch limits.

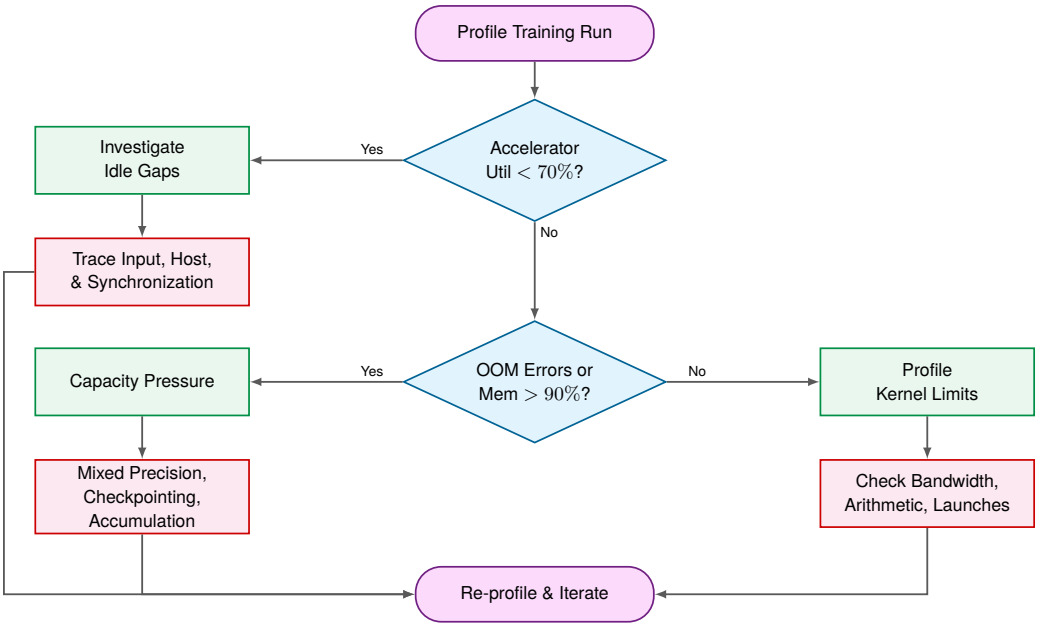

Figure 8.7: Training Optimization Decision Flowchart: A heuristic path from profiling signals to candidate optimizations. Begin with accelerator activity and memory pressure, then investigate the limiting dependency or kernel resource before selecting an intervention. The 70 percent utilization and 90 percent memory thresholds are illustrative triage values rather than universal definitions of data-, memory-, or compute-bound execution.

Each fix moves the bottleneck, so optimization is iterative and governed by Amdahl's law: a speedup applied to one stage is capped by the share of step time that stage occupies, the bound that equation 11.1 formalizes. Resolving input starvation through asynchronous prefetching, for instance, drives accelerator utilization upward until memory bandwidth or compute saturation limits step time. Each intervention requires re-profiling to identify the newly emerged critical path, continuing the cycle until accelerator execution units operate near peak theoretical throughput or application performance targets are achieved.

8.6.2 Data prefetching and overlapping

Prefetching and overlapping put the systematic framework to work on the bottleneck the data pipeline left open. ResNet-50's host workers prepare images more slowly than the H100 consumes them, so the accelerator is busy only about 52 percent of the time (section 8.4.2). That figure already assumes the host prepares the next batch while the accelerator computes the current one. Run serially, preparation and computation add, and the accelerator would be busy only about 34 percent. Overlap recovers the difference by hiding host work behind computation, but it cannot raise the supply rate itself, so closing the rest of the gap for ResNet-50 requires more host workers or decoding on the accelerator. The techniques below are most effective when profiling shows computational units idle while waiting for data.

In ML training, a "Read" stage is rarely a simple disk fetch. For image workloads it encompasses JPEG decoding, random crops, and color jitter applied on CPU cores before the tensor is ready to transfer; for language workloads it encompasses tokenization, subword encoding, and sequence padding. The Gantt schedule in figure 8.8 isolates the serial bottleneck of unbuffered ingestion. The GPU Train row remains completely idle during file-open intervals (Open 1, Open 2) and read stages (Read 1, Read 2), stretching the two-epoch schedule out to 01:35 because compute steps cannot begin until host-side decoding and transfer finish.

Prefetching addresses these inefficiencies by loading data into memory before its scheduled computation time. During the processing of the current batch, framework data pipelines such as `tf.data` load and prepare subsequent batches, maintaining a consistent supply of ready data (Murray et al. 2021).

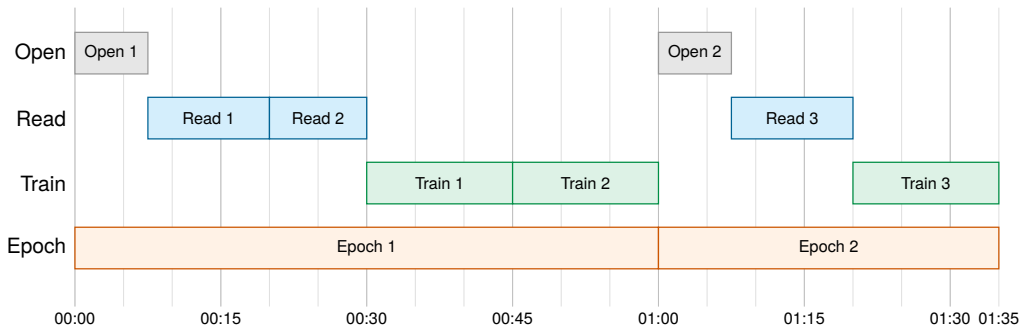

Figure 8.8: Illustrative Sequential Data Fetching: Under the assumed stage durations, file-open, read, and train operations execute serially while the GPU remains idle during file operations. The schedule spans approximately 95 min and provides a schematic baseline for the overlap comparison.

Overlapping extends prefetching by coordinating multiple pipeline stages to execute concurrently. As the system processes the current batch on the accelerator, background host threads load and preprocess subsequent batches. Aligning the serial schedule of figure 8.8 against the overlapped timeline in figure 8.9 demonstrates this latency hiding: concurrent staging of Open 2 and Read 3 behind active execution eliminates idle bubbles between training blocks (Train 1 through Train 3), compressing total wall-clock duration from approximately 95 min down to 65 min (a 31.6 percent reduction). Actual gains depend on stage balance and available concurrency.

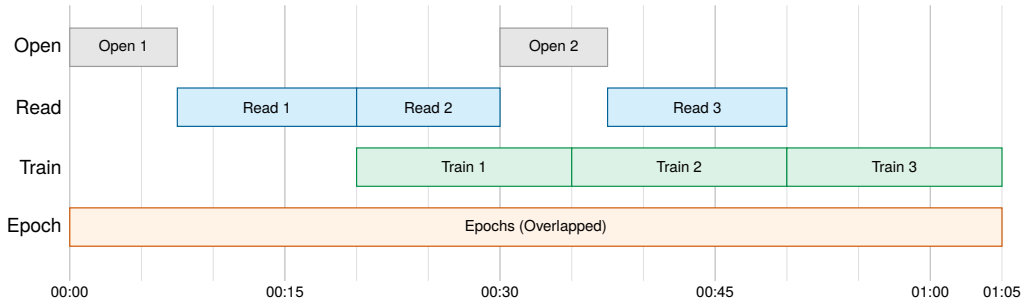

Figure 8.9: Illustrative Overlapped Data Prefetching: File-open and read work overlaps accelerator training while preserving the same individual stage durations as the serial schedule. The schematic schedule spans approximately 65 min, compared with 95 min for the serial schedule.

8.6.2.1 Prefetching mechanics

The overlapped schedule requires enough host workers and buffering to make the next batch ready before the device requests it. Worker count controls preparation capacity; queue depth absorbs variation in preparation time. Neither changes the slowest-stage bound established by equation 8.6.

Machine learning frameworks expose the control variables for this trade-off. Listing 8.5 demonstrates PyTorch's DataLoader configuration, where num_workers = 4 sets preprocessing parallelism and prefetch_factor = 2 maintains a buffer of 8 batches ready for accelerator consumption.

Listing 8.5: DataLoader Prefetch Configuration: Four workers with a prefetch factor of two maintain up to eight batches in the host-side prefetch window.

```
loader = DataLoader(
    dataset, batch_size=32, num_workers=4, prefetch_factor=2
)
```

The parameters `num_workers` and `prefetch_factor` are not generic performance toggles. They determine CPU parallelism and buffer depth, which means they shift pressure from accelerator idle time to host memory and CPU scheduling. The third knob, `pin_memory=True`, lets host-to-device copies overlap accelerator execution through DMA; its cost is page-locked host memory that the rest of the system can no longer page.

↩ The DataLoader's three knobs, worker count, prefetch depth, and pinned memory for DMA transfers, are established in section 7.5.3.

Buffer management is the main trade-off. A buffer that is too small causes the GPU to wait for data preparation, reintroducing the idle time prefetching was meant to remove. An overly large host-side buffer consumes memory that could otherwise support input processing and other host work. The right configuration coordinates CPU preparation, storage I/O, and GPU computation so each resource has work ready at the moment it can use it. These techniques yield the greatest benefit when storage access is slow, preprocessing is complex, or datasets are large.

8.6.2.2 Practical considerations

Prefetch buffers and overlap depth are tunable, so the same machinery adapts to whichever stage binds, whether slow storage, limited network bandwidth, or computational throughput. Prefetching and overlapping deliver the greatest gains when preprocessing lies on the critical path but can run concurrently with model computation. In an illustrative image pipeline, random cropping (10 ms), color jittering (15 ms), and normalization (5 ms) total 30 ms per batch. Overlap can hide up to the concurrent accelerator-computation time; any excess remains on the critical path. NLP workloads similarly benefit when tokenization and subword processing would otherwise block the training loop.

The primary trade-off is memory: prefetch buffers consume host memory, or device memory when a separate device-side queue is used, in proportion to buffer depth and batch size. With batch size 256 high-resolution images (1024×1024 pixels), one buffered batch requires approximately 3.2 GB. With num_workers = 4 and prefetch_factor = 2, the 8-batch prefetch window can hold about

25.8 GB. Tuning these parameters requires empirical testing because excessive workers contend for CPU, storage, and memory resources, while insufficient buffering reintroduces data stalls. Start with a modest worker count, increase it while measuring throughput and memory, and stop when additional workers no longer reduce accelerator idle time. When the input pipeline already exceeds compute demand, deeper prefetching adds complexity without improving throughput.

8.6.3 Mixed-precision training

Running a modern training job entirely in 32-bit floating point (FP32) leaves the accelerator's 16-bit Tensor Cores idle and doubles the byte footprint of every forward activation kept in HBM. Mixed-precision training removes both bottlenecks by executing matrix multiplications and storing activations in a 16-bit format while retaining 32-bit precision for sensitive accumulations and parameter updates. Section D.4.1 compares FP32, FP16, BF16, FP8, and INT8 precision-range trade-offs. A training recipe commonly combines FP32 with either FP16 or BF16; it does not ordinarily use FP16 and BF16 interchangeably in the same path. The resulting speed, memory, and accuracy effects depend on the workload and hardware (Micikevicius et al. 2018; Wang and Kanwar 2019; Kalamkar et al. 2019).

A neural network's stored FP32 weights require 4 bytes per parameter, while FP16 and BF16 weights use 2 bytes. For a model with 10^9 parameters, the working copy of the weights shrinks from 4 GB to 2 GB. That saving does not carry over to the static training state. The common FP16 recipe keeps FP32 master weights and FP32 Adam moments, so it spends 2 + 2 + 4 + 8 = 16 bytes per parameter on weights, gradients, master copy, and moments, exactly what FP32 Adam spends on its 4 + 4 + 8. Mixed precision's memory benefit therefore comes from the tensors that really are stored in 16 bits, above all the activations, together with the halved bytes moved for every 16-bit read, write, and gradient exchange.

Mixed precision's throughput benefit is larger than its memory benefit. Figure 8.10 plots peak dense throughput by number format across four generations of data center accelerators. From V100 to B200 the FP32 rate grew 4.8×, the FP16/BF16 tensor rate grew 18×, and the lowest supported format, 4-bit floating point (FP4) on B200, delivers 72× the V100's FP16 tensor rate. Hardware gains now arrive almost entirely through tensor units built for lower precision. On B200 the FP16/BF16 tensor path is 30× faster than FP32, so a training job that stays in FP32 leaves nearly all of the chip's arithmetic idle.

The numerical differences between these formats shape their use cases. Table 8.9 shows that BF16's 8-bit exponent gives it approximately the same normal exponent range as FP32, while FP16's 5-bit exponent gives a minimum positive normal value of about 6.1×10^{-5} and a maximum finite value of $65{,}504$. FP16 subnormals extend toward 6×10^{-8}, although their treatment depends on the operation and hardware mode. FP32 provides about seven decimal digits of precision, FP16 about three, and BF16 about two to three. BF16 therefore trades mantissa precision for the exponent range that often simplifies deep-learning training.

Table 8.9: Precision Format Comparison: The choice between FP16 and BF16 depends on whether dynamic range (BF16's strength) or precision (FP16's advantage) matters more for the specific workload. Minimum normal values shown are the practical thresholds for training, as subnormal values may flush to zero on many GPUs. On the H100, dense FP16 and BF16 Tensor Cores reach 15× the FP32 CUDA-core peak.

Property	FP32	FP16	BF16
Exponent bits	8	5	8
Mantissa bits	23	10	7
Min normal value	10^{-38}	6.1×10^{-5}	10^{-38}
H100 peak throughput ratio	1×	15×	15×

The choice between formats depends on model characteristics and hardware support. BF16's wider exponent range reduces overflow and underflow concerns, while FP16 provides more mantissa bits but often requires loss scaling. Framework autocast policies and fused kernels choose higher-precision accumulation for numerically sensitive operations when needed; loss reduction, softmax,

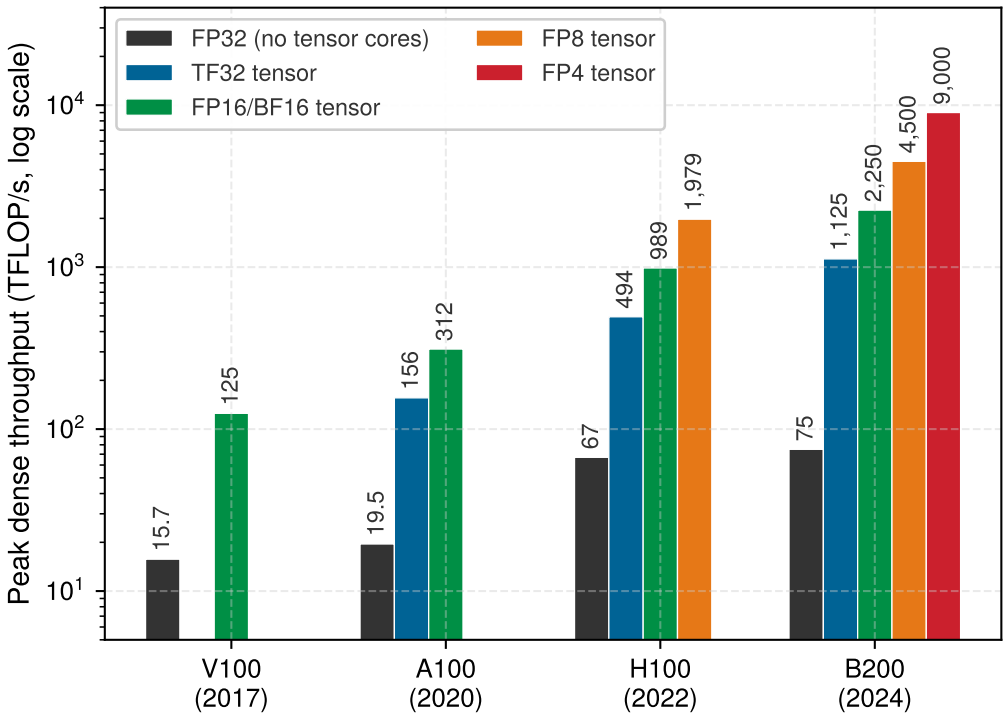

Figure 8.10: Peak Throughput by Number Format: Peak dense throughput of four generations of data center accelerators in each number format they support, on a logarithmic axis. Each step down among the tensor formats roughly doubles the peak rate on the same silicon, the first step from FP32 onto the tensor paths gains far more, and nearly all of the generational gain arrives in the 16-bit and lower formats rather than in FP32. Vendor peak specifications (NVIDIA Corporation 2020b, 2021a, 2023b, 2024).

normalization, and optimizer updates are common candidates, but their exact execution dtype is implementation-dependent.

Figure 8.11 traces this conventional FP16 execution cycle across six numbered stages: FP32 master weights are downcast to FP16 for the forward pass, loss scaling shifts small gradient values into representable range before backpropagation, and the resulting scaled gradients are unscaled and cast back to FP32 prior to the parameter update. Modern framework implementations may store or accumulate particular tensors differently, and BF16 recipes commonly omit loss scaling because of their wider exponent range.

Modern accelerator architectures pair dense matrix execution units with reduced-precision numerical formats to maximize arithmetic throughput. NVIDIA introduced Tensor Cores for FP16 operations in the Volta architecture (NVIDIA 2017) and added native BF16 execution in Ampere (NVIDIA Corporation 2020a), matching the native BF16 support Google developed for Tensor Processing Units (Wang and Kanwar 2019). These specialized functional units execute low-precision matrix multiply-accumulate operations at four to sixteen times the rate of standard 32-bit floating-point ALUs.

Mixed-precision training turns those hardware capabilities into a split numerical policy. Eligible matrix multiplications and convolutions execute in FP16 or BF16 on tensor units, while reductions, accumulations, and parameter updates retain higher precision. The performance gain comes from both arithmetic throughput and data movement: lower-precision units pack more multiply-accumulates into each cycle and each unit of silicon area, while narrower tensors halve data transfer volumes across caches and high-bandwidth memory. Higher precision remains necessary where wide reductions, small parameter updates, or sensitive normalizations can accumulate rounding error. Framework autocast policies enforce this split dynamically, selecting lower-precision execution for compute-intensive matrix multiplications while preserving FP32 for numerically fragile operations.

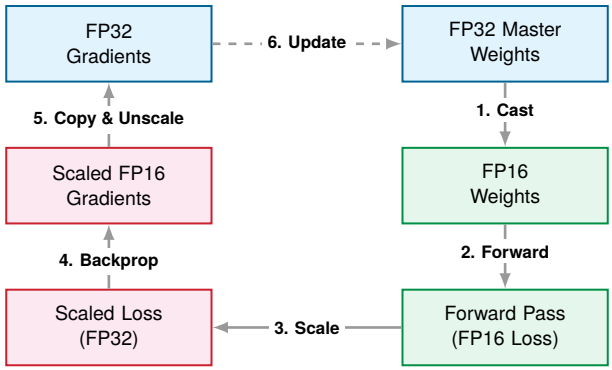

Figure 8.11: Conventional FP16 Mixed-Precision Training: A schematic six-step recipe casts FP32 master weights for lower-precision computation, scales the loss, computes scaled gradients, then unscales them for an FP32 update. Framework implementations may vary, and BF16 usually does not require this loss-scaling path.

8.6.3.1 Loss scaling

FP16's 5-bit exponent limits its representable dynamic range, creating severe underflow hazards during backpropagation. When computing gradients across deep networks, successive chain-rule multiplications frequently produce gradient magnitudes smaller than FP16's minimum positive normal value ($2^{-14} \approx 6.1 \times 10^{-5}$). While IEEE 754 FP16 defines subnormal numbers down to $\approx 6 \times 10^{-8}$, hardware accelerators often flush subnormal inputs and outputs to zero to prevent pipeline stalls. When gradients underflow to zero, weight updates stall and training fails to converge.

Loss scaling counters underflow by exploiting the linearity of differentiation: $\nabla_\theta(s_{\text{loss}} \cdot \mathcal{L}) = s_{\text{loss}} \cdot \nabla_\theta \mathcal{L}$. Multiplying the scalar loss $\mathcal{L}$ by a large scaling factor s_{loss} (such as 2^{10} or 2^{15}) prior to backpropagation shifts the gradient distribution rightward into FP16's normal representable range. Once backpropagation completes, the accumulated gradients are divided by s_{loss} (unscaled) before applying the optimizer update.

Deep learning frameworks automate this process through dynamic loss scaling; section 7.4.3.3 describes the `GradScaler` machinery that scales the loss, unscales the gradients, and skips any step whose gradients overflow. The training decision is how the scale factor adapts. Because gradient norms fluctuate during training, a static scale factor risks either underflow (if s_{loss} is too small) or numerical overflow past FP16's maximum finite value of $65{,}504$ (if s_{loss} is too large). A dynamic scaler therefore skips each overflowing step so that nonfinite gradients never reach the FP32 master weights, halves s_{loss} at each skip, and doubles s_{loss} after a configurable growth window without overflow (such as 2,000 consecutive steps). Together these adjustments keep gradients near the upper end of the dynamic range without saturating.

8.6.3.2 Mixed-precision benefits

Mixed-precision training delivers gains across three interacting system dimensions: memory footprint, arithmetic throughput, and communication volume. Halving operand width cuts the storage of every 16-bit tensor by 50 percent, so a one-billion-parameter model's working weights drop from 4 GB to 2 GB. As the 16-bytes-per-parameter accounting above showed, FP32 master weights and moments give that saving back in the static state, so the footprint that actually shrinks is the activations. Computationally, reduced precision routes dense matrix multiplication kernels to high-throughput Tensor Core pipelines (section 8.6.3.3). In distributed topologies, transferring 16-bit rather than 32-bit gradients halves collective AllReduce traffic across the interconnect. These effects compound: reclaimed activation memory permits larger micro-batches, Tensor Cores accelerate kernel execution, and narrower tensors reduce gradient exchange latency. The following case study evaluates these memory effects on GPT-2 XL at batch 32, the configuration the activation notebook left far over the H100's capacity.

Napkin Math 8.6: GPT-2 mixed precision memory savings

Problem: What does mixed precision save when GPT-2 XL (1.5B parameters) trains at batch 32 and sequence length 1,024 on one H100, and what does it leave unchanged?

FP32 baseline:

- Parameters and gradients (FP32): 12 GB (6 GB parameters + 6 GB gradients)
- Activations: ~574 GB
- Optimizer states (Adam first and second moments in FP32): 12 GB
- Total: ~598 GB

FP16 mixed precision:

- Parameters (FP16): 1.5B parameters at 2 bytes each = 3 GB
- Activations (FP16): ~287 GB
- Gradients (FP16): 3 GB
- FP32 master weights: 6 GB (for precise optimizer updates)
- Optimizer states (Adam first and second moments in FP32): 12 GB
- Total: ~311 GB, about 3.6× the H100's 80 GB

Systems insight: Mixed precision halves the activations and leaves the static state unchanged at 24 GB. At batch 32 the remaining activations still dominate, and most of them are the quadratic attention-score matrices, which FlashAttention (section 8.6.4) removes next.

Memory savings alone do not guarantee stable training. In the FP16 training recipe used here, maintaining FP32 master weights is necessary because parameter updates $\Delta w = -\eta \cdot g$ (learning rate times gradient) are typically orders of magnitude smaller than the weight values w. In FP16, where the 10-bit mantissa provides roughly three decimal digits of precision, adding an update that is more than $2^{11} \approx 2048$ times smaller than the weight magnitude results in arithmetic swamping: the updated weight rounds back to its original value. This loss of an increment through rounding is distinct from the update value itself underflowing. Retaining master weights in FP32 preserves these incremental updates across thousands of optimizer steps, casting to 16 bits only when staging weights for the forward pass. Autocast policies similarly isolate wide reductions, layer normalizations, and softmax layers in FP32 to prevent catastrophic cancellation.

Once numerical stability is established, reduced-precision arithmetic and reduced memory traffic can shorten execution when they reduce work on the critical path. Comparing complete training recipes does not isolate the contribution of precision alone; model quality, batch size, optimizer representation, and activation policy must be accounted for. The following scenario models these compound throughput, schedule, and infrastructure cost gains for a GPT-2 XL training run.

Napkin Math 8.7: GPT-2 mixed precision throughput and cost

Problem: Holding utilization fixed, how much faster and cheaper is GPT-2 XL's run on one H100 when its matrix products run in BF16 instead of in 32-bit formats?

Peak rates by path: FP32 on scalar units 67 TFLOP/s; TF32 on Tensor Cores 494 TFLOP/s; BF16 on Tensor Cores 989 TFLOP/s.

Run time and cost at 50 percent utilization and $4/hour per accelerator:

- FP32: about 518 days, $49,751
- TF32: about 70 days, $6,748
- BF16: about 35 days, $3,370

Quality gate: The comparison is valid only if a controlled validation run shows that the BF16 recipe meets the same acceptance criteria as the 32-bit baseline. The scenario does not assume a particular perplexity difference.

Systems insight: The peak ratios, 2× over TF32 and 15× over FP32, bound the gain rather than predict it. Holding utilization fixed assumes that every part of the step speeds up with the matrix units, but elementwise kernels, optimizer updates, and input waits do not run on Tensor Cores, so by Amdahl's law the measured speedup is smaller. A real decision requires measured throughput, billing, and quality validation for the target workload.

Realizing these speedups requires empirical profiling rather than assuming automatic acceleration. For small models or memory-bound workloads not dominated by large matrix multiplications, data type casting and kernel launch overheads can offset the arithmetic throughput advantage. Furthermore, whether an accelerator supports native BF16 or requires FP16 loss scaling depends on the underlying microarchitecture.

8.6.3.3 Mixed-precision hardware support

Specialized matrix execution units deliver the wall-clock speedup of mixed precision by spending fewer bits per operand. Accelerators pair these low-precision multiply units with higher-precision accumulation registers to maintain numerical stability during dense matrix reductions.

The Volta-generation Tensor Cores introduced earlier in this section perform 4×4 matrix multiply-accumulate operations in a single clock cycle, a datapath that section 11.4.2 examines in detail. For FP16 inputs, a single Tensor Core executes:

$$\mathbf{D}_{\text{tc}} = \mathbf{A}_{\text{tc}} \times \mathbf{B}_{\text{tc}} + \mathbf{C}_{\text{acc}}$$

where $\mathbf{A}_{\text{tc}}$ and $\mathbf{B}_{\text{tc}}$ are FP16 inputs and $\mathbf{C}_{\text{acc}}$ and $\mathbf{D}_{\text{tc}}$ may use FP32 accumulation. Higher-precision accumulation reduces rounding error, although it does not eliminate numerical error or cancellation.

Hardware peak specifications define the theoretical ceiling on this acceleration. The reference H100 exposes 67 TFLOP/s of FP32 throughput on standard CUDA cores and 989 TFLOP/s of dense FP16 or BF16 Tensor Core throughput, a 15× peak ratio, and adds FP8 Tensor Cores at 1,979 TFLOP/s without sparsity, about 2× its FP16/BF16 rate. These figures represent hardware ceilings rather than end-to-end training guarantees: matrix multiplications map directly to Tensor Cores, but data movement, non-Tensor-Core kernels, communication, loss scaling, and optimizer updates remain. While the batched matrix multiplication $\mathbf{QK}^T$ in transformer self-attention ($2 \times B \times N_{\text{heads}} \times S^2 \times d_{\text{head}}$ FLOPs) maps directly to these tensor units, Amdahl's law dictates that the remaining memory-bound elementwise operations, communication collectives, and optimizer updates bound the realized end-to-end speedup.

Brain Float 16 (BF16) maintains FP32's 8-bit exponent while reducing the mantissa to 7 bits. This design choice prioritizes dynamic range preservation over precision, which matters for gradient-based learning where values span many orders of magnitude. Google's TPUs natively support BF16, while NVIDIA's Ampere architecture (A100) and newer provide full hardware support.

The range advantage of BF16 appears exactly where loss scaling was needed for FP16. A gradient below FP16's smallest normal value of 6.1×10^{-5}, which some hardware flushes to zero, is still an ordinary normal number in BF16, whose smallest normal value of about 10^{-38} matches FP32's exponent range. BF16 therefore usually avoids the loss scaling needed by FP16, although accumulation precision and rounding still matter.

NVIDIA's Hopper architecture (H100) adds FP8 Tensor Core paths for 8-bit floating-point values (1.98 PFLOP/s on H100 dense vs. 0.99 PFLOP/s for FP16 dense, without sparsity); FP8's two bit layouts and the per-tensor scaling they require are developed in section 10.3.1. Table 8.10 summarizes when each precision is appropriate:

Table 8.10: Precision Selection Guide: Format choice depends on hardware support, kernel coverage, numerical behavior, and validation results. FP8 requires an explicit scaling strategy; BF16 provides a wider exponent range than FP16; FP16 often uses loss scaling; and FP32 remains available for sensitive operations or unsupported lower-precision paths.

Precision	When to Use	Hardware Requirement
FP8	Throughput-oriented training with validated scaling	Supported FP8 hardware
BF16	Wide exponent range without FP16 loss scaling	Supported BF16 accelerator
FP16	Higher mantissa precision with managed loss scaling	Supported FP16 accelerator
FP32	Higher precision or unsupported lower-precision path	GPU

In addition to accelerating compute-bound matrix operations, reduced precision relieves memory bandwidth bottlenecks by altering operational arithmetic intensity. On modern accelerators, large matrix multiplications reside in the compute-bound regime of the roofline model, whereas element-wise operations (such as bias additions, layer normalization, and residual connections) reside firmly in the memory-bound regime. The H100 illustrates the physical imbalance between arithmetic capability and memory bandwidth: its HBM3 bus supplies 3,350 GB/s, whereas sustaining its 67 TFLOP/s of FP32 throughput without operand reuse would demand 268 TB/s if every FLOP required fresh data from memory. Although operand reuse reduces actual traffic for dense matrix multiplications, operations with low arithmetic intensity remain strictly bandwidth-limited.

For memory-bound kernels, execution time is determined by bytes transferred across the memory bus rather than arithmetic clock cycles. Converting 32-bit operands to 16-bit FP16 or BF16 halves the byte volume transferred across the HBM bus, doubling the theoretical throughput of memory-bound operations even without engaging Tensor Cores. Realized bandwidth gains depend on cache hit rates, kernel fusion, and format conversion costs.

Section 7.4.3.3 describes how `autocast` and `GradScaler` implement the split between 16-bit and FP32 operations inside the framework. The policy decision that remains for the training recipe is which format to run, and listing 8.6 makes it a single switch: the FP16 path enables gradient scaling, and the BF16 path disables it.

Listing 8.6: Mixed-Precision Training: Autocast selects eligible lower-precision operations, while gradient scaling is enabled for the FP16 path and omitted for BF16.

```
import torch

model = TransformerModel().cuda()
optimizer = torch.optim.Adam(model.parameters(), lr=1e-4)
amp_dtype = (
    torch.float16
)  # torch.bfloat16 usually does not need loss scaling
scaler = torch.amp.GradScaler(
    "cuda", enabled=(amp_dtype == torch.float16)
)

for inputs, targets in dataloader:
    optimizer.zero_grad()

    # Automatic precision selection per operation
    with torch.amp.autocast("cuda", dtype=amp_dtype):
        output = model(inputs)
        loss = criterion(output, targets)

    # Scale loss to prevent gradient underflow
    scaler.scale(loss).backward()

    # Unscale gradients before optimizer step
    scaler.step(optimizer)
    scaler.update()  # Adjust scaling factor dynamically
```

Because hardware support for low-precision formats evolved across accelerator generations, the optimal mixed-precision recipe depends on the target architecture. Table 8.11 outlines the precision trade-offs across three generations of NVIDIA GPUs.

Table 8.11: Precision Strategy by GPU Architecture: V100 supports FP16 Tensor Core training, A100 adds native BF16, and H100 adds FP8 paths whose use requires recipe-specific validation.

Architecture	Recommended Precision	Key Considerations
V100 (Volta)	FP16 with loss scaling	No native BF16 Tensor Core path; clipping depends on the training recipe
A100 (Ampere)	BF16 or FP16	BF16 avoids FP16 loss scaling; TF32 can accelerate eligible FP32 matrix operations
H100 (Hopper)	BF16, FP16, or validated FP8	FP8 requires an FP8-aware recipe; 1,979 TFLOP/s is a peak ceiling

Throughput gains across these generations came from new tensor execution units built for narrower formats, and measured speedups also reflect software stacks, kernels, and batch dimensions that changed alongside the hardware. The peak-rate ratios in Notebook 8.7 bound what a format switch can deliver on one H100. In practice, BF16 is the default where the hardware supports it, and FP16 with loss scaling is the fallback.

8.6.4 FlashAttention: IO-aware attention optimization

Mixed-precision training addresses two bottlenecks, compute throughput because Tensor Cores run faster on 16-bit operands, and memory capacity because each value uses fewer bytes. For transformer models, a third bottleneck often dominates, and the roofline analysis has already located it. Counting only its score-matrix traffic, materialized attention in GPT-2 Small reaches about 32 FLOP/byte, well left of the H100 ridge point in figure 8.1, because its quadratic intermediate matrices are written to HBM during the forward pass and read back during backpropagation. Halving the bytes per value does not change that quadratic traffic, so even with reduced precision the compute units can sit idle while the processor waits for data.

The same quadratic term dominates GPT-2 XL's memory. At batch 32 and 1,024 tokens, the stored score, probability, and dropout matrices account for about 201 GB of the 287 GB of mixed-precision activations, about 70 percent. An attention kernel that never stores them leaves 85.6 GB of activations; with the static state the step needs 109.6 GB, still about 24 GB more than the H100's 80 GB (85.9 GB in decimal units), so removing attention's traffic is necessary but not sufficient.

FlashAttention (Dao et al. 2022) addresses this bandwidth bottleneck by treating attention as an IO problem. Processing attention in SRAM-sized tiles avoids materializing the full $S \times S$ matrix in HBM and reduces traffic without changing the mathematical output, which is how the roofline preview moved attention rightward toward, and for favorable shapes past, the ridge.

8.6.4.1 The standard attention memory bottleneck

Standard self-attention materializes an $S \times S$ score matrix and an $S \times S$ probability matrix in off-chip HBM for every attention head, turning long-sequence training into a memory-bandwidth and capacity bottleneck:

$$\text{Attention}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) = \text{softmax}\left(\frac{\mathbf{Q}\mathbf{K}^T}{\sqrt{d_{\text{head}}}}\right)\mathbf{V} \tag{8.9}$$

Here, $\mathbf{Q}$, $\mathbf{K}$, and $\mathbf{V}$ are the query, key, and value matrices for a sequence of length S, and d_{head} is the key-vector dimension used to scale the dot products before softmax. Because the intermediate product $\mathbf{Q}\mathbf{K}^T$ is written out to HBM before softmax and read back immediately afterward, attention becomes an I/O problem even when the matrix products themselves map cleanly onto Tensor Cores.

The memory bottleneck emerges from materializing the $S \times S$ intermediate matrices for scores and probabilities. For a sequence length of 4,096 with head dimension $d_{\text{head}} = 64$ (typical for a single attention head), the attention score matrix alone requires $4{,}096^2 \times 4$ bytes = 67.1 MB in FP32. This section counts FP32 scores throughout, since autocast policies commonly keep softmax in FP32;

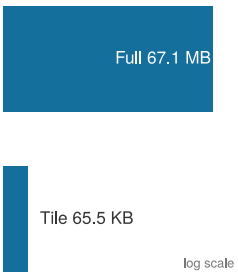
at FP16 every figure halves, as in the roofline estimate, while the quadratic growth stays the same. With 16 heads, this grows to 1.1 GB just for intermediate attention matrices, not including the keys, queries, values, or output tensors.

GPU memory hierarchy creates the opportunity for I/O-aware attention. HBM offers large off-chip capacity, while much smaller on-chip SRAM has substantially higher bandwidth and lower latency. Attention implementations that materialize the quadratic intermediates in HBM must write and later read them during backpropagation. Because that traffic grows with the square of sequence length, it takes a growing share of step time as sequences lengthen.

The backward pass requires the information represented by the attention probabilities, but an implementation may either save those intermediates or recompute them. For $\mathbf{A} = \mathrm{softmax}(\mathbf{S})$ and $\mathbf{S} = \mathbf{Q}\mathbf{K}^T/\sqrt{d_{\text{head}}}$, one gradient expression is:

$$\frac{\partial \mathcal{L}}{\partial \mathbf{Q}} = \frac{1}{\sqrt{d_{\text{head}}}} \cdot \mathrm{dsoftmax}\left(\frac{\partial \mathcal{L}}{\partial \mathbf{A}}, \mathbf{A}\right) \cdot \mathbf{K}$$

where dsoftmax denotes the softmax Jacobian-vector product. A conventional implementation may save the probability matrix for this computation; saving both probabilities and raw scores is not mathematically required. FlashAttention instead saves compact normalization statistics and recomputes tiled score and probability blocks during backward propagation, avoiding full quadratic intermediates in HBM.



8.6.4.2 IO-aware attention through tiling

FlashAttention eliminates the need to materialize full $S \times S$ attention matrices in HBM by computing attention incrementally through tiling. Instead of computing the entire attention matrix at once, the algorithm partitions **Q**, **K**, and **V** into tiles small enough to fit in fast SRAM, computes attention scores for these tiles, and incrementally accumulates results.

The key algorithmic insight relies on the structure of equation 8.9. Softmax normalizes each row of scores by a sum over the entire row, which seems to require the whole row before any output can be formed, yet the online softmax algorithm removes that requirement. Ordinary softmax, $\mathrm{softmax}(\mathbf{x})_i = e^{\mathbf{x}_i}/\sum_j e^{\mathbf{x}_j}$, is computed stably by first subtracting the row maximum. The online form instead keeps two running statistics per row as blocks of scores arrive: the largest score seen so far, m, and the sum of exponentials taken relative to that maximum, z. When a new block raises the maximum from m to m', everything accumulated so far was exponentiated relative to the old maximum, and multiplying it by $e^{m-m'}$ re-expresses it relative to the new one. The same factor rescales the partially accumulated output. After the last block, dividing the output by z gives exactly the softmax-weighted result, as if the whole row had been seen at once.

Algorithm 8.2 decomposes this computation by partitioning the queries and the keys/values into tiles small enough to fit in SRAM, then streaming over the key/value tiles while maintaining the running softmax statistics needed to assemble each output tile, without ever forming the full score matrix.

No full $S \times S$ score or probability matrix is written to HBM. A 128×128 FP32 score tile, for example, occupies 65.5 KB compared with 67.1 MB for a 4096×4096 matrix. Other inputs, outputs, and running statistics remain, so the tile is not necessarily the largest tensor in the entire kernel.

FlashAttention swaps the full attention matrix for small SRAM tiles.

Algorithm 8.2 FlashAttention: tiled attention with online softmax

Require: queries $\mathbf{Q}$, keys $\mathbf{K}$, values $\mathbf{V}$ for a length-S sequence; tile size b_{tile}
Ensure: attention output $\mathbf{O}$, without materializing the $S \times S$ score matrix

for each query tile $\mathbf{Q}_i$ **do**
  in SRAM: $\mathbf{O}_i^{\text{acc}} \leftarrow \mathbf{0}$, $m_i \leftarrow -\infty$, $z_i \leftarrow 0$
  for each key/value tile $(\mathbf{K}_j, \mathbf{V}_j)$ **do**
    load $\mathbf{Q}_i, \mathbf{K}_j, \mathbf{V}_j$ into SRAM; $\mathbf{S}_{ij} \leftarrow \mathbf{Q}_i \mathbf{K}_j^T / \sqrt{d_{\text{head}}}$
    $m_i' \leftarrow \max(m_i, \text{rowmax}(\mathbf{S}_{ij}))$ ▷ *new stable max*
    $\mathbf{O}_i^{\text{acc}} \leftarrow \mathbf{O}_i^{\text{acc}} \odot e^{m_i - m_i'} + e^{\mathbf{S}_{ij} - m_i'} \mathbf{V}_j$
    $z_i \leftarrow z_i \odot e^{m_i - m_i'} + \text{rowsum}(e^{\mathbf{S}_{ij} - m_i'})$; $m_i \leftarrow m_i'$
    discard $\mathbf{S}_{ij}$ ▷ *never written to HBM*
  end for
  $\mathbf{O}_i \leftarrow \mathbf{O}_i^{\text{acc}} / z_i$; write $\mathbf{O}_i$ to HBM
end for

8.6.4.3 Memory and IO complexity analysis

FlashAttention improves both activation memory and memory IO, which are the limiting costs in bandwidth-bound attention. Standard attention requires $\mathcal{O}(S^2)$ memory to store score matrices $\mathbf{S}$ and attention-probability matrices $\mathbf{A}$ across all sequence positions. FlashAttention reduces the stored activation footprint to $\mathcal{O}(S)$ by keeping only input and output tensors $(\mathbf{Q}, \mathbf{K}, \mathbf{V}, \mathbf{O})$ plus a small SRAM buffer for the current tile.

For $S = 4096$, $d_{\text{head}} = 64$, one materialized FP32 score matrix occupies $4096^2 \times 4$ bytes = 67.1 MB per head. The three FP32 input tensors occupy $(3 \times 4096 \times 64) \times 4$ bytes ≈ 3.1 MB per head, a component-size ratio of 21.3× between one quadratic intermediate and the inputs. The comparison that decides memory is the whole per-head footprint each algorithm keeps for the backward pass. The conventional baseline assumed here stores the inputs, the output, and both the score and probability matrices, about 138.4 MB. FlashAttention stores the inputs, the output, and two numbers per row (the running maximum and sum), about 4.2 MB, roughly 32.7× smaller, and the gap widens as S grows because only the standard footprint is quadratic.

These stored-tensor totals exclude gradient buffers, temporary workspace, and the live SRAM tile, so they are not estimates of peak training memory. Implementations may also retain fewer quadratic intermediates than the conventional baseline assumed here.

The IO pattern changes for the same reason. Standard attention reads $\mathbf{Q}$, $\mathbf{K}$, and $\mathbf{V}$ from HBM, writes score, probability, and output matrices during the forward pass, then rereads those stored matrices during the backward pass before writing the gradients $d\mathbf{Q}$, $d\mathbf{K}$, and $d\mathbf{V}$ (shorthand for $\partial \mathcal{L} / \partial \mathbf{Q}$ and its counterparts). The resulting HBM traffic includes the same $\mathcal{O}(S^2)$ term that made the activation footprint large. FlashAttention forms score and probability blocks in SRAM and never writes the full $S \times S$ tensors to HBM. In the backward pass, it recomputes the needed blocks rather than reading stored full matrices. The exact HBM IO complexity depends on tile size and available SRAM because key and value blocks are streamed repeatedly across query blocks, so the bound is not simply $\mathcal{O}(S \cdot d)$.

Both approaches require $\mathcal{O}(S^2 d)$ asymptotic FLOPs for dense attention, so FlashAttention's gain comes from traffic, not arithmetic. The resulting reduction in HBM traffic can shift the kernel toward compute-bound execution and produce a net speedup, but the final bottleneck remains shape- and hardware-dependent.

8.6.4.4 Implementation and hardware utilization

FlashAttention's performance gains materialize through careful exploitation of GPU memory hierarchy. Modern frameworks can dispatch eligible attention operations among fused and fallback implementations based on hardware, inputs, and layouts; profiling verifies which path ran and whether it helped. Listing 8.7 contrasts standard and optimized attention implementations.

Listing 8.7: Attention Implementation Comparison: Standard attention materializes the full $S \times S$ matrix in HBM, while FlashAttention uses PyTorch's optimized implementation or the dedicated flash-attn library.

```
import torch
import torch.nn.functional as F

# Standard attention (materializes n-by-n matrix)
def standard_attention(q, k, v):
    # q, k, v: [batch, heads, seq_len, head_dim]
    scores = torch.matmul(q, k.transpose(-2, -1)) / (
        q.size(-1) ** 0.5
    )
    attn = F.softmax(scores, dim=-1)  # n-by-n matrix in HBM
    output = torch.matmul(attn, v)
    return output

# FlashAttention (no n-by-n materialization)
def flash_attention(q, k, v):
    # Can use FlashAttention when inputs and hardware are eligible
    output = F.scaled_dot_product_attention(q, k, v)
    return output

# Explicit FlashAttention 2 (flash-attn library)
from flash_attn import flash_attn_func

def flash_attn_2(q, k, v):
    # q, k, v: [batch, seq_len, heads, head_dim]
    # Different layout for optimized memory access
    output = flash_attn_func(q, k, v)
    return output
```

Dao et al. (2022) reports end-to-end GPT-style training speedups and separate attention-kernel benchmarks showing that IO-aware attention reduces memory traffic and improves runtime. Runtime and memory savings depend on batch size, head count, sequence length, precision, and the kernel implementation, and a capacity threshold still requires the complete training memory budget, including the state outside attention. Later versions refine the same idea: FlashAttention-2 (Dao 2023) reports a further 1.5–2$\times$ speedup through better parallelism, and FlashAttention-3 (Shah et al. 2024) adds asynchronous memory operations and FP8 support on Hopper GPUs.

8.6.4.5 When to use FlashAttention

For transformer training with long sequences, FlashAttention is usually the first attention implementation to test. It often becomes essential once sequence length pushes standard attention into an HBM-capacity or HBM-bandwidth bottleneck, especially around the multi-thousand-token regime where the $S \times S$ attention matrices dominate memory. A100- and H100-class GPUs with fast on-chip SRAM benefit most. The returns diminish for short sequences where tiling overhead is not worthwhile, on older GPU architectures without comparable SRAM bandwidth, and for nonattention architectures such as convolutional neural networks and multilayer perceptrons.

In practice, deep learning frameworks handle much of FlashAttention's integration, but the decision still depends on layout, precision, and memory budget. PyTorch's `scaled_dot_product_attention` can dispatch to FlashAttention when hardware, inputs, and backend constraints permit; hand-written attention must use an eligible primitive. Three practical checks determine whether the fast path actually runs and pays off: tensor layouts must match library expectations (contiguous memory and the expected dimension ordering), execution must use FP16 or BF16 (because FlashAttention kernels target mixed precision), and gradient checkpointing should be combined with FlashAttention whenever additional activation-memory savings are needed beyond the attention scores.

The integration is often a single-line change, swapping a manual attention call for `F.scaled_dot_product_attention`, as listing 8.7 shows. The engineering decision is still the same one established by the roofline analysis: use the optimized primitive when the bottleneck is HBM traffic, and let the library manage the tiling and SRAM scheduling needed to remove it.

8.6.4.6 IO-aware design beyond attention

FlashAttention is an instance of **IO-aware algorithm design**: because modern accelerators are compute-abundant relative to memory bandwidth, traffic governs runtime for a bandwidth-bound kernel even when FLOPs do not change. This principle extends beyond attention. In IO-aware matrix multiplication, tiling algorithms like those in CUTLASS minimize DRAM traffic by maximizing data reuse in fast caches. A naive $N \times N$ matrix multiply performs $\mathcal{O}(N^3)$ FLOPs and, without reuse, $\mathcal{O}(N^3)$ memory traffic; blocking keeps tiles in fast memory and moves traffic toward the $\mathcal{O}(N^2)$ lower bound.

The same byte-movement principle reappears in communication-efficient distributed training, where gradient compression trades extra computation (compression/decompression) for reduced network bandwidth consumption. Low-power edge devices with limited memory bandwidth benefit even more from IO-aware algorithms. Trading 10 percent more arithmetic to halve memory traffic approaches a $2\times$ energy reduction in the limit where data movement accounts for the entire budget, and falls short of that bound whenever arithmetic carries a meaningful share, because halving one additive term of a sum cannot more than halve the sum.

Eliminating off-chip materialization of the $\mathcal{O}(S^2)$ attention matrices reclaims accelerator memory across three architectural trade-offs. First, it enables longer sequence contexts on fixed hardware, with the workable context boundary determined by the complete training recipe. Second, freeing activation memory allows larger micro-batch sizes that improve hardware arithmetic saturation, provided gradient dynamics remain stable. Third, the contracted activation footprint permits deeper transformer stacks within a given memory budget, although end-to-end multi-billion-parameter feasibility continues to depend on parameter sharding, optimizer states, and remaining layer activations.

FlashAttention performs the same arithmetic but moves fewer bytes, which is why counting bytes before FLOPs is the first step on any bandwidth-bound kernel. Bandwidth is not the only memory limit, however. The capacity required to hold activations and optimizer states at the same time can still exceed the accelerator, and when models or batch sizes outgrow device memory, two complementary techniques trade computation for memory.

8.6.5 Gradient accumulation and checkpointing

FlashAttention left GPT-2 XL's batch-32 step about 24 GB over the H100's capacity, and the excess now consists of ordinary activations, the layer inputs, projections, and feed-forward intermediates that backpropagation must read. Two techniques remove it without adding hardware. Gradient accumulation builds the batch from smaller micro-batches that each fit, and activation checkpointing keeps fewer activations and recomputes the rest during the backward pass. Both were named earlier, accumulation with mini-batch processing (section 8.3.2.1) and recomputation with activation memory (section 8.3.3.2). Using them correctly requires knowing when accumulated gradients equal the large-batch gradient, what each technique costs in time, how checkpoints are placed (the $\sqrt{N_L}$ schedule), and which loss-normalization errors most often break accumulation.

8.6.5.1 Gradient accumulation and checkpointing mechanics

Gradient accumulation changes how many examples contribute to one update; checkpointing changes which activations remain resident between the forward and backward passes.

Gradient accumulation To execute large batch training on memory-constrained accelerators, systems split an effective logical batch across smaller sequential micro-batches. Three consecutive micro-batches evaluate independent losses ($\mathcal{L}_1, \mathcal{L}_2, \mathcal{L}_3$) and gradients ($\mathbf{g}_1, \mathbf{g}_2, \mathbf{g}_3$, where $\mathbf{g}_j = \nabla_\theta \mathcal{L}_j$), accumulating into a single unified tensor ($\mathbf{g}_1 + \mathbf{g}_2 + \mathbf{g}_3$) before triggering the optimizer step (figure 8.12).

In PyTorch, gradient accumulation is usually implemented by dividing each micro-batch loss by the number of accumulation steps and calling `optimizer.step()` only after processing the entire

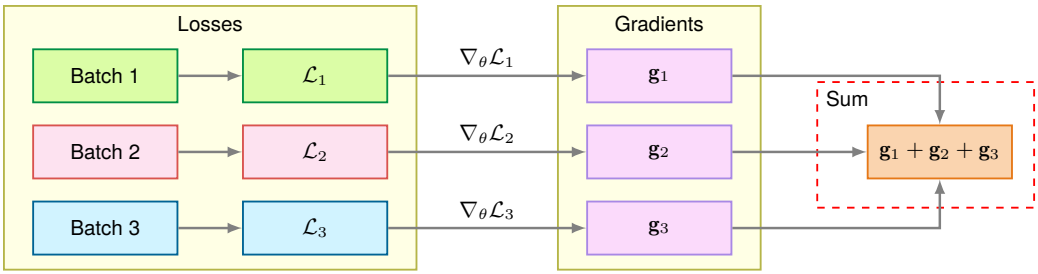


Figure 8.12: Gradient Accumulation: Three micro-batches each compute independent losses and gradients, which sum into a single combined gradient for one parameter update. This simulates training with a batch three times larger without requiring the memory to hold all samples simultaneously.

effective batch. Under that averaging convention, no learning-rate adjustment is needed solely because of accumulation. The implementation follows five steps:

1. Perform the forward pass for a micro-batch.
2. Compute the gradients during the backward pass.
3. Accumulate the gradients into a buffer without updating the model parameters.
4. Repeat steps 1–3 for all micro-batches in the effective batch.
5. Update the model parameters using the accumulated gradients after all micro-batches are processed.

Gradient accumulation can reproduce the gradient of a larger batch under controlled assumptions. For an effective batch size $B = k \times B_{\text{micro}}$ where k is the number of accumulation steps and B_{micro} is the micro-batch size, equation 8.10 confirms that the accumulated gradient equals the true batch gradient:

$$\nabla \mathcal{L}_B = \frac{1}{B} \sum_{i=1}^{B} \nabla \mathcal{L}_i = \frac{1}{k} \sum_{j=1}^{k} \left(\frac{1}{B_{\text{micro}}} \sum_{i \in \mathcal{B}_j} \nabla \mathcal{L}_i \right) \tag{8.10}$$

This equivalence holds when each example's computation is identical and the loss is averaged consistently. The right-hand side shows that averaging k micro-batch gradients (each computed over B_{micro} examples) produces the same result as computing the gradient over all $B = kB_{\text{micro}}$ examples at once. Stateful layers such as BatchNorm, stochastic operations such as dropout and data augmentation, finite-precision accumulation order, and step-indexed schedules can break exact equivalence, so large-batch accumulation still requires validation.

Gradient accumulation exchanges memory capacity for computation time. Table 8.12 separates the memory benefit from the compute and scheduling costs that remain.

Table 8.12: Gradient Accumulation Trade-Offs: Accumulation reduces resident activation memory and preserves total example-level arithmetic. Wall-clock cost depends on micro-batch efficiency, kernel-launch overhead, and whether distributed synchronization is deferred until the accumulated update.

Dimension	Effect
Memory	$\mathcal{O}(B_{\text{micro}})$ instead of $\mathcal{O}(B)$, yielding a $k\times$ reduction in activation memory
Computation	Unchanged total FLOPs, as all B examples are still processed
Time	k micro-batch forward and backward passes precede each optimizer step; smaller micro-batches can reduce utilization and add launch overhead

Accumulation preserves the total example-level arithmetic but can change efficiency because smaller micro-batches use the accelerator differently and launch kernels more often. With distributed `no_sync()` accumulation, one gradient synchronization occurs after the k local micro-batches rather than after each one. The model in equation 8.11 gives the per-update time:

$$T_{\text{effective}} = \sum_{j=1}^{k} T_{\text{micro},j} + T_{\text{sync}} + T_{\text{update}} \tag{8.11}$$

Here $T_{\text{micro},j}$ is the measured forward/backward time for micro-batch j, T_{sync} is the synchronization time paid for the accumulated update, and T_{update} is the optimizer-step time. In distributed data-parallel training, standard framework wrappers automatically fire asynchronous gradient-synchronization hooks during every backward pass. When accumulating gradients across k micro-batches, leaving these hooks active would trigger redundant AllReduce operations on every micro-batch; wrapping the first $k-1$ micro-batches in a `model.no_sync()` context suppresses this communication, synchronizing gradients only on the final k-th step. That synchronization boundary may contain several bucketed AllReduce calls.

The wall-clock penalty relative to processing the effective batch at once is workload-dependent and must be measured rather than inferred from the memory-reduction factor. When gradient accumulation is combined with distributed data parallelism across multiple machines, additional considerations arise for gradient synchronization timing and effective batch size calculation across the cluster; advanced distributed systems texts treat these patterns in depth.

Activation checkpointing Activation checkpointing reduces activation memory by trading additional FLOPs for lower HBM occupancy during backpropagation. Only selected boundary tensors are retained in device memory; intermediate activations are dropped during the forward pass and recomputed on demand as the backward pass traverses in reverse (figure 8.13, where retained tensors are solid green, dropped ones dashed gray, and recomputed ones orange). Algorithm 8.3 states the schedule layer by layer.

Algorithm 8.3 Gradient checkpointing (activation recomputation)

Require: N_L-layer network; checkpoint set $\mathcal{C} \subseteq \{1, \dots, N_L\}$ (e.g., every $\sqrt{N_L}$ layers)
Ensure: parameter gradients, at reduced peak activation memory
1: **for** $\ell = 1$ to N_L **do**
2: forward layer ℓ; store its activation only if $\ell \in \mathcal{C}$ ▷ *drop the rest*
3: **end for**
4: **for** $\ell = N_L$ down to 1 **do**
5: **if** the activation of layer ℓ was dropped **then**
6: recompute the forward segment from the nearest stored checkpoint through layer ℓ
7: **end if**
8: compute the layer's gradient; free the activation
9: **end for**
10: **return** the accumulated gradients

In this segment schedule, recomputed intermediate values remain available until their backward consumers finish; recomputing a segment afresh for each layer would add more work. For layers with comparable activation sizes and forward costs, spacing checkpoints uniformly every $\sqrt{N_L}$ layers reduces peak activation memory from $\mathcal{O}(N_L)$ to $\mathcal{O}(\sqrt{N_L})$ at the cost of one additional forward pass of arithmetic per training step (T. Chen et al. 2016). This increases executed step computation from roughly $3\times$ to $4\times$ the forward-pass FLOPs, trading extra arithmetic operations for a substantially reduced activation footprint. The useful model FLOP count O is unchanged, so the additional work enters the training-time law through effective utilization η_{hw}. Actual fit and wall-clock overhead still depend on the full memory budget and execution profile. Section 8.6.5.2 derives why $\sqrt{N_L}$ spacing minimizes this footprint and works out its cost for GPT-2's 48 layers.

Frameworks like PyTorch provide tools such as `torch.utils.checkpoint` that split a model into segments and manage the recomputation, but the recompute cost remains. Checkpointing is most effective for deep architectures with dozens or hundreds of layers, such as transformers or large convolutional networks, where activation storage exceeds the GPU's capacity before arithmetic throughput is exhausted.

The two techniques address different terms. Gradient accumulation bounds the activation memory tied to batch size, while checkpointing bounds the memory held by each layer's intermediate activations, so together they widen the range of models that fit on available hardware.

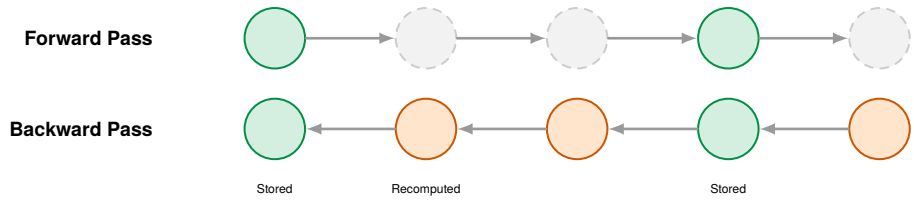

Figure 8.13: Activation Checkpointing: Trading memory usage for recomputation during backpropagation enables training deeper neural networks. By storing only a subset of activations from the forward pass and recomputing others on demand, this technique reduces peak memory requirements at the cost of increased training time.

8.6.5.2 Optimal checkpoint placement strategy

Algorithm 8.3 stated the $\sqrt{N_L}$ schedule without justifying it. For a network with N_L layers of comparable activation size and recomputation cost, each storing $M^{(\ell)}_{\text{activations}}$ bytes of activations, table 8.13 quantifies how the number and placement of checkpoints determines the memory-compute trade-off. Sub-linear checkpointing strategies can reduce memory consumption from $\mathcal{O}(N_L)$ to $\mathcal{O}(\sqrt{N_L})$ with additional forward arithmetic; the resulting wall-clock overhead depends on execution, while the reduced footprint can enable deeper models on existing hardware.

Table 8.13: Checkpointing Memory-Compute Trade-Offs: Different checkpoint strategies trade memory savings against recomputation overhead. The optimal number of checkpoints balances these factors.

Strategy	Memory Cost	Recompute Cost
No checkpointing	$N_L \times M^{(\ell)}_{\text{activations}}$	0 forward ops
One checkpoint ($n_{\text{ckpt}} = 1$)	$M^{(\ell)}_{\text{activations}} + N_L \times M^{(\ell)}_{\text{activations}}$	$(N_L - 1)$ forward ops
n_{ckpt} checkpoints	$n_{\text{ckpt}} \times M^{(\ell)}_{\text{activations}} + (N_L/n_{\text{ckpt}}) \times M^{(\ell)}_{\text{activations}}$	$(N_L - n_{\text{ckpt}})$ forward ops

The memory column counts two things, the stored checkpoints and the one segment that must be rematerialized at a time during backward, which holds N_L/n_{ckpt} layers of activations. The one-checkpoint row shows why both terms matter. With a single checkpoint the only segment spans the whole network, so backward rebuilds all N_L layers of activations at once and the peak is no lower than storing everything. Checkpoints pay off only when they are spread out so that each recomputed segment is short. The recompute column counts layer forwards. Every layer that is not itself a checkpoint is run forward once more, $(N_L - n_{\text{ckpt}})$ layer forwards in all, which is nearly one full forward pass when n_{ckpt} is much smaller than N_L.

Setting the derivative of total memory cost $(n_{\text{ckpt}} \times M^{(\ell)}_{\text{activations}} + (N_L/n_{\text{ckpt}}) \times M^{(\ell)}_{\text{activations}})$ with respect to the checkpoint count n_{ckpt} to zero yields the analytical optimum at $n_{\text{ckpt}} = \sqrt{N_L}$. In the standard $\sqrt{N_L}$ checkpointing scheme, this costs roughly one extra forward pass, about one-third more total step compute, in exchange for minimizing activation footprint under this analytical model. For GPT-2 with forty-eight transformer layers, the operational difference is substantial: uncheckpointed training requires $48 \times M^{(\ell)}_{\text{activations}}$ in full activation storage, whereas uniform checkpointing ($\sqrt{48} \approx 7$ checkpoints) requires $7 \times M^{(\ell)}_{\text{activations}} + (48/7) \times M^{(\ell)}_{\text{activations}} \approx 14 \times M^{(\ell)}_{\text{activations}}$, saving 71 percent activation memory for approximately 33 percent additional total step computation (by recomputing one forward pass over the uncheckpointed layers during backpropagation).

The GPT-2 notebook below uses eight equal segments of six layers. It applies the same boundary-plus-live-segment accounting with unequal storage costs: a segment input contains only the hidden tensor, whereas the reconstructed layer state also includes attention and feed-forward intermediates. The equal-state optimum above is therefore a useful baseline, not an optimality claim for that transformer schedule. Counting the two components separately produces the candidate memory budget without assuming a reduction factor.

Napkin Math 8.8: GPT-2 segment checkpointing

Problem: With mixed precision and FlashAttention-style attention, can a segment schedule fit GPT-2 XL's batch-32 step on one H100, and what does it cost in arithmetic?

Schedule: Partition the 48 transformer layers into 8 contiguous segments of 6 layers. During forward execution, retain each segment's input and discard its internal backward state. During backward execution, reconstruct one segment, retain its internal state while differentiating that segment, then free it before reconstructing the preceding segment. Each layer therefore executes one additional forward pass; against a forward-plus-backward step costing about three forward passes, the extra arithmetic is about one-third. This is work accounting, not a wall-clock penalty.

Math: Each retained segment input has shape batch $\times$ sequence length $\times$ hidden width, $32 \times 1{,}024 \times 1600 \times 2$ bytes. Keep all 8 inputs resident while adding the complete saved-state estimate for the 6 layers of one reconstructed segment. This deliberately counts the active segment's input in both terms, making the estimate conservative rather than omitting a live boundary.

- Retained segment inputs: 0.84 GB
- Live reconstructed segment: 10.7 GB
- Activation allowance: 11.5 GB, against 85.6 GB without checkpointing (7.4× smaller)
- Static state plus activations: 35.5 GB, leaving about 50 GB of the H100's capacity

Systems insight: Checkpointing admits the batch-32 step by replacing retained layer interiors with small boundary tensors and one live reconstructed segment. The remaining capacity must still hold output and loss buffers, temporary backward workspaces, and allocator overhead, which a runtime peak-memory measurement confirms. Gradient accumulation offers the alternative trade, keeping every activation of a smaller micro-batch and paying in update frequency instead of recomputation.

Not all operations are equally expensive to recompute, which motivates selective checkpointing: the practical rule is to spend recomputation on high-memory layers rather than on operations whose activations are already cheap to retain. Table 8.14 compares where activation memory is large enough to justify recomputation.

Table 8.14: Selective Checkpoint Placement: Placement compares the state saved at a block boundary with the work required to reconstruct it. Attention and feed-forward costs depend on sequence length, width, kernel implementation, and whether memory-efficient attention is already in use.

Layer type	Memory cost	Recompute cost	Checkpointing strategy
Attention blocks	Shape-dependent; materialized attention can add quadratic intermediates	High and sequence-length-dependent	Checkpoint block boundaries when saved state justifies recomputation
Feed-forward blocks	Often dominated by expanded hidden activations	High and width-dependent	Checkpoint when expanded activations dominate memory
Normalization	Small standalone outputs	Low	Usually handled within a larger checkpointed block

8.6.5.3 Memory and computational benefits

Both techniques reduce activation-memory requirements without adding hardware, though each targets a different dimension of the activation footprint. Gradient accumulation produces an effective batch larger than the resident micro-batch without storing all of its activations simultaneously; while a larger effective batch reduces sampling variance, it does not by itself guarantee faster convergence or better generalization. Conversely, activation checkpointing reduces the per-layer memory footprint of intermediate activations by discarding and recomputing them as needed, freeing capacity for deeper models, additional layers, or higher-resolution inputs. For lighthouse 8.1, accumulation

provides a direct way to reach a chosen effective batch size while keeping the resident micro-batch within one H100's memory.

Napkin Math 8.9: GPT-2 gradient accumulation strategy

This GPT-2-scale scenario uses the lighthouse's one-accelerator run time and a registry rental price to show gradient accumulation; it does not reconstruct GPT-2's historical training bill.

Memory Constraints

- With FlashAttention-style attention and no checkpointing, a micro-batch of $B_{\text{micro}} = 16$ needs about 67 GB, within one H100's 80 GB.
- A resident effective batch of $B = 512$ would therefore require 512 ÷ 16 = 32 accelerators.

Accumulation Configuration

- Use 8 accelerators and accumulate 4 micro-batches of 16 sequences each.
- Each accelerator processes 16 × 4 = 64 sequences per update, giving a global effective batch of 8 accelerators × 64 = 512.

A distributed `no_sync()` context can defer AllReduce until the final micro-batch.

Trade-off Analysis

- Idealized wall-clock time: 4× longer (105 hours against 26 hours) because fewer accelerators perform the same arithmetic work
- Memory overhead: accumulation normally reuses parameter-gradient buffers, although bookkeeping and temporary storage remain
- Communication: both configurations synchronize once per 512-sequence update, but participant count and topology differ
- Equal-work cost: $3,370 either way at $4/hour per accelerator, before utilization and communication effects

Why this works: Under the equivalence conditions stated above, averaged per-example gradients are additive. Each accelerator first accumulates a local gradient over its 64 examples:

$$\frac{1}{4}\sum_{j=1}^{4}\left[\frac{1}{16}\sum_{i=1}^{16}\nabla\mathcal{L}(x_{ji})\right]$$

AllReduce then averages those local gradients across 8 accelerators, producing the global effective batch:

$$\frac{1}{8}\sum_{r=1}^{8}\nabla\mathcal{L}^{(r)}_{\text{local}}, \qquad B = 8 \times 64 = 512$$

Operational comparison

Resident configuration:

- 32 accelerators × 16 sequences = 512 resident sequences per update
- Gradient synchronization spans 32 accelerators
- Hourly cost: $128/hour

Accumulated configuration:

- 8 accelerators × (16 sequences × 4 micro-batches) = 512 sequences per update
- Gradient synchronization occurs once per update across 8 accelerators, all within one server
- Hourly cost: $32/hour
- Hourly reduction: $96/hour, or 75 percent

Quality gate

- Match the examples and their order, loss normalization, optimizer state and step schedule, and stochastic-layer behavior.
- Compare held-out loss or perplexity and the optimization trajectory across repeated runs rather than assuming that the effective batch alone guarantees equivalent quality.
- Expect small round-off differences from the changed summation order; require convergence within a declared tolerance rather than bitwise identity. No perplexity result is assumed here.

Systems insight: Accumulation lowers accelerator count and hourly burn, but ideal scaling preserves accelerator-hours; actual cost depends on utilization and communication.

Listing 8.8 places one AllReduce after 4 local micro-batches, making the synchronization boundary explicit.

Listing 8.8: Gradient Accumulation Training Loop: Four local micro-batches of 16 sequences accumulate before one synchronization boundary and optimizer update across eight accelerators; the abstract AllReduce may represent multiple gradient buckets.

```
optimizer.zero_grad()
for step in range(4):  # Accumulation steps
    micro_batch = next(dataloader)  # 16 sequences
    loss = model(micro_batch) / 4  # Average effective-batch loss
    loss.backward()  # Accumulate gradients
# Now gradients represent 64 local sequences
all_reduce(gradients, op=SUM)  # Sum across 8 accelerators
gradients /= 8  # Convert the sum to the global mean
optimizer.step()  # Update with effective batch=512
```

8.6.5.4 Practical considerations

Gradient accumulation is most valuable when optimal batch sizes exceed GPU memory capacity. Transformer language models often use effective batches of hundreds of thousands to millions of tokens; if memory only permits a smaller number of sequences per device, accumulation bridges the gap without requiring additional hardware. Activation checkpointing complements this by enabling deeper architectures and is commonly used in transformer-scale training.

Both techniques introduce explicit trade-offs. Activation checkpointing recomputes discarded activations during backward propagation; with ordinary segment checkpointing, each discarded activation is typically reconstructed once, while recursive schedules may behave differently. Gradient accumulation reduces parameter-update frequency because each update follows k micro-batches. When each micro-batch loss is divided by k, the accumulated gradient follows the effective-batch mean convention. If losses are summed instead, the gradients must be rescaled before the optimizer step or the learning-rate convention changed accordingly. Framework and codebase conventions differ, making normalization a common source of subtle bugs.

8.6.6 GPT-2 optimization walkthrough

Training GPT-2 XL at batch 32 on a single H100 exposes the physical boundaries that govern large-model optimization. The tensor allocation first exceeds accelerator memory, and once it fits, a naive input pipeline starves the execution engines. Each step below fixes whatever blocks the next, memory feasibility first and execution evidence second, before any accelerator is added.

Napkin Math 8.10: GPT-2 optimization on one H100

Step 1: Establish the baseline memory footprint.

The trace starts with GPT-2 XL at batch 32 and sequence length 1,024, FP32 tensors throughout, standard attention, and a single-threaded synchronous data loader. Weights, gradients, and Adam moments take 24 GB, and FP32 activations take 574 GB, so the step needs 598 GB, about 7× the H100's 80 GB (85.9 GB in decimal units). The run fails the machine constraint before throughput matters.

Step 2: Apply mixed precision.

The first intervention targets memory feasibility rather than speed. Mixed precision (notebook 8.6) halves the activations and leaves the static state unchanged, reducing the step to 311 GB. The allocation still exceeds the accelerator.

Step 3: Replace standard attention with FlashAttention.

Never storing the quadratic score matrices removes most of the remaining activations and brings the step to 109.6 GB, still above capacity. With this kernel, the largest batch that stays resident is about 23 sequences, so the configuration overflows somewhere between batch 16 and batch 32.

Step 4: Fit the batch.

Two techniques close the gap. Accumulating two micro-batches of 16 keeps the same arithmetic per update and needs 66.8 GB. Segment checkpointing (notebook 8.8) keeps all 32 sequences resident in 35.5 GB but adds about 33 percent more arithmetic per step. The walkthrough takes accumulation, because the batch it needs fits without recomputation; checkpointing is the choice when a larger resident micro-batch matters more than arithmetic. Runtime measurement must still verify that backward workspaces, output and loss buffers, and allocator overhead fit in the remaining capacity.

Step 5: Read the profile.

Fitting the model resolves capacity but does not guarantee efficient execution. With single-core tokenization, host preparation takes longer than the device's step (example 8.1), so a serial pipeline keeps the accelerator busy only about 48 percent of the time (equation 8.7). The diagnostic focus shifts from machine memory capacity (M) to the data pipeline (D) in D·A·M terms: reducing accelerator memory further would not touch the dominant exposed delay.

Step 6: Apply prefetching and parallel preparation.

Eight worker processes, page-locked (pinned) host memory for asynchronous DMA transfers, and a prefetch queue overlap host preparation with accelerator computation, and the parallel preparation interval falls well inside the device's step. In the ideal overlapped model the accelerator is then busy for the whole step. A busy accelerator is not yet an efficient one; MFU measures how much of that busy time does useful model arithmetic, and re-profiling must establish whether memory bandwidth, arithmetic throughput, or another stage now limits execution.

Result: At the assumed 50 percent utilization, one step takes 0.60 s, the accelerator processes about 55,000 tokens/s, and the run takes about 35 days on one accelerator (about 47 days with segment checkpointing at the same executed rate). Table 8.15 collects the result.

Table 8.15: GPT-2 XL on One H100: Memory figures are calculated from the model shape; the busy-time result follows from the tokenization and step-time scenario; run time, energy, cost, and carbon follow from the assumed utilization, the accelerator's thermal design power, and registry values for facility overhead, electricity price, and grid carbon intensity. The FP32 baseline does not fit, so it has no run to measure.

Metric	FP32 baseline	Optimized	Technique applied
Static training state	24 GB	24 GB	Unchanged at 16 bytes per parameter
Activations per step	574 GB	42.8 GB	FP16, FlashAttention, two micro-batches of 16
Total memory	**598 GB**	**66.8 GB**	9× smaller
Fits one H100	No	Yes	Capacity 80 GB (85.9 GB)
Accelerator busy time	N/A	Whole step (ideal)	Prefetching, eight workers
Throughput	N/A	55,000 tokens/s	At the assumed utilization
Run time	N/A	35 days	One accelerator
Facility energy	N/A	661 kWh	Accelerator power × PUE 1.12
Electricity cost	N/A	$79	At $0.12/kWh
Carbon	N/A	0.28 t	Average grid intensity

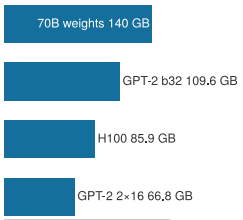
Systems insight: The order of interventions follows a dependency, not a preference. Memory feasibility comes first because a configuration that does not fit produces no profile at all. Once it runs, the profile decides what comes next; in this scenario exposed input waits made the data pipeline the target ahead of any kernel tuning, because a faster kernel cannot shorten a step spent waiting for its input. After each intervention, re-profiling determines whether input delivery, memory bandwidth, arithmetic throughput, or another execution cost now limits progress.

This walkthrough demonstrates why training optimization is a sequential diagnostic discipline rather than an arbitrary collection of techniques. Each intervention addresses a constraint established by the memory calculation or the profile. Mixed precision halves activation storage, FlashAttention removes the quadratic attention term, and accumulation brings the batch within capacity without extra arithmetic, a 9× modeled memory reduction in all. Prefetching then addresses exposed input waits once execution begins. The result is a run of about 35 days on one accelerator.

Checkpoint 8.3: From a feasible configuration to a validated run

The walkthrough combines memory calculations with a modeled execution profile. Use the distinction to decide what an actual run must verify.

- ☐ **Evidence**: Which walkthrough values are calculated from tensor sizes, which follow from assumed utilization or tokenization rates, and which require measurement on the target system?
- ☐ **Capacity and throughput**: Why does fitting the tensor budget establish neither peak runtime memory nor efficient execution, and what must be measured next on hardware?
- ☐ **Quality gate**: Before accepting the composed optimizations, how does an engineer verify that the revised precision and effective batch preserve progress toward the same validation target?



Single-accelerator optimizations address complementary constraints: mixed precision enables higher-throughput arithmetic, FlashAttention avoids materializing full attention matrices in HBM, accumulation and checkpointing bound activation memory, and asynchronous prefetching hides host input latency. Even fully optimized, however, a run of GPT-2 XL's size occupies one accelerator for about 35 days, and larger runs are bounded by the arithmetic throughput of an individual chip.

Scaling beyond single-device compute or memory capacity requires distributing computation across multiple accelerators. This architectural transition introduces inter-device communication

overhead, collective synchronization barriers, and fault-tolerance constraints that become the primary determinants of scaling efficiency.

8.7 Scaling Training Systems

The GPT-2 walkthrough fits the batch-32 step on one H100 and finishes the run in about 35 days. One accelerator cannot finish sooner, and some models cannot fit at all. Spread across the 8 accelerators of one server with perfect scaling, the same run would take about 4.4 days. A 70-billion-parameter model needs about 140 GB for its FP16 weights alone and far more for full training state, which no single accelerator holds, motivating sharding, offload, or multiple devices.

Two micro-batches of 16 fit one H100; batch 32 without checkpointing and a 70B model do not.

When a chosen workload still exceeds one device's memory or schedule, spreading it across devices provides aggregate memory and compute. Other responses include reducing the model, batch, sequence length, or training scope; offloading state; and parameter-efficient adaptation, which trains only a small set of added parameters on top of a frozen model. Scaling beyond one device begins with multi-GPU configurations inside one machine and may extend across nodes. The major parallelism strategies make different communication trade-offs; a full treatment of distributed-training implementation lies beyond this chapter.

Not all workloads benefit equally from adding GPUs. Adding accelerators helps only until communication and synchronization consume the time saved. Figure 8.14 charts this scaling decay on a log-log speedup plot up to 256 GPUs, contrasting ideal linear scaling against compute-bound (ResNet), balanced (a large language model (LLM) over NVLink), and communication-bound regimes. The widening divergence between the ideal linear dashed reference and the plateauing modeled curves illustrates the communication overhead that accumulates as synchronization compounds. In this fixed-fraction model, even unlimited parallel compute leaves the non-scaling fraction of the original runtime, so the limiting speedup is its reciprocal, the Amdahl bound of equation 11.1.

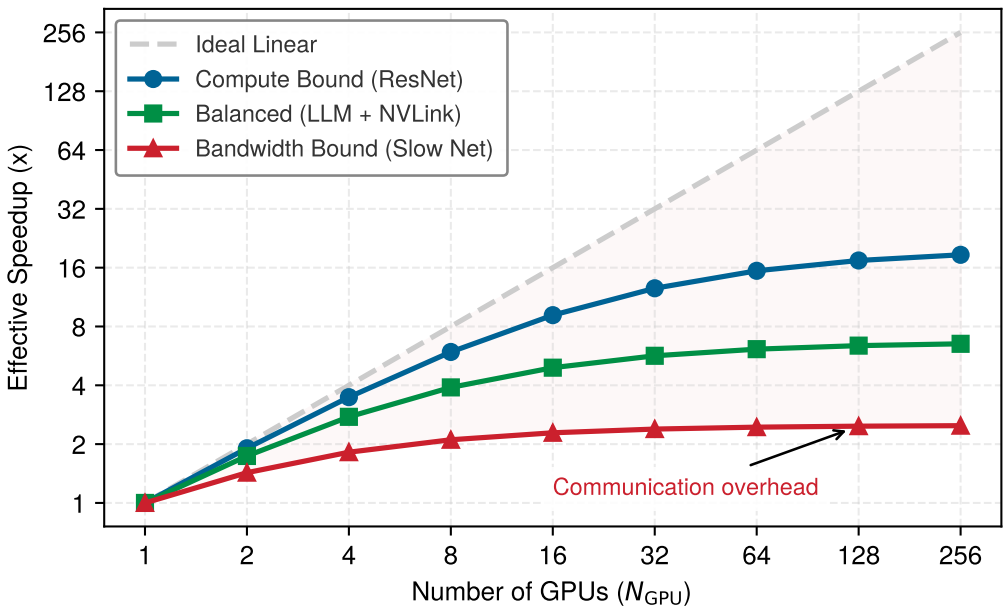


Figure 8.14: Communication Overhead: An Amdahl-style model compares ideal linear scaling against workloads with varying non-scaling communication and synchronization fractions. Real communication overhead scales dynamically with device count, network topology, message size, and overlap efficiency.

The red curve's widening gap from the dashed ideal is that communication overhead made visible, and shrinking that gap is what the distributed strategies in section 8.7.1 exist to do. Those strategies are older than deep learning: training platforms inherit dense matrix multiplication kernels and tightly synchronized parallel execution from high-performance computing (HPC), and

from warehouse-scale computing they inherit cluster orchestration and automated fault recovery for multi-day jobs, the lineage that matters once a run spans many machines.

The same inheritance appears inside one training system as pressure at three scales. At data scale, large corpora require high-throughput input pipelines to avoid accelerator starvation. At model scale, billion-parameter architectures force a choice between replicating weights across devices and partitioning the model. At infrastructure scale, coordinating multiple accelerators introduces synchronization overhead that can dominate training time. The stage interfaces formalized in section 3.4.1 govern what each scale may assume of the others.

8.7.1 Single-node multi-GPU training

Multi-GPU training within a single node introduces the core parallelism strategies. AlexNet[16] (Krizhevsky et al. 2012) split its convolutional layers across two GTX 580 GPUs because the 3 GB device memory limit prevented single-chip execution, making cross-GPU connectivity an immediate architectural constraint. Confining multi-accelerator topologies to single-node interconnects (such as PCIe or NVLink) isolates these strategies before cross-rack network fabrics enter.

The two foundational strategies partition different things. Data parallelism replicates the model and partitions the data, while model parallelism partitions model state or computation. This distinction determines memory requirements, communication patterns, and scaling behavior.

[16] **AlexNet (2012)**: The paper reports 60M parameters and a 3 GB single-GPU ceiling, but does not attribute the limit to one memory component. Its model-parallel design placed roughly half the kernels on each GPU and allowed communication only in selected layers, explicitly trading memory capacity against communication.

8.7.1.1 Data parallelism

Data parallelism replicates the entire model on each GPU, with each processing different batches. After computing gradients locally, GPUs synchronize via gradient averaging. Input batches split across parallel GPU workers for independent forward and backward passes, then converge into an AllReduce collective, which sums the gradients from every worker and returns the result to each of them, so every replica applies the identical parameter update (figure 8.15).

When a model and its optimizer state fit comfortably within single-device memory, data parallelism serves as the primary scaling baseline because local forward and backward kernels run at native memory bandwidth without inter-device synchronization. Gradient aggregation is the principal recurring communication cost; some implementations also synchronize buffers or other state. Historically, frameworks supported multi-GPU execution within a single node using multithreaded wrappers like PyTorch's `DataParallel` (DP). However, this single-process design suffers from two severe architectural bottlenecks: the Python runtime remains throttled by the Global Interpreter Lock (GIL), and a primary coordinator (GPU 0) must sequentially scatter mini-batches and gather outputs over PCIe, saturating host-device interconnect bandwidth and creating severe compute and memory imbalances. Modern systems commonly use PyTorch's `DistributedDataParallel` (DDP); TensorFlow's `MirroredStrategy` also provides replicated training but has a different execution model. With an independent Python process per accelerator, DDP avoids cross-replica contention for one Python GIL; each process maintains its own model replica and local optimizer, relying on decentralized collective AllReduce operations that bucket gradients into contiguous buffers and overlap synchronization directly with backward-pass computation.

Synchronizing gradients is the step that data parallelism adds, and for GPT-2 XL inside one server its cost can be derived directly. Each replica holds FP16 gradients of 3 GB, and every replica must end the step with their sum. Ring AllReduce (Patarasuk and Yuan 2009) arranges the N_{GPU} accelerators in a logical ring and splits the gradient into N_{GPU} chunks. In a reduce-scatter phase, each accelerator passes a chunk to its neighbor $N_{\text{GPU}} - 1$ times, adding the chunk it receives to its own, until each holds one fully summed chunk; in an all-gather phase, the summed chunks circulate $N_{\text{GPU}} - 1$ more times until every accelerator holds all of them. Each accelerator therefore sends $2(N_{\text{GPU}} - 1)/N_{\text{GPU}}$ of the gradient bytes D_{vol}, nearly twice the gradient however large the ring, and over a link of bandwidth BW the bandwidth term of the synchronization time is

$$T_{\text{comm}} \approx \frac{2(N_{\text{GPU}} - 1)}{N_{\text{GPU}}} \cdot \frac{D_{\text{vol}}}{\text{BW}} \tag{8.12}$$

For 8 H100s the factor is 1.75, so each accelerator sends 5.25 GB per step, which takes about 12 ms at 450 GB/s per direction over NVLink. Against a 596 ms step when each replica processes the full batch of 32 sequences, synchronization is about 2 percent of the step even without overlap. Splitting

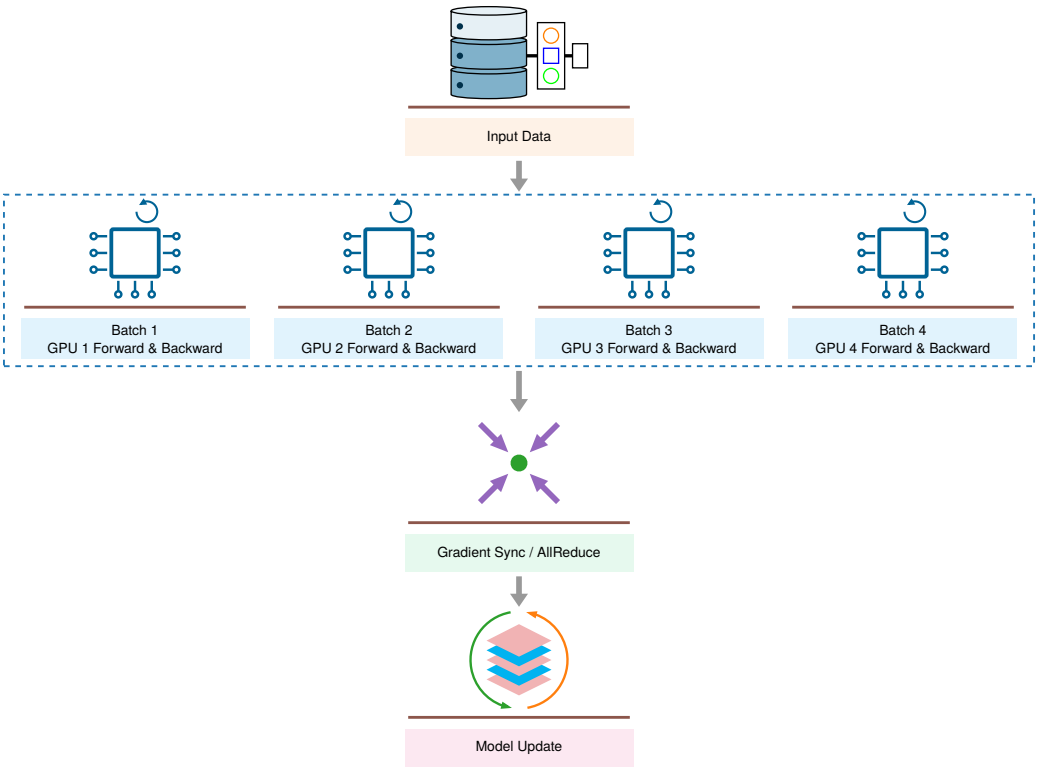

Figure 8.15: Data Parallelism: Each GPU holds a complete model copy, processes a different data shard, and synchronizes gradients. Throughput can approach linear scaling only while computation dominates synchronization, input, and imbalance costs.

a fixed batch of 32 eight ways shrinks each replica's compute to 75 ms while the gradient bytes stay the same, raising the unhidden share to about 14 percent. Data parallelism inside one server is cheap for GPT-2 XL as long as each replica keeps enough work to amortize a synchronization whose size depends only on the parameter count; frameworks hide most of what remains by launching bucketed AllReduce calls while the backward pass is still computing earlier layers' gradients.

Unsharded data parallelism has a hard constraint. Every accelerator holds a complete model replica and its full training state, 16 bytes per parameter in the mixed-precision Adam recipe, or 24 GB for GPT-2 XL on each of the 8 accelerators. The Zero Redundancy Optimizer (ZeRO) (Rajbhandari et al. 2020) removes that redundancy by sharding training state across the data-parallel replicas in three stages. ZeRO-1 shards the 12 bytes of FP32 master weights and Adam moments, leaving 8.2 GB per accelerator for GPT-2 XL; ZeRO-2 also shards the gradients, leaving 5.6 GB; and ZeRO-3, which fully sharded data parallelism (FSDP) (Zhao et al. 2023) implements, also shards the FP16 parameters, leaving 3 GB. The same arithmetic brings the Llama 3 8B full fine-tune that overflowed one accelerator in section 8.3.3.3 down to about 16 GB of static state per accelerator. The memory comes back as communication. ZeRO-1 and ZeRO-2 keep the data-parallel volume, because a reduce-scatter of gradients followed by an all-gather of updated parameters moves the same bytes as one AllReduce, while ZeRO-3 must also gather each layer's parameters before its forward and backward computation, about 1.5 times the data-parallel volume (Rajbhandari et al. 2020). A model that still exceeds local memory after sharding requires pipeline or tensor partitioning.

8.7.1.2 Model parallelism

Model parallelism partitions the model itself across GPUs, which becomes necessary when the model exceeds single-GPU memory. AlexNet adopted an early form of this strategy: selected convolutional layers split their kernels and channels across two GPUs, with communication at selected connections. Figure 8.16 illustrates a different, layerwise partition of the same broader

model-parallel idea: Device 1 through Device 3 sequentially process layers 1–16, 17–32, and 33–48, streaming boundary activations forward during the forward pass and propagating loss gradients in reverse during backpropagation.

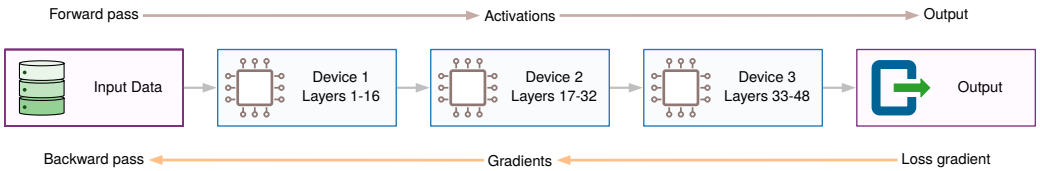

Figure 8.16: Model Parallelism: The model is partitioned across devices, with intermediate activations passing between them. This enables training models larger than single-GPU memory at the cost of sequential dependencies.

Systems Perspective 8.4: Data vs. model parallelism

When a selected workload is partitioned across N_{GPU} devices, the split may divide examples, model state, layers, or tensor operations. For a model with parameters P and batch size B, data and model parallelism provide two starting points.

Data parallelism (split the batch): For a fixed global batch, each of N_{GPU} workers processes about $1/N_{\text{GPU}}$ of the examples, but every worker holds a model replica and ordinarily its associated training state. Dense gradient communication is proportional to P per update. Scaling departs from the ideal as local batches shrink or synchronization and input costs grow.

Model parallelism (split model computation): Each accelerator stores and computes a portion of the model. An even partition may approach P/N_{GPU} parameters per worker, but embeddings, buffers, imbalance, and replicated state alter that estimate. Communication depends on the partition: layerwise pipeline parallelism exchanges activations at stage boundaries, while tensor parallelism performs collectives within partitioned layers.

Systems insight: Data parallelism is the simplest candidate when the complete training state fits per worker and more throughput is needed. Model-state, pipeline, or tensor partitioning becomes necessary when it does not, often in combination with data parallelism.

When a model exceeds the memory capacity of a single accelerator, its depth can be partitioned across sequential devices. Figure 8.17 stages this pipeline allocation across a four-accelerator execution chain, grouping 24 transformer blocks into contiguous six-block partitions (Blocks 1–6 through 19–24) that exchange boundary activations over the interconnect.

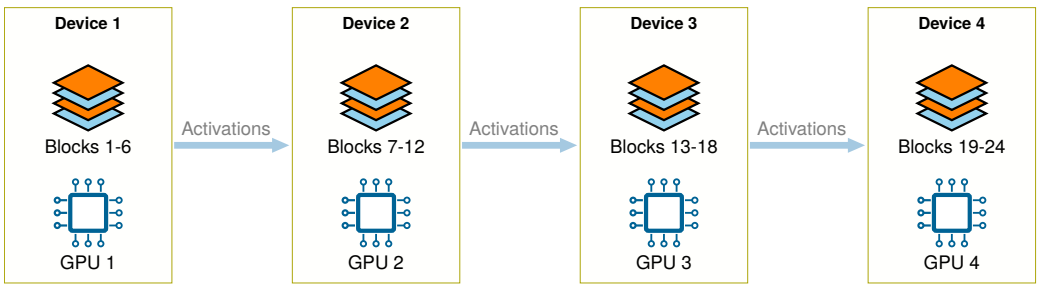

Figure 8.17: Layer-Wise Model Partitioning: Distributing consecutive transformer layers across sequential devices bounds network communication to intermediate activations (forward) and boundary gradients (backward). However, sequential layer dependencies leave downstream devices idle during forward passes unless micro-batches are pipelined.

The main bottleneck in naive layer-wise partitioning is device serialization. Because layer evaluation is strictly sequential, Device 1 computes layers 1–6 while Devices 2–4 sit idle waiting for forward activations. During the backward pass, the dependency reverses: Device 4 computes first while upstream devices wait for returning gradients. This idle duration constitutes the *pipeline*

bubble, which caps theoretical hardware utilization at $1/N_{\text{GPU}}$ under naive sequential execution. It differs from the accelerator bubbles of the staged training pipeline, which arise when one device's data-loading, transfer, and compute stages run at mismatched rates; a pipeline bubble arises even with perfectly fed devices, because each device must wait for another device's layers. Mitigating this idle time requires either pipelining micro-batches across stages or partitioning tensor dimensions within layers so that all devices compute simultaneously.

Both remedies fit inside one node. Pipeline parallelism splits each batch into micro-batches and streams them through the stages, so Device 2 works on the first micro-batch while Device 1 starts the second, and the bubble shrinks to the time spent filling and draining the pipeline at the start and end of each batch (Huang et al. 2019; Narayanan et al. 2019). Tensor parallelism instead splits the matrix operations of each layer across devices, so every device works on every layer at once (Shoeybi et al. 2019). The price is communication inside every layer, because the partial results must be combined before the next layer can begin. That frequency is why tensor parallelism is normally kept within one node, on its fastest links.

Within a node, GPUs may communicate through high-bandwidth links such as NVLink (up to 900 GB/s aggregate bidirectional bandwidth for the represented H100 configuration). Effective collective bandwidth depends on topology and contention and is lower than a raw aggregate link specification. Data parallelism communicates gradients via collective AllReduce operations, while layerwise model parallelism communicates activations point-to-point at partition boundaries. Data parallelism suits models that fit on one accelerator, whereas larger models require sharded training state or a split model.

8.7.2 Scaling beyond a single node

One machine is this book's scope, but its boundary is worth knowing. When a model's parameter footprint, optimizer state, or training duration exceeds the capacity of an 8-accelerator node, distributed training extends across machines. The strategies of this section still apply, but three things change once training leaves the node. First, bandwidth drops sharply because machines are joined by a network such as Ethernet or InfiniBand rather than NVLink, reducing link throughput by one to two orders of magnitude so that gradient synchronization that overlapped with the backward pass inside a node can come to dominate each step. Second, placement must match each strategy to a tier of the network: the frequent intra-layer communication of tensor parallelism stays inside the node, whereas the once-per-step gradient exchange of data parallelism can cross slower inter-node links. Third, hardware failure becomes a routine operational event across thousands of accelerators during a multi-day run, making automated checkpointing and restart an essential part of the training design. Each of these is a subject of its own in large-scale distributed training; within one machine the same principles appear in their simplest form, which is why the single-node case comes first.

↪ Empirical protocols for quantifying multi-accelerator scaling efficiency and communication loss are developed in section 12.5.2.2.

8.7.3 When to scale: The physical ceiling

Even a perfectly tuned single accelerator hits hard physical walls: a 70-billion-parameter model overflows 80 GB of HBM on weights alone, and a 10^{24}-FLOP pretraining run at 10^{15} sustained FLOP/s would take 32 years on one chip. Until a run meets one of those walls, however, distributing state across devices adds communication traffic, synchronization barriers, and new failure modes that can slow a job that would have fit locally. Single-device optimizations therefore come first to separate solvable local bottlenecks from genuine capacity or schedule limits: lower-precision execution (section 8.6.3) when numerical stability permits, gradient accumulation (section 8.6.5) to build target batch sizes without activation blowup, activation checkpointing (section 8.6.5.1) to trade redundant forward compute for memory headroom, and overlapped data prefetching (section 8.6.2) when host ingestion limits the critical path.

Table 8.16 structures this progression as a resource lookup keyed to measured hardware bottlenecks rather than arbitrary parameter thresholds.

Table 8.16: Scaling Decision Guidelines: Choose the least distributed configuration that satisfies measured memory, throughput, and schedule requirements. Model architecture, training state, input pipeline, hardware, and topology all affect the boundary.

Observed constraint	Candidate approach	Rationale
Training state fits one device and time is acceptable	Single GPU	Minimizes communication and operational complexity
State or throughput exceeds one device but fits one node	Single multi-GPU node	Uses fast local interconnects before crossing the network
Required state or schedule exceeds one node	Multi-node cluster	Adds aggregate memory or compute at a communication cost
Input service rate is below accelerator demand	Parallel or distributed input pipeline	Adds input throughput where profiling shows it is needed

A measured single-device baseline guides scaling decisions, while a decisive capacity or compute-time lower bound can establish the need for additional resources before every local optimization is attempted. Once local tuning is exhausted or ruled out by lower bounds, resource expansion must match the specific physical limit that has been reached. Memory exhaustion occurs when model weights, gradients, optimizer states, and activations exceed the VRAM of a single GPU: a 70-billion-parameter model requires about 140 GB in FP16 for weights alone, exceeding the reference H100's capacity and leaving little or no headroom on higher-capacity variants once training state is included. Training wall-clock time binds when the estimated duration on one device exceeds the project's deadline, as in a 10^{24}-FLOP workload that would take roughly 32 years at 10^{15} FLOP/s sustained. Input throughput binds when the host pipeline cannot sustain the aggregate accelerator consumption rate, which calls for more input-service capacity rather than more training accelerators; dataset size alone does not determine this limit because reuse, compression, locality, transformation cost, and storage bandwidth govern delivery rate.

Data parallelism also meets a statistical ceiling. Each added replica enlarges the global batch, and beyond the critical batch size met in the discussion of batch size and parameter updates (section 8.4.4.1), larger batches stop reducing the number of updates needed to reach a target loss (McCandlish et al. 2018). Past that point, more replicas raise throughput in samples per second without shortening the time to target quality, so a scaling decision needs both the hardware ceiling and the batch at which the recipe's convergence flattens.

These three limits are technical, but scaling carries a cost beyond complexity and capacity. Adding devices amplifies the energy consumption and environmental impact of training, so efficiency optimization becomes an environmental concern as much as a performance one.

Napkin Math 8.11: The carbon footprint of training

Context: Training large models requires substantial energy and compute. The physical ceiling appears once training time is converted to energy, cluster power multiplied by training time ($E_{\text{total}} = P_{\text{cluster}} \cdot T_{\text{train}}$), quantifying environmental scale:

1. Workload: Training a 7 billion-parameter model for 1 trillion tokens.
2. Compute: $O \approx 4.2 \times 10^{22}$.
3. Efficiency: 494 TFLOP/s sustained on the H100 (700 W thermal design power).
4. **Execution time**: $T_{\text{train}} \approx 0.96$ days on 1,024 GPUs.
5. **Energy footprint**: $E_{\text{total}} = P_{\text{cluster}} \cdot T_{\text{train}} = (N_{\text{GPU}} \cdot P_{\text{device}} + N_{\text{nodes}} \cdot P_{\text{host}}) \cdot T_{\text{train}}$ evaluates to (1,024 GPUs $\times$ 700 W + 128 hosts $\times$ 200 W) $\times$ 23 hours $\approx$ 17,104.8 kWh.

Impact: Under the assumed constant GPU and host-CPU power, this modeled subtotal equals 19.0 months of average household electricity use. GPU thermal design power is a scenario input rather than measured draw; memory, storage, network equipment, and facility overhead are not separately included, so the subtotal is not total facility energy.

Systems lesson: Doubling hardware utilization η_{hw} at constant cluster power P_{cluster} halves execution time T_{train} and total energy E_{total}. Under average grid carbon intensity, doubling efficiency saves ~8,552.4 kWh of electricity and avoids 3.7 t of emissions. Environmental audits must measure $E_{\text{total}} = \int P_{\text{cluster}}(t)\,dt$ rather than relying on GPU utilization metrics alone.

Scaling changes the binding constraint rather than removing it. Data parallelism adds throughput, sharded and model parallelism add memory capacity, pipeline parallelism recovers utilization lost to idle stages, and tensor parallelism makes layers larger than one device feasible, but each adds communication and coordination cost. The implementation details of multi-node distributed training, including collective communication primitives, fault tolerance mechanisms, and elastic scheduling, build directly on the single-machine principles covered throughout this chapter and are treated in depth in advanced distributed systems texts.

Checkpoint 8.4: Scaling decisions

Scaling trades compute bottlenecks for communication bottlenecks.

- ☐ **Hard limits**: Identify which resource limit binds a given training run: memory capacity, compute throughput, or input-service rate.
- ☐ **Single-node first**: Explain how a single-node baseline and relevant local optimizations inform scaling, and when a physical lower bound can justify scaling before all tuning is exhausted.
- ☐ **Data vs. model parallelism**: Justify why data parallelism fails when model states exceed single-accelerator memory, and identify what model parallelism must partition.
- ☐ **Communication overhead**: Explain why scaling efficiency degrades with accelerator count, and identify the communication metrics that dictate this ceiling.
- ☐ **Scaling ceiling**: Estimate the theoretical speedup ceiling via Amdahl's law when unparallelized synchronization accounts for 10 percent of step time, and determine where adding accelerators yields diminishing returns.

8.8 Fallacies and Pitfalls

The approach developed throughout this chapter quantifies costs through the iron law, diagnoses bottlenecks through profiling, applies targeted optimizations, and scales only when necessary. The following fallacies and pitfalls are the errors that most often waste training compute.

Fallacy: *Larger models always yield better performance.*

Teams sometimes treat scale as a monotonic lever: if a 7B-parameter model works well, a 20B-parameter model must work better. A 20B model requires approximately 320 GB of nonactivation training state in the stated mixed-precision Adam recipe (40 GB FP16 parameters + 40 GB FP16 gradients + 80 GB FP32 master weights + 160 GB Adam states). Whether it outperforms a 7B model depends on data quantity and quality, training compute, optimization, and evaluation, not on parameter count alone.

Pitfall: *Assuming distributed training automatically accelerates development.*

More accelerators do not guarantee faster training because communication, smaller local batches, input limits, and imbalance can consume the gain. The chapter's own derivation shows the mechanism: splitting GPT-2 XL's batch of 32 across eight H100s shrinks each replica's compute while the gradient bytes stay fixed, so unoverlapped synchronization grows to about 14 percent of the step. In a hypothetical 8 GPUs scenario, the same effect lets synchronization occupy 30–50 percent of step time, so speedup reaches only 4–6× rather than the ideal 8×. The decision requires measured end-to-end time and scaling efficiency.

Fallacy: *Hyperparameters transfer directly from small-scale experiments to large-scale training.*

A learning rate that works at batch size 512 may not transfer to batch size 4,096. The linear scaling rule (Goyal et al. 2017) would increase the rate from 0.1 to 0.8 for this eightfold change, often with warmup, but it is an empirical recipe rather than a requirement or convergence guarantee. Large-scale runs must validate the learning rate, schedule, optimizer state, and effective batch together.

Pitfall: *Treating mixed precision training as a simple toggle without validation.*

The H100's peak ratios bound the gain at 2× over the TF32 Tensor Core path and 15× over FP32 scalar units, but elementwise kernels, optimizer updates, and input waits do not speed up with the matrix units, so the measured gain is smaller. FP16 commonly requires loss scaling (Micikevicius et al. 2018), while BF16 usually does not (Wang and Kanwar 2019; Kalamkar et al. 2019) (section 8.6.3 compares the two formats). Either recipe can change numerical behavior, so throughput and convergence must be validated on the target workload.

Fallacy: *Memory and computation can be optimized independently.*

Memory *and* compute are coupled: in this illustrative profile, accelerator utilization drops from 90 percent at batch 256 to 60–70 percent at batch 16. Gradient accumulation (effective batch 512, physical batch 64) shows a 5-percentage-point utilization gap for 8× activation-memory reduction. Tuning these parameters independently can therefore extend training time materially, because the utilization lost at the smaller physical batch applies to every step of the run (section 8.6.5 develops this trade-off).

Pitfall: *Budgeting training memory as if it only contains model weights.*

Sizing training memory from weights alone omits gradients, optimizer state, master weights when used, activations, temporary workspaces, and allocator overhead. In the chapter's mixed-precision Adam recipe, the static state alone is 16 bytes per parameter before activations. Other optimizers and sharding strategies change this budget. Activation memory then depends on batch size, sequence length, architecture, kernels, and checkpointing; no universal multiple of the weight footprint applies.

Fallacy: *The accelerator is always the training bottleneck.*

Data loading often creates idle time, yet teams optimize computation first. On the reference H100, ResNet-50's demand outruns the host cores available to it and leaves the accelerator busy only about 52 percent of the time, and GPT-2 XL with single-core tokenization is busy only about 48 percent; a faster accelerator fixes neither, while parallel preparation and overlap (section 8.6.2) address both. Profile before assuming the GPU is the bottleneck.

Pitfall: *Optimizing kernels before profiling the input pipeline.*

Kernel-level tuning is attractive because accelerator utilization is easy to inspect, but a starved accelerator can look like an inefficient one. Before changing precision, rewriting kernels, or adding accelerators, measure dataloader throughput, host preprocessing time, and storage wait. If the accelerator is waiting for batches, feeding it reliably beats faster kernels.

8.9 Summary

Training cost is governed by three quantities that this chapter first kept separate and then joined. The training-time law, $T_{\text{train}} = O/(R_{\text{peak}} \times \eta_{\text{hw}})$, sets the time a run takes, and device power multiplied by that time sets its energy. The four-term memory budget decides what fits, and in a standard mixed-precision Adam recipe the static state alone reaches 8× the FP16 weights before a single activation is stored. The min-of-three pipeline model decides whether the accelerator is fed at all. GPT-2 XL tied the three together. Its $6PD$ operation count set a run of about 35 days on one H100, its weights, optimizer state, and activations overflowed that accelerator at batch 32 before any arithmetic began, and its single-threaded data loader could starve the device once the step fit.

Every intervention in the chapter relieves one term and burdens another, which is the conservation of complexity at work. Mixed precision raises R_{peak} and shrinks activation memory and traffic, but it leaves the static state unchanged and requires loss scaling or a wider-exponent format. Checkpointing trades extra forward arithmetic for activation memory, accumulation trades update frequency for

batch size, prefetching hides input time at the cost of host memory, and FlashAttention removes quadratic HBM traffic by recomputing tiles. Scaling to more devices adds aggregate memory and compute but turns gradient synchronization into a new term on the critical path. The profile, not the menu of techniques, decides which trade is worth making.

The same pressures shaped the hardware. Dense matrix patterns drove Tensor Cores, frameworks exposed them through mixed-precision APIs, and reduced-precision training pushed later accelerators toward BF16 and FP8. The bitter lesson explains why this matters. If capability grows with the computation a general method can absorb, every point of utilization lost to stalls is capability forgone at a fixed budget.

The counting rules developed across the chapter fit on one page (table 8.17). Together they estimate, before any profiler runs, how long a run takes, what it costs in energy, whether its step fits in memory, and which stage of its pipeline binds.

Table 8.17: Key Equations: The chapter's counting rules in the notation of the sections that derive them, so that a training run can be estimated before it is profiled. The activation rule sums per-example saved state over layers; the transformer estimates in the chapter specialize it to batch, sequence length, and hidden width.

Quantity	Formula	Where derived
Training time	$T_{\text{train}} = \frac{O}{R_{\text{peak}} \times \eta_{\text{hw}}}$	equation 8.1
Training work	$O \approx 6PD$ FLOPs (2 forward, 4 backward per parameter per token)	section 8.1.1
Training energy	$E_{\text{total}} = P_{\text{device}} \times T_{\text{train}}$ at constant power	section 8.2
Training memory	$M_{\text{total}} = M_{\text{weights}} + M_{\text{gradients}} + M_{\text{optimizer}} + M_{\text{activations}}$; 16 bytes per parameter of static state in mixed-precision Adam	equation 8.4
Activation memory	$M_{\text{activations}} = B \times \sum_{\ell=1}^{N_L} \left(s_\ell + M_{\text{activations}}^{(\ell)} \right)$	equation 8.3
Pipeline throughput	$R_{\text{training}} = \min \left(R_{\text{preprocessing}}, \frac{\text{BW}_{\text{host}}}{D_{\text{vol}}^{(\text{batch})}}, \frac{R_{\text{sustained}}}{O_{\text{batch}}} \right)$	equation 8.6
Model FLOPs utilization	$\text{MFU} = O_{\text{model}} / (R_{\text{peak}} \cdot T_{\text{step}})$	section 8.5
Checkpointed activations	$n_{\text{ckpt}} \times M_{\text{activations}}^{(\ell)} + (N_L / n_{\text{ckpt}}) \times M_{\text{activations}}^{(\ell)}$, minimized at $n_{\text{ckpt}} = \sqrt{N_L}$	table 8.13
Effective batch	$B = k \times B_{\text{micro}}$ per device	equation 8.10
Ring AllReduce time	$T_{\text{comm}} \approx \frac{2(N_{\text{GPU}}-1)}{N_{\text{GPU}}} \cdot \frac{D_{\text{vol}}}{\text{BW}}$	equation 8.12

Compute and memory deserve equal weight in that estimate, because the step that fits is not always the step that is cheapest to compute (table 8.18).

Table 8.18: Memory and Compute per Training Step: Step FLOPs follow from six FLOPs per parameter per token or three forward passes per image; static state is 16 bytes per trained parameter in the mixed-precision Adam recipe; activations come from the chapter's per-layer estimates or, for ResNet-50, its stated FP32 scenario.

Workload (step)	FLOPs per step	Static state	Activations	Fits one H100
GPT-2 XL, 32 sequences of 1,024 tokens	295 TFLOP	24 GB	287 GB stored; 85.6 GB with FlashAttention	With FlashAttention and two micro-batches of 16
ResNet-50, 32 images	787 GFLOP	0.4 GB	About 12 GB (FP32 scenario)	Yes; the binding term is the input feed
Llama 3 8B fine-tuning, 4 sequences of 2,048 tokens	395 TFLOP	128 GB (full)	36.5 GB	Only with adapters (53 GB)

Key Takeaways: Why training costs millions

- **Training cost is an iron-law budget**: $T_{\text{train}} = \frac{O}{R_{\text{peak}} \times \eta_{\text{hw}}}$ makes every optimization accountable: reduce work, raise effective throughput, or improve utilization. A change that misses the dominant term only moves cost around the training loop.
- **Memory determines whether a step fits**: Standard mixed-precision Adam holds 16 bytes per parameter, 8× the FP16 inference weights, before activations. Optimizer state and batch-dependent activations, not weights alone, determine whether training fits.
- **Profiles choose the remedy**: Profile, diagnose, fix, and re-profile. Compute-bound jobs need better arithmetic or algorithms; memory-bound jobs need less state or traffic; data- and communication-bound jobs need pipeline or parallelism changes.
- **Precision and IO-aware kernels shift bottlenecks**: FP16 with FP32 accumulation can improve throughput and shrink activation memory (the static state is unchanged), while FlashAttention avoids materializing the full $S \times S$ matrix in HBM; realized gains depend on workload and hardware.
- **Checkpointing trades recomputation for memory**: The segment schedule counts retained boundaries and one live reconstructed segment, reducing GPT-2 XL's batch-32 activations from 85.6 GB to 11.5 GB for about one-third more arithmetic. Use it when memory, not compute, binds.
- **Composed optimizations can postpone scale-out**: Mixed precision, FlashAttention, and gradient accumulation turn GPT-2 XL's 598 GB batch-32 step into a modeled 66.8 GB that fits one H100, for a run of about 35 days. Use relevant local levers before accepting distributed communication and operational overhead.

Training is where the iron law becomes a daily instrument. A profile read against the law names the dominant term, and the engineering task is to apply the least costly intervention that changes it before reaching for more hardware. The analysis took the model and training corpus as given, while changing how the system executed their work, including the extra arithmetic needed for recomputation. A further lever is which examples enter that workload in the first place.

What's Next: From training to data selection

Training produces learned parameters by spending compute on every example. Once the training loop is efficient, the next question is whether every example earns that cost. Repeated or low-information samples consume the same forward pass, backward pass, optimizer update, and communication as examples that add coverage or correct a weakness.

Chapter 9 therefore turns upstream from execution to workload composition, and in doing so opens the book's optimization sequence, which asks whether work is necessary before asking how to simplify or accelerate it. It starts from a supply imbalance. Accelerator fleets can grow usable compute faster than the stock of high-quality data, so extracting more learning from each example begins to matter more than collecting more examples. Its measure is the information-compute ratio, the learning an example returns per unit of training compute, and redundancy, representativeness, uncertainty, and class coverage all enter through it. A useful subset must reduce work without erasing rare cases or shifting the effective training distribution. When that balance holds, a carefully selected subset can approach full-dataset accuracy while lowering the cost of every epoch and making additional experiments affordable. The optimization target is no longer only how efficiently the system processes an example, but which examples the system should process at all.

III

OPTIMIZATION AND ACCELERATION

Part III

Optimization Principles

A working model is rarely an efficient one. Part II established how to construct ML systems that respect physical constraints; Part III addresses how to meet real-world demands on time, memory, and energy. Efficiency is also what keeps the bitter lesson affordable, because models grow with the computation available while budgets and deployment envelopes do not. Each optimization navigates a frontier, improving one metric (accuracy, latency, energy) while managing the cost to others, and each is a form of co-design. Data selection shapes the workload the algorithm sees, while compression and acceleration trade mathematical structure for physical feasibility. The principles here are the bounds and cost models of efficiency, which determine *why* some models are fast and affordable while others are slow and prohibitively expensive.

Principle 5: The Pareto frontier

Bound: After objective directions are normalized, a feasible point lies on the Pareto frontier exactly when no other point is at least as good on every objective and strictly better on one. No feasible design lies beyond that frontier, so moving along it improves one objective only by worsening another.

- **Quantization**: Trades numerical precision for reduced memory footprint.
- **Pruning**: Trades model capacity for smaller representations and can improve speed when the resulting sparsity or removed structures are supported by the target hardware.
- **Distillation**: Trades training compute for inference efficiency.

Implication: Systems engineers navigate this frontier to find the operating point appropriate to a specific deployment environment. There is no universal optimum.

Navigating the Pareto frontier requires knowing *which* resource to optimize. Before selecting a technique, engineers must diagnose whether the workload is limited by computation, memory movement, or dispatch latency. Arithmetic intensity supplies the first test. The introduction derived its threshold, the ridge point, by setting the iron law's memory term equal to its compute term, and Part II placed training kernels on either side of that threshold in a roofline plot. Here the roofline becomes an explicit rule for choosing an optimization.

Principle 6: Arithmetic intensity law

Bound: Attainable throughput (R_{attain}) is no greater than the minimum of peak compute (R_{peak}) and DRAM bandwidth (BW) times operational intensity at the cache–DRAM boundary (I) (Williams et al. 2009):

$$R_{\text{attain}} \leq \min(R_{\text{peak}}, I \times \text{BW})$$

Operational intensity and DRAM bandwidth must both be measured at the cache–DRAM boundary; this ideal bound excludes launch, synchronization, and other fixed overheads.

Implication: Adding peak compute does not raise the ideal roofline bound for a bandwidth-bound kernel. Engineers must identify whether the bottleneck is compute, bandwidth, or another system term before selecting an optimization.

Many important ML kernels fall on the memory-bound side of the ridge point, especially low-reuse operations such as embedding lookup, normalization, softmax, depthwise convolution, and small-batch inference paths. Dense matrix multiplications and convolutions can instead be compute-bound when batching and hardware utilization are high. This split is a consequence of the memory wall: processor speed has historically outpaced memory bandwidth, and the cumulative gap has widened over three decades (Wulf and McKee 1995; Gholami et al. 2024). Neural networks, with their large weight tensors and uneven temporal locality, are especially vulnerable, so table 8.19 maps each bottleneck regime to the optimizations that address its dominant term and the changes that leave it untouched.

Table 8.19: The Bottleneck Diagnostic: Before optimizing, identify which iron law term dominates. Optimizing the wrong term leaves the dominant bottleneck unchanged and usually yields little or no end-to-end improvement.

If the workload is…	Dominant Term	Optimization That Works	Optimization That is Wasted
Bandwidth-Bound	D_{vol}/BW	Quantization, pruning, batching	Faster accelerator (more FLOP/s)
Compute-Bound	$O/(R_{\text{peak}} \cdot \eta_{\text{hw}})$	Better kernels, Tensor Cores, faster accelerator	More memory bandwidth
Overhead-Bound	L_{lat}	Kernel fusion, async dispatch, bounded microbatching under the latency SLO	More FLOP/s or bandwidth alone

Wall-clock time is only one cost of crossing the memory wall; the energy required to move data off-chip exposes a second constraint. Even when a memory-bound kernel meets its latency target, fetching operands repeatedly from off-chip DRAM dominates the power budget on both battery-powered devices and data center racks.

Principle 7: The energy-movement principle

Decomposition: Total workload energy depends jointly on per-event energy and event counts. In the cited 45 nm reference, moving a 32-bit value from DRAM can cost roughly 100–1,000× more energy per event than a 32-bit floating-point operation, depending on operation type (Horowitz 2014). Here, D_{vol} is bytes moved and O is operations executed; E_{move} denotes the energy per byte moved from DRAM, so one 32-bit access costs $4\,E_{\text{move}}$, and E_{compute} denotes the energy of one 32-bit floating-point operation in the cited 45 nm technology.

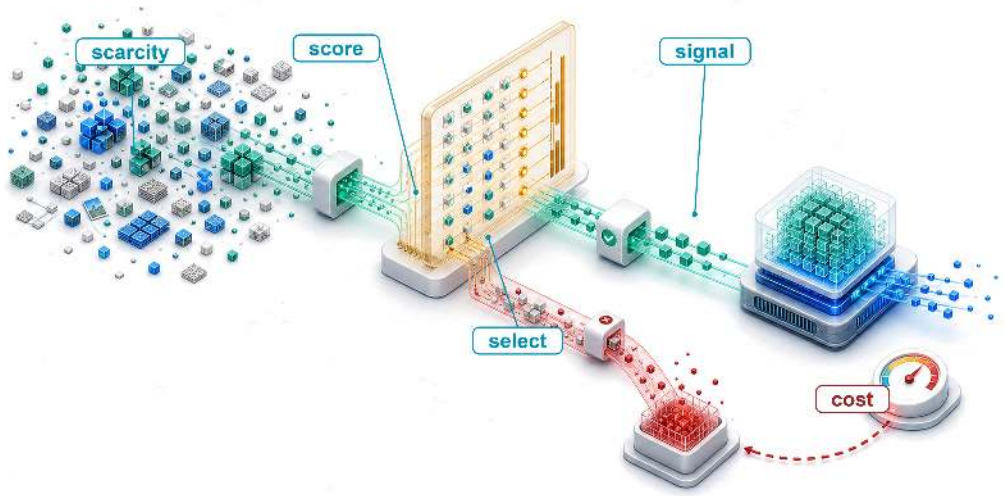
$$E_{\text{total}} \approx D_{\text{vol}} \times E_{\text{move}} + O \times E_{\text{compute}}, \qquad 4\,E_{\text{move}} \gg E_{\text{compute}} \quad \text{for the cited reference}$$

Implication: When memory movement dominates workload energy, optimization strategies should prioritize kernel fusion (avoiding intermediate off-chip traffic) and quantization (reducing data size); when computation dominates, reducing operation counts and improving arithmetic kernels remain central.

Even with perfect data locality and optimal bottleneck targeting, a final constraint limits how much speedup any optimization can deliver. The introduction stated Amdahl's law for an inference pipeline whose preprocessing and postprocessing capped the gain from a faster model, and later chapters applied it case by case, to data-ingestion workers and to communication overhead in training. Stated as a principle, it bounds every optimization in this part.

Principle 8: Amdahl's law

Bound: The maximum speedup of a system is limited by the fraction of the workload that cannot be accelerated (Amdahl 1967). Here, f_{parallel} is the fraction of baseline execution time accelerated and G is that fraction's speedup, either an accelerator's gain G_{accel} or a worker count N_{workers}; the fixed-work model assumes the remaining fraction is unchanged and the acceleration introduces no additional overhead.



$$\text{Speedup} = \frac{1}{(1 - f_{\text{parallel}}) + \frac{f_{\text{parallel}}}{G}}$$

Implication: If 95 percent of a model runs 100× faster on an accelerator, the total system speedup is only about 16.8×, and no accelerator, however fast, can push it past 20×. This explains *why* data loading and preprocessing often become the ultimate bottlenecks in highly optimized systems.

Part III applies these principles across the three multiplicative factors of the iron law in the order the D·A·M taxonomy suggests (Appendix A gives the full diagnostic framework). On the data axis, chapter 9 asks first whether fewer samples can achieve the target quality (Samples/Task). Where algorithm meets machine, chapter 10 asks whether each sample's pass can use fewer operations or fewer bits per value (FLOPs/Sample and D_{vol}). On the machine axis, chapter 11 asks how to execute each remaining operation in less time (Seconds/FLOP). Each chapter ends with a favorable local number (a smaller dataset, a smaller model, or a kernel placed under its roofline), and chapter 12 closes the loop by testing whether those predicted savings survive end-to-end execution without violating quality constraints.

Purpose

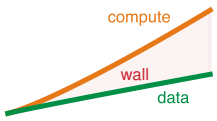
How can a carefully selected subset retain most of the value of a much larger dataset?

Training pays to acquire, label, score, move, and process examples even though their learning value differs. Large datasets contain redundant, noisy, or target-misaligned samples, while scarce regions may lack the cases a model needs, such as the rare conditions under which a deployed system is most likely to fail. Training on every example treats a near-duplicate and a rare failure case as equally worth paying for, and at scale much of the compute budget can go to relearning what the model already knows. That heterogeneity turns the choice of examples into a systems optimization rather than a data-cleaning chore. The objective is therefore not the smallest dataset but the lowest end-to-end cost of reaching target quality without losing rare cases, underrepresented groups, or deployment-relevant coverage. Every strategy adds its own overhead: examples must be scored, generated, shuffled, stored, or validated, and those costs can erase the savings they promise. That judgment must be made end to end, because gains in labeling or training can be erased by selection latency, storage access, or distributed coordination. A method is worth applying only when the learning it preserves or creates exceeds the work required to apply it. This distinction matters across repeated experiments, where useful reductions compound, across adaptation, where the value of an example changes with the model and target distribution. In D·A·M terms, it is data-algorithm co-design: shape the training signal so each unit of machine work yields more useful learning.

Learning Objectives

- Explain data selection as data-algorithm co-design that controls sample value, training work, and labeling cost
- Calculate the information-compute ratio and apply the compute-optimal tokens-per-parameter check to diagnose a data-starved run
- Apply the selection inequality to test whether selection overhead beats full-dataset training cost
- Compare deduplication, coreset selection, and quality pruning for reducing redundant pretraining data
- Design curriculum, active learning, synthetic-data, or label-free strategies for changing data value during training
- Evaluate whether a selection pipeline keeps the accelerator fed under storage locality, data echoing, and multi-accelerator consistency constraints
- Select data-selection investments using return on investment, break-even, and amortization analysis

9.1 The Data Wall



Every example a training run processes costs the same forward pass, backward pass, and optimizer update, whether it teaches the model something new or repeats what the model already knows. A duplicated image, a mislabeled record, and a rare boundary case cost the same arithmetic while contributing very different learning signals. This waste becomes acute at the **data wall**, the point at which the compute available for training grows faster than the supply of novel, high-quality examples to spend it on.[1] Chapter 8 made each of those steps as cheap as one machine allows and accounted for a whole run as roughly $6PD$ floating-point operations for P parameters and D tokens. Once each step is cheap, the next saving lies upstream, in choosing which examples deserve a step at all. For the full GPT-2 XL run that chapter 8 costed on one H100, the question becomes how many of those steps were worth taking.

Increasing the amount of training data has long been a standard way to improve models. Scaling laws[2] (Kaplan et al. 2020; Hoffmann et al. 2022) quantify how model performance can improve with dataset size, and teams have responded by collecting and generating more examples. Accelerator fleets, however, can expand usable compute faster than the supply of novel, high-quality human-generated text and images. Much of the easily accessible public web has already been incorporated into large training corpora, and expert labeling capacity grows slowly; chapter 4 measured the growth of training corpora, and figure 4.6 sets the largest of them against the estimated stock of public text, between 10^{14} and 10^{15} tokens, which they reach late this decade at the fitted rate. That is the wall at frontier scale, on fleets far larger than one machine, and it shifts engineering effort from collecting everything available to extracting more learning signal from each stored and processed sample.

GPT-2 XL shows the same wall on one machine. The arithmetic needs only the corpus size, the token budget of the original run, and the fitted compute-optimal balance between parameters and tokens.

WebText, GPT-2's training corpus (Radford et al. 2019), holds 40 GB of text, about 10 billion tokens at roughly 4 bytes per token. The compute-optimal balance fitted by the Chinchilla study, about 20 training tokens per parameter (developed in section 9.2.3), asks for 30 billion unique tokens for GPT-2's 1.5 billion parameters, 3× what WebText holds. The original run spent about 1.5×10^{21} FLOPs, which at six FLOPs per parameter per token processed about 167 billion tokens, so the model saw its corpus roughly 17 times. One machine with 8 H100 accelerators running at 50 percent model FLOPs utilization (MFU), the fraction of peak arithmetic a training run actually delivers (definition 8.3), completes that budget in about 4.4 days and 590 kWh of accelerator energy. Less than a week of one machine's compute therefore passes over the whole corpus many times. An engineering team in that position can repeat epochs over the same text, where gradient updates on familiar tokens yield diminishing loss reductions, or it can lower quality thresholds to admit uncurated web text, where

[1] **Data wall**: Unlike compute (which scales with capital expenditure) or algorithms (which improve through research), the stock of high-quality human-generated text grows slowly; Epoch AI's updated projections estimated that, under the paper's modeled consumption assumptions, models could use datasets roughly equal in size to the stock of public human-generated text between 2026 and 2032 (Villalobos et al. 2024). The point for systems design is not a fixed calendar deadline; it is that data can become a supply constraint rather than merely an economic one. The wall does not change how many operations (O) a run performs. It lowers the learning each of those operations yields, because

Compute outruns high-quality data supply; the widening gap is the data wall.

[2] **Scaling laws**: Jared Kaplan and colleagues at Johns Hopkins and OpenAI empirically demonstrated in 2020 that language model loss follows power-law relationships with model size, dataset size, and compute budget over the regimes they studied (Kaplan et al. 2020). Their fitted data exponent was approximately $\alpha = 0.095$ in $\mathcal{L} \propto D^{-\beta}$. The value is not universal, but the diminishing-return shape makes it possible to reason about when selection becomes more cost-effective than collection.

↩ GPT-2, the bandwidth-bound lighthouse for decoder-only language models, is established in section 6.7.4.2.

noisy and misaligned tokens degrade downstream evaluation. Instead of accepting either penalty, the team can invest in data selection (refining quality filters, constructing difficulty curricula, and synthesizing missing edge cases) to raise the learning return per FLOP.

When *compute* is abundant and *quality data* is scarce, the optimization priority inverts. Selection, not faster kernels, then extracts more learning per dollar, and for teams whose accelerator budget exceeds their curated corpus, the bottleneck shifts from accelerator access to the quality, legality, and diversity of the training data.

The bitter lesson applies here in data terms. A filter written from human intuition about which examples matter is the hand-built expertise the lesson warns against, whereas selection that uses the model's own signals, such as loss, gradient norms, or embedding similarity, scales with compute. Either way, improved rankings must be established against downstream quality and coverage.

Data engineering makes data correct; data selection asks which correct examples are worth training on. When selection removes processing at matched quality, it shrinks the Data factor (Samples/Task) and therefore the total operations (O) term in the iron law (principle 3). Selection therefore needs sample value stated relative to compute cost, and the information-compute ratio of section 9.2.1 measures that value as learning signal gained per unit of training compute.

↩ The bitter lesson, that general methods using more computation outperform encoded human expertise, is established in section 1.4.

Definition 9.1: Data selection

Data selection is the process of retaining, prioritizing, or generating training examples to minimize the end-to-end cost of reaching target quality while preserving required coverage.

1. **Significance**: Each excluded example removes a forward pass, a backward pass, and an optimizer update, so selection reduces Samples/Task and therefore total operations (O) directly.
2. **Distinction**: A dataset can pass every data engineering check and still contain many examples that teach the model nothing new; selection judges informativeness and diversity, not correctness.
3. **Common pitfall**: Minimizing dataset size instead of end-to-end cost. Scoring, labeling, and lost coverage can erase the savings of a smaller set.

Holding epoch count, batch size, and per-sample work fixed, a 50 percent reduction in dataset size directly halves the required forward passes, backward passes, and gradient updates. For the GPT-2 run above, it would halve both the 4.4 days on one eight-H100 machine and the 590 kWh of accelerator energy, provided the training schedule does not compensate by adding optimization steps. When data selection is combined with model compression and hardware acceleration, those reductions compound across all three axes of the iron law.

Systems Perspective 9.1: Data selection and the iron law

In the multiplicative D·A·M form of the iron law of ML systems (equation 1.2, where $T = (\text{Samples/Task}) \times (\text{FLOPs/Sample}) \times (\text{Seconds/FLOP})$), data selection reduces the first factor (Samples/Task), model-level optimizations reduce the second (FLOPs/Sample), and machine-level optimizations reduce the third (Seconds/FLOP, by increasing $R_{\text{peak}} \cdot \eta_{\text{hw}}$ and cutting memory and latency stalls). Selection removes work before those downstream optimizations execute it.

Because the three D·A·M factors multiply, their speedups compound. A 2× reduction in dataset size with 2× fewer operations per sample and 2× higher effective machine throughput yields an 8× reduction in run time because each axis divides the work or time the next axis sees. Unpacking the machine factor into the three physical terms of equation 1.3 ($T = \frac{D_{\text{vol}}}{\text{BW}} + \frac{O}{R_{\text{peak}} \cdot \eta_{\text{hw}}} + L_{\text{lat}}$) states the condition for realizing that full product: while halving the number of training steps cuts all three terms in half, the algorithmic and hardware speedups achieve their

full multiplier only when the dominant physical bottleneck, whether compute, data movement (D_{vol}/BW), or fixed overhead (L_{lat}), falls in step.

These compute savings propagate throughout the hardware hierarchy. By decreasing total data volume (D_{vol}), deduplication and coreset selection alleviate storage bandwidth demands, network fabric ingress, and host-to-accelerator PCIe transfers that otherwise leave the accelerator's arithmetic units waiting on input. Upstream, active learning curbs annotation budgets by directing human labeling to samples chosen for uncertainty, diversity, or other task-relevant query criteria.

Yet selection is not free. Every selection strategy incurs its own runtime overhead to score, filter, shuffle, or coordinate samples. An online selection algorithm that executes additional forward passes to rank sample difficulty can consume more accelerator cycles than it saves if its selection overhead exceeds the subsequent reduction in training time. A pipeline claiming a training-time saving must make filtering plus subset training faster than full-data training at the same target quality, the selection inequality of section 9.2.6. Labeling savings and reusable representations require the broader cost accounting of section 9.8.

A learning-theory view of this problem counts the samples needed to reach a test error and treats each sample as free. The systems view counts the FLOPs, bytes, labels, seconds, and joules needed to reach the same quality, including the cost of choosing the samples. In the D·A·M taxonomy, data selection works on the data axis, deciding whether an example warrants processing at all before the algorithm fixes the operations each example costs and the machine fixes how fast those operations run. Removing an example therefore lightens both adjacent boundaries, the storage and input traffic between data and machine and the learning return between data and algorithm.

↩ The D·A·M taxonomy and its three diagnostic axes are established in section 1.5.

The engineering toolkit for intelligent data selection follows a deliberate optimization ordering, first asking whether a sample is worth processing and only then how to process the remaining workload efficiently. Static pruning acts first by fixing the retained subset before target-model training begins, even when its scoring step uses a smaller proxy model. Because a sample's usefulness changes as the model learns, dynamic selection then adapts which examples the training loop sees and which receive human labels during training through curriculum learning and active learning. Where real data still falls short after pruning and reordering, synthetic generation creates missing high-value samples on demand through augmentation, simulation, or examples labeled by a larger trained model (a *teacher*). Learning from unlabeled data complements these three levers by redefining what constitutes a supervision signal: rather than selecting among labeled examples, semi-supervised and self-supervised methods derive learning targets from the structure of unannotated data, and which levers to use, in what order, depends on the workload (figure 9.1).

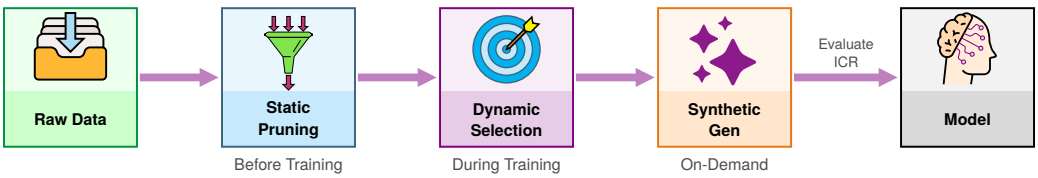


Figure 9.1: An Example Data Selection Pipeline: One possible combination of interventions for increasing data value. The three intervention points are Static Pruning before target training, Dynamic Selection during training, and Synthetic Generation on demand. The sequence is illustrative rather than required: synthetic data can enter independently and can itself be pruned or dynamically selected. The final evaluation determines whether the quality gain justifies the compute cost through the Information-Compute Ratio (ICR).

Two lighthouses carry the chapter, each in its own role. GPT-2 XL, bandwidth-bound when it decodes one token at a time but compute-bound when it trains on long batches (chapter 8), carries the wall itself, the compute-optimal diagnosis of whether a run is data-starved, and token-level deduplication. ResNet-50 on ImageNet, the book's compute-bound lighthouse, carries coresets, labels, augmentation, the input pipeline that must feed it, and the decision of which lever to fund. Its training crosses into an input-bound regime whenever the host cannot decode images as fast as the accelerator consumes them (section 8.4.1), and that crossing returns when selection runs on the machine. The measures of value in the next section use both, and both run on the book's

reference machine, the H100, so every saving can be stated in accelerator seconds and joules. The recommendation lighthouse (DLRM), MobileNetV2, and keyword spotting return only in the closing comparison of section 9.8, where each turns out to be bound by a different resource.

Every lever in the chapter removes work at one stage of the machine and adds work of its own, so each must pass a test before it is accepted (table 9.1). Each test in the right-hand column depends on measuring what an example is worth, which is the subject of the next section.

Table 9.1: Chapter Map: Each section of the chapter, the work its lever removes and adds on the machine, and the test the lever must pass before it is accepted.

Section	Lever and when it acts	Work it removes	Work it adds	Test it must pass
Measuring Data Value	Yardsticks for every lever	None	Pilot runs at several data sizes	Defines the tests below
Static Pruning	Deduplication, quality filtering, coreset; before training	Tokens and examples processed in every epoch	Hashing and proxy scoring passes	Selection inequality at matched quality and coverage
Dynamic Selection	Curriculum learning, active learning; during training	Warmup FLOPs; labels	Difficulty scoring, pool scoring rounds, retraining	Time to target quality; label cost against a random baseline
Synthetic Data Generation	Augmentation, generative synthesis, distillation; on demand	Collection and labeling of scarce cases	Host transforms, generator inference, stored teacher targets	Validation on real deployment data
Learning from Unlabeled Data	Semi-supervised and self-supervised learning	Task-specific labels	Extra training compute; pretraining	Total label and compute cost; reuse across tasks
Selection Engineering	Running any lever on the machine	Accelerator idle time	Scoring latency, random reads, worker coordination	The accelerator stays fed and the inequality holds end to end
Choosing a Selection Strategy	Costing the levers and picking among them	Investment in levers that do not pay	Engineering and infrastructure investment	Return on investment over the runs that share it

9.2 Measuring Data Value

A ResNet-50 trained on an aggressively filtered ImageNet subset can hold its aggregate accuracy while failing on rare classes that the filter discarded as low-density noise, and a GPT-2 run on a filtered corpus can cost less per epoch while needing more epochs to reach the same loss. A measurement framework is therefore needed to show what a reduction actually saves. Every data selection technique claims to improve efficiency, but only measurement separates genuine training savings from work that has merely moved to another pipeline stage, or from degradation on safety-critical tail distributions. The measures build from the information-compute ratio through a diagnostic of whether a run is data-limited, metrics that tie sample reduction to accuracy, and checks that a reduced set still covers the cases deployment needs, to the selection inequality that every training-time claim must satisfy.

9.2.1 The information-compute ratio

Retaining every example in a training corpus preserves coverage at the cost of spending FLOPs on redundant signal, whereas over-aggressive pruning saves compute at the expense of rare-slice recall. Data selection therefore moves along a Pareto frontier (principle 5) between accuracy and cost, the set of operating points that no alternative beats on one objective without losing on the other. Weighing that trade-off requires measuring how much learning signal each sample yields per unit of hardware work. Data engineering already measured task-relevant signal against one cost, the data gravity of moving bytes, in the data selection gain of equation 4.3. Selection needs the same ratio with training compute in the denominator, because a sample that is cheap to move can still cost a full forward and backward pass. That ratio is the **information-compute ratio** (ICR).

↪ Locating a model's operating point on the accuracy-efficiency frontier, and moving along it with compression, is developed in section 10.5.1.

Let $\Delta\mathcal{I}$ be the learning signal a sample or batch adds and ΔO the training operations spent processing it. In practice $\Delta\mathcal{I}$ is measured as the gain in a fixed evaluation metric, such as percentage points of validation accuracy, so ICR carries units of metric gain per FLOP. The ratio relates the two:

$$\text{ICR} = \frac{\Delta\mathcal{I}}{\Delta O}$$

A higher ICR indicates that each FLOP of training yields more measured learning signal over the stated interval. Validation gain and training FLOPs can be observed for a specified experiment with a fixed evaluation protocol; the causal contribution of an individual example generally cannot. Uncertainty and gradient-based scores instead rank candidate examples before their downstream benefit is known. Those rankings require validation against measured quality, compute cost, and deployment-critical slice coverage. The core metrics in section 9.2.4 supply complementary evidence for that evaluation rather than interchangeable measurements of per-example information, and they also track how ICR decays as the dataset grows.

9.2.2 Diminishing returns and the ICR frontier

As a training run adds more examples from the same source, a growing share of those examples repeat patterns the model has already seen, and the information-compute ratio falls. The **ICR frontier** is the dataset size beyond which the marginal ICR, the learning returned by the next FLOP spent on more data, drops below what that FLOP could return elsewhere: a larger model, a different data source, or an earlier stop.

To illustrate diminishing returns, let $\mathcal{I}(D)$ be the information content of a dataset of size D and assume $\mathcal{I}(D) \propto \log D$. This is a simplified analytical model rather than a universal law. If compute cost scales linearly with the per-sample operation count O_{sample}, then total operations are $O = O_{\text{sample}} \cdot D$, and the resulting marginal ICR follows equation 9.1:

$$\text{ICR}(D) = \frac{d\mathcal{I}/dD}{dO/dD} \approx \frac{1/D}{O_{\text{sample}}} = \frac{1}{O_{\text{sample}} \cdot D} \tag{9.1}$$

The derivative ratio describes the return on an infinitesimal increase in dataset size. For two controlled finite allocations, the corresponding incremental ratio divides the additional evaluation gain by the additional training FLOPs, using the same evaluation metric and protocol. The coreset comparison that follows instead averages gain over one epoch of each dataset; that average does not establish the return on the next increment.

Under this illustrative model, marginal ICR falls as $1/(O_{\text{sample}} \cdot D)$, so doubling the dataset halves the learning each additional FLOP yields. Inverted, the compute spent per unit of learning grows linearly with D. ICR never reaches zero in this model and the curve has no knee of its own, so the frontier is located by comparing marginal ICR with the threshold the engineer sets, not read off the curve. That saturation is distinct from the data wall (a limit on how much new, high-quality data exists), but the two compound. When new data is scarce *and* marginal data is weak, selection becomes the main lever. Beyond the frontier, additional data still adds compute but returns less learning than the threshold demands. In this regime additional data inflates the O term of the iron law without a commensurate gain in ICR. Measured in dollars rather than FLOPs, the same excess lowers the return on compute (RoC) of equation 1.6, the accuracy gained per added dollar of infrastructure.

Data selection turns the total operations (O) term in the iron law from a fixed constant into a variable. A 2× improvement in measured ICR halves the FLOPs required to reach the same measured gain. It produces the same ideal time reduction as a 2× throughput increase only when the workload is compute-bound and the saved work lies on the critical path. ICR focuses specifically on compute; the cost model of section 9.8.1 extends the same reasoning to acquisition, labeling, and storage costs.

↩ Return on compute, the economic lens that measures accuracy gains against infrastructure spending, is established in section 1.8.1.

The ratio becomes concrete on a *coreset*, a deliberately selected subset intended to preserve the full dataset's learning signal. Computing ICR for an ImageNet coreset used to train the ResNet-50 lighthouse shows how large the efficiency gap could become once dataset size, per-sample model cost, and selection strategy meet concrete FLOP budgets. The scenario uses assumed accuracy gains to illustrate the arithmetic; it is not a reported result for the scoring method (EL2N) that section 9.3.4 develops.

Napkin Math 9.1: Computing ICR: Coresets

Problem: Training the ResNet-50 lighthouse model on ImageNet for one epoch costs 3.2×10^{16} FLOPs. Under the scenario's assumed accuracy gains, how would retaining 50 percent of the data change the information-compute ratio? The calculation holds the per-sample work fixed and does not include selection overhead.

Setup:

- Dataset: ImageNet (1.28M)
- Model: ResNet-50 lighthouse (~8.2 GFLOP per forward pass, roughly 24.6 GFLOP for a forward plus backward training step, depending on implementation)
- One epoch: 1.28M $\times$ 24.6 GFLOP = 3.2×10^{16} FLOPs
- Assumed accuracy improvement per epoch (early training): 5 percentage points

Random selection (baseline):

- Process all 1.28M samples uniformly
- Accuracy gain: 5 percentage points
- $\text{ICR}_{\text{random}}$ = 5 percentage points / (3.2×10^{16} FLOPs) = 1.6×10^{-16} per FLOP

Difficulty-scored coreset (EL2N, a training-dynamics score defined in section 9.3.4; 50 percent of data):

- Process 640.6K selected samples
- Assumed accuracy gain: 4.5 percentage points (90 percent of the full-data gain)
- Compute: 640.6K $\times$ 24.6 GFLOP = 1.6×10^{16} FLOPs
- $\text{ICR}_{\text{coreset}}$ = 4.5 percentage points / (1.6×10^{16} FLOPs) = 2.9×10^{-16} per FLOP

Systems insight: Under these assumptions, the selected subset achieves 1.8× higher ICR with a 0.5 percentage points smaller accuracy gain. The comparison is learning per FLOP over one epoch of each dataset. It does not show that the coreset reaches the full-data run's final accuracy, which must be checked separately at equal quality, and a real decision also requires measured gains, selection overhead, and coverage checks.

Checkpoint 9.1: Data selection efficiency

The goal is to improve ICR subject to target quality and required coverage, then verify that the resulting pipeline reduces the cost it is intended to address.

Metric checks

- ☐ **ICR application**: Given two training runs with identical accuracy gains but different compute budgets, determine which achieved higher ICR.
- ☐ **Data efficiency**: The coreset notebook reports 1.8× higher ICR but a smaller per-epoch gain. Explain what would have to change for a 50 percent subset to match the full-data gain, which would give it 2× higher ICR and so deliver the same measured gain for half the training FLOPs.

Pipeline checks

- ☐ **The three stages**: Map static pruning, dynamic selection, and synthetic generation to the training lifecycle.

A reduction in sample count remains a claim until it is shown to translate into end-to-end efficiency without silently compromising generalization. Notebook 9.1 holds per-sample work fixed and assumes its accuracy gains. Testing the claim on a real workload first requires knowing whether

the run is limited by data at all, and then measured metrics that weigh arithmetic savings, data movement overhead, and task quality across the complete pipeline.

9.2.3 The compute-optimal frontier

Pruning a dataset when the model is already starved for unique tokens hurts accuracy rather than saving time, whereas collecting more data for an under-trained model wastes money on collection. Before evaluating any selection technique, a team must therefore test whether the training run is limited by data or by compute. Neural scaling-law experiments (Kaplan et al. 2020; Hoffmann et al. 2022) fit power-law relationships over particular model families, datasets, and compute ranges. Controlled sweeps can use those fitted relationships to compare model and data allocations, though no single ratio diagnoses every training run.

The Chinchilla study[3] (Hoffmann et al. 2022) fit a compute-optimal balance between model size and training data within its experimental regime. Allocations on either side of that fitted balance used the study's compute budget less effectively. The optimal balance defines a **compute-optimal frontier**: the best achievable performance at each compute budget when data and model size are properly balanced. Plotted over normalized training compute, the frontier separates the optimal operating envelope from the compute-starved and data-starved allocations in the suboptimal region below it (figure 9.2).

[3] **Chinchilla**: Chinchilla is a 70-billion-parameter language model trained on 1.4 trillion tokens. In the experiments reported by Hoffmann et al. (2022), it outperformed the larger GPT-3 on most evaluated tasks under a similar training-compute budget. The fitted compute-optimal allocation scaled parameters and tokens at roughly equal rates within the study's experimental regime; it is not a universal prescription for every architecture, dataset, or training recipe.

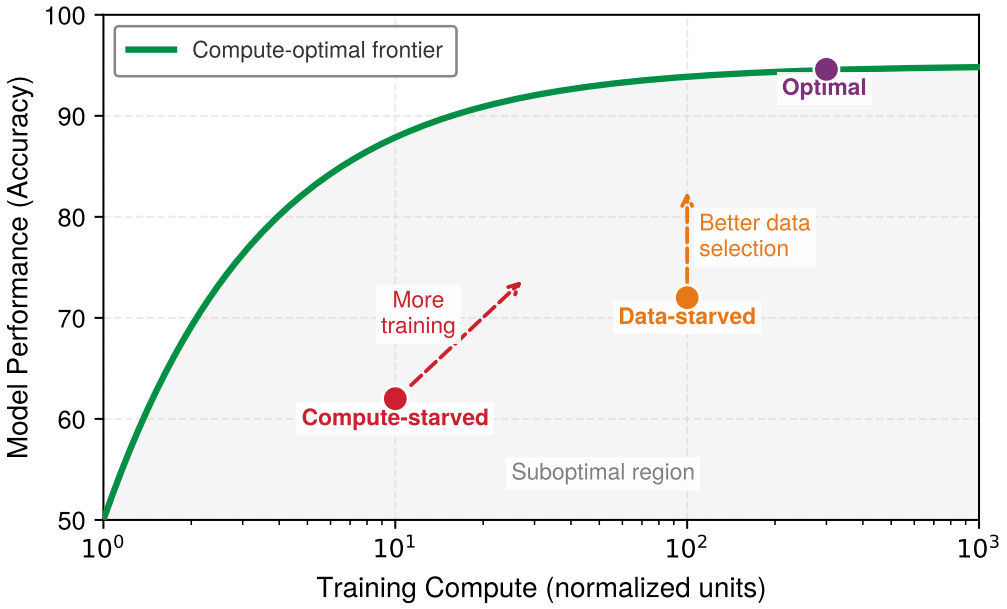

Figure 9.2: Illustrative Compute-Optimal Frontier: The green curve is a conceptual frontier over normalized compute, not a fitted result from Chinchilla. Points below it illustrate allocations that a controlled model-size and token-count sweep might identify as data- or compute-limited.

The frontier answers one allocation question, whether the next unit of compute at a given budget should go to more parameters or to more training tokens. A run is *data-starved* when it trains on too few unique, useful tokens for its parameter count, so its tokens-per-parameter ratio sits well under the fitted balance, and the same compute would yield more accuracy with more or better data. Against a frontier fitted from controlled sweeps, an operating point's location motivates further experiments. The directional vectors charted in figure 9.2 illustrate two candidate interventions: additional training compute and improved data selection at fixed compute. Controlled changes to model size, data, and training allocation determine which intervention helps; a point below the frontier does not identify a unique remedy. Points near a fitted frontier remain specific to the model family, dataset, objective, and compute range used to estimate it.

Interpreting the Chinchilla result

Within the fitted Chinchilla regime, compute-optimal model parameters and training tokens grew at roughly equal rates.[4] Training a dense transformer costs approximately $6PD$ FLOPs for P parameters and D tokens, the forward-plus-backward accounting derived for the GPT-2 lighthouse in section 8.1.1. Under an equal scaling regime where parameters and tokens grow proportionally ($P \propto D$), total compute scales quadratically ($O \propto D^2$), directly implying that optimal token count scales as the square root of the compute budget ($D_{\text{opt}} \propto \sqrt{O}$). Doubling compute therefore corresponds to about $\sqrt{2}-1$, or 41.4 percent, more tokens under those assumptions. The commonly quoted 20 tokens per parameter is a useful reference point from that study, not a universal optimum.

GPT-2 sits well short of that reference. WebText supplies about 6.7 unique tokens per parameter, a third of the fitted balance, and the original run made up the difference by repeating those tokens about 17 times (section 9.1). Repetition keeps the arithmetic budget but not the learning per FLOP, which is the regime where selection, rather than more compute, moves the run toward the frontier.

[4] **Tokens per parameter**: The ratio D/P compares training tokens with model parameters; GPT-3 used approximately 1.7 tokens per parameter (Brown et al. 2020), while Llama 2 70B used approximately 28.6 (Touvron, Martin, et al. 2023). These descriptive ratios do not establish whether either run is compute-optimal under a different architecture, corpus, objective, or hardware budget. Controlled model-size and token-count sweeps are required for that diagnosis.

Applying the diagnostic

If a training run underperforms expectations, extending one run can reveal whether additional optimization steps still help, but a plateau does not identify data starvation by itself. Learning-rate schedules, optimization limits, model capacity, and data quality can all produce a plateau. A reliable diagnosis compares controlled runs that vary model size, token count, and compute allocation while holding the evaluation protocol fixed. When controlled runs do point to the data, the remedy that keeps compute fixed is better selection, which changes the shape of the learning curve itself. Seeing that change requires switching axes, from the frontier's training compute to dataset size, where the core metrics measure what a reduction preserves.

9.2.4 Core metrics

Reporting accuracy at a single subset size hides whether a selection method learned faster early on, plateaued lower, or never reached the full dataset's target quality. Three metrics track those distinct behaviors across the learning curve and complement the measured information-compute ratio (section 9.2.1). Performance-per-data (PPD) measures average accuracy gain per sample, which becomes gain per FLOP once per-sample cost is fixed; the area under the learning curve (AULC) summarizes performance across a common dataset-size range; and the data compression ratio (DCR) measures retained sample reduction at a fixed target accuracy. None of the three establishes the causal value of an individual example.

Performance-per-data

The most direct metric, **performance-per-data (PPD)**, measures accuracy gain per sample:

$$\text{PPD}(n) = \frac{\text{Accuracy}(n) - \text{Accuracy}(0)}{n}$$

where n is the number of training samples. A higher PPD indicates greater average improvement per sample over the stated interval. Its shape must be measured because diminishing returns and their onset are workload-dependent.

Area under the learning curve

Rather than comparing at a single point, the **area under the learning curve** (AULC) integrates performance across all dataset sizes:

$$\text{AULC} = \int_0^D \text{Accuracy}(n)\, dn$$

where n is the dataset size and D is the total dataset size.

For the same metric and integration range, a higher AULC means stronger integrated performance across dataset sizes, though one strategy need not outperform the other at every size. Comparisons must use the same upper limit D or normalize the integral. Measuring AULC requires training at

several dataset sizes, so the metric itself spends compute, and when it guides a selection decision that cost belongs to the selection overhead.

In the illustrative curves of figure 9.3, efficient selection bends into an accuracy plateau near 25 percent of the data while uniform random sampling climbs gradually across the entire budget, so over the same range the efficient curve encloses the larger area. The horizontal separation between the curves is the reduction in required samples, and at an identical 20 percent data budget the vertical gap is the accuracy that selection adds without any additional compute.

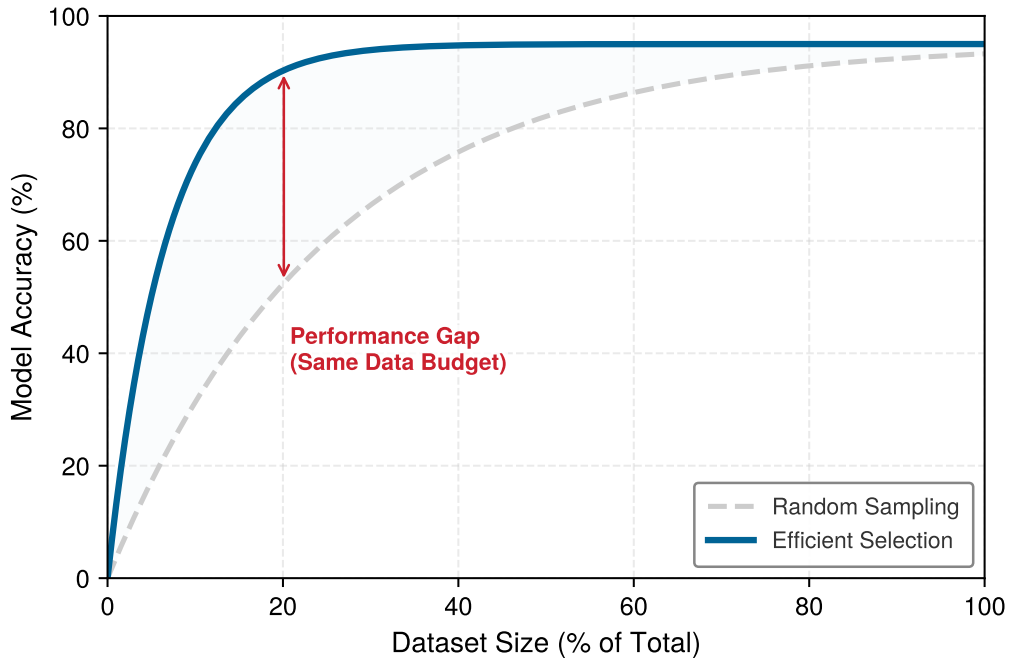

Figure 9.3: Illustrative Diminishing Returns of Data: The synthetic data-efficient curve (blue) reaches the same plateau with fewer samples than random sampling (gray). The vertical red arrow marks the modeled performance gap at a fixed dataset size; measured curves need not have this shape.

Data compression ratio

For coreset methods, the **data compression ratio** (DCR) measures how much data reduction is achieved at a target accuracy:

$$\text{DCR} = \frac{D_{\text{total}}}{D_{\text{subset}}} \text{ at Accuracy}_{\text{target}}$$

A DCR of 5× means the coreset achieves target accuracy with 20 percent of the data. Applied to the coreset notebook, the three metrics behave differently. Over one epoch, the full ImageNet set gains 5 percentage points while the half-size coreset gains 4.5 percentage points, so the coreset's PPD is higher by the same 1.8× as its ICR, because per-sample work is fixed. DCR cannot be computed from that notebook at all, because the two runs never reach a common target accuracy. Exposing that missing equal-quality check is exactly the job DCR is designed for, and even when a reduced dataset matches the full dataset's aggregate accuracy, those learning-curve metrics cannot show whether the retained subset still covers every slice deployment needs.

9.2.5 Validating a reduced dataset

When the half-size ImageNet coreset drops 640,000 images, it can hold top-1 test accuracy while quietly stripping out a rare class, shifting the training distribution away from production traffic, or

concentrating mislabeled examples in the retained subset. Validating a curated dataset therefore requires checking coverage, distribution alignment, and label quality alongside aggregate accuracy. Coverage metrics check whether coreset selection kept enough examples from each class and demographic group. Even when class counts hold, the retained subset can skew toward atypical examples, so distribution alignment metrics (such as KL divergence and the population stability index, the drift statistics of section 4.12.1) test whether the curated training set has drifted from the deployment distribution. Where selection also guides annotation, label quality metrics (inter-annotator agreement and confident learning, which flags examples whose given label disagrees with a model's confident out-of-sample prediction) verify that active learning did not introduce systematic labeling errors. A 50 percent dataset reduction is worth keeping only when all three checks pass alongside target accuracy, calibration, and robustness.

The validation target can itself be unreliable. Benchmark accuracy can overstate generalization when test sets fail to capture operational distribution shifts, demanding the same scrutiny for evaluation benchmarks as for curated training sets.

↪ Coverage, label-quality, and distribution-alignment checks are developed into a full data-benchmarking protocol in section 12.9.2.

Example 9.1: The benchmark replication gap

Scenario: Classifiers evaluated on newly collected test sets experienced 3 to 15 percentage-point accuracy drops on CIFAR-10 and 11 to 14 points on ImageNet (Recht et al. 2019).

Diagnosis: The replicated collection produced slightly harder images than the original test sets. The study found that benchmark adaptivity did not explain the gap, even though repeated use of a fixed test set remains a general evaluation risk.

Systems lesson: Evaluation-set construction affects measured generalization. Data-selection pipelines should validate curated subsets on independently collected and deployment-relevant test sets rather than trusting one long-reused benchmark.

An efficiency gain measured against a single benchmark can evaporate under distribution shift, so a curated subset must demonstrate consistent quality across multiple held-out distributions before its reported reduction ratio is trusted. Even when quality holds across those distributions, the time spent selecting the subset must still be weighed against the training time it saves.

9.2.6 The selection inequality

The efficiency measures so far count learning against training compute alone, yet a selection method also spends time choosing, and a claim that it shortens training must count that time. To reduce overall training time at a fixed quality target, selection plus subset training must take less time than training on the full corpus. Let $T_{\text{selection}}$ be total wall-clock selection overhead, including candidate scoring and any prerequisite scorer preparation charged to the training run. Let $T_{\text{train}}(D)$ be wall-clock training time for a dataset of size D, and let D_{subset} and D_{total} be the retained and full sample counts. Equation 9.2 formalizes this break-even condition as the **selection inequality**:

$$T_{\text{selection}} + T_{\text{train}}(D_{\text{subset}}) < T_{\text{train}}(D_{\text{total}}) \tag{9.2}$$

Equivalently, isolating the allowable selection overhead yields $T_{\text{selection}} < T_{\text{train}}(D_{\text{total}}) - T_{\text{train}}(D_{\text{subset}})$. The upper bound on selection latency depends strictly on how much training execution the subset eliminates; no arbitrary overhead fraction applies across workloads. When an engineering pipeline can amortize scorer preparation or checkpoint extraction across multiple downstream training runs (section 9.8.3), $T_{\text{selection}}$ reflects only the marginal scoring pass over the candidate pool. Conversely, if an auxiliary proxy must be trained from scratch for a single isolated run, that preparatory compute adds directly to $T_{\text{selection}}$. When $f(x)$ repeatedly scores the candidate pool with the full target model, those extra scoring passes and their cross-worker coordination can take longer than the training steps they remove, making the run slower overall.

Example 9.2: Selection inequality in practice

Scenario: A computer vision team selects a 128,117-image coreset (10 percent) from the 1.28 million ImageNet training images to shorten ResNet-50 training on one H100 sustaining 25 percent of its peak, the training chapter's compute-bound rate. Pretrained checkpoints for both the target architecture and a lightweight proxy are already available from earlier exploration, so this comparison accounts only for a marginal scoring pass over the candidate pool.

Diagnosis: Against a 211-minute full-data run of 100 epochs, marginal full-model scoring (Option A: target ResNet-50) adds 42 seconds of selection overhead and still saves 188.8 minutes (89.7 percent). Marginal proxy-model scoring (Option B: ResNet-18) drops selection overhead to 18 seconds and saves 189.1 minutes (89.9 percent), only 24 seconds more.

Systems lesson: Both options satisfy the selection inequality by a wide margin, because a single scoring pass costs at most one forward pass over the dataset (one-third of a full-data epoch for the target ResNet-50) and less with the proxy, while training on the 10 percent coreset shrinks every one of the 100 epochs. Scorer choice also becomes decisive when selection rescores dynamically every epoch or when the scoring architecture is significantly larger than the target, multiplying selection latency while subset training savings remain fixed.

End-to-end wall-clock time divides into selection overhead and subset training, and the split decides the outcome across three regimes (figure 9.4): lightweight proxy scoring limits selection overhead to 5 percent while training on the 40 percent subset (yielding 55 percent net savings), whereas heavyweight scoring expends 60 percent overhead on selection, wiping out all subset-training efficiency gains.

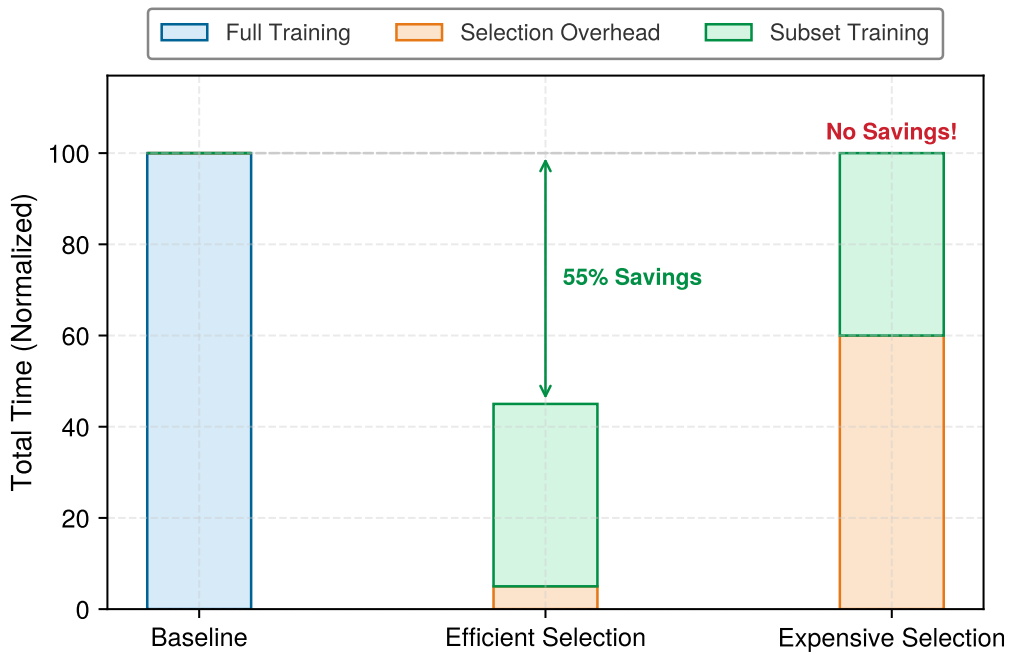

Figure 9.4: The Selection Inequality: In this illustrative example, data selection only improves end-to-end training time at matched quality if the overhead of selection plus training on the subset is less than training on the full dataset. A lightweight selection function (proxy model, cached embeddings) keeps selection overhead low; an expensive selection function (full model forward pass) can negate the savings.

This overhead compounds when selection runs dynamically across epochs rather than once offline. If per-epoch rescoring approaches the training work saved by the pruned subset, the net systems

advantage vanishes. Measured this way, a selection strategy is judged against its stated objective, counting the overhead of scoring, filtering, and staging samples alongside the training, labeling, or reuse savings it claims at target quality. Teams that optimize selection algorithms against isolated benchmarks rather than end-to-end pipeline constraints find that intuitive heuristics backfire: scoring overhead consumes accelerator cycles, optimization trajectories destabilize, or generalization silently degrades. These measures apply to the three levers in the order in which they act, and static pruning comes first because it fixes the subset before target-model training, though its scoring process may use a trained proxy.

9.3 Static Pruning

Web-scale scraping routinely gathers boilerplate text, duplicate images, and malformed records, and each one costs GPT-2 six FLOPs per parameter for every token, or ResNet-50 a full forward and backward pass, before a single useful gradient is calculated. Static pruning removes these low-value records upstream of the training loop. By dropping redundant and corrupt records before target-model training begins, static pruning shrinks the operation count (O) without changing model architectures or execution kernels.

9.3.1 The case for smaller datasets

In many training runs, a large fraction of examples contributes almost no gradient signal while still costing a full forward and backward pass. Empirical scaling studies confirm that dataset volume alone does not determine model accuracy, because large corpora carry substantial redundancy. On CIFAR-10, Paul et al. (2021) report that EL2N pruning (which scores each example by its prediction error early in training) removed half of the training data without reducing accuracy. On ImageNet-1K, Sorscher et al. (2022) report that a self-supervised prototype metric discarded 20 percent of the data without sacrificing performance. The pattern extends to language modeling, where web-scraped corpora like The Pile[5] and C4[6] contain enough duplicate and templated content to make deduplication a systems issue. In the datasets studied by Lee et al. (2022), deduplicated training reduced memorization while preserving or improving perplexity. Still, these reported gains are benchmark-specific: pruning effectiveness depends on how redundant the dataset is, which selection algorithm is used, and the capacity of the target model, so teams must validate aggressive pruning on their own task before committing to it.

Individual data points need not provide equal value for training. This heterogeneity follows in part from how classifiers learn decision boundaries. Many samples fall far from a boundary: a picture of a dog in good lighting may become easy once the model has learned its dominant features, while ambiguous and underrepresented cases can remain informative. Label quality also affects data requirements. Conflicting labels can push updates in opposing directions, so reaching a target error may require more examples or more passes over them. The size of that penalty depends on the task and training procedure. A **data quality multiplier** therefore comes from comparing learning curves at the same held-out error, rather than assigning a universal convergence rate to all noisy data.

Napkin Math 9.2: The data quality multiplier

Problem: Two hypothetical pilot learning curves reach the same held-out error using different amounts of clean and noisy data. With epoch count and per-sample work held fixed, what training-work multiplier do these sample counts imply?

Setup: Consider a representative evaluation where a fixed model architecture and training recipe reach target error $\epsilon = 0.01$ (1 percent) under clean versus noisy training partitions:

- Clean data: $D_{\text{clean}} = 10{,}000$
- Noisy data: $D_{\text{noisy}} = 16{,}000$

Result: Dividing the noisy-data count by the clean-data count gives 1.6×. Under the fixed training recipe, the noisy dataset therefore requires 1.6× as much training work to reach the same error.

5 **The Pile**: An approximately 886 GB English text corpus (reported as 825 gibibytes by the source) aggregating twenty-two subdatasets, including PubMed, ArXiv, GitHub, Project Gutenberg, Common Crawl, Stack Exchange, Wikipedia, and USPTO patents (Gao et al. 2020). Its multi-source design makes it a useful example of data diversity: each source family has a different duplication, quality, and domain-coverage profile, so selection pipelines must preserve coverage while removing redundant text.

6 **C4 (Colossal Clean Crawled Corpus)**: C4 applies filtering to Common Crawl data, including language detection, deduplication of repeated three-sentence spans, and removal of pages that fail heuristic quality checks, producing approximately 750 GB of cleaned English text (Raffel et al. 2020). Filtering has its own compute cost and can remove useful material, so its ROI and quality effects must be measured rather than inferred from corpus size alone.

Systems insight: The avoided training work sets a budget for cleaning. Cleaning pays for itself only when correction or review costs less than the work it removes, with required coverage preserved. If the two learning curves require different epoch counts, compare total examples processed to the target instead of unique sample counts. The decision depends on measured learning curves and pipeline costs, not on the presence of noise alone.

9.3.2 Data deduplication

The cheapest samples to remove are the ones that repeat what the dataset already contains. Repeated content costs a full forward and backward pass on every presentation, even when that repetition adds little useful learning signal. Exact hashing and shingle-based near-duplicate detection can identify candidates for removal without training a scoring model. Deduplication therefore comes first among the static levers, but near-duplicate thresholds must be validated so the pipeline does not remove useful distributional signal.

The simplest form of deduplication uses hash-based methods for exact matches. By computing a cryptographic hash (MD5 or SHA-256) for each sample and removing those with identical hashes, practitioners can eliminate the byte-for-byte duplicates that accumulate in large web-scraped corpora. This process is computationally cheap, scaling linearly with dataset size, and can be parallelized trivially.

Near-duplicate detection addresses content that differs at the byte level while retaining substantial token- or character-shingle overlap. For text, MinHash[7] with Locality-Sensitive Hashing[8] (LSH) approximates Jaccard similarity[9] efficiently. In practice, the pipeline converts each document into a set of overlapping character or word w-shingles, compresses these sets into fixed-length MinHash signatures where the probability of hash collision equals Jaccard similarity, and partitions the signatures into L bands of r rows using LSH. Documents matching across all rows in any single band collide in the same bucket, restricting expensive similarity verification to likely candidates and avoiding an impossible $\mathcal{O}(D^2)$ all-pairs comparison across a corpus of D web documents numbering in the billions. It can detect lightly edited content with high overlap, but it does not establish semantic paraphrase equivalence.

For images, perceptual hashing produces signatures robust to minor transformations like resizing and compression, identifying visually similar candidates stored in different formats. Embedding-based similarity can retrieve semantic near-neighbor candidates by computing dense representations (CLIP[10] (Radford et al. 2021) for images, sentence transformers for text), though proximity does not itself prove duplication and the approach incurs higher computational overhead. Across both modalities, deduplication can reduce repeated-content memorization and avoid spending FLOPs on exact or near duplicates, yet it can also alter the corpus's intentional empirical weighting, so thresholds and downstream quality must be validated rather than assuming that every duplicate is harmful.

On GPT-2's run, deduplication costs little and returns hours of accelerator time. Lee et al. (2022) found that near-duplicate removal affected between 3.04 percent (C4) and 13.63 percent (RealNews) of the corpora they studied. If WebText carried a comparable share, removing it would cut the same fraction of the 167 billion tokens GPT-2 processed, saving about 3 hours to 14 hours of the 4.4 days that one eight-H100 machine needs, or 18 kWh to 80 kWh of accelerator energy. Finding the duplicates reads the 40 GB corpus once, about 6 seconds at the 7 GB/s of the machine's local NVMe storage, and holds a 128-hash MinHash signature for each of WebText's roughly 8 million documents, about 4.1 GB of host memory. Hashing runs on host CPUs rather than on the accelerators, so the cost of deduplication lands on a different stage of the machine from the work it removes; the open question for a corpus this size is which near-duplicates are safe to remove, not whether the machine can afford to find them. Once those duplicates are gone, the next target is records that are unique but broken.

9.3.3 Data pruning by quality

A unique training example can still waste compute or actively damage the model if its content is garbled or its label contradicts the true class. **Quality-based pruning** removes samples that carry no usable signal or push gradients in the wrong direction. In supervised datasets, label error detection

↩ Deduplication as a deterministic data-cleaning step that keeps training and serving pipelines consistent is established in section 4.7.1.

7 | **MinHash**: Invented by Broder (1997) to detect duplicate web pages for AltaVista, the algorithm creates compact signatures using random hash functions such that similar documents produce similar signatures with high probability. Each signature compresses a document to a fixed-size sketch, enabling pairwise similarity estimation in $\mathcal{O}(s)$ time for sketch size s.

8 | **Locality-sensitive hashing (LSH)**: LSH hashes MinHash signatures into buckets so that similar signatures are more likely to collide. Candidate generation avoids an exhaustive all-pairs comparison, while runtime and memory depend on signature width, banding, bucket sizes, and the number of candidates that require verification.

9 | **Jaccard similarity**: Defined as $|\mathcal{A} \cap \mathcal{B}|/|\mathcal{A} \cup \mathcal{B}|$ for two sets $\mathcal{A}$ and $\mathcal{B}$, ranging from 0 (disjoint) to 1 (identical). For deduplication, the metric compares sets of shingles across documents of different lengths. The threshold must be calibrated for the shingle definition, corpus, and downstream quality because no universal cutoff separates duplicates from legitimately related documents.

10 | **CLIP (Contrastive Language-Image Pretraining)**: Pretrained on 400 million image-text pairs, CLIP maps semantically related images and text into a shared embedding space (Radford et al. 2021). Embeddings can retrieve candidates for review, but semantic proximity is not proof that two samples are duplicates. Generating embeddings also costs substantially more than computing perceptual hashes, with the ratio depending on model and hardware.

is often the highest-return form of quality pruning. Tools like Cleanlab identify samples where the assigned label may be incorrect based on model confidence patterns across training: a sample that the model consistently predicts as class A while its label says class B may be a hard boundary case, a distribution shift, a model blind spot, or an annotation mistake. Because those causes call for different remedies, the score should trigger review rather than automatic deletion, so confirmed errors can be corrected or removed without discarding hard examples.

Where label error detection checks whether the target contradicts the input, outlier removal checks whether the input itself sits far from any cluster center in feature space. Such points can indicate sensor noise, annotation errors, or file corruption, whereas in heavy-tailed domains they can also be the rare edge cases that define deployment risk, so outlier thresholds must stay conservative and the affected slices should be reviewed before removal.

Unlabeled pretraining corpora have no class labels to audit, so low-information filtering instead applies domain-specific heuristics to drop samples that carry too little signal to justify a training step. For text corpora, pipelines remove high-perplexity garbled strings (perplexity measures how surprising a text is to a language model, so high values can flag incoherent text as well as valid specialist or rare-language writing) alongside low-perplexity boilerplate or repetitive templates; for image datasets, they filter blurry, corrupted, or near-uniform frames. Because hand-written heuristics can miss subtler quality differences across billions of documents, industrial pretraining pipelines pair them with *classifier-based filtering*, which trains a lightweight linear classifier (such as fastText) using curated reference text (e.g., Wikipedia, books, and scientific papers) as positive examples and uncurated web dumps as negative examples. The classifier assigns each scraped document a continuous quality score, allowing the pipeline to drop millions of low-quality pages at gigabyte-per-second ingestion speeds before ranking the clean examples that remain.

9.3.4 Coreset selection algorithms

Once duplicates and defective records are gone, the remaining samples are unique and valid but still unequal in value, which is the heterogeneity described in section 9.3.1. Ranking them requires systematic selection criteria. **Coreset selection**[11] turns the static pruning decision into a coverage problem: keep the smallest subset that preserves the statistical properties of the entire dataset. The systems decision is where to spend the selection budget, whether on cheap coverage metrics that preserve distributional structure or on costlier training-dynamics scores that better target the decision boundary. That decision also needs a guardrail before any score is applied: classes, demographic groups, time windows, and rare failure modes that matter at deployment require minimum representation, because the highest-average-ICR subset can still remove the examples that define production risk.

Geometry-based methods select samples that cover a chosen representation without requiring target-model training. The k-Center algorithm,[12] a facility-location-style objective, selects samples that reduce the maximum distance from any point to its nearest selected center under the chosen embedding and metric. Herding takes a different approach: Welling's original procedure iteratively constructs representative pseudo-samples whose feature statistics approximate observed moments (Welling 2009), and related moment-matching objectives can guide subset selection from a fixed pool. These methods are computationally attractive because they operate on feature representations, but their scores are not inherently label-aware.

Training-dynamics methods use a proxy model to identify examples that may be important. GraNd (Gradient Normed) and **EL2N (error L2-norm)**[13] score samples by gradient magnitude or prediction error early in training (Paul et al. 2021). The exact alternative, influence functions (Koh and Liang 2017), measures how removing a sample changes validation loss, but it requires the inverse Hessian $\mathbf{H}^{-1}$ of the loss across all P parameters, with $\mathcal{O}(P^2)$ memory and $\mathcal{O}(P^3)$ arithmetic, which rules it out for models with millions or billions of parameters.

Systems methods circumvent this barrier by relying on lightweight first-order approximations: GraNd scores samples using expected gradient norm ($\|\nabla_\theta \mathcal{L}\|_2$), while EL2N observes that early in training, the gradient norm with respect to linear layers is strongly correlated with output prediction error ($\|\hat{\mathbf{y}} - \mathbf{y}\|_2$, the distance between the predicted probability vector $\hat{\mathbf{y}}$ and the one-hot label $\mathbf{y}$). This enables practitioners to score prediction error using a single forward pass without computing backward-pass gradients. Error and uncertainty differ: a confident prediction of the wrong class can

[11] **Coreset (core set)**: In computational geometry, a small subset can approximate a specified geometric objective within a controlled error factor (Agarwal et al. 2005). Machine learning adapts this idea as a selection principle, but a guarantee for an embedding and distance objective does not by itself guarantee neural-network accuracy. The retained subset must still be validated on the target task.

[12] **k-center algorithm**: Its greedy strategy iteratively picks the point farthest from the existing centers under a chosen embedding and metric. Sener and Savarese use this core-set framing for convolutional-neural-network active learning (Sener and Savarese 2018). The resulting coverage bound applies to that geometric objective, not directly to downstream accuracy or rare-class preservation.

[13] **EL2N (error L2-norm) and GraNd (gradient normed)**: These methods score samples based on their error or gradient norm early in training, identifying samples the model finds most difficult. The practicality of this approach relies on *transferability*, where scores from a small proxy model can guide data selection for a much larger target model. For instance, a proxy trained for five epochs can generate scores to curate a dataset for a full 90-epoch production training run (Paul et al. 2021).

have high EL2N despite low predictive uncertainty. High scores identify examples the proxy finds difficult, but they can also identify noise or unrepresentative samples and therefore need coverage and quality checks. The same work reports useful score transfer across several architectures, which can enable less expensive proxy-based selection. A third training-dynamics signal, forgetting events,[14] tracks how often a sample is correctly classified and later misclassified during training (Toneva et al. 2019).

[14] **Forgetting events**: This method identifies valuable examples by tracking when the model "forgets" them, transitioning from a correct to an incorrect classification during training. The central trade-off is the high cost of this analysis, which requires a full training run. However, the resulting importance scores can transfer from small proxy models to larger target models (for example, ResNet-18 to ResNet-50), enabling inexpensive proxy-based selection when ranking quality holds for the target task (Toneva et al. 2019).

Each algorithm in table 9.2 balances upfront scoring computation against downstream training reduction. Because geometry-based and training-dynamics methods optimize different proxies, their relative ranking depends on dataset scale, feature representations, target model capacity, and scoring budgets; a score is computationally justified only when downstream training savings exceed evaluation overhead.

Table 9.2: Coreset Selection Algorithm Comparison: D = dataset size, K = coreset size. Geometry-based and training-dynamics methods optimize different proxies, so their quality ranking depends on the dataset, representation, target model, and scoring budget.

Method	Compute Cost	Requires Training	Best For	Limitation
k-Center	$\mathcal{O}(D^2)$ or $\mathcal{O}(DK)$	No	Coverage, exploration	Ignores label information
Herding	$\mathcal{O}(DK)$	No	Distribution matching	Matches chosen moments
GraNd	$\mathcal{O}(\text{epochs} \times D)$	Yes (few epochs)	Decision boundaries	Requires proxy training
EL2N	$\mathcal{O}(\text{epochs} \times D)$	Yes (few epochs)	Error-based scoring	Can rank noise as hard
Forgetting	$\mathcal{O}(\text{full training})$	Yes (full)	Hard examples	Expensive to compute

Geometry-based methods prioritize coverage in a chosen feature representation, while training-dynamics methods use signals such as error or forgetting. Uncertainty sampling, which active learning uses as a query rule (section 9.4.2), concentrates the budget near the current decision boundary; EL2N instead ranks prediction error, which can also be high for confidently wrong examples away from the boundary. Figure 9.5 contrasts that boundary-focused allocation with uniform random sampling of the same five-point budget. It illustrates one family of selection rules; a geometry-based method such as k-center would instead spread its picks to cover the feature space.

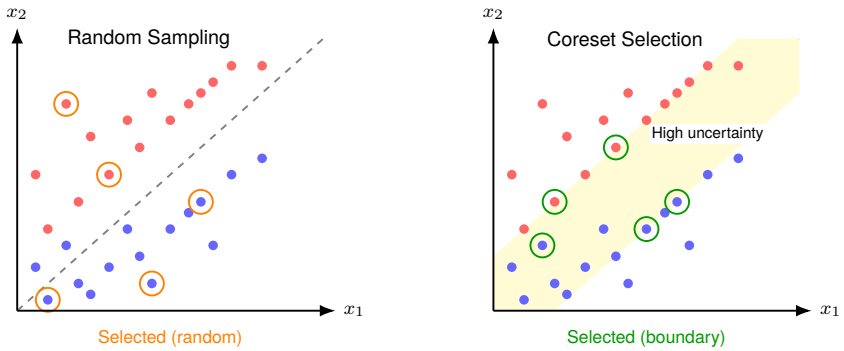

Figure 9.5: Illustrative Boundary-Focused Selection: Both panels select five samples, isolating allocation rather than budget. Random sampling distributes those choices across the feature space; a boundary-focused rule such as uncertainty sampling concentrates them in the shaded band around the current decision boundary.

EL2N with a small proxy model offers one practical balance between scoring cost and selection quality. The approach trains a lightweight model for a few epochs, computes EL2N scores, and selects a subset subject to coverage and quality checks. The proxy must provide rankings that transfer to the target model, and the investment pays off only when downstream training savings exceed selection overhead. A concrete scenario shows the workflow; whether its 10 percent subset preserves accuracy is exactly what validation must establish.

Example 9.3: Coreset selection in practice

Scenario: An engineering team aims to select a 128,117-image coreset (10 percent) from the 1.28 million ImageNet training images for faster ResNet-50 iteration.

Diagnosis: Naive random subsampling can miss rare classes and boundary examples. Training a lightweight proxy model for 5 epochs calculates EL2N error scores, prioritizing high-error examples while checking rare-class coverage.

Systems lesson: Proxy-based coreset selection replaces some full-data passes with targeted scoring compute. It accelerates full-model training only when the proxy ranking transfers and coverage checks preserve rare classes and edge cases.

Listing 9.1 turns proxy prediction error into reusable selected indices. The `compute_el2n_scores` function spends a small amount of probe compute to measure which samples still confuse a briefly trained model, and `select_coreset` retains the highest-scoring examples. This top-k sketch needs quality and coverage checks before its subset replaces the full training pool. The scoring pass requires an unshuffled dataloader so each score position remains aligned with its dataset index.

Listing 9.1: EL2N-Based Coreset Selection: The `compute_el2n_scores` function trains a proxy model for a few epochs, then measures prediction error via L2 distance from one-hot labels. High scores identify samples the proxy finds difficult, including potentially noisy examples. The `select_coreset` function illustrates ranking by this score; production use also requires coverage, noise, and target-quality validation.

```
def compute_el2n_scores(model, dataloader, num_epochs=5):
    """Compute EL2N scores.

    Returns L2 norm of (prediction - one_hot_label).
    """
    # Train proxy model for a few epochs to get meaningful predictions
    train_proxy(model, dataloader, num_epochs)

    scores = []
    model.eval()
    for x, y in dataloader:
        logits = model(x)
        probs = softmax(logits, dim=1)
        # One-hot encode labels
        one_hot = zeros_like(probs).scatter_(1, y.unsqueeze(1), 1)
        # EL2N score = L2 distance between probabilities and one-hot target
        el2n = (probs - one_hot).norm(dim=1)  # High = large prediction error
        scores.extend(el2n.tolist())
    return scores

def select_coreset(scores, dataset, fraction=0.1):
    """Select top-k samples with the largest prediction errors."""
    k = int(len(dataset) * fraction)
    # Sort by score descending (largest prediction error first)
    indices = argsort(scores, descending=True)[:k]
    return Subset(dataset, indices)

# Illustrative 10% subset; validate accuracy and coverage before use
scores = compute_el2n_scores(proxy_model, full_loader)
coreset = select_coreset(scores, full_dataset, fraction=0.1)
train_full_model(model, coreset)
```

A coverage floor changes the indices retained by the score ranking. Consider disjoint classes A and B, a total coreset budget K as in table 9.2, and task-validated minimum counts a and b for the respective classes. First reserve the highest-scoring a eligible examples from A and the highest-scoring b from B. Fill the remaining $K - a - b$ slots from the global ranking, skipping indices already

reserved. The allocation is infeasible if $K < a + b$, if either class lacks enough eligible examples to meet its floor, or if the eligible pool is smaller than K; the pipeline must revise the budget or acquire missing coverage before training.

Suppose the unconstrained top-K ranking contains only A examples and the budget can meet both floors. Reserving B's floor replaces the lowest-scoring b members of that all-A subset with the highest-scoring eligible B examples, while the remaining slots still follow the score order. Coverage thus has an explicit opportunity cost in the selection score. Overlapping demographic or operational slices require joint constraint handling because one example may satisfy several floors; summing those floors as if the slices were disjoint can reject a feasible budget. Even a feasible allocation establishes only retained counts. Independent evaluation must still establish target quality and performance on the required slices.

Together, these three static pruning techniques (deduplication, quality filtering, and coreset selection) shrink O before training begins, subject to the same fixed-schedule caveat as before: a schedule that adds compensating epochs or steps gives back part of the saving. Static pruning answers a question about *what* to keep, but it treats the answer as fixed, training every epoch on the same retained subset. A sample's usefulness, however, can change as the model learns, because examples that challenge an undertrained model may become easy after sufficient gradient updates. Dynamic selection techniques address this limitation by adapting the training data at each stage based on what the model has already mastered.

9.4 Dynamic Selection

How much a sample teaches changes as the model learns. Early in optimization, broad coverage provides stable gradients that establish general feature representations. As parameters converge, the gradient norms of mastered examples decay toward zero; on a ResNet-50 run over ImageNet, these are the clean, centered images of common classes. Executing forward and backward passes on these samples continues to consume accelerator execution cycles and high-bandwidth memory (HBM) transfers while producing negligible parameter updates, driving their effective ICR toward zero. Dynamic selection mitigates this waste by adapting batch composition to the model's current state. This shifts selection from an offline preprocessing step into the active execution loop, modifying the operation count (O) at runtime. The same adaptive logic extends to labels, where active learning decides which examples receive a human label as the model's uncertainty shifts.

9.4.1 Curriculum learning

Random shuffling feeds hard boundary cases, noisy labels, and outliers to an untrained model before its early features have stabilized, while still spending full epochs on simple examples long after the model has mastered them. **Curriculum learning**[15] (Bengio et al. 2009; Soviany et al. 2022) orders the training stream instead of shuffling it uniformly, starting with simpler examples and gradually introducing harder ones as parameters converge. Ordering the stream changes which gradients dominate at each stage of training: easy examples provide stable early signals, while examples scored as hard can contain useful boundary information, label noise, or outliers. An easy-to-hard schedule can smooth training on some workloads, but its benefit depends on the difficulty score, pacing rule, model, and data; any claimed epoch reduction must therefore be treated as illustrative rather than guaranteed.

Implementing a curriculum requires two components: a difficulty scorer that ranks samples, and a pacing function that controls how quickly hard samples are introduced. A common choice is linear pacing:

$$\text{samples}_{n_{\text{epoch}}} = \texttt{sort_by_difficulty}[: D \cdot \min(1, n_{\text{epoch}}/N_{\text{warmup}})]$$

where n_{epoch} is the current epoch, D is the total dataset size, and N_{warmup} is the number of warmup epochs before the full dataset becomes available. Early epochs train on the easiest fraction $n_{\text{epoch}}/N_{\text{warmup}}$ of the D samples; after warmup, training proceeds on the full dataset. From a systems standpoint, dynamically re-sorting multi-terabyte datasets epoch-by-epoch destroys sequential I/O read-ahead and stalls accelerators on storage latency. Production data loaders implement curricula by pre-sorting data offline into discrete difficulty-tiered shards or buckets. During training, workers stream shards sequentially from storage while maintaining local shuffle buffers within each

[15] **Curriculum learning**: From Latin *currere* ("to run"), originally meaning "the course to be run," a metaphor that maps directly to the technique, with training data as a course run in deliberate order and the easy stretches first. Curriculum learning can act as a continuation method for nonconvex optimization, with easier examples shaping the early optimization trajectory before harder examples are introduced. From a systems perspective, the ICR of a sample can vary during training, which motivates changing the mix of examples over time.

tier, preserving high sequential storage bandwidth while maintaining batch diversity and gradient stability.

The pacing rule fixes one saving before any benchmark is run. Summed over the warmup, the loader serves $\sum_{n_{\text{epoch}}=1}^{N_{\text{warmup}}} D \cdot n_{\text{epoch}}/N_{\text{warmup}} = D(N_{\text{warmup}}+1)/2$ samples in place of $N_{\text{warmup}} \cdot D$, so the warmup epochs cost roughly half their full-data FLOPs. A curriculum can therefore save compute in two distinct ways, through cheaper warmup epochs and through any reduction in the total epochs needed to reach target quality, and a claimed saving must say which of the two it measured.

The difficulty scorer is a systems choice because it trades probe-compute overhead against ordering quality, as table 9.3 shows. Loss and confidence scoring gain better ordering at the cost of extra inference, heuristics avoid compute but require domain knowledge, and self-paced scoring moves adaptation into the training loop itself.

Table 9.3: Difficulty Scoring Strategies for Curriculum Learning: The rows compare each scorer's signal source with the system prerequisite or trade-off it introduces.

Strategy	Difficulty Score	Best For
Loss-Based	Loss from probe model (low = easy)	General-purpose; requires probe training
Confidence-Based	Teacher model confidence (high = easy)	When teacher available; distillation setups
Domain Heuristics	Sentence length, image complexity	No extra compute; domain knowledge required
Self-Paced	Current model's loss (updated each epoch)	Adaptive; no probe needed

To see how curriculum savings translate to systems accounting, consider an illustrative workload where a linear-warmup curriculum reaches target accuracy in 115 epochs compared to 150 epochs for the standard shuffled baseline, an apparent 23.3 percent epoch reduction. Counting epochs alone, however, obscures the actual systems cost. Because linear pacing serves fewer samples during warmup, early epochs consume fewer FLOPs than post-warmup epochs; conversely, difficulty scoring and shard reordering introduce data-loading overhead that must be offset by the training speedup.

Alternative curriculum strategies diverge further in their computational demands. In a learned curriculum, an auxiliary network dynamically weights examples, down-weighting likely mislabeled instances, rather than enforcing a fixed difficulty schedule. Conversely, *anti-curriculum* presents the hardest examples first when boundary definition accelerates early convergence, while *self-paced learning* continuously updates sample difficulty using the current model's training loss. Because optimal sample ordering depends on the architecture, optimizer, and label noise, curriculum gains cannot be assumed from nominal epoch reductions; they must be verified by measuring end-to-end wall-clock time at the target quality metric, and they still assume that every candidate sample already has a label.

9.4.2 Active learning

Curriculum learning optimizes the order in which samples are presented but assumes all samples are already labeled. This assumption breaks down in specialized domains where labeling requires substantial expertise, time, or money. Active learning[16] (Settles 2012; Ren et al. 2021), which section 4.6.5 introduced as a way to stretch a labeling budget, becomes a selection loop here. Rather than labeling everything upfront, it shifts the optimization target from choosing which labeled samples to train on to choosing which unlabeled samples are worth labeling.

Active learning replaces one-shot collection with an iterative loop of five stages (figure 9.6): the selection strategy queries the unlabeled pool based on model uncertainty, routes ambiguous instances to a human oracle, merges newly labeled data into the training set, and retrains the model to update uncertainty scores over the remaining pool. The effectiveness of this loop depends critically on the query strategy used to select samples for annotation (Settles 2009, 2012; Ren et al. 2021). The simplest approach, uncertainty sampling, selects samples where the model is least confident, such as predictions near 0.5 probability for binary classification. Scoring with a single model is inexpensive, yet it can overconcentrate queries near one ambiguous region and miss parameters the model is confidently wrong about. Query-by-committee addresses that single-model blind spot by training

16 **Active learning**: The "active" component is the learning algorithm itself selecting which unlabeled samples a human expert should label next. This reframes the problem from a computational optimization (training on given data) to a financial one: maximizing model improvement per dollar spent on expert labeling. Querying the most informative examples can substantially reduce labeling needs compared with random sampling, but the multiplier is task-, model-, and oracle-dependent.

↩ The labeling budget, and what each label costs at scale, are established in section 4.6.2.

multiple models and selecting samples where they disagree most, capturing epistemic uncertainty at the cost of ensemble inference. When practitioners can invest even more compute per candidate, expected model change selects the samples that would induce the largest gradient update if labeled, trading per-sample gradient evaluations for a more direct estimate of parameter impact. Because any purely uncertainty- or gradient-driven rule can still cluster an entire acquisition batch inside one narrow pocket of feature space, diversity sampling complements these methods by selecting samples that are dissimilar from currently labeled data, spreading the annotation budget across the input distribution.

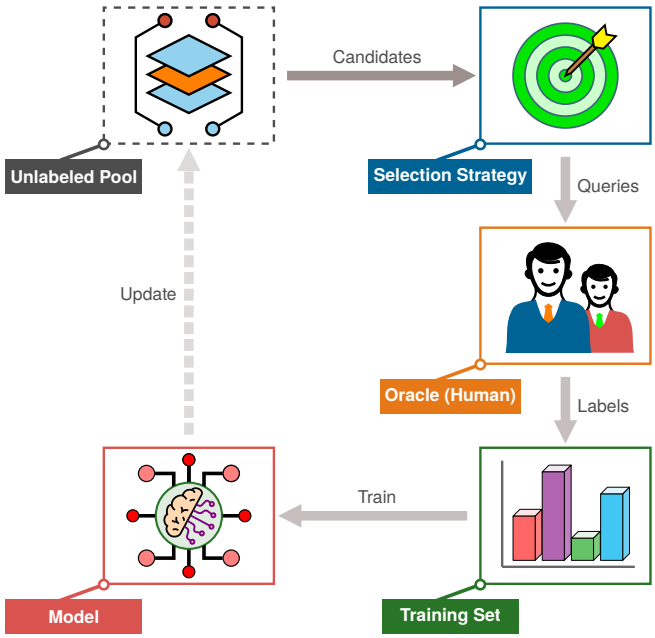

Figure 9.6: The Active Learning Closed Loop: The selection cycle trades proxy-scoring compute for queries chosen from an unlabeled pool for oracle annotation. Uncertainty, diversity, and coverage criteria seek more useful information per annotation than undirected sampling.

Active learning pays off most clearly in domains where every label requires scarce specialist judgment. When a ResNet-50-class image classifier moves from ImageNet to chest X-rays, for instance, every label requires a radiologist, and the model may be confident on common conditions but uncertain about rarer cases. By focusing human annotation on these ambiguous cases, active learning directs expensive expert time toward the examples most likely to move the decision boundary. Because annotation cost and turnaround in such domains dominate the compute needed to score candidates, routing only the examples the model is least sure about to the expert changes the economics of both labeling and per-epoch training work.

Napkin Math 9.3: The active learning ROI

Problem: A hospital team has 1 Million unlabeled scans, a \$5/label specialist-label cost, and a \$500,000 budget. How does uncertainty sampling change labeling cost and per-epoch training work relative to the budget-matched random baseline?

Scenario A: Naive Labeling

- **Cost**: Labeling all 1 Million scans would cost \$5,000,000 (10× over budget).
- **Budget-matched baseline**: $\$500,000 \div \$5/\text{label} = 100,000$ random scans.
- **Naive labeling outcome**: Random selection does not guarantee rare-pathology coverage.

Scenario B: Active Learning

- **Strategy**: Uncertainty sampling selects 50,000 scans for specialist labeling.
- **Cost**: $50,000 \times \$5/\text{label} = \$250,000$ (50 percent under budget).
- **Training work**: $100,000 \div 50,000 = 2\times$ fewer examples per epoch than the budget-matched random baseline.
- **Active learning outcome**: Matching 100,000 random scans requires empirical validation.

Systems insight: Against the budget-matched random baseline, selection saves $\$500,000 - \$250,000 = \$250,000$; accuracy still requires empirical validation.

The notebook's 2× label reduction is an assumption, and the size of that multiplier is what decides the outcome. In the illustrative learning curves of figure 9.7, uncertainty sampling reaches 90 percent accuracy with roughly 2,500 annotations while uniform random sampling needs about 10,000, a 4× gap.

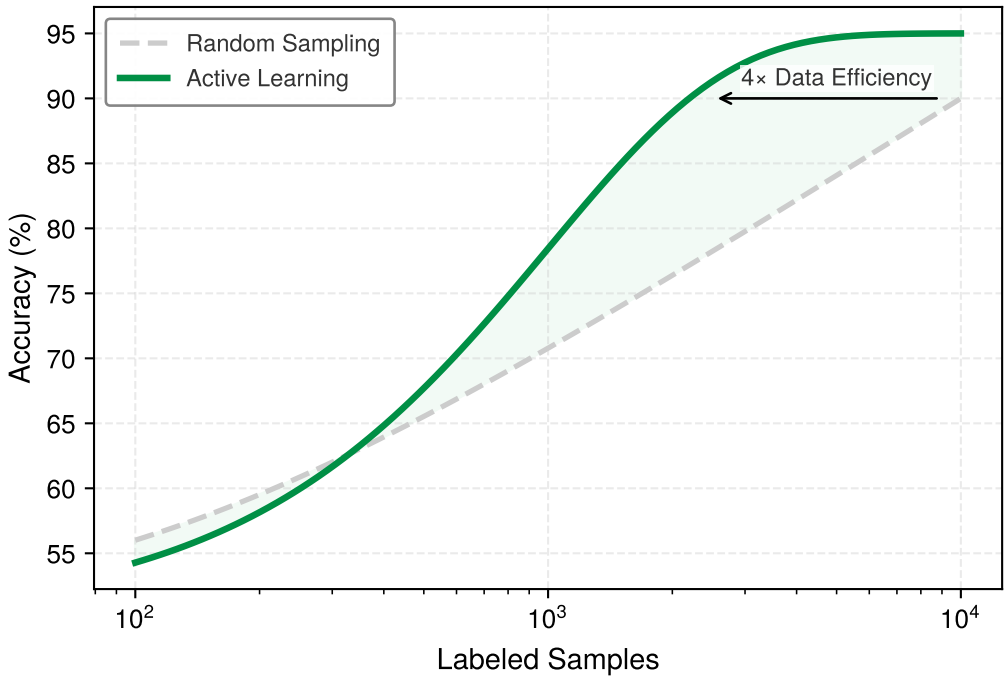

Figure 9.7: The Active Learning Multiplier: Model accuracy is plotted against labeled samples on a logarithmic axis. In this illustrative scenario, active learning (green solid) reaches the same accuracy with fewer labels than random sampling (gray dashed); the arrow marks an approximately 4× label-efficiency gap near 90 percent accuracy.

At a fixed price per label, label count and labeling dollars are the same axis, so the figure and notebook 9.3 differ only in the multiplier they assume. The notebook plans on the conservative 2×; the figure shows what a more favorable task would look like. Because the realized multiplier depends on the task, the model, and the query rule, a team budgets on the conservative value and measures the real one on its own data. Active learning also incurs scoring, acquisition, and repeated-retraining costs, so end-to-end savings can be smaller than the label-count gap; beyond saving labeling cost, however, a suitable query rule concentrates review on uncertain, diverse, or failure-relevant examples that uniform sampling rarely surfaces.

Example 9.4: Hard negative mining in a smart doorbell

Scenario: A smart doorbell vision detector receives continuous video feeds dominated by empty backgrounds (easy negatives) and normal pedestrian poses.

Diagnosis: Random frame sampling can miss rare false positives such as statues, laundry piles, and human-shaped shadows. Active learning routes uncertain predictions ("Person: 51%") and sampled production errors to human reviewers for targeted labeling.

Systems lesson: Hard-negative mining can improve labeling efficiency by spending review effort on suspected false positives and other difficult negatives. The query stream still needs diversity and coverage checks so confident but systematically wrong cases are not excluded.

Curriculum learning and active learning both choose among examples that already exist. When the pool itself lacks the cases a model needs (rare classes with too few examples, edge cases that never appear in the wild, records that privacy rules keep out of reach), no ordering or labeling policy can supply them, and the remaining lever is to create them.

9.5 Synthetic Data Generation

Real-world data collection encounters physical and legal boundaries: autonomous fleets cannot safely crash vehicles to acquire catastrophic collision trajectories, healthcare systems cannot transmit protected patient telemetry across institutional firewalls, and edge products must handle acoustic environments before any deployed fleet exists to record them. When the source corpus contains few or none of the cases deployment will face, neither static pruning nor dynamic selection can extract signal that is not there. Synthetic data generation, which section 4.4.3 introduced as one acquisition channel among several, becomes here a deliberate lever for constructing the training distribution directly. The strategy shifts from *curation*, choosing among existing records, to *creation*, making new inputs, perturbations, or supervisory targets.

9.5.1 Data augmentation

A vision model trained repeatedly on identical images can memorize their exact pixel layouts rather than the object class, yet storing multiple transformed copies of every image on disk would multiply the archive's storage footprint. **Data augmentation** avoids that storage cost by transforming existing samples on the fly during ingestion; every ResNet-50 epoch on ImageNet sees freshly cropped, flipped, and color-shifted variants of the same images. Label-preserving transformations add diversity without expanding durable storage or acquiring new data, but they move cost into the training pipeline. On host CPU worker threads, decoding and spatial transformations can saturate the cores and starve the accelerator across the PCIe bus. Offloading them to accelerator kernels relieves the CPU, yet inputs still cross the host-to-device link, and the transformations consume HBM and compute cycles that would otherwise perform gradient updates.

For image data, transformations encode invariances required at deployment (Shorten and Khoshgoftaar 2019). Geometric operations (rotation, flipping, cropping, scaling) encourage viewpoint invariance when they preserve the label, while photometric adjustments (brightness, contrast, color jitter) simulate sensor noise and varying illumination. Stronger methods mask or mix images: Cutout[17] applies random rectangular zero-masks to prevent reliance on localized features; MixUp (H. Zhang et al. 2018) constructs virtual samples by taking linear combinations of image pairs and their one-hot labels ($\tilde{x} = \lambda_{\text{mix}} x_i + (1 - \lambda_{\text{mix}}) x_j$, with mixing weight $\lambda_{\text{mix}} \in [0, 1]$); and CutMix[18] pastes rectangular patches from one image into another while blending labels proportionally to the patch area. Both mixing methods operate through linear combinations and block copies in device memory, so they add negligible FLOP overhead.

Text has no smooth geometric transformations, because tokens are discrete. Back-translation[19] paraphrases by passing target-language text through a translation model to produce synthetic source sentences. Simpler transforms such as synonym substitution, token insertion, or deletion risk corrupting labels unless validated for the task.

Automated policy searches replace hand-tuned transformation schedules. AutoAugment[20] uses reinforcement learning to search over operations, at a search cost of about 15,000 GPU-hours on

17 **Cutout**: Randomly masks square regions of input images during training, forcing the model to recognize objects from partial information rather than relying on any single discriminative region (DeVries and Taylor 2017). Unlike dropout (which zeroes neurons in feature space), Cutout operates in input space. The original Cutout experiments produced 0.3–2.0 percentage-point gains across CIFAR-10/100 and SVHN with negligible compute overhead, making it a high-ICR augmentation technique when occlusion-style invariance matches the task: more information per sample at near-zero additional cost to the pipeline.

18 **CutMix**: Replaces Cutout's zeroed-out region with a patch from a different training image, mixing labels proportionally to patch area (30 percent of image A replaced by image B yields a 70/30 label split) (Yun et al. 2019). This addresses Cutout's weakness: zeroed regions waste pixel information that could carry learning signal. The CutMix paper reports ImageNet top-1 improvements of 2.28 percentage points for ResNet-50 and 1.70 percentage points for ResNet-101, while also improving localization behavior. The method provides stronger regularization than either Cutout or MixUp alone with little additional data-pipeline cost.

19 **Back-translation**: In the method described by Sennrich et al. (2016), target-language monolingual text is translated into the source language, and the synthetic source is paired with the unchanged target for machine-translation training. The systems trade-off is latency because each synthetic source requires translation-model inference. Pipelines can precompute these examples offline rather than generating them in the data loader.

ImageNet. RandAugment[21] eliminates this search cost by parameterizing the policy with just two values: the number of transformations applied to each image and a single global distortion magnitude. Even the best augmentation schedule, however, can only perturb examples the dataset already contains.

9.5.2 Generative synthesis

Cropping or color-shifting existing images cannot invent a rare object class, an unseen weather condition, or a collision scenario that never occurred in the recorded dataset. When a pipeline needs examples that perturbations of existing records cannot supply, **generative synthesis** constructs new input-label pairs (x, y) by sampling from generative models or physical simulators. The three main engines differ in cost per sample and in how realistic their outputs are:

1. Generative Adversarial Networks (GANs) train a generator against a discriminator. Once trained, feed-forward generator inference requires a single forward pass, providing low latency and high sample throughput. However, GAN training is vulnerable to mode collapse, in which the generator covers only part of the data distribution and loses the tail variety needed for edge-case coverage.
2. Diffusion models generate samples by iteratively removing noise over many sequential steps. Latent diffusion systems such as Stable Diffusion[22] enable precise semantic conditioning from text prompts while operating in a compressed latent space. A sampling recipe with 20 to 50 denoising steps runs the backbone that many times per generated batch, so offline generation is often preferable.
3. Physical simulation engines (such as CARLA for autonomous driving or Isaac Sim and Unity for robotics) generate data without neural inference, by running physics and rendering pipelines. They produce exact ground-truth annotations (3D bounding boxes, depth maps, velocity vectors) from internal state at no labeling cost, and the bottleneck shifts to host CPU physics and graphics rendering throughput.

Regardless of the generative engine, synthetic samples inevitably diverge from the statistical distributions of real deployment environments. That divergence determines whether synthetic training transfers to production or fails on the first real-world input.

9.5.3 Bridging the domain gap

A model trained purely on synthetic data can reach high validation accuracy in the simulator while failing in production because it latched onto rendering or generator artifacts that do not exist in the real world. This **domain gap**[23] is the statistical shift between the synthetic training distribution and production deployment data. Synthetic and real feature densities can sit at different locations in feature space, misaligning the decision boundaries learned from each (figure 9.8). The marginal densities alone do not determine either decision boundary; class-conditional structure and real-data evaluation are needed to establish how the shift affects classification.

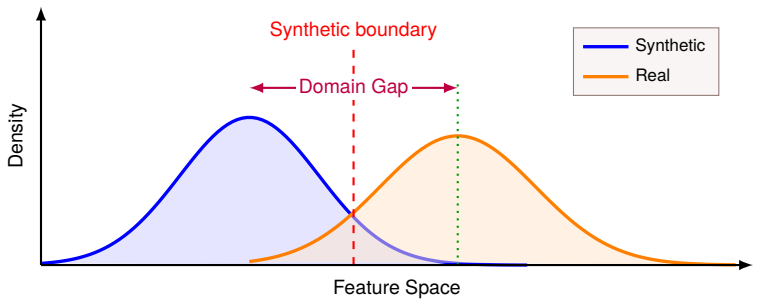

Figure 9.8: The Domain Gap Problem: Synthetic data (blue) and real data (orange) occupy shifted feature distributions. The dashed red synthetic boundary and dotted green real-data boundary illustrate possible misalignment; marginal feature densities alone do not determine class boundaries.

Two complementary strategies address this distribution mismatch. Domain randomization[24]

[20] **AutoAugment**: Treats augmentation policy design as a reinforcement learning search problem: a controller selects operations (rotate, translate, shear, equalize), their magnitudes, and application probabilities to maximize validation accuracy (Cubuk et al. 2019). The original ImageNet search used approximately 15,000 GPU-hours, motivating later methods that reduce the search space.

[21] **RandAugment**: Collapses AutoAugment's policy search to two hyperparameters, a transformation count and a shared magnitude (Cubuk et al. 2020). That small search space matches or exceeds AutoAugment on the reported benchmarks at far lower search cost, making it practical when 15,000 GPU-hours of policy search cannot be justified.

[22] **Stable Diffusion**: Performs iterative denoising in a compressed latent space, enabling targeted text-to-image examples (Rombach et al. 2022). Its iterative generation is substantially more compute-intensive than geometric transforms, so it fits cases where novelty matters more than per-sample throughput.

[23] **Domain gap**: The statistical divergence between synthetic and real data distributions, measurable with metrics such as maximum mean discrepancy (MMD) or Frechet Inception Distance (FID). For ML systems, the gap becomes training-serving skew: a simulator-trained model can validate well on synthetic data while failing silently on real deployment data.

[24] **Domain randomization**: Makes synthetic data deliberately varied by randomizing textures, colors, lighting, and physical properties. The goal is not photorealism; it is enough variation to improve coverage of deployment conditions, shifting the cost bottleneck from rendering fidelity to coverage.

takes an aggressive approach: rather than trying to match the real world precisely, it trains on varied synthetic data by randomizing lighting, textures, backgrounds, and camera parameters during generation. The aim is to make deployment conditions fall within the variation seen during training, though coverage is never guaranteed by randomization alone; the method is effective in robotics and autonomous-driving settings when the simulator spans the relevant physical and visual factors and the result is validated on real data.

Domain adaptation takes the opposite approach by explicitly aligning synthetic and real distributions. Feature alignment methods train on synthetic data while simultaneously minimizing the distance between synthetic and real feature distributions, often using adversarial training to learn domain-invariant representations. Fine-tuning offers a simpler path: pretrain on abundant synthetic data to learn general features, then fine-tune on a small real dataset to adapt to deployment conditions. Self-training combines these ideas by using a synthetic-trained model to pseudo-label real unlabeled data, then retraining on the combined labeled set. In practice, mixing synthetic and real data provides a real-data anchor while retaining some synthetic coverage: moving the mix from all-synthetic toward all-real trades a larger domain gap for a higher collection cost, and the best ratio depends on the domain, simulator fidelity, model family, and validation protocol rather than on any universal recipe.

Augmentation, noise injection, and simulation can grow a small seed set into a training corpus; the keyword spotter's data budget, including how much synthetic augmentation saves against recording real utterances, is worked through in section 4.3.1. The same creation strategy becomes riskier when samples come from learned generators. In recursive training, *model collapse*[25] can amplify errors and reduce diversity over generations. Synthetic data therefore requires provenance, mixture controls, and validation against real deployment data rather than an unverified assumption that more generated samples help. When the input examples themselves are already on disk, a trained model can instead enrich their labels.

[25] **Model collapse**: Formally analyzed by Shumailov et al. (2024), this phenomenon can arise when errors and missing tail coverage compound during recursive training. Tail distributions contain rare but important patterns that appear infrequently in training data. When generation $n+1$ trains on output from generation n under these conditions, successive generations can further compress the tails, producing increasingly homogeneous data. The degradation can be rapid in recursive training settings, which is why training on unanchored synthetic outputs risks catastrophic collapse of tail diversity.

9.5.4 Knowledge distillation

A hard one-hot label such as $[1, 0, 0]$ tells a classifier which class is right, but discards everything a stronger model knows about which wrong classes look similar. Where augmentation (section 9.5.1) and generative synthesis (section 9.5.2) create new inputs, **knowledge distillation**[26] (Hinton et al. 2015; Gou et al. 2021) creates richer targets for inputs the corpus already holds. A larger trained model (the teacher) labels each training example with its full probability distribution over classes, such as $[0.70, 0.20, 0.10]$ in place of $[1, 0, 0]$, and a compact student network trains against those soft targets, smoothed by a temperature parameter T_{distill}. Because each soft target records which wrong classes the teacher found plausible, every example carries more supervision than its one-hot label. Section 10.2.3.1 develops distillation as a compression technique, including its loss and temperature mechanics; as a data lever, its cost lies in generating, storing, and reading those targets.

Distillation trades accelerator HBM capacity against storage I/O bandwidth:

- **Online distillation**: The teacher model resides directly in accelerator memory alongside the student model during training. The system computes teacher forward passes concurrently with student execution, eliminating persistent storage overhead for soft targets. However, co-locating an overparameterized teacher consumes accelerator memory and arithmetic throughput, restricting the student's maximum per-accelerator batch size and increasing step latency.
- **Offline distillation**: The teacher generates predictions across the corpus during an offline precomputation pass, storing dense logit vectors to disk. This frees accelerator memory entirely for student training, but expands dataset storage volume and input pipeline bandwidth. For a classification vocabulary of K classes, storing uncompressed float32 logits increases the per-sample label footprint from a single integer index ($\lceil \log_2 K \rceil$ bits) to $4K$ bytes, an expansion of more than three orders of magnitude once K reaches the thousands.

[26] **Knowledge distillation**: Soft teacher probabilities reveal structural similarities across classes that one-hot encodings omit, and a temperature parameter controls how strongly those probabilities are smoothed. Distillation introduces teacher inference costs that must be justified by improved student sample efficiency or accuracy.

For ResNet-50 on ImageNet the offline footprint is concrete. Storing FP32 logits for 1,000 classes across every training image takes 5.1 GB, against 2.6 MB for the integer labels they replace, a 2,000× expansion that every epoch must read back through the input pipeline. That storage and read traffic, rather than the loss function, is what data selection must budget for. Generation and distillation both

supply labeled signal the corpus lacks; a complementary route reduces how many labels training needs in the first place, by extracting supervision from the unlabeled data the corpus already holds.

9.6 Learning from Unlabeled Data

Labels are often the scarcest input in a training pipeline. Active learning still pays an expert for every example it selects, and synthesis pays for every example it creates. Learning from unlabeled data attacks that cost from the other side. Semi-supervised learning lets a model trained on a small labeled seed supply provisional labels for the rest of the pool. Self-supervised learning removes task labels from pretraining altogether, and foundation models spread the resulting pretraining cost across many downstream tasks. Each approach trades additional training compute for fewer labels, so each is judged by total cost at matched quality rather than by label count alone.

9.6.1 Semi-supervised learning

In the chest X-ray adaptation of section 9.4.2, a hospital may hold 50,000 scans of which only 500 have been reviewed and labeled[27] by radiologists, a labeling rate of 1 percent. **Semi-supervised learning** puts the remaining 49,500 images to work by shifting the trade-off from human annotation to accelerator compute: it uses the small labeled subset to anchor training on the larger unlabeled pool, extracting supervisory signals from unannotated inputs. Models trained this way can approach fully supervised accuracy with far fewer manual labels, provided the unlabeled pool matches the target distribution and the result is validated on labeled data.

Unlabeled data, although it cannot teach the mapping from inputs to outputs, contains structural information about the input distribution $p(x)$ that can constrain the hypothesis space. Under smoothness and cluster assumptions, a decision boundary that cuts through a dense region assigns different labels to nearby inputs and is less plausible than one in a low-density region. Semi-supervised methods exploit these assumptions, which must be checked against the target task.

Three techniques implement this distribution-regularization insight. Pseudo-labeling[28] trains on the labeled subset, generates model predictions on the unlabeled pool, and incorporates samples exceeding a confidence threshold as synthetic ground truth for subsequent retraining. The confidence threshold governs a critical systems trade-off: setting it too low admits label noise that degrades learning, while setting it too high discards informative examples and wastes the unlabeled pool. Confident mistakes can survive either threshold, so confidence must be checked against labeled validation evidence rather than treated as proof of correctness.

Consistency regularization[29] enforces that the model produce invariant predictions across perturbed versions of the same input. When transformations such as cropping, rotation, or color shifts preserve the task label, the loss function penalizes prediction divergence between two stochastic views of an unlabeled sample. Hybrid approaches like FixMatch[30] unify both mechanisms: they generate a pseudo-label on a weakly augmented view when prediction confidence exceeds a threshold, then train the model to predict that label on a strongly augmented variant of the same input.

Label propagation frames semi-supervised learning as graph diffusion: it constructs an affinity graph over sample representations and propagates labels from labeled nodes to unlabeled neighbors. This approach works well when representations form well-separated clusters, though constructing and querying the similarity graph across large datasets introduces substantial memory and nearest-neighbor search overhead.

> Example 9.5: FixMatch on CIFAR-10
>
> **Scenario**: A semi-supervised image classification pipeline trains on CIFAR-10 with only 250 labeled samples (25 per class) alongside unlabeled data (Sohn et al. 2020).
>
> **Diagnosis**: The fully labeled CIFAR-10 training set contains 50K labels. FixMatch generates high-confidence pseudo-labels (>0.95 threshold) on weakly augmented unlabeled images and enforces consistency on strongly augmented variants, reaching 94.9 percent accuracy in the cited experiment.
>
> **Systems lesson**: Semi-supervised learning trades additional training compute for fewer manual labels. In an illustrative cost scenario at $1 per label, a supervised baseline with 4,000 labels

27 **Illustrative clinical labeling economics**: The review-rate and hourly-rate ranges are scenario assumptions rather than reported measurements. Under those inputs, labeling 500 scans requires 7–10 hours and costs $1,000–3,000; labeling all 50,000 costs $94,000–300,000. The arithmetic illustrates why semi-supervised learning can be attractive when expert labels are expensive, but actual review time, adjudication, prevalence, and validation requirements must be measured.

28 **Pseudo-labeling**: Uses a trained model's own confident predictions as ground-truth labels for unlabeled data; the technique's effectiveness depends on a virtuous cycle in which accurate predictions on easy unlabeled examples expand the training set and improve the model, which then labels harder examples accurately. The failure mode is equally self-reinforcing, because incorrect pseudo-labels feed the model's own misclassifications back into training through *confirmation bias*.

29 **Consistency regularization**: The method rests on a task-dependent smoothness assumption, that two inputs x_1 and x_2 related by a label-preserving perturbation should receive the same prediction. It is conceptually distinct from data augmentation (which creates more training examples) because it explicitly enforces prediction consistency as a loss term, even for unlabeled data where the "correct" label is unknown. The systems consequence is additional computation for generating and comparing predictions under multiple perturbations, a trade-off that can favor compute-rich, label-poor settings.

costs $4,000 in labels plus $50 of compute, or $4,050. FixMatch at 250 labels costs $250 in labels but 5× the compute, $250, for $500. Preparation expense falls by 8.1×; the end-to-end saving depends on the real unlabeled-data and compute costs.

The objective of semi-supervised learning is lower total labeling and compute cost at matched quality, which can justify a lower ICR when annotation savings exceed the added training expense. Neither the label reduction nor the compute increase carries over unchanged from one task to another; table 9.4 shows how far the label count fell on one benchmark.

[30] **FixMatch**: The confidence gate is strict; in the original experiments a pseudo-label is kept only when the prediction on the weak view exceeds 0.95 (Sohn et al. 2020). Every unlabeled image still costs a forward pass on its weak view whether or not it passes the gate, part of the extra training compute that buys the reduction in manual labels.

Table 9.4: FixMatch Label Efficiency on CIFAR-10: With 250 labels (0.5 percent of the dataset), FixMatch reaches 94.9 percent accuracy while using 200× fewer labels than the full training set contains.

Label Budget	Method	Accuracy	Label Efficiency
50,000 (100%)	Full training set	—	Label-count reference
4,000 (8%)	FixMatch	95.7%	12.5× more efficient
250 (0.5%)	FixMatch	94.9%	200× more efficient
40 (0.08%)	FixMatch	88.6%	1250× more efficient

The efficiency column counts labels only, relative to the full labeled set. It does not claim that FixMatch matches a fully supervised model, which would have to be compared at equal accuracy. These efficiency gains also depend on benign distribution assumptions. Semi-supervised learning assumes that unlabeled data comes from the same distribution as labeled data, and it struggles when unlabeled data contains out-of-distribution samples (the model confidently mislabels them), when class imbalance is severe (pseudo-labels amplify majority class bias), or when the labeled set does not cover all classes (preventing label propagation for unseen classes). A held-out set with true labels is the check that catches such a mismatch.

Each technique can reduce dependence on task-specific labels, but none eliminates the need for labeled evaluation. The progression raises a related possibility, that task-specific labels may not be necessary for pretraining. The structure of data itself (cat images resemble other cat images, and coherent sentences follow grammatical patterns) may provide a supervision signal, while downstream quality still requires task-aligned validation.

9.6.2 Self-supervised learning

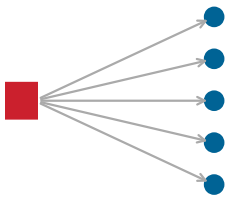
GPT was trained to predict the next token in a sequence. BERT was trained to fill in masked tokens. Neither pretraining objective required task-specific human labels. **Self-supervised learning**[31] (SSL) generalizes this insight: by designing *pretext tasks* that derive supervision from the data's structure, models can learn reusable representations from unlabeled data at scale. Where active and semi-supervised learning reduce the demand for labels, SSL changes the accounting by making unlabeled structure the pretraining signal. Within the intervention map of figure 9.1, SSL sits beside the three levers and extends the usable pool; the question shifts from which labeled samples to train on to how unlabeled samples can support pretraining. It responds to one aspect of the data wall introduced in section 9.1 by broadening what counts as a training signal, while leaving corpus quality, licensing, coverage, and labeled evaluation requirements intact.

Labels are one form of supervision; a pretext task can also derive a learning signal from the structure of the data, as table 9.5 summarizes.

[31] **Self-supervised learning**: The pretext task, such as next-token or masked-token prediction, provides a supervisory signal derived from the data itself. This reduces dependence on task-specific human labels but can require substantial pretraining compute. Amortization depends on how broadly the resulting model is reused.

Table 9.5: Self-Supervised Pretext Tasks by Modality: Each task extracts supervision from data structure rather than human labels, enabling pretraining on large-scale unlabeled corpora.

Modality	Self-Supervised Task	Supervision Signal
Text	Masked language modeling	Predict [MASK] from context
Text	Next-token prediction	Predict next token in sequence



Modality	Self-Supervised Task	Supervision Signal
Images	Contrastive learning	Same image (augmented) vs. different images
Images	Masked autoencoding	Reconstruct masked patches
Multi-modal	CLIP-style alignment	Match image-text pairs

Pretext tasks generate supervision signals automatically. Masked-token objectives can encourage models to learn grammatical and semantic structure; next-token prediction teaches continuation structure; and contrastive image objectives encourage visual features that are invariant to selected transformations. These approaches build on convolutional neural network and transformer families, but the systems accounting matters: self-supervision removes task-specific annotation from the pretraining gate rather than removing data cost. Pretraining can begin on unlabeled corpora without waiting for example-level labels, but collection, filtering, licensing, storage, and processing remain. If the representation transfers, one pretraining run serves many tasks and each task needs far fewer labels; task-specific adaptation and evaluation still carry their own data requirements.

When its pretraining cost is reused across tasks, SSL supports the **foundation model paradigm**[32] (Bommasani et al. 2021). The core data selection principles (coreset selection, curriculum learning, and active learning) remain essential within this paradigm. Pretraining corpus curation applies deduplication and quality filtering at web scale, while downstream selection dictates which fine-tuning examples maximize task-specific transfer.

Pretext objectives differ in what they stress on the machine. Contrastive learning trains a model to map two augmented views of the same image to nearby representations while pushing the representations of different images apart. Those other images are the *negatives*, and the objective learns better with more of them. SimCLR (T. Chen et al. 2020) draws its negatives from the rest of the mini-batch, with batches of up to 8,192 examples, so the negative count is paid for in activation memory and, across accelerators, in all-gather traffic that collects every device's representations. Momentum Contrast (MoCo) (He et al. 2020) instead keeps recent representations in a queue produced by a slowly updated copy of the encoder (the momentum encoder), which decouples the number of negatives from batch size. Masked autoencoders split an image into small square patches, hide most of them, and train the model to reconstruct what is hidden; because the encoder sees only the visible patches, it spends far less memory and compute per image. Autoregressive pretraining, by contrast, scales with tokens. For data selection, the common point is that pretraining turns raw structure into reusable signal that multiplies the value of scarce labels; because the pretraining run itself is expensive, however, whether self-supervised pretraining pays off depends on how many downstream tasks reuse it.

[32] **Foundation model**: The name emphasizes that these models serve as a shared base for many downstream tasks, but this creates a single point of failure. Defects in the foundation model's pretraining data (biases, factual errors, memorized private content) can propagate to multiple applications built upon it, depending on transfer and downstream adaptation. From a systems perspective, this homogenization risk means that data selection quality during pretraining has an outsized blast radius: a curation error that would affect one task in the train-from-scratch paradigm can affect many downstream deployments.

One pretraining corpus defect can affect many downstream tasks.

9.6.3 Foundation-model amortization

Pretraining a self-supervised model on a massive unlabeled corpus can consume thousands of accelerator hours, an upfront bill that rarely pays off if the resulting checkpoint serves only a single downstream classifier. **Cost amortization** makes that investment economical by splitting work into two phases: an expensive pretraining pass run once on unlabeled data, and lightweight task-specific adaptations, usually fine-tuning, reused across many applications (table 9.6).

Table 9.6: Illustrative Foundation-Model Amortization: The label and compute ranges are scenario assumptions. They illustrate why reuse can lower marginal task cost when representations transfer, not a universal fine-tuning ratio.

Approach	Labels per Task	Compute per Task	Data Acquisition
Train from scratch	100K–1M labeled	100% full training	Task-specific collection
Fine-tune foundation model	100–1K labeled	1–5% of full training	Reuse pretraining corpus

Take a company building 10 specialized classifiers. Under the scenario assumptions, each task trained from scratch needs 100,000 labels at $1 per label, for $1M across all tasks and a modeled compute burden of 10,000 GPU-hours. The fine-tuning scenario instead pays 10,000 GPU-hours

↩ Fine-tuning's memory and compute cost on one accelerator, set by which parameters it updates, is established in section 8.3.3.3.

once, then assigns 1,000 labels and 50 GPU-hours of compute to each task, bringing the modeled fine-tuning label bill across all 10 tasks to $10K. Assuming both approaches reach the same target quality on every downstream task, labeling cost drops by 100× and per-task marginal compute by 20× as direct consequences of the chosen scenario values, while total compute becomes favorable only after enough downstream tasks amortize pretraining.

The compute-only crossover occurs when enough downstream tasks share the pretraining cost, provided the representations transfer at the required quality. A dollar crossover also depends on labeling savings, compute prices, and other costs that differ between the approaches. The side-by-side bar charts in figure 9.9 contrast the cost structures across ten downstream tasks: training from scratch expends a constant 1,000 GPU-hours per task (totaling 10,000 GPU-hours), whereas the foundation model approach absorbs a 10,000 GPU-hour pretraining bar upfront but collapses subsequent task fine-tuning to just 50 GPU-hours per bar.

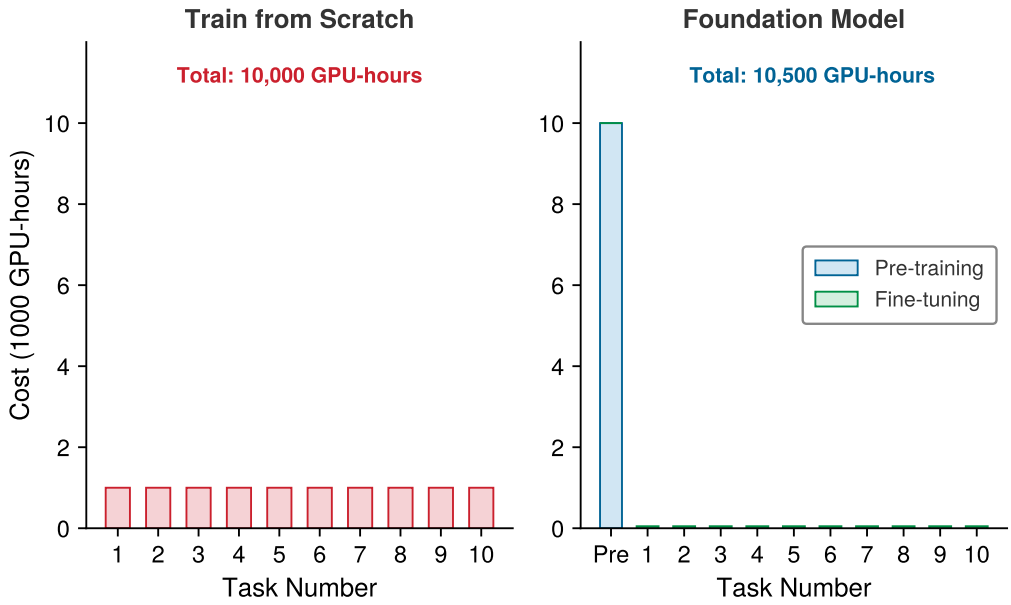


Figure 9.9: Cost Amortization in Foundation Models: In this illustrative scenario, training from scratch (left) requires 1,000 GPU-hours per task (10,000 GPU-hours total for 10 tasks). The foundation model approach (right) pays 10,000 GPU-hours upfront for pretraining but reduces each subsequent task to just 50 GPU-hours. At 10 tasks the totals are comparable (10,000 GPU-hours vs. 10,500 GPU-hours), but the per-task marginal cost drops by 20×, and the compute-only crossover favoring the foundation model occurs around 10.5 tasks. The plotted 10-task snapshot therefore remains just below that break-even point.

Every lever is now in view: pruning, reordering, labeling, creating, and learning without labels. Each has been judged so far by the work it removes; the next question is whether the machine can run it without giving that saving back.

9.7 Selection Engineering

A naive active learning loop that scans the entire dataset every epoch to select the "best" samples can turn a compute-bound training job into an I/O-bound bottleneck. **Selection engineering** is the work of making a chosen technique deliver its promised speedup on real hardware and real data pipelines. The pipeline must keep scoring cheap, reads sequential, and the accelerator fed.

The machine sets the scale for every one of those patterns. One ImageNet epoch of ResNet-50 on one H100 passes through four stages: images are read from local storage, decoded and augmented on host CPUs, copied across PCIe into accelerator memory, and consumed by the accelerator's arithmetic. Pruning shrinks the last stage directly; whether the other stages shrink, stay the same, or grow depends on how the selection is engineered (figure 9.10).

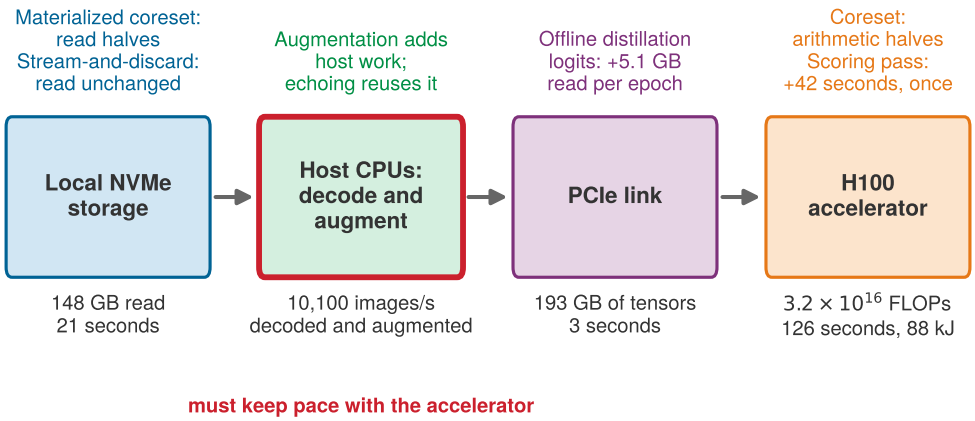

Figure 9.10: ResNet-50 Data Path on One H100: One ImageNet epoch crosses four stages: local storage, host decoding and augmentation, the PCIe link, and the accelerator. Loads under each stage are per full epoch at the compute-bound rate; notes above each stage name the lever that acts there. A materialized coreset halves the storage read and the arithmetic, stream-and-discard filtering halves only the arithmetic, offline distillation targets add bytes to every stage before the accelerator, and a scoring pass adds one third of an epoch of forward arithmetic once. The host stage, outlined in red, must decode and augment every image at the accelerator's rate.

Napkin Math 9.4: One pruned ResNet-50 epoch on the H100

Problem: ResNet-50 trains on the 1.28 million ImageNet training images for 90 epochs on one H100, and a coreset keeps 50 percent of the images. How much accelerator time and energy does the coreset save once its scoring pass is paid?

Compute: Each image costs 24.6 GFLOP forward and backward, so a full epoch is 3.2×10^{16} FLOPs. At the 25 percent of peak that ResNet-50 sustains in training (section 8.4.2), the H100 finishes it in about 126 seconds, which at its 700 W board power is about 88 kJ. The pruned epoch takes about 63 seconds and 44 kJ.

Selection: An EL2N-style scoring pass is one forward pass over the full pool, a third of an epoch's arithmetic, about 42 seconds and 29 kJ, paid once. Over 90 epochs the coreset saves about 4 MJ and 2 hours of accelerator time, 135× the scoring energy.

Data path: To stay compute-bound, the accelerator must receive about 10,100 images per second. Reading the 148 GB ImageNet archive from local NVMe at 7 GB/s takes about 21 seconds per epoch, and copying the decoded 8-bit tensors (193 GB) across PCIe at 64 GB/s takes about 3 seconds, both inside even the pruned epoch. The stage that must keep up is the host CPU, which has to decode and augment 10,100 JPEG images every second. The training chapter's host supplies only about 5,250 per accelerator, so an epoch actually takes about 244 seconds until decode capacity grows; the seconds below are the compute-bound figures selection can claim once the host keeps up.

Systems insight: Pruning halves the Data factor (Samples/Task), cutting total arithmetic O and accelerator energy in half, but it halves the storage read (D_{vol}/BW) only if the retained subset is written out as its own shards; streaming the full archive and discarding half leaves storage traffic unchanged. The seconds come from FLOPs, and whether they are realized

depends on the slowest stage of the data path, which for ResNet-50 is often host decoding (section 8.4.1).

Each lever also adds memory or storage of its own and compute or I/O of its own, and those costs land on different stages of the same data path (table 9.7).

Table 9.7: Memory and Compute Cost of Each Lever: Values for the chapter's two lighthouses on the reference H100 machine. Each lever adds memory or I/O at one stage of the data path while removing work at another, so the stage it loads must not become the new bottleneck.

Lever (lighthouse)	Memory or storage it adds	Compute or I/O it adds	Work it removes
MinHash deduplication (GPT-2, WebText)	4.1 GB of signatures in host memory	One 40 GB read (6 seconds) plus host hashing	3.04% to 13.63% of tokens processed
EL2N coreset scoring (ResNet-50, ImageNet)	One score per image (5.1 MB)	One forward pass over the pool (42 seconds, 29 kJ)	Half of every epoch (63 seconds, 44 kJ)
Coreset materialization	A 74 GB repacked subset, written once	One read and one partial write of the archive	Half of every later epoch's storage read
Stream-and-discard filtering	None	The full 148 GB read every epoch (21 seconds)	Accelerator work only; storage traffic unchanged
Offline distillation targets (ResNet-50)	5.1 GB of FP32 logits in place of 2.6 MB of labels	One teacher forward pass over the pool, then a 5.1 GB read every epoch	Teacher residency in accelerator memory during training

Those added costs surface in four places (scoring, storage reads, host preparation, and coordination across workers), and each has an engineering pattern that keeps it off the critical path.

9.7.1 The selection bottleneck

Evaluating a selection function $f(x)$ over a large candidate pool before forming every batch can easily cost more compute than training on the unselected data. While a conventional loader follows a predetermined sampling plan, active learning and adaptive curricula score candidates dynamically during training, introducing **selection latency**. In the ResNet-50 example of section 9.2.6, one static scoring pass with the target model costs a third of an epoch and is paid once. Rescoring the full ImageNet pool before every one of the 100 epochs instead adds 70 minutes of forward passes to 21 minutes of subset training, more than three times the training it serves, and cuts the saving from 90 percent to 57 percent. The selection inequality (equation 9.2) still holds, but scoring has become the largest term, and a heavier scorer or a smaller retained fraction would break it.

Engineering pipelines keep selection latency off the critical path through proxy models, cached embeddings, and indexed retrieval. A smaller proxy model curtails scoring time provided its sample ranking transfers accurately to the target architecture, and running the scoring pass in reduced numerical precision raises arithmetic throughput and cuts memory traffic when ranking fidelity permits. For similarity-based or diversity-based selection, vector indices such as FAISS[33] replace expensive corpus-wide scans with approximate nearest-neighbor retrieval over precomputed embeddings. These techniques decouple selection evaluation from primary model training and shrink $T_{\text{selection}}$, but even zero-cost scoring can still slow down training if fetching the selected indices stalls the storage layer.

9.7.2 The random-access penalty

Selecting a sparse subset of examples scattered across a dataset turns large sequential shard transfers into thousands of nonsequential reads, forfeiting hardware readahead, OS page caching, and bulk controller prefetching. Training already pays for shuffling through the access factor F_{access} that scales effective storage throughput in the data-pipeline model of section 8.4.2.1, and selection pushes that factor lower by design because the retained records no longer sit contiguously on disk. Because disk heads must physically seek and flash controllers must execute random block lookups, two subsets

33 **FAISS (Facebook AI Similarity Search)**: Provides GPU-accelerated similarity search using exact, approximate, and compressed-domain index designs (Johnson et al. 2019); Johnson, Douze, and Jegou report billion-vector graph construction on multiple GPUs, showing why vector-index infrastructure matters for web-scale selection. For data selection pipelines, FAISS-style indexing supports k-nearest-neighbor retrieval for coreset selection, embedding-based deduplication, and stratified clustering for balanced sampling. Without this infrastructure, embedding-based selection would often fall back to expensive full-corpus scans.

↩ Random access is measured in IOPS and streaming access in sequential throughput, the two storage metrics established in section 4.10.1.

of equal size can differ sharply in wall-clock training time according to their access locality. Table 9.8 quantifies this small-read penalty across storage tiers for 4 KB transfers.

Table 9.8: Illustrative Small-Read Penalty: Registry device anchors compare sequential bandwidth with random 4 KB reads under a simplified IOPS conversion. Real throughput depends on request size, queue depth, concurrency, caching, and service configuration; the cloud row is only a qualitative scenario.

Storage Tier	Sequential Throughput	Random I/O (IOPS)	Random Throughput (approx)	Random Penalty
HDD (7.2k)	~150 MB/s	~100 IOPS	~0.4 MB/s	375×
SATA SSD	~550 MB/s	~10K IOPS	~40 MB/s	13.8×
NVMe SSD	~3,500 MB/s	~500K IOPS	~2,000 MB/s	1.75×
Cloud (S3)	Configuration-dependent	Not IOPS-comparable	Configuration-dependent	Potentially extreme

Data loaders (whose general mechanism section 7.5.3 develops) avoid the problem by packing examples into large shards and shuffling inside a memory buffer. Sharded dataset formats, such as WebDataset and FFCV, pack thousands of individual examples into contiguous, sequentially readable archive chunks. Rather than fetching scattered individual samples from disk, the loader streams large sequential shards into host memory and populates a **shuffle buffer**. The training loop samples pseudo-randomly from this in-memory buffer, preserving peak storage read bandwidth while satisfying the statistical requirement of randomized mini-batches.

Converting a logical set of selected indices into sequential physical reads requires choosing between two storage strategies. For static pruning (such as a fixed coreset or a deduplicated corpus), the pipeline can materialize the subset offline by repacking the retained records into new, contiguous shards. This step incurs a one-time sequential read and write cost alongside additional disk storage, but ensures that every subsequent training epoch transfers only retained bytes from storage. Conversely, when the selection policy updates dynamically across training iterations or active-learning rounds, repeatedly repacking multi-terabyte shards on disk would choke the filesystem on write bandwidth. Data loaders instead stream the original, full-volume shards sequentially into host memory and discard unselected records before populating the shuffle buffer. This online filtering preserves sequential read throughput and eliminates seek penalties, but it leaves physical storage traffic unchanged: the host continues to read 100 percent of the corpus bytes from disk even when accelerators train on only a 10 percent subset. Systems engineers must count this ongoing read traffic on storage-bound nodes and include offline materialization costs when evaluating the selection inequality, and even after storage reads are streaming at full speed, host-side decoding and augmentation can still starve the accelerator.

Checkpoint 9.2: Selection overhead and storage access

Equation checks

- ☐ **Selection cost**: Explain why $T_{\text{selection}} + T_{\text{train}}(D_{\text{subset}})$ must be strictly less than $T_{\text{train}}(D_{\text{total}})$ for the technique to reduce end-to-end training time.
- ☐ **Overhead management**: Explain how proxy models and cached embeddings keep $T_{\text{selection}}$ low.

Systems implications

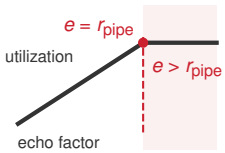
- ☐ **I/O patterns**: Explain why nonsequential access for dynamic selection reduces dataloader throughput relative to sequential reads.

9.7.3 Data echoing

Even with sequential reads, the host CPU often cannot decode and augment samples fast enough. Heavy data transformations, such as 3D rotations, MixUp, JPEG decoding, or on-the-fly generative synthesis, demand substantial host processing per sample. When the host pipeline produces batches

slower than the accelerator executes forward and backward passes, the accelerator idles, starved for input; this is the feeding problem reappearing inside the selection loop. The resulting collapse in accelerator utilization extends training wall-clock time, neutralizing the efficiency gains achieved by pruning the dataset.

↩ Accelerator bubbles, which open when the data-loading stage cannot keep pace with the accelerator, are established in section 8.4.1.



Data echoing[34] (Choi et al. 2019) reuses data multiple times before fetching new samples, trading freshness for accelerator utilization when the input pipeline is slower than training. Echoing before randomized augmentation can produce different transformed inputs on each repetition, while echoing later in the pipeline may repeat identical tensors.

[34] **Data echoing**: The key subtlety is *where* in the pipeline to insert the echo point. Echoing before augmentation (upstream echoing) can apply different random augmentations to each repetition, while echoing after augmentation feeds identical tensors to the accelerator. Useful echo factors and realized speedups depend on the workload, batch size, insertion point, and shuffling policy (Choi et al. 2019).

The optimal echo factor depends on the ratio r_{pipe} of upstream processing time to downstream training time, where T_{prep} is the time the data pipeline needs to produce a batch and T_{GPU} is the time the accelerator needs to train on it:

$$r_{\text{pipe}} = \frac{T_{\text{prep}}}{T_{\text{GPU}}}$$

In this two-stage rate model, $r_{\text{pipe}} > 1$ means the data pipeline bottlenecks training. An echo factor $e < r_{\text{pipe}}$ partially recovers idle accelerator cycles, while $e \geq r_{\text{pipe}}$ removes input waiting entirely, provided repeated samples remain statistically productive. Raising e beyond r_{pipe} adds no throughput and only reduces gradient diversity. When $r_{\text{pipe}} < 1$, the input pipeline already outruns the accelerator, so echoing has nothing to recover.

Echoing raises accelerator utilization until e reaches r_{pipe}; beyond it, nothing is gained.

Napkin Math 9.5: Worked example: Data echoing ROI

Scenario: Training ResNet-50 on ImageNet on one H100 fed by the training chapter's host, where host preparation is the slow stage (section 8.4.2).

Rates:

- Data pipeline throughput: 5,250 images/s (the host cores available to one accelerator, each reading, decoding, and augmenting about 375 images/s)
- Accelerator training throughput: 10,100 images/s (forward and backward pass at the compute-bound rate of notebook 9.4)
- Ratio $r_{\text{pipe}} = T_{\text{prep}}/T_{\text{GPU}}$ = (1/5,250 images/s) / (1/10,100 images/s) = 10,100 images/s/5,250 images/s ≈ 1.92 (accelerator waiting 48.0 percent of the time)

Without echoing:

- Effective throughput: 5,250 images/s (limited by data pipeline)
- Training time for 90 epochs: $90 \times 1.28\text{M}$ / 5,250 images/s = 21,963 seconds (6.1 hours)
- Accelerator utilization: 52.0 percent

With echo factor: $e = 2$, inserted after the measured reading, decoding, and augmentation stage.

- Each already-augmented batch is processed twice, amortizing the measured upstream work; the repeated pass introduces no fresh augmentation
- Effective throughput: 10,100 images/s, the accelerator's full rate, because an echo factor above the ratio leaves the accelerator no time waiting
- Unique images per second: 5,250 images/s (unchanged)
- Training time: $90 \times 1.28\text{M}$ / 10,100 images/s = 11,416 seconds (3.2 hours) if echoed data is equally valuable

Trade-off: Repeated samples are not guaranteed to be as useful as fresh samples; the data echoing paper evaluates echo factor, insertion point, and shuffling because those choices determine whether reuse preserves predictive performance. In one network-fed ResNet-50/ImageNet configuration, Choi et al. (2019) reports a 3.25× reduction in wall-clock time to the target metric.

Systems insight: Data echoing can trade sample diversity for accelerator utilization when the input pipeline is the bottleneck. For the training chapter's input-bound ResNet-50, overlap alone left the accelerator about half idle; an echo factor of 2 closes that gap without adding host cores. The useful echo factor must be measured for the workload because it depends on the batch size, insertion point, augmentation, shuffling, and target metric.

Echoing can introduce correlations when the same example appears within or across nearby batches, so implementations must preserve adequate shuffling and validate the target metric. Choi et al. (2019) did not observe a negative batch-normalization interaction in their ResNet-50 or Single Shot MultiBox Detector (SSD) experiments, but that result does not guarantee the same behavior for every workload.

These implementation patterns determine whether data selection yields net systems throughput. Proxy selection curtails probe compute when scoring rankings transfer to target architectures. Sharded file formats and shuffle buffers reconcile pseudo-random batch creation with hardware-level sequential streaming, while data echoing recovers stalled accelerator cycles when ingestion throughput limits the training loop. They still leave a coordination question when several accelerator workers share one host: each worker scores or trains on its own shard, yet the selected indices and scoring checkpoint must still describe one coherent dataset, because shared storage and host memory do not automatically make each worker's local view representative of the corpus.

9.7.4 Selection across multiple accelerators

When parallel worker processes divide a dataset into local shards across two to eight accelerators on one host, each worker sees only a fraction of the corpus and may score its shard with a slightly different model checkpoint. Without cross-worker coordination, shard-local coreset rankings miss rare global classes, independent hash tables fail to catch duplicates split across workers, and asynchronous active-learning workers select samples using stale uncertainty scores. While a single-process pipeline sorts one global ranking, follows one curriculum schedule, and queries one shared candidate pool, a multi-accelerator pipeline must reconstruct a representative global subset from local shard views while all workers contend for the same host memory capacity, storage bandwidth, and host-to-device links.

Whether distributed selection stays faithful to the global dataset or collapses into local shard heuristics depends on how much cross-worker coordination each technique requires against the bandwidth available to sustain it. On one host, score gathering and index dispatch compete for CPU time and memory bandwidth with decoding and batch preparation. Evaluating selection therefore requires analyzing statistical fidelity alongside these shared resources.

These are independent requirements. A coreset can remain representative yet cost too much to coordinate, while a cheap shard-local method can scale but systematically miss rare groups visible only in the global corpus. A distributed design therefore needs two acceptance tests: compare selected-data quality with a centralized or otherwise auditable reference, and compare selection overhead with the end-to-end training time it saves. Passing only one test is insufficient.

9.7.4.1 Strategies for distributed selection

In a basic data-parallel layout, each worker processes a distinct shard and model synchronization is handled separately. Data selection can add dependencies across those shards (table 9.9).

Table 9.9: Selection Dependencies in Distributed Training: The table starts from a common centralized formulation of each technique and identifies the coordination problem introduced by sharding. Distributed variants may relax rather than reproduce the centralized result exactly.

Technique	Single-Process Assumption	Distributed Challenge
Coreset Selection	Global view of dataset	Each worker sees only its shard
Active Learning	Centralized uncertainty scoring	Scoring requires model synchronization
Curriculum Learning	Global difficulty ordering	Workers may have different "hardest" samples

Technique	Single-Process Assumption	Distributed Challenge
Deduplication	One shared duplicate map	Shard-local hashes miss cross-shard duplicates

The selection dependencies admit two broad architectures, each at a different point in the trade-off between consistency and scalability. Centralized selection keeps selection global while training stays distributed. A coordinator process scores the full dataset and dispatches the selected indices to the workers, which preserves selection quality but makes the coordinator a single bottleneck that can serialize scoring or index dispatch. Whether that overhead is acceptable depends on the selection payload, refresh rate, worker count, and copies through shared host memory, and adding accelerator workers does not increase the host memory available to the coordinator. Hierarchical selection distributes the selection computation itself. Each worker selects candidates from its own shard, and the coordinator merges and reranks them before dispatching the final indices (figure 9.11). Shard-local selection reduces coordinator load but introduces a quality trade-off, because local quotas and score distributions may not preserve the global ranking or rare groups spread unevenly across shards. The merge step therefore needs normalization, coverage constraints, or a second global pass.

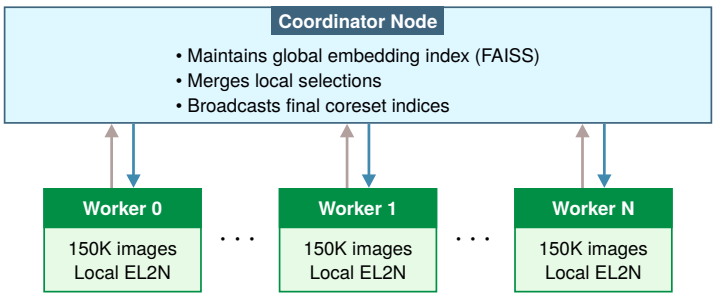


Figure 9.11: Distributed Coreset Selection Architecture: Parallel shard-local scoring reduces the work assigned to a centralized rank-merging coordinator. Workers send local EL2N scores upward; the coordinator merges them and broadcasts final coreset indices. All boxes are processes on one host; the coordinator is a selection role, and each worker drives one accelerator. The design is beneficial only when this coordination overhead remains below the training time saved by the coreset.

Shard locality affects training as well as selection. Each worker maintains an independent shuffle buffer over a non-overlapping shard, and because randomization is local to each worker's memory buffer rather than global across the corpus, rare classes or boundary cases concentrated in specific shards receive uneven exposure across workers unless the dataset is stratified and shards are balanced prior to distribution.

Cross-shard deduplication needs the same global view as hierarchical selection. Workers can compute MinHash signatures locally, but a shared merge must compare candidates across shard boundaries. Independent local hash tables cannot detect a duplicate whose counterpart belongs to another worker. The merge must fit the host's memory budget or operate in bounded batches, rather than assuming that more workers supply more host capacity.

9.7.4.2 Consistency challenges in active learning

Shard-local selection already needs a coherent score scale, but active learning introduces an additional complication because the model changes during selection. Consider what happens when Worker A scores samples using the model at step t while Worker B simultaneously updates the model to step $t+1$. Worker A's scores are now stale and may select samples that the updated model would rank differently.

The scoring schedule therefore defines the meaning of a query, not merely its cost. A reproducible system versions the model checkpoint, candidate-pool snapshot, scoring rule, and selected indices together. It can then measure how much ranking agreement decays with checkpoint age and choose a refresh interval from that evidence rather than from an arbitrary number of steps.

Several strategies mitigate this staleness problem, each with distinct overhead characteristics:

- **Synchronous scoring**: All workers pause training and score simultaneously, guaranteeing consistency but at substantial cost in accelerator utilization.
- **Periodic score refresh**: Workers re-score every k_{refresh} epochs rather than every batch, trading freshness for reduced overhead.
- **Checkpoint-robust selection**: The system selects samples that show high uncertainty under multiple model checkpoints, favoring decisions that are less sensitive to checkpoint choice. Agreement across past checkpoints is a robustness heuristic; ranking quality still needs validation as the model evolves.

Positive ROI can erode quickly when workers coordinate frequently during training. Selection across workers adds coordination overhead whose size depends on what is synchronized and how often. That overhead must remain smaller than the training time saved, and when it approaches that limit, a simpler strategy or a longer refresh interval restores the margin.

The communication path adds a further constraint. Gradient synchronization may use accelerator collectives over local interconnects, while embedding vectors, score arrays, and coreset indices may pass through host memory and CPU dispatch. Selection can therefore expose host-memory, PCIe, storage, or process-synchronization bottlenecks that the training profile alone does not reveal. Extending the design to independent machines adds network topology and remote-storage constraints; those are a further scaling problem beyond the one-host design developed here.

Operational feasibility, however, does not guarantee economic viability. A deduplication pipeline that costs more to build than one training run saves loses money on a single run and pays off only if enough runs reuse it. Deploying selection techniques therefore requires financial accounting of capital, compute, and human annotation budgets.

9.8 Choosing a Selection Strategy

The hospital team in notebook 9.3 could not label every scan, because doing so would have cost $5,000,000, 10× over its budget. Allocating capital between human annotation and accelerator compute is a primary systems decision, and a team under a fixed budget must determine whether the next dollar buys more downstream accuracy as specialist annotations or as additional accelerator hours. A cost model settles the question, and the choice among levers follows from it in four steps: the total cost of data, the break-even point of a selection pipeline, the amortization of one-time investments across the runs that share them, and a decision process worked on the ResNet-50 vision team of section 9.2.6.

9.8.1 Data costs and return on investment

Budgeting a training project from cloud GPU and object-storage invoices alone misses the licensing and human annotation bills that often dwarf compute cost. The **total cost of training data** spans acquisition, labeling, storage retention, and accelerator compute across the full data lifecycle:

$$C_{\text{total}} = C_{\text{acquire}} + C_{\text{label}} + C_{\text{store}} + C_{\text{process}}$$

Labeling (C_{label}) represents the expenditure that data selection targets most directly, whereas storage (C_{store}) and processing (C_{process}) scale mechanically with retained byte volume and the number of accelerator passes. Table 9.10 itemizes these four cost components alongside their operational drivers.

Table 9.10: Total Cost of Training Data: The four cost components span the full data lifecycle. Here D is the total sample count, D_{labeled} is the labeled subset, $D_{\text{vol,store}}$ is stored byte volume, T_{months} is retention time, N_{epochs} is the number of training passes, and O_{sample} is per-sample training work. The ranges are scenario anchors rather than universal market prices.

Component	Formula	Illustrative Range
$C_{\textbf{acquire}}$	$D \times c_{\text{sample}}$	\$0.001–\$10/sample (web scrape vs. licensed)
$C_{\textbf{label}}$	$D_{\text{labeled}} \times c_{\text{label}}$	\$0.01–\$200/sample (crowd vs. expert)
$C_{\textbf{store}}$	$D_{\text{vol,store}} \times c_{\text{storage}} \times T_{\text{months}}$	\$0.02–\$0.10/GB/month
$C_{\textbf{process}}$	$D \times N_{\text{epochs}} \times O_{\text{sample}} \times c_{\text{FLOP}}$	Proportional to training FLOPs

The interplay of these four cost terms becomes concrete when evaluating an ImageNet-scale vision model training run. Calculating each term explicitly shows how easily data acquisition and human labeling outspend the accelerator hours needed to fit the weights.

Napkin Math 9.6: Cost breakdown: ImageNet-scale training

Table 9.11 itemizes one illustrative acquisition, labeling, storage, and compute scenario at ImageNet scale. The resulting ratio follows from the stated licensing, annotation, storage, runtime, and compute-cost assumptions; it is not a typical ratio for every supervised workload.

Table 9.11: Illustrative ImageNet-Scale Cost Breakdown: Itemized acquisition, labeling, storage, and compute costs under the stated scenario assumptions. Each amount follows from the rate shown beside it, using the book's published crowd-labeling, object-storage, and cloud-GPU rates. Data costs dominate this particular calculation because licensing and annotation are included while the training run itself is short.

Cost Component	Calculation	Amount
Raw data (1.2M images)	Licensed dataset, flat fee	$50,000
Labels (crowd annotation)	1.2M × $0.05/label	$60,000
Storage (cloud object store)	150 GB × $0.02/GB/month × 12 months	$36
Training campaign (30 runs, each 100 epochs in 3.5 h on 1 H100)	105 GPU-hours × $4/GPU-hour	$421
Total		**$110,457**
Data vs. Compute ratio		99.6% data, 0.4% compute

Systems insight: Acquisition and labeling can dwarf compute cost in supervised vision workloads, as they do under these assumptions. The compute figure covers the whole training campaign at the compute-bound rate of notebook 9.4, not one run: a published model is the survivor of sweeps, restarts, and ablations, and costing a single run would understate compute roughly thirtyfold. Even so, acquisition and labeling remain the larger share. The run count is an assumption like any other, so a complete ROI calculation must state it and count both categories rather than assuming which one dominates.

Data selection techniques insert algorithmic filtering into the training pipeline to reduce downstream costs. Scoring consumes accelerator cycles, generates host-device memory traffic, or requires custom pipeline stages, so a strategy is justified only if the downstream savings exceed these overheads. Return on investment (ROI), the savings net of the investment per unit invested, makes that test explicit. Because a selection investment is often reused across a training campaign, the general form counts the N_{runs} runs that share it, the **amortized ROI**:

$$\text{Amortized ROI} = \frac{N_{\text{runs}} \times \text{Per-Run Savings} - \text{One-Time Investment}}{\text{One-Time Investment}} \times 100\% \tag{9.3}$$

A single run sets $N_{\text{runs}} = 1$ and recovers the ordinary ratio of savings minus investment to investment, whereas the balance between investment and savings varies across selection strategies. Table 9.12 maps the primary cost drivers and benefit mechanisms across four standard techniques; their net return depends on corpus volume, model scale, and existing pipeline infrastructure.

Table 9.12: ROI Profiles for Data Selection Techniques: The table identifies costs and possible savings. No technique guarantees positive ROI. A training-time claim must satisfy the selection inequality; labeling savings or reusable data investments require their corresponding total-cost comparison at target quality.

Technique	Investment (Cost)	Savings (Benefit)
Deduplication	One-time compute for hashing + infrastructure	Reduced storage and repeated-sample processing
Coreset Selection	Proxy model training + selection compute	Fewer retained samples if target quality and coverage hold

Technique	Investment (Cost)	Savings (Benefit)
Active Learning	Inference on unlabeled pool + human-in-the-loop latency	Lower labeling demand when query selection transfers
Data Augmentation	CPU/GPU cycles for transforms	Effective dataset size increase without new data acquisition

The profiles in table 9.12 compare those costs directly. Deduplication requires an upfront investment in hashing or embedding infrastructure, but can pay off across many epochs and runs by eliminating redundant storage and compute. Coreset selection demands training a proxy model to score the dataset; it only breaks even if the compute saved by dropping samples exceeds the cost of that proxy training. Active learning shifts the cost from human labelers to machine inference, generating high ROI when human time is expensive, though it introduces human-in-the-loop latency that can stall automated pipelines. Finally, data augmentation requires zero new data acquisition but shifts the burden to the CPU or GPU, trading compute cycles for effective dataset expansion. Each technique is worth adopting only when its savings exceed what it costs to set up and run, which makes locating that exact crossover threshold the next step.

9.8.2 Break-even analysis

If candidate scoring is computationally heavy or the unlabeled pool is massive, a selection policy can spend more money scoring candidates than it saves on omitted labels or training steps. The **break-even point** marks the operating boundary where the financial savings from omitted samples exactly equal the computational and operational overhead of selecting them.

Suppose labeling costs \$10/sample, active learning starts from 1,000 labeled samples (\$10,000), issues 100 queries per round at \$50 inference cost (the expense of scoring the candidate pool U with the active model), and the random-labeling baseline requires 5,000 samples for target accuracy. If active learning reaches target accuracy with only 2,000 labeled samples, the following comparison reports net savings relative to the stated labels-plus-scoring cost. This calculation includes labels and pool scoring only, assumes both methods reach the same target accuracy, and excludes retraining, engineering, storage, and annotation-delay costs. It reports net savings per dollar of that stated active-learning budget, using a different denominator from the investment ROI of equation 9.3:

$$\text{Random labeling cost} = 5{,}000 \times \$10/\text{sample} = \$50{,}000$$

$$\text{Active learning cost} = 2{,}000 \times \$10/\text{sample} + 10 \text{ rounds} \times \$50 = \$20{,}500$$

$$\text{ROI} = \frac{\$50{,}000 - \$20{,}500}{\$20{,}500} = 143.9\%$$

Within this labels-plus-scoring boundary, break-even occurs when avoided labeling costs equal selection overhead. A complete dollar comparison must also deduct any additional retraining, engineering, storage, and delay-related expense relative to the random-labeling baseline. When an unlabeled candidate pool U contains millions of uncurated examples, repeatedly scoring it across multiple rounds scales scoring cost with $|U| \times c_{\text{infer}}$, meaning an algorithmic reduction in labeled samples can be erased if proxy inference costs are not carefully bounded. When one fixed budget funds both scoring and labeling, every dollar spent scoring the pool is a dollar withdrawn from labels, so practical loops narrow U with metadata or a cheap heuristic before the active model scores it. Even a pipeline that loses money on a single run, however, can cross break-even once its output is reused across an entire training campaign.

9.8.3 Amortization across training runs

Charging the entire engineering and preprocessing bill of a static curation pipeline to a single training run makes a profitable campaign investment look like a net loss. Filters such as MinHash deduplication, exact n-gram indexing, and embedding clustering require substantial upfront engineering and compute to build once, while production model development is inherently iterative: hyperparameter search, architecture sweeps, ablation studies, and seed checks repeatedly train on the same curated corpus. The amortized ROI of equation 9.3 therefore spreads that upfront curation

investment across every run in the campaign, as table 9.13 itemizes for an illustrative MinHash deduplication pipeline.

Table 9.13: Deduplication Infrastructure Cost Components: The one-time investment covers engineering effort and initial compute; the per-run savings accrue with every subsequent training run on the deduplicated data.

Component	Cost
Build deduplication pipeline	$50,000 (engineering time)
Compute MinHash signatures (one-time)	$5,000
Per-run savings	$10,000/run

Because the initial infrastructure and signature-generation costs are fixed, each subsequent training run compounds the net financial return. Three operational factors govern whether curation infrastructure reaches break-even:

- **Repeated training runs**: Hyperparameter search, model iterations, and scheduled retraining reuse the same selection infrastructure many times.
- **Shared datasets**: A cleaned or deduplicated corpus can support multiple teams or model architectures.
- **Broadly reusable techniques**: Methods such as deduplication transfer across models, whereas task-specific coresets may not.

Table 9.14 tracks how amortized return scales with campaign run count under these cost parameters. A pipeline that loses money on a one-off experiment crosses break-even within a handful of retraining cycles and compounds its savings across larger campaigns.

Table 9.14: Amortized ROI over Multiple Training Runs: Under this scenario's costs and savings, a deduplication pipeline that loses money on its first use becomes profitable when reused across enough runs. Infrastructure investments should be evaluated over their expected lifetime rather than from one use.

Number of Runs	Amortized ROI
1 run	-81.8% (net loss)
5 runs	-9.1% (near break-even)
10 runs	+81.8% (positive)
50 runs	+809.1% (highly profitable)

Deduplication achieves high investment leverage because eliminating redundant sequences reduces host-storage footprint and avoids wasted gradient updates across every downstream architecture. Sample-selection methods conditioned on proxy gradients or uncertainty scores transfer within a model family or between related architectures, but their rankings must be revalidated when the target model, task, or data changes, which narrows their amortization window relative to deduplication. For exploratory or one-off training runs, low-overhead methods like uniform random sampling or basic augmentation may offer better ROI. A static scoring pass can still pay for itself in one run if its measured savings exceed its cost at target quality.

Checkpoint 9.3: Accepting a data intervention

A smaller training pool is one observation in the acceptance decision. Connect the measurements to the constraint the intervention was meant to relieve.

- ☐ **Time savings**: Identify the scoring, coordination, and training times needed to compare a selected subset with full-data training at the same target quality.
- ☐ **Cost objective**: Explain how an active-learning pipeline could reduce total expenditure even if it takes longer to train, and identify the costs that must enter that comparison.

□ **Coverage**: Decide whether unchanged aggregate accuracy is sufficient when a deployment-critical rare slice regresses, and name the additional validation evidence needed. For the disjoint-class allocation in section 9.3.4, explain why reducing K below $a + b$ requires revising the selection plan before training, even if every remaining example has a high score.

With time, labeling, and amortized costs expressed in one accounting, every technique in the chapter can now be weighed against the claim it makes. A training-time saving must satisfy the selection inequality, a labeling saving must beat the random-labeling baseline after scoring and any other differing costs, and a reusable investment must recover its one-time cost across the runs or tasks that share it. Costing each technique separately, however, does not say which one to reach for first when several of them compete for the same budget.

9.8.4 Decision process

When labeling budget, redundancy, rare classes, privacy, and convergence speed conflict, systems engineering requires identifying the primary binding constraint. Table 9.15 collects the three levers with order-of-magnitude ranges drawn from scenarios like those worked in this chapter; each must reduce the cost it targets after counting its overhead and preserving target quality and required coverage. Self-supervised pretraining, which changes the training signal rather than the sample set, enters the decision through the labeling-cost branch of the tree that follows.

Table 9.15: Three-Stage Data Selection Pipeline: The ranges illustrate possible outcomes rather than portable expectations. Actual gains depend on the dataset, model, selection method, and target metric.

Stage	When Applied	Techniques	Order-of-Magnitude Scenario Range
Static pruning	Before training	Coreset Selection, Deduplication, Quality Filtering	30–50% dataset reduction
Dynamic selection	During training	Curriculum Learning, Active Learning, Semi-Supervised	10–30% faster curricula; 2–100× fewer labels
Synthetic generation	On-demand	Augmentation, Generative Models, Distillation	2–10× effective data expansion

Once the dominant constraint is named, it points to a candidate technique, and the five lighthouse workloads, each bound by a different resource, show the pairing in practice. Privacy carries a condition of its own. When privacy requirements limit direct use of real records, privacy-audited synthesis can reduce that use, provided the synthetic data is checked for leakage of the records it was derived from.

Lighthouse 9.1: Lighthouse data selection

Data selection principles apply to all five lighthouse models, though the dominant constraint determines the technique. Table 9.16 maps each workload to a priority. Compute-bound ResNet-50 training benefits from coreset selection, while GPT-2 XL training relies on deduplication and quality filtering to cut the raw tokens it must process. MobileNetV2 is compute-bound in its efficient regime, and its binding deployment constraints, latency and power, apply at inference, where no choice of training data changes the cost of a prediction. The data lever that matters is therefore the one that helps a small model generalize, augmentation matched to its capacity (compact networks underfit under distortion that a large model absorbs), and the work is validating that the augmentation preserves the invariances the deployment environment requires. DLRM, the capacity-bound lighthouse, spends much of its terabyte-scale embedding capacity on cold IDs that appear rarely in training data. It uses interaction deduplication to cut redundant examples and embedding pruning to shrink those tables, but removing repeated interactions shrinks a table only when IDs disappear or the allocation, hashing, or sharing

policy changes. Finally, keyword spotting, the power-bound lighthouse, is bound for data selection by a scarce, costly seed set as much as by its power and memory budget, and it overcomes that scarcity by using augmentation and synthesis to build robust datasets from minimal seed samples.

Table 9.16: Data Selection Priorities by Lighthouse: Primary bottleneck and candidate data-selection priority for each lighthouse workload. The pairing suggests a hypothesis to test; the dominant resource constraint alone does not guarantee that a technique pays off.

Lighthouse	Primary Bottleneck	Data Selection Priority
ResNet-50	Compute	Coreset selection directly reduces training FLOPs
GPT-2 XL	Training compute (tokens × FLOPs/token)	Deduplication and quality filtering cut tokens processed; curriculum may improve token efficiency
MobileNetV2	Latency/Power	Validate augmentation against the target model and deployment invariances
DLRM	Memory capacity	Interaction deduplication cuts examples; embedding pruning shrinks tables only when cold IDs are dropped or rehashed
Keyword Spotting	Data scarcity (small seed set)	Augmentation and synthesis create datasets from minimal seeds

Across these workloads, data selection functions as a systems optimization tailored to relieve whichever physical resource binds the pipeline.

The lighthouse mapping assumes a single dominant constraint, but real projects face several at once. The triage flowchart in figure 9.12 therefore routes candidate strategies hierarchically from the root bottleneck (labeling expense, compute limits, or data scarcity) through operational checks on oracle availability, dataset redundancy, teacher or simulator support, and unlabeled-pool size to isolate actionable techniques.

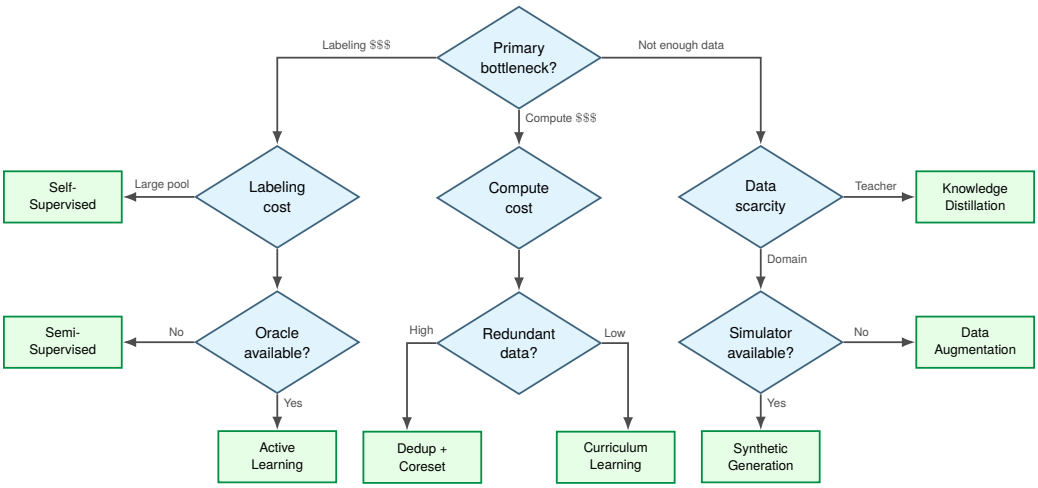

Figure 9.12: Data Selection Decision Tree: The tree begins with the primary bottleneck (labeling cost, compute cost, or data scarcity) and narrows each branch using available pools, oracles, redundancy, teachers, or simulators. Its leaves identify candidate techniques; projects with multiple binding constraints may require more than one branch.

The tree identifies candidates; an engineering decision must still test their cost and quality. The vision workload in example 9.2 provides a concrete comparison. Its target-model and proxy scorers retain the same fraction of data, but they need not retain the same examples. A cheaper ranking can therefore win the time comparison and lose the deployment-quality comparison.

Step 1: Assess the bottleneck

The vision team's stated objective is shorter training turnaround at the existing quality target. The full-data baseline takes 211 minutes, and both candidates retain 10 percent of the images. This places the decision in the compute-cost branch. The retained fraction alone does not settle it; the selection inequality and the slice-coverage check do.

A different binding constraint would change the comparison. If labels were the limiting expense, fewer annotations could justify additional training time. If controlled sweeps instead diagnosed a shortage of useful tokens, the data-scarcity branch would be relevant even with idle accelerators. Naming the objective determines which saving the candidate must actually deliver.

Step 2: Check prerequisites

Both vision candidates require access to the full image pool, a scoring model, and stable sample indices. The proxy additionally needs a ranking that transfers to the target model; its lower execution cost does not establish that prerequisite. Table 9.17 places these requirements alongside those of the alternative branches.

Table 9.17: Technique Prerequisites: Each technique carries specific infrastructure and data requirements that must be verified before implementation. A technique with excellent theoretical gains but unmet prerequisites will fail in practice, making this checklist the first step in technique selection.

Technique	Prerequisites
Active Learning	Access to oracle, unlabeled pool, retraining infrastructure
Coreset selection	Proxy model or embedding extractor, full dataset accessible
Curriculum Learning	Difficulty scoring method, pacing schedule
Semi-Supervised	Some labeled data, unlabeled data from same distribution
Self-Supervised	Large unlabeled corpus, pretraining compute budget
Augmentation	Domain knowledge of invariances, augmentation library
Synthetic Generation	Generative model or simulator, domain gap mitigation

Step 3: Estimate ROI

For the stated vision scenario, target-model scoring plus subset training takes 21.8 minutes (Option A), while proxy scoring plus subset training takes 21.4 minutes (Option B). These figures evaluate the marginal scoring pass using existing checkpoints. Both options beat the full-data baseline in the cost model. The proxy reduces only the scoring term; the retained training work is identical.

Suppose pilot validation in this hypothetical decision confirms that both runs reach the aggregate target under the modeled schedule, but only Option A meets every deployment-critical slice threshold. Option B regresses on a rare class. Option A is then the acceptable choice despite its more expensive scoring pass, saving 188.8 minutes against the baseline. Option B remains a candidate for repair, not deployment: enforce the coverage floor from section 9.3.4, rescore or enlarge the subset as needed, and repeat the time-to-quality comparison. Additional examples or passes change its cost, so the original proxy saving cannot simply be carried forward. If both candidates passed all quality gates at the stated times, Option B would win this time comparison.

A time saving must still justify any engineering investment. If the proxy checkpoint does not already exist and its training is charged entirely to a single run, that preparatory training erases Option B's modest time advantage over Option A. Section 9.8.1 accounts for that investment, and section 9.8.3 spreads one-time costs across the N_{runs} planned experiments. Reusing the proxy is economically useful only while its ranking continues to pass the same quality checks.

Step 4: Combine techniques

Data selection techniques are not mutually exclusive, but combining them does not guarantee additive gains. A representative workflow deduplicates the raw corpus, applies a coverage-aware coreset filter, orders retained batches through an empirical curriculum, and applies runtime augmentations during batch collation. Pretrained representations alter the baseline trajectory further. Every additional stage must justify its compute overhead, because cascading filters frequently discard overlapping subsets while their scoring latencies accumulate; stages compound efficiency gains only

when their effects do not overlap and their overhead remains small, so combined savings must be measured rather than assumed.

A choice made at the data layer does not stay there. This decision process weighs a technique by its own scoring cost and the training work it removes, but a smaller or reordered corpus also changes what the model learns to represent, and the compression and deployment stages downstream inherit that representation. A selection that looks optimal in isolation can therefore move cost into those later stages, so the chosen strategy must be checked against the layers it feeds.

9.9 Cross-Layer Interactions

Halving a training corpus halves the forward and backward passes, yet the resulting model may be no cheaper to compress or serve. Real ML systems combine data selection with model compression and hardware acceleration, and these cross-layer interactions amplify or undermine each other in ways no single layer reveals.

Model compression (post-training weight pruning, lower-precision representation, and distillation) acts on the trained network, and its arithmetic reductions reach serving latency only when the target execution substrate and runtime kernels support the resulting sparsity or precision patterns (Hoefler et al. 2021). The training corpus shapes the representations that compression later works on. A model trained on an uncurated, repetitive corpus can spend capacity on redundant features that post-training pruning then discards, whereas a curated corpus of diverse, informative examples can yield more compact representations from the start. That effect is an empirical hypothesis to verify, not a property of every selected dataset. The two levers therefore compose without substituting for each other. Data selection reduces training work and shapes learned representations, model compression shrinks the deployment artifact, and their combined impact is measured on serving latency and task accuracy rather than inferred from the upstream dataset reduction.

↪ Why accelerators turn structured sparsity patterns into wall-clock speedup while unstructured sparsity rarely pays off is developed in section 11.4.5.3.

↪ Co-designing post-training pruning and quantization under the silicon contract is developed in section 10.1.

Production deployments execute these techniques as one pipeline in two stages: data selection and training turn raw inputs into a trained model, and post-training compression and hardware acceleration then deploy that artifact (figure 9.13). Every stage along this end-to-end path amplifies or attenuates downstream efficiency.

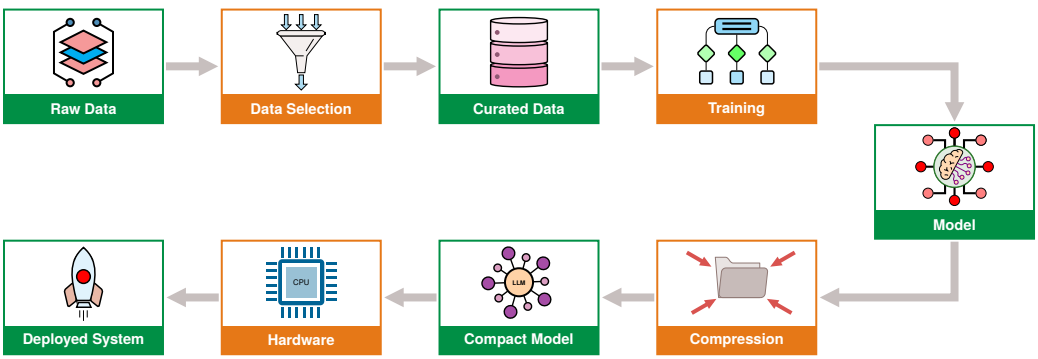

Figure 9.13: The Optimization Stack: Data artifacts flow through selection and training before the resulting model enters compression and deployment. Upstream changes propagate quality and cost effects downstream, but reducing training data does not automatically simplify the model or deployment hardware.

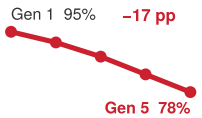
Tracing artifacts through the pipeline in figure 9.13 shows why data selection sits at the head of the optimization stack: pruning raw inputs reduces upstream training FLOPs, but does not automatically shrink parameter footprint, improve quantization headroom, or relax serving latency constraints in the downstream compression and hardware stages. Each downstream tier inherits both the computational savings and any representational deficits created upstream; an aggressive filter that discards rare but critical edge cases can force downstream engineers to train longer or abandon aggressive quantization to preserve task accuracy. The failure modes that follow show how data selection breaks down in production.

9.10 Fallacies and Pitfalls



Scaling a training corpus tenfold can multiply storage, I/O, and accelerator bills while barely moving test accuracy, yet an uncalibrated selection filter can just as easily spend more time scoring candidates than it saves in training or silently erase a safety-critical rare class. These failures fall into three groups: conceptual fallacies about what data selection can achieve, implementation pitfalls that arise when correct strategies meet systems bottlenecks, and transfer errors that occur when benchmark results are applied uncritically to new domains.

Fallacy: *More data always improves the model enough to justify its cost.*

More data does not imply proportional accuracy gains because learning curves follow power-law diminishing returns. Test loss diminishes sub-linearly with dataset size ($\mathcal{L}(D) \propto D^{-\beta}$ for a fitted exponent β), meaning each successive error reduction demands a multiplicatively larger corpus. In an illustrative learning-curve scenario, scaling a dataset tenfold from 1M to 10M samples yields only 4 percentage points of accuracy gain. That $10\times$ volume expansion still costs a tenfold increase in storage I/O, host-to-device transfers, and accelerator FLOPs. Teams should measure the learning curve of their own workload rather than assume that more data delivers proportional value.

Pitfall: *Replacing real-data validation with synthetic-only training data.*

Synthetic samples cost almost nothing to acquire, so generative models can look like a replacement for data collection. Synthetic-only training fails in two ways. First, synthetic data can differ from the deployment distribution (section 9.5.3, figure 9.8), so the model learns features that fail to transfer; only real-data labels reveal the effect. Second, recursive training on model-generated data can trigger model collapse (Shumailov et al. 2024), which progressively erodes distribution tails: in this scenario, evaluation accuracy degrades from 95 percent to 78 percent across five recursive generations, suffering a 17 percentage-point collapse. Synthetic mixtures must therefore be validated against curated real data.

Illustrative model collapse: accuracy erodes with each recursive synthetic generation.

Fallacy: *Data selection is merely data cleaning.*

A dataset can be completely clean and correctly labeled yet redundant: once the model has minimized loss on a feature cluster, further identical samples add almost no gradient signal and still consume memory bandwidth and accelerator FLOPs. Cleaning corrects intrinsic defects; selection raises the learning return per FLOP by choosing examples for task-relevant information and coverage (figure 9.5; section 9.3.4). In the worked coreset scenario of notebook 9.1, the selected subset reached 1.8× higher ICR.

Pitfall: *Treating data selection as a budget-only tactic.*

Selection can look like a technique for resource-constrained teams, as if frontier foundation models could brute-force convergence by scaling the cluster. The data wall binds at every scale. At frontier scale, token consumption converges toward the finite ceiling of high-quality human text (figure 4.6); at GPT-2 scale, one eight-H100 machine passes over the whole WebText corpus about 17 times in 4.4 days (section 9.1). The economic return of selection also scales with cluster expenditure: a 10 percent efficiency gain on a $100M frontier training run saves $10M under these assumptions. Amortizing scores and cached embeddings across repeated runs (section 9.8.3) strengthens the case further.

Fallacy: *Selection overhead is too small to change training economics.*

The selection inequality (equation 9.2) requires $T_{\text{selection}} + T_{\text{train}}(D_{\text{subset}}) < T_{\text{train}}(D_{\text{total}})$ at matched quality. Consider a baseline training run requiring 8 hours, where training on an optimized coreset takes 2 hours. If a complex selection algorithm requires 10 hours to compute sample importance, the selection step alone consumes 5× the duration of the accelerated training run and exceeds the full training baseline itself, a net wall-clock loss. In the illustrative comparison, proxy-based EL2N scoring completes in 30 minutes, just 6.2 percent of the full-training baseline, which satisfies the inequality.

Pitfall: *Pruning rare classes without a coverage floor.*

Standard selection objectives minimize aggregate loss, which gives tail slices little influence over sampling. In a 1M dataset where rare classes comprise 0.1 percent of the data (1,000 examples), an unstratified 10 percent coreset retains only 100 rare-class examples in expectation, far below the

illustrative 150-sample retention floor assumed here. An appropriate floor must be validated from task-specific learning curves and critical-slice performance. Importance sampling can compensate by weighting losses by inverse selection probabilities, but extreme weights inflate gradient variance and force smaller learning rates. As recommended in section 9.3.4, production coreset pipelines enforce hard stratification floors per class or critical slice before spending the remaining selection budget.

Fallacy: *Deduplicating training data is enough to make evaluation reliable.*

Web-scale pipelines scrape training, validation, and benchmark splits from common crawls, which introduces silent cross-split leakage. When an evaluation set contains near-duplicates of training documents, the metric measures memorization rather than generalization. A deduplication study found that train-test overlap affects over 4 percent of validation examples across standard language-modeling benchmarks (Lee et al. 2022). Deduplicating the training partition alone leaves this contamination untouched; cross-partition deduplication is required, using n-gram matching or MinHash LSH (section 9.3.2). For a frozen evaluation set, the fix removes the overlapping training records and preserves the evaluation set and its provenance.

Pitfall: *Active learning without considering annotation latency.*

Textbook formulations of active learning assume an oracle that labels queries instantly. Production annotation queues introduce delays such as the illustrative 14-day latency between sample dispatch and label return assumed here. This latency breaks the active learning feedback loop in two ways. If accelerator clusters halt training while awaiting labels, expensive hardware sits idle, destroying cluster compute utilization. Conversely, if training continues asynchronously on background data while annotations are pending, model weights drift across training steps; by the time the labels arrive, the uncertainty scores that justified querying those samples are obsolete. Dispatching large batches to amortize the turnaround adds redundancy within the batch unless diversity penalties are applied.

Fallacy: *If a technique works on ImageNet, it will work on my dataset.*

CIFAR-10 and ImageNet are highly redundant across canonical object classes, which allows coreset pruning of often 30 to 50 percent without measurable accuracy loss. Histopathology, satellite imagery, and industrial defect detection have heavy-tailed feature distributions in which safety-critical patterns appear in a few rare samples. A 50 percent cut tuned on ImageNet can remove the few examples that separate subtle pathologies. Geometric coreset algorithms also depend on embeddings, and a feature extractor pretrained on natural images may not resolve fine-grained domain distinctions. Teams should measure the redundancy of their own data and validate retention across critical slices before pruning.

Pitfall: *Optimizing data selection metrics instead of deployment metrics.*

Selection algorithms optimize aggregate surrogates such as area under the learning curve (AULC) or performance-per-data (PPD, section 9.2.4). A selection policy retaining a 10 percent coreset can achieve superior aggregate PPD by prioritizing dense clusters of common, easy samples that accelerate average convergence, while discarding ambiguous edge cases and rare slices. Production failures, however, occur on tail slices, edge cases, and protected sub-populations rather than on averages. A policy without subgroup constraints can pass global validation and still fail in deployment. As the measurement framework of section 9.2 requires, policies must be evaluated on stratified, slice-level benchmarks, even when doing so slightly lowers average PPD.

9.11 Summary

Feeding every available example into a training run wastes accelerator compute, storage bandwidth, and annotation budget on redundant or noisy records because marginal learning signal varies by orders of magnitude across raw samples. Data selection therefore treats training volume as an engineering variable rather than a fixed constraint, minimizing total cost across compute, storage, labeling, energy, and wall-clock time so a curated subset can match or outperform a much larger uncurated corpus.

This systems perspective becomes actionable through three quantitative tools: the ICR, the selection inequality, and the total data cost model. The information-compute ratio quantifies learning gained per floating-point operation, providing a proxy for sample value that must be evaluated alongside coverage and target quality. The selection inequality tests a training-time claim by requiring scoring plus subset training to take less time than full-data training at matched quality. Together with return-on-investment and break-even analysis, these formulations determine whether a proposed selection mechanism saves resources or merely shifts expenditure between stages.

The three levers act at different points: static pruning removes redundancy before training, dynamic selection prioritizes informative examples during training, and synthetic generation creates data where none exists. Together, these levers answer the data wall, the gap between rapidly growing compute capacity and slowly growing high-quality data.

Learning from unlabeled data sits beside these levers rather than within them. Semi-supervised learning stretches a small labeled seed across an unlabeled pool, and self-supervised pretraining moves the bulk of representation learning into an unannotated upstream phase, so downstream tasks can reach target quality with far fewer task-specific labels; the worked amortization scenario assumes 100× fewer. The compute-only crossover occurs at roughly 10.5 tasks under the scenario assumptions. Labeling savings enter a separate dollar comparison that also requires compute prices and other differing costs.

In production, the difficult part is rarely the scoring rule itself. It is keeping selection from becoming the next bottleneck. Proxy models and cached embeddings bound scoring time, shard-based loaders keep storage access sequential, and data echoing recovers accelerator cycles when ingestion lags. On one H100, a half-size ResNet-50 coreset saves about 63 seconds and 44 kJ per epoch against a one-time scoring pass of about 42 seconds, and those seconds are realized only when the host keeps the accelerator fed. Controlled model-size and data sweeps diagnose whether a run is data-limited or compute-limited in the first place, and PPD, AULC, and DCR then show whether a reduction delivered what it promised at the binding resource.

Every row of the opening chapter map (table 9.1) has now been derived, and the formulas behind its tests fit on one page (table 9.18). Together they let an engineer estimate, before committing a training run, whether a lever saves more than it costs.

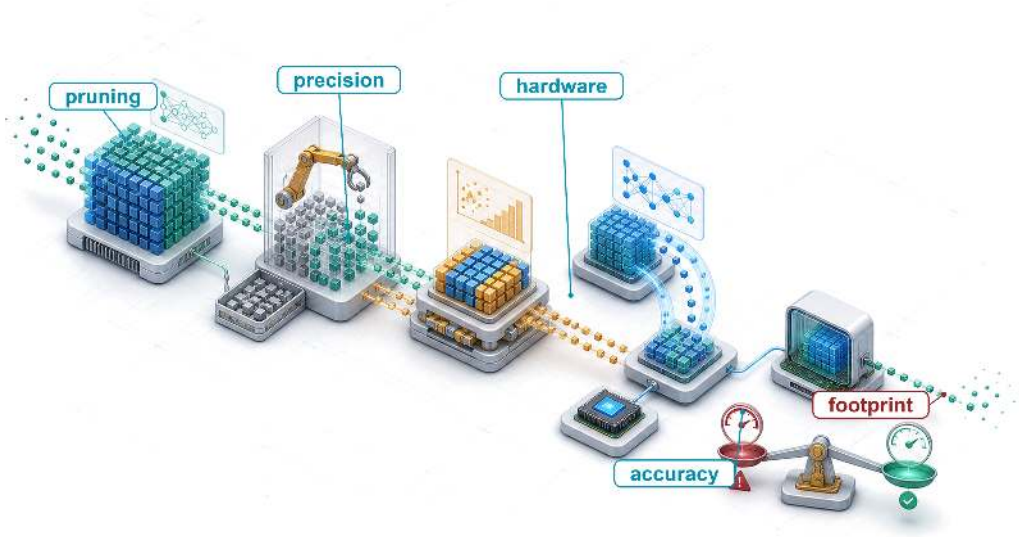
Table 9.18: Key Equations: The chapter's counting rules in the notation of the sections that derive them. The training-compute rule is the dense-transformer accounting of the GPT-2 lighthouse; the curriculum rule assumes linear pacing over N_{warmup} warmup epochs.

Quantity	Formula	Where derived
Information-compute ratio	$\text{ICR} = \Delta\mathcal{I}/\Delta O$	section 9.2.1
Marginal ICR (log-information)	$\text{ICR}(D) \approx 1/(O_{\text{sample}} \cdot D)$	equation 9.1
Training compute	$O \approx 6PD$; compute-optimal tokens $D_{\text{opt}} \propto \sqrt{O}$	section 9.2.3
Performance-per-data	$\text{PPD}(n) = [\text{Accuracy}(n) - \text{Accuracy}(0)]/n$	section 9.2.4
Data compression ratio	$\text{DCR} = D_{\text{total}}/D_{\text{subset}}$ at target accuracy	section 9.2.4
Selection inequality	$T_{\text{selection}} + T_{\text{train}}(D_{\text{subset}}) < T_{\text{train}}(D_{\text{total}})$	equation 9.2
Curriculum warmup samples	$D(N_{\text{warmup}} + 1)/2$ in place of $N_{\text{warmup}} \cdot D$	section 9.4.1
Offline distillation targets	$4K$ bytes per sample in place of $\lceil \log_2 K \rceil$ bits	section 9.5.4
Input-pipeline ratio	$r_{\text{pipe}} = T_{\text{prep}}/T_{\text{GPU}}$; echoing helps up to $e = r_{\text{pipe}}$	section 9.7.3
Total cost of data	$C_{\text{total}} = C_{\text{acquire}} + C_{\text{label}} + C_{\text{store}} + C_{\text{process}}$	section 9.8.1
Amortized return on investment	Savings across N_{runs} runs, less the one-time investment, per unit invested	equation 9.3

Key Takeaways: Curate, do not accumulate

- **Selection optimizes system cost**: The objective is minimizing total cost across compute, storage, labeling, and energy rather than reducing sample counts alone. The information-compute ratio measures learning gained per FLOP spent; total-cost accounting and pipeline measurements establish whether that gain serves the system objective.
- **Start with deduplication**: Exact deduplication is often the lowest-risk first technique because it removes repeated bytes without a learned scoring pass. Apply near-duplicate and semantic deduplication only after validating thresholds against downstream quality metrics.
- **Training-time savings must exceed selection overhead**: At matched quality, $T_{\text{selection}} + T_{\text{train}}(D_{\text{subset}}) < T_{\text{train}}(D_{\text{total}})$. Lightweight proxy models and cached embeddings keep $T_{\text{selection}}$ low, whereas unoptimized selection algorithms can consume all the compute they save.
- **Dynamic selection adapts the training mix**: Curriculum learning changes presentation order, while active learning changes which samples receive labels. Either improves efficiency when its scoring rule, coverage, and refresh overhead are validated.
- **Self-supervised pretraining can amortize adaptation cost**: Pretraining once and fine-tuning many times spreads pretraining cost across downstream tasks. The worked scenario assumes a 100× label reduction and a 20× marginal-compute reduction; realized savings depend on transfer quality and reuse.
- **Synthetic data is a supplement, not a replacement**: Synthetic samples augment scarce tail cases effectively, but cannot substitute entirely for empirical data. Unanchored synthetic training introduces domain-gap degradation, and recursive synthetic loops trigger catastrophic model collapse.
- **Validated workload reduction compounds downstream**: When selection safely eliminates examples or tokens without adding compensating steps, that work never reaches later model or machine optimizations. Dynamic scoring and synthesis add their own costs, so the combined saving must be measured rather than assumed.

Examples differ greatly in how much they teach per byte transferred and per FLOP executed, and selection spends compute on the ones that teach most. Within the D·A·M taxonomy, selection operates at the head of the system: every redundant sample or uninformative token safely eliminated directly reduces operation count (O) in the iron law of ML systems (principle 3) and can avoid downstream training reads. Scoring may still read the entire pool, and shard streaming may read discarded records, so reductions in data volume (D_{vol}) must count scoring and shard-read traffic separately. When selection overhead satisfies the inequality at matched quality, the reduction removes work before downstream compression or hardware acceleration sees it. Model-based scoring offers a way to invest additional compute in selection, consistent with the bitter lesson, but a stronger scorer justifies that investment only if its improved rankings save more downstream work than it costs. The Pareto frontier (principle 5) applies upstream of the model as well. Each retained fraction is an operating point that trades coverage and rare-slice accuracy against compute, and no single fraction is optimal for every workload.



What's Next: From data to algorithms

Data selection changes *what* the system learns from. Chapter 10 turns to *how* the model represents what it has learned. It starts from the deployment envelope the model must fit and adjusts three things to fit it: the model's structure through pruning and distillation, its numerical precision through quantization, and the way the remaining operations map onto the hardware that executes them.

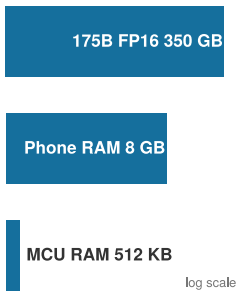
Purpose

Why do the models that win benchmarks rarely become the models that run in production?

A capable trained model is not automatically a deployable one. Cloud, Edge, Mobile, and TinyML environments each impose physical constraints that research benchmarks ignore, including memory budgets measured in megabytes rather than gigabytes, latency targets measured in milliseconds rather than seconds, and power envelopes measured in milliwatts rather than kilowatts. Research optimizes for accuracy on held-out test sets; production optimizes for accuracy per dollar, accuracy per watt, and accuracy per millisecond. Models that win benchmarks are frequently larger, slower, and more resource-intensive than production envelopes permit. Bridging this gap requires a systematic discipline of compression that trades capabilities the deployment does not need for physical constraints it cannot violate. Because many trained models carry more numerical precision, parameters, or representational capacity than the target workload requires, some of that surplus can be removed while preserving predictive behavior, though a smaller representation is not automatically a faster one. Unless the hardware and runtime software stack exploit the new precision or structure, a nominal size reduction merely moves the bottleneck while latency remains unchanged: removing half the weights in a tensor leaves execution time and energy untouched if the underlying hardware still fetches, stores, and multiplies every zero. Applied effectively, compression reduces model size by integer factors, transforming a research artifact that runs only on data center accelerators into a production asset capable of executing on a mobile phone, sensor node, or embedded microcontroller. The engineering goal is to make the right model viable within its physical environment, which differs fundamentally from making a model as small as possible. In D·A·M terms, model compression

enacts algorithm-machine co-design directly on the network, reshaping its mathematical structure to satisfy the physical limits of the target hardware.

Learning Objectives



- Explain compression as algorithm-machine co-design that trades surplus capacity for memory, latency, and energy constraints
- Compare pruning, distillation, and quantization by the resource each relaxes and where each lands on the accuracy-efficiency frontier
- Calculate parameter memory, precision, and sparsity reductions to estimate best-case compression gains
- Apply post-training, quantization-aware, and weight-only strategies under accuracy and hardware constraints
- Select structured pruning and operator choices that map to available accelerator kernels
- Design compression pipelines that order pruning, distillation, and quantization and account for why their combined gains do not multiply
- Evaluate measured latency, energy, and accuracy on target hardware rather than relying on FLOP counts

10.1 Fitting the Deployment Budget

A trained model arrives with demands on memory capacity, latency, and energy that were set by the server accelerators it trained on, not by the device it must run on. The target device instead enforces a strict **deployment budget**: the memory, time, and energy it grants to each result the model produces. Memory capacity bounds the bytes of weights and activations that can stay resident, a frame rate or token rate bounds the milliseconds available for each result, and a battery or thermal envelope bounds the joules that each result may consume. Bringing a model's demands inside that budget, by changing what the model computes, how its values are stored, and how its operations execute, is the work of model compression.

Chapter 9 lowered the cost of producing a trained model by spending training compute only on examples that carry signal. Its savings end where the trained model begins. A model trained on a curated subset has the same parameter count, numerical precision, and memory footprint as one trained on the full corpus, so it can still overflow a phone's memory or leave inference bound by memory bandwidth. Chapter 11 then examines the silicon that executes a model. Compression comes before it because compression decides what that silicon is asked to run: how many operations, how many bytes per value, and which kernels.

The gap is easiest to see at its extreme. A 7-billion-parameter language model requires 14 GB merely to store its weights in FP16. A smartphone offers 8 GB of RAM shared across the operating system, background applications, and the user interface, so even if the operating system surrendered its entire memory pool to one process, the weights would not fit. Fitting in memory would only expose a second limit, the token rate. At batch size one, dense autoregressive decoding is memory-bandwidth bound because generating each token reads every weight from DRAM, and no other request shares those bytes. Over a flagship phone's 51.2 GB/s low-power DDR (LPDDR) bus, streaming 14 GB takes about 270 ms per token and about 2 J of DRAM access energy, so the memory traffic alone would draw about 8 W, above the phone's sustained thermal envelope of 3–5 W. A model of this size is the extreme case; the rest of the chapter works with models that come closer to fitting, where the engineering choices are less obvious.

Frontier weights dwarf phone and microcontroller memory; compression bridges the gap.

Under the silicon contract (principle 4), compute throughput, memory bandwidth, memory capacity, and fixed launch overhead determine which physical resource binds first for a given model on a given machine. Training sets those quantities generously. Server-class accelerators supply the aggregate memory and floating-point throughput that wide layers, high numerical precision, and large auxiliary state require, because training must hold gradients, optimizer moment buffers, and activation caches across backward passes. Inference deployment relaxes several of these demands because execution is forward-only, intermediate activation buffers can be reused after their last consumer, and optimizer states disappear, even though residual branches still extend some tensor lifetimes and autoregressive decoding retains KV state across tokens. While mixed-precision methods improve training throughput by selectively adopting FP16 or BF16, deployment

can reduce precision further, to INT8, INT4, or specialized microformats, when the target's execution units support them. Model compression is the systematic process of meeting the silicon contract of a constrained execution context, reducing parameter footprint, memory traffic, or arithmetic operations while preserving task accuracy.

↩ Mixed-precision training with FP16 and BF16, including loss scaling and FP32 accumulation, is established in section 8.6.3.

Across deployment targets, the disparity in weight memory spans about six orders of magnitude, from the 350 GB of FP16 weights in a 175-billion-parameter frontier model to the 512 KB of on-chip SRAM in an embedded microcontroller. The bitter lesson explains why this gap persists. General methods that scale with compute keep winning benchmarks, so the winning models grow with available training compute while a phone's or microcontroller's memory and power envelope stays fixed for the life of the device. Compression is the deployment-side counterweight to scale.

↩ The bitter lesson, that general methods which scale with compute keep displacing hand-engineered ones, is established in section 1.4.

The record of language models shows how much ground that counterweight can recover. Figure 10.1 follows the smallest dense model reported to score at least 60 percent on the Massive Multitask Language Understanding (MMLU) benchmark (Hendrycks et al. 2020) at each point in time. That size fell from 280 billion parameters for Gopher at the end of 2021 to 3 billion for Qwen2.5-Coder-3B, a code-specialized model, in 2024, about 93× smaller in under three years (Epoch AI 2026a). Better training data, longer training, and distillation from larger models all contributed, so the decline is not compression alone, but it shows that a capability first reached at frontier scale can later fit a far smaller deployment budget.

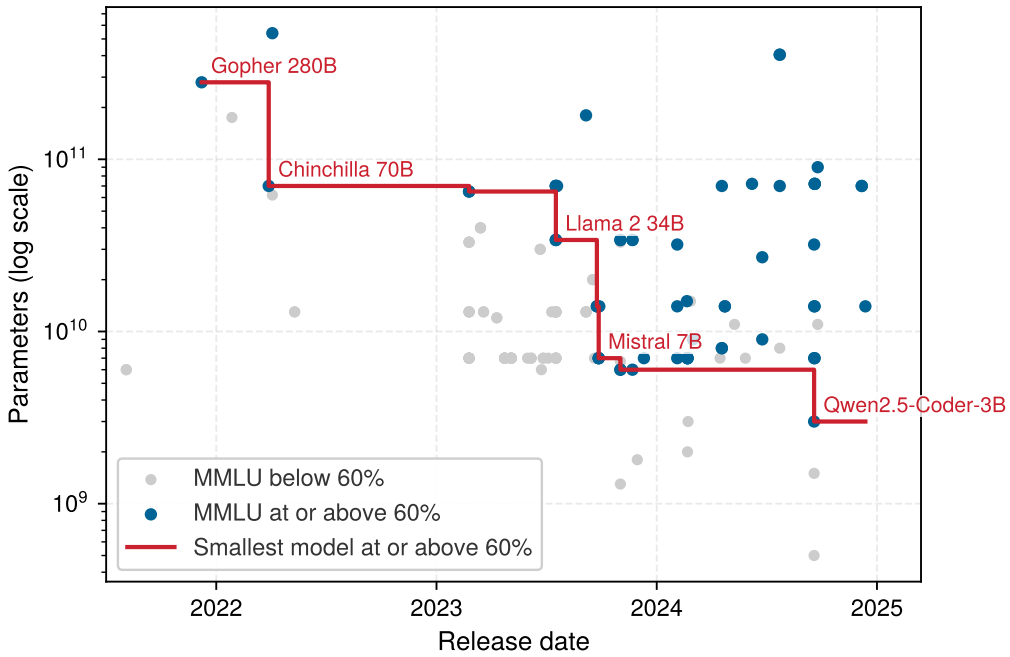


Figure 10.1: Smallest Model Reaching a Fixed Score: Parameter counts of dense language models against release date on a logarithmic axis, with models scoring at least 60 percent on the MMLU benchmark in blue and the rest in gray. The red step line tracks the smallest model at or above that score released up to each date. Scores are as reported by each source, and parameter counts come from model names, so the line is a lower envelope of reported results rather than a controlled comparison. Data from Epoch AI (2026a).

Bridging the gap between frontier models and fixed deployment targets requires an engineering framework with predictable physical trade-offs. Every compression technique removes specific structure from the model, whether unnecessary weights, surplus numerical bits, or redundant operator subgraphs. Designing a production deployment requires identifying which resource binds first on the target platform and analyzing how successive approximations compound across the memory hierarchy. The framework this chapter builds works on three tiers: what the model computes (its structure), how many bits represent each value (its precision), and how the result

executes on the target processor (its implementation). Benefits compound only when transformations relieve distinct binding bottlenecks and the runtime supports the resulting graph.

Definition 10.1: Model compression

Model compression is a family of techniques that reduce a trained model's computational cost and memory footprint by eliminating redundant parameters (pruning), reducing numerical precision (quantization), or transferring learned behavior into a smaller architecture (distillation), while preserving as much predictive accuracy as possible.

1. **Significance**: In the iron law (principle 3), compression targets both the Algorithm factor (FLOPs/Sample, and therefore total operations O) and the Machine factor (Seconds/FLOP, through its physical data-movement and compute terms). INT8 quantization of a 175-billion-parameter LLM leaves FLOPs/Sample unchanged but cuts weight memory from 350 GB (FP16) to 175 GB, a 2× reduction in D_{vol}, while dedicated low-precision matrix units can raise R_{peak} when kernels and layouts use the supported INT8 path. Unstructured pruning to 50 percent sparsity halves the nonzero parameter count, but executed operations fall only when the runtime can skip those zeros through a supported sparse format or kernel without inflating Seconds/FLOP via index-traffic stalls.
2. **Distinction**: Unlike post-training compression methods such as pruning and quantization, neural architecture search discovers efficient architectures from scratch by exploring a design space. Here, NAS is treated as a related structural optimization technique, because it changes the representation before training rather than compressing a finished model post hoc.
3. **Common pitfall**: Compression techniques do not compose without interference. Pruning changes weight distributions and operation patterns; quantization adds calibration and kernel constraints. Their combination can lose accuracy or fail to accelerate without joint validation.

The three tiers form a stack that descends from algorithmic software toward physical silicon, the same direction in which chapter 7 lowered a computational graph to kernels. At the top sits what operations the model executes, in the middle how many bits encode each operand, and at the bottom how kernels map onto the processor's compute and memory structures (figure 10.2).

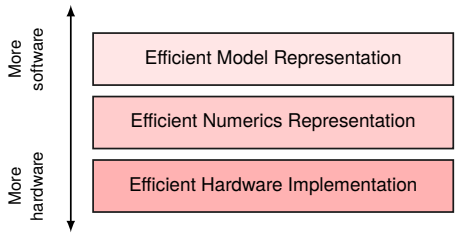

Figure 10.2: Three Tiers of Compression: Model optimization progresses from software-level representation (pruning, distillation, NAS) down through numerical precision (quantization) to hardware execution (kernel fusion, sparsity engines). Lowering abstraction moves optimizations closer to physical silicon, where representation decisions dictate achievable execution efficiency.

Each tier removes a different kind of surplus across the two levels of the iron law. The top tier, efficient model representation, removes structure and lowers the Algorithm factor (FLOPs/Sample). Pruning drops weights or whole channels that contribute little to accuracy, knowledge distillation trains a compact student to match a larger teacher, and neural architecture search (NAS) looks for layer shapes that meet an explicit latency or memory bound. The middle and bottom tiers leave FLOPs/Sample unchanged and instead lower the Machine factor (Seconds/FLOP). In the middle tier, efficient numerics representation removes bits. Quantization maps floating-point values to 8-bit or 4-bit integers, which shrinks weight memory and bus traffic (D_{vol}) by two to four times and lets

integer units execute each operation at higher peak rate (R_{peak}) and lower energy. In the bottom tier, efficient hardware implementation removes wasted execution. Kernel fusion keeps intermediate activations in on-chip memory instead of sending them back to DRAM (shrinking D_{vol}) and reduces launch overhead (L_{lat}), while sparsity pays off only when its zeros follow a pattern the hardware can skip, such as two zeros in every group of four weights, so that cutting FLOPs/Sample does not inflate Seconds/FLOP.

These three tiers are tightly coupled across the compilation and execution boundary. Pruning alters weight distributions and activation profiles, changing the dynamic ranges required for subsequent quantization-range calibration. Quantization reduces data-movement volume across the memory bus, shifting a previously memory-bound workload toward compute-bound execution where kernel fusion and tile scheduling dominate. Achieving compounding performance gains requires co-designing transformations across all three tiers rather than applying them in isolation, a composition strategy that section 10.5.3 develops through a staged pipeline.

Every technique in this chapter answers to the conservation-of-complexity heuristic that opened Part I. Complexity tends to move among the Data, Algorithm, and Machine axes rather than disappear, so engineers must account for where each technique sends cost and risk. It is a heuristic, not a literal conservation law, and removing genuinely avoidable work can reduce total cost. Pruning may reduce parameters while asking the runtime to exploit sparse structure; distillation may reduce inference cost while adding a teacher-student training phase; quantization may reduce data movement while spending numerical precision. The engineer's task is to move complexity to where the cost is lowest given deployment constraints.

Which tier of the optimization stack yields the highest return depends entirely on the physical machine hosting the workload. A data-center server equipped with several high-bandwidth memory (HBM) accelerators tolerates multi-gigabyte models but demands high token throughput under concurrency. A smartphone or an embedded microcontroller operates under severe physical ceilings on memory capacity, bus bandwidth, and thermal dissipation.

10.1.1 Deployment budgets and the running cases

Cloud serving, a phone camera, and an embedded microcontroller each break down on a different term of the deployment budget, so compression begins by asking which term a given model violates and what it costs to stop violating it. Cloud inference centers on throughput (requests per second per dollar), where supported integer quantization paths increase serving density and kernel fusion reduces per-request kernel launch overhead (Choudhary et al. 2020; Dean et al. 2018). Mobile and edge deployments must fit within tight physical memory bounds while meeting deterministic real-time deadlines. A serialized camera pipeline that must finish each frame before the next arrives at 30 frames per second has about 33 ms per frame. A pipelined design that overlaps capture, inference, and display can sustain 30 frames per second even when each frame takes longer than 33 ms end to end, so it must check frame rate and per-frame latency as two separate budgets.

TinyML makes physical fit a deployment requirement. A microcontroller with only a few hundred kilobytes of SRAM and limited model storage *cannot* accommodate a 100 MB model without a compatible placement strategy, regardless of predictive accuracy (Banbury et al. 2020). Persistent weights may reside in flash or other supported storage, while runtime buffers occupy working memory. Without paging, the peak SRAM working set must fit the available SRAM; the model artifact must separately fit its storage budget. Capacity is also a hard bound on mobile and cloud devices, though their placement options differ.

↩ The latency, memory, and power envelopes defining cloud, edge, mobile, and TinyML tiers are established in section 2.1.

Meeting real-time deadlines on commodity mobile hardware depends as much on the hardware-supported precision path as on absolute memory capacity. When execution units provide hardware acceleration exclusively for fixed-point arithmetic, precision selection dictates whether a workload executes on energy-efficient neural processing units or falls back to power-hungry general-purpose cores. That choice decides the chapter's running case, a camera pipeline that must meet an interactive frame rate within a phone's thermal budget (Example 10.1).

Example 10.1: The running case: Real-time blur on a phone

Scenario: A labeled composite. A camera application deploys a MobileNetV2-based segmentation model for real-time background blur on mid-tier smartphones at 30 FPS.

Diagnosis: An uncompressed FP32 MobileNetV2 model runs on the phone's CPU at only 8 FPS, about 125 ms per frame against a 33 ms budget, while holding the CPU at a power level the thermal envelope cannot sustain. The phone's NPU or DSP accelerates integer matrix arithmetic, not FP32, so the uncompressed model cannot use it.

Systems lesson: INT8 quantization cuts raw parameter payload by 4×, but most of the gain from 8 FPS to 35 FPS comes from what INT8 unlocks, a move from the CPU onto the integer accelerator. The precision change is the enabler; the change of processor supplies most of the speed. The frame rates are illustrative, so speed and power still require device measurement.

The chapter follows that camera pipeline through the structural and hardware tiers of the stack. MobileNetV2 is the book's compute-bound lighthouse in its efficient regime. Depthwise separable convolutions keep its arithmetic small, and at batch one on a phone its frame time goes to arithmetic and activation traffic rather than to reading weights. The precision tier needs a workload whose time is set by bytes, so it follows GPT-2 XL decoding on the same phone. GPT-2 XL is the book's bandwidth-bound lighthouse, and every token it generates streams every weight. Two callouts mark the ends of the memory constraint. DLRM (Naumov et al. 2019), the capacity-bound lighthouse, shows precision deciding whether embedding tables fit, and keyword spotting (KWS) (Y. Zhang et al. 2017), the power-bound lighthouse, shows precision deciding whether a model fits a microcontroller's SRAM and energy budget. ResNet-50, the compute-bound lighthouse, serves twice, as the teacher that distills into MobileNetV2 and as the subject of the closing INT8 deployment profile. Rather than running every technique on all five, the chapter returns to each workload where it exposes the binding resource most clearly.

Table 10.1 places the cases' weight bytes and work beside the deployment budget, and two of its rows explain how the chapter divides the work. MobileNetV2's FP32 weights stream across the phone's 51.2 GB/s memory bus in about 0.27 ms, roughly 1 percent of the 33 ms frame budget, so the frame is spent on its 600 MFLOP of arithmetic and on activation traffic, and the structural and execution tiers are the levers that matter. GPT-2 XL's FP16 weights fit in the phone's memory but take about 59 ms to stream for every generated token, so precision, which shrinks the bytes behind each weight, is the lever that matters. Even MobileNetV2 at INT8 exceeds the TinyML envelope by about 6.7×, while the purpose-built depthwise separable convolutional network (DS-CNN) keyword spotter fits it after INT8 quantization.

↩ The iron law of ML systems, which splits execution time into data-movement, compute, and fixed-overhead terms, is established in section 1.7.

Table 10.1: Deployment Budget for the Running Cases: Weight memory, work per result, and the time a flagship phone's 51.2 GB/s memory bus needs to read the weights once, against the phone and TinyML memory envelopes. Work counts two FLOPs per multiply-accumulate; GPT-2 XL's work and streaming time are per generated token, and MobileNetV2 must finish each frame within the 33 ms budget of a 30 FPS camera. DLRM represents recommendation-model embedding pressure (Naumov et al. 2019); DS-CNN represents the TinyML keyword-spotting case (Y. Zhang et al. 2017). The accounting covers weights only; activations, the KV cache, workspace, and metadata are excluded, and the DLRM row is a single reference configuration whose production counterparts can be far larger. Numbers in parentheses show how many times the model exceeds device memory.

Model and precision	Weight memory	Work per result	Weight streaming on the phone	Phone (8 GB)	TinyML (~512 KB)
MobileNetV2, FP32	14 MB	600 MFLOP per frame	0.27 ms	fits	no (26.7×)
MobileNetV2, INT8	3.5 MB	600 MFLOP per frame	0.07 ms	fits	no (6.7×)
ResNet-50, FP32 (teacher)	102.4 MB	8.2 GFLOP per image	2 ms	fits	no (195.3×)
GPT-2 XL, FP16	3 GB	3 GFLOP per token	59 ms	fits	no (5722×)
GPT-2 XL, INT4	0.75 GB	3 GFLOP per token	15 ms	fits	no (1430.5×)

Model and precision	Weight memory	Work per result	Weight streaming on the phone	Phone (8 GB)	TinyML (~512 KB)
DS-CNN (KWS), INT8	200 KB	20 MFLOP per inference	runs on a microcontroller	fits	fits
DLRM (reference)	100 GB	lookup-dominated	does not fit	no (11.6×)	no (190734.9×)

The chapter descends the optimization stack one tier at a time (table 10.2). Structural optimization changes what the model computes and carries the camera pipeline through pruning, low-rank factorization, distillation from a ResNet-50 teacher, efficient architecture design, architecture search, and input-dependent computation. Numerical precision changes how each surviving value is stored and carries GPT-2 XL decoding from numerical formats and their energy, through the quantization methods, to the conditions under which fewer bits run faster. Hardware implementation changes how the remaining operations execute, through the fusions and sparse kernels that compression makes possible and the gap between paper savings and measured ones. Choosing and combining techniques maps a binding constraint to the levers that relieve it, sequences them on the camera pipeline, and turns to the toolchains that apply them. Measuring compression gains closes the chapter on a ResNet-50 INT8 deployment profile, which chapter 11 takes up. The descent begins at the top of the stack, with the structure of the model itself.

Table 10.2: Chapter Map: Each section of the chapter works one tier of the optimization stack, from what the model computes down to how it executes, and names the iron law term that tier most affects and the condition under which its paper savings become measured ones.

Section	Tier of the stack	What changes	Iron law term most affected	Condition for a measured gain
Structural Optimization	Model representation	Which weights, channels, layers, and paths exist	Operations O, and weight bytes in D_{vol}	Removed structure leaves smaller dense tensors or a supported sparse format
Numerical Precision	Numerics representation	Bits per weight and activation	Bytes moved D_{vol}, and energy per operation	The target has a kernel path for the format
Hardware Implementation	Hardware implementation	Which kernels run, and what they skip	D_{vol}, fixed overhead L_{lat}, and efficiency η_{hw}	The compiler can fuse the pattern and the kernel can skip the zeros
Choosing and Combining Techniques	All three tiers	Which levers apply, and in what order	Whichever term binds	The binding resource is identified before any lever is applied
Measuring Compression Gains	The deployed system	Nothing in the model; the claims are measured	All terms, end to end	Measured on the target hardware against quality limits

10.2 Structural Optimization: Changing What the Model Computes

A standard ResNet-50 trained on ImageNet contains over 25 million parameters, yet with careful magnitude pruning and retraining about 80 percent of its weights can be removed for roughly a one-point loss in top-1 accuracy (Gale et al. 2019). Modern neural networks routinely carry far more parameters than deployment requires.[1] Unused capacity still consumes memory, computation, and energy. Structural optimization is the first tier of the stack, **efficient model representation**, by modifying *what* the model computes. Although additional capacity can aid optimization during training, parameters that do not improve the deployed model still impose deployment cost. The job is to remove capacity the task does not need without removing what it does need, and operating along the Pareto frontier[2] means deciding where the conservation-of-complexity heuristic sends the cost, whether into training-time discovery, runtime sparse indexing, or student-model capacity.

These techniques address the challenge through complementary structural mechanisms. Pruning eliminates redundant parameters from an existing network, and low-rank factorization stores an existing weight matrix as a product of two thin ones. Knowledge distillation transfers learned

[1] **Overparameterization**: C. Zhang et al. (2017) demonstrated that networks large enough to fit ImageNet can also memorize completely random labels, showing that training capacity can exceed the structure needed for natural labels. Pruning studies then show the deployment consequence, that trained models often contain many parameters that can be removed or sparsified with modest task loss when pruning and fine-tuning are done carefully (Gale et al. 2019; Blalock et al. 2020). The redundancy is not a universal 10× constant; it depends on architecture, dataset, sparsity pattern, and runtime support.

[2] **Pareto frontier in compression**: EfficientNet traces the frontier concretely, from B0 (77.1 percent accuracy, 390 million FLOPs) to B7 (84.4 percent, 37 billion FLOPs), a 95× compute increase for 7.3 percentage points of accuracy, quantifying how steep the trade-off becomes at the frontier's edge (Tan and Le 2019).

behavior into an independently designed compact network, efficient architecture design and neural architecture search build a network that is efficient on the target by construction (Hutter et al. 2019), and adaptive computation decides for each input how much of the network runs. In production pipelines, these techniques frequently compose, as when a NAS-discovered architecture, supervised by a distilled teacher, is pruned before final quantization.

The camera pipeline gives every structural technique the same test. MobileNetV2 must finish a frame within 33 ms on the phone, and its weights are not what fills that budget, so a structural change pays off only if it removes multiply-accumulates or activation traffic that the phone actually executes. The analysis below evaluates what structural artifact each method produces, what fine-tuning or recovery step it requires, and which hardware execution conditions allow it to deliver physical speedups. Pruning comes first because it exposes the systems constraint most directly. Eliminating mathematical parameters translates to physical hardware acceleration only when the resulting sparsity pattern aligns with the memory hierarchy and compute units of the target processor.

10.2.1 Pruning

For the camera pipeline, pruning[3] is the first lever to try because it starts from the trained MobileNetV2 rather than from a new design. Removing whole channels from its convolutions shrinks every layer that consumes them and cuts the multiply-accumulates that fill the 33 ms frame budget. Removing scattered individual weights, by contrast, leaves the same layers in place and saves bytes or time only if the runtime stores the zeros compactly and skips them. The safe removable fraction depends on the architecture, task, pruning pattern, and recovery procedure, and every pruning design turns on three choices: *what* to prune (individual weights vs. entire structures), *how* to score what is expendable (magnitude, gradients, or activations), and *when* to prune (after training, during training, or at initialization).

> **Definition 10.2: Pruning**
>
> ***Pruning*** is a model-compression technique that sparsifies the parameter space by removing the weights or structures whose removal increases the training loss least.
>
> 1. **Significance**: It can convert dense matrices into sparse structures, reducing memory footprint and total data volume (D_{vol}) when the sparse representation, metadata, and recovery procedure preserve acceptable quality.
> 2. **Distinction**: Unlike quantization, which reduces the precision of every weight, pruning reduces the count of weights by identifying and eliminating redundancy.
> 3. **Common pitfall**: A frequent misconception is that pruning "automatically" speeds up execution. In reality, without specialized sparse execution support, the resulting sparse matrices may actually run slower than dense ones due to irregular memory access patterns. A speedup requires a storage format and a kernel that skip the zeros, not merely a faster processor.

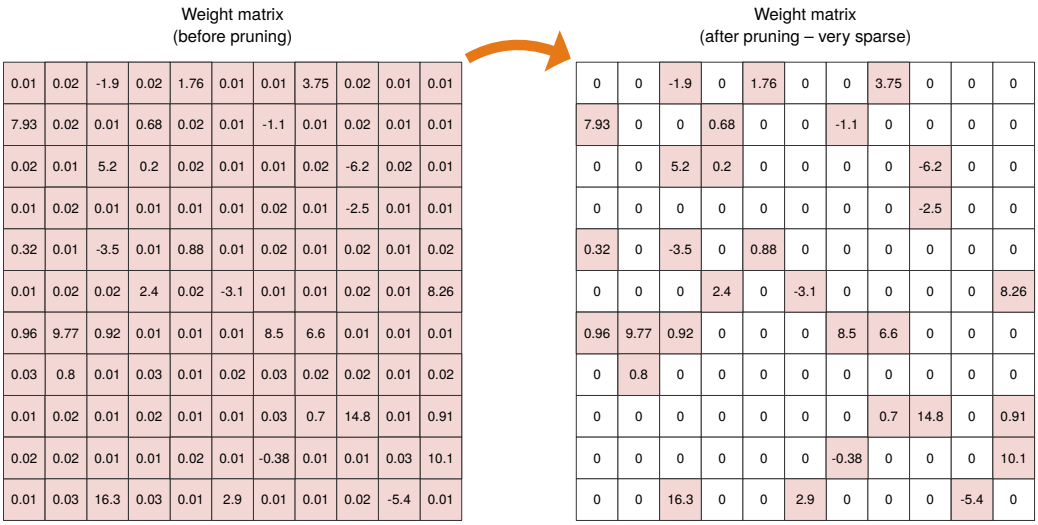
The formal pruning objective seeks a sparse parameter tensor $\hat{\mathbf{W}}$ that minimizes empirical loss subject to a parameter budget k_{nz}:

$$\min_{\hat{\mathbf{W}}} \mathcal{L}(\hat{\mathbf{W}}) \quad \text{subject to} \quad \|\hat{\mathbf{W}}\|_0 \leq k_{\text{nz}}$$

where $\|\hat{\mathbf{W}}\|_0$ is the ℓ_0 **norm** (the count of nonzero parameters). Solving this cardinality-constrained optimization is combinatorial, so practical methods use heuristics[4] such as **magnitude-based pruning**. The thresholding heuristic keeps the largest weights and zeroes the rest (listing 10.1). Applied to an 11×11 weight tensor, it collapses sub-threshold entries to zero while irregular, high-magnitude weights persist across the grid (figure 10.3).

[3] **Optimal Brain Damage**: Introduced by LeCun, Denker, et al. (1989), the method achieved 4× parameter reduction, with proportional memory savings, in a handwriting recognizer by using a diagonal approximation to second-derivative (Hessian) information to estimate the loss increase from removing each weight. A full Hessian has $\mathcal{O}(P^2)$ entries for P parameters, but Optimal Brain Damage avoids storing that full matrix by approximating its diagonal. Modern-scale pruning still favors cheaper criteria such as magnitude because even diagonal curvature estimation adds training cost.

[4] **Heuristic**: From Greek *heuriskein* (to discover), the same root as Archimedes' "eureka." In pruning, the dominant heuristic (larger magnitude means more important) works well empirically but creates a systems trap. Magnitude-based pruning applied globally can remove most parameters from overparameterized layers while leaving critical bottleneck layers largely intact, giving the appearance of aggressive compression while preserving much of the compute and memory cost in the layers that matter (Blalock et al. 2020). Iterative prune-retrain cycles with per-layer budgets are therefore often safer than naive global magnitude pruning, because each cycle lets the network redistribute importance before the next cut.



Listing 10.1: Magnitude-Based Pruning: Removes weights below a threshold to create sparse matrices, reducing the number of nonzero parameters from 9 to 4 ($k_{\text{nz}} = 4$).

```
import torch

# Original dense weight matrix
weights = torch.tensor(
    [[0.8, 0.1, -0.7], [0.05, -0.9, 0.03], [-0.6, 0.02, 0.4]]
)

# Simple magnitude-based pruning: keep only the 4 largest weights
threshold = 0.5
mask = torch.abs(weights) >= threshold
pruned_weights = weights * mask

print("Original:", weights)
print("Pruned (4 nonzeros):", pruned_weights)
```

Figure 10.3: Sparse Matrix Transformation: Magnitude-based pruning replaces weights below a numerical threshold with exact zeros (white cells) while preserving salient high-magnitude connections (colored cells). The resulting sparsity cuts parameter count, but realizing hardware speedups requires translating these unstructured zero entries into sparse storage formats or specialized execution kernels.

The resulting sparse matrix retains only the high-magnitude values (colored cells) while near-zero weights become exact zeros. In models amenable to pruning, much of the representational capacity remains intact after removing low-magnitude weights, establishing magnitude thresholding as an effective baseline heuristic.

To make pruning computationally tractable during gradient-based training, practical methods often relax the combinatorial ℓ_0 constraint with continuous penalties such as ℓ_1-regularization ($\lambda_{\text{L1}}\|\mathbf{W}\|_1$), where λ_{L1} scales the sparsity penalty applied to weight tensor $\mathbf{W}$. Penalizing weight magnitudes drives non-essential parameters toward zero, making downstream thresholding easier. Practitioners typically couple this with **iterative pruning**, removing parameters in successive increments interleaved with fine-tuning cycles to recover lost accuracy (Gale et al. 2019; Blalock et al. 2020).

10.2.1.1 Target structures

The choice of what to prune depends on the deployment target's hardware constraints and which resource is the binding bottleneck. When memory capacity is primary, **neuron pruning** can provide direct relief in models whose fully connected layers dominate parameter storage. Removing entire

neurons and their associated weights and biases reduces layer width and parameter count. Profiling must first establish that these layers, rather than embeddings, activations, or another component, are the actual bottleneck.

When convolutional inference latency on commodity accelerators is the bottleneck, **channel pruning** (also called filter pruning) is a strong candidate. Eliminating entire channels or filters reduces feature-map depth and the multiply-accumulate count in subsequent layers. The resulting subnetwork remains dense and regular, so it can map to conventional GPU and Tensor Processing Unit (TPU) kernels without an unstructured sparse format. Realized latency still depends on the resulting dimensions, kernels, and memory traffic.

When a model contains removable stages, **layer pruning** removes entire layers from the network. Each removal eliminates all computation in that stage, but it also reduces representational depth and may change tensor shapes, residual paths, or downstream interfaces. The remaining layers must absorb the lost function, typically through fine-tuning or retraining. The nominal operation saving therefore does not guarantee proportional latency, because graph rewrites, kernel shapes, and memory traffic still govern execution. Layer pruning demands careful task validation and end-to-end profiling. Side by side, the two granularities differ in what they remove. An individual filter slice contracts intermediate feature depth, while an excised layer collapses a full computational stage (figure 10.4).

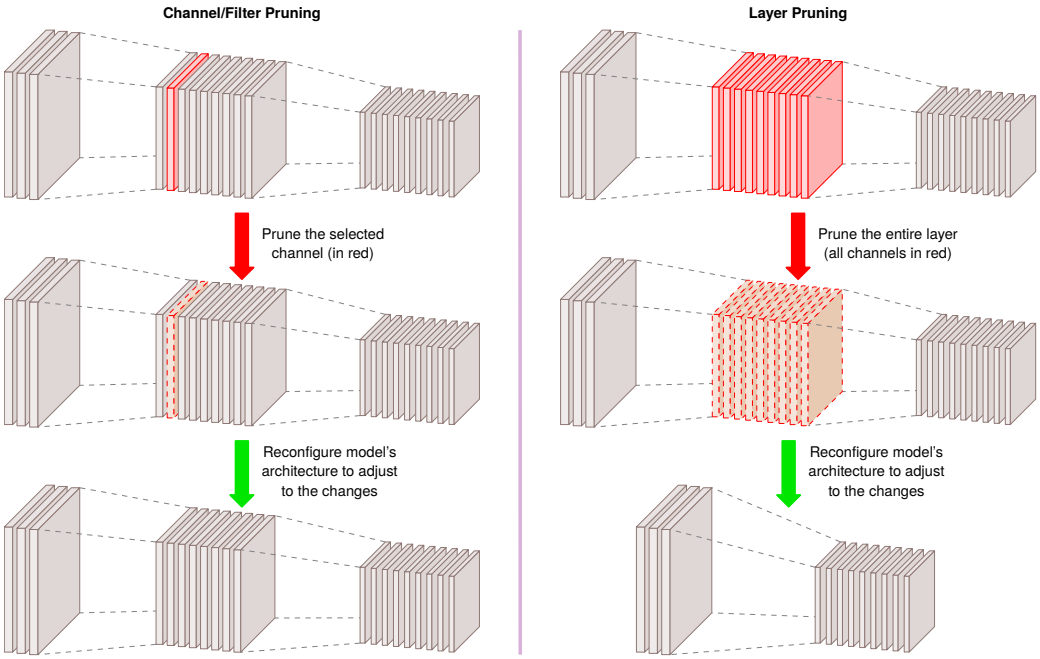

Figure 10.4: Channel vs. Layer Pruning: Structural pruning operates at different architectural granularities. Channel pruning (left) removes feature map slices within convolutional layers while preserving overall network topology and dense execution, whereas layer pruning (right) eliminates entire computational stages, requiring graph rewiring and risking greater capacity loss to achieve larger per-operation savings.

Channel and layer pruning place different demands on accelerator hardware. Channel pruning contracts the inner dimensions of dense general matrix multiply (GEMM) operations, because eliminating output channels in layer ℓ reduces the input channel dimension in layer $\ell + 1$. The tensors remain dense and avoid sparse pointer lookups, but their dimensions still decide how well single instruction, multiple data (SIMD) lanes and Tensor Core tiles fill. Pruning a 256-channel layer to 250 channels, for example, removes about 2 percent of the work yet can leave a matrix unit that processes channels in groups of 8 running a partly empty final tile, so the layer may run no faster. Pruning to 248 keeps every tile full. The camera pipeline's MobileNetV2 shows the same rule in its design, since its reference implementation rounds every channel count to a multiple of 8,

and a pruning policy for the phone keeps the pruned counts on that grid. The preferred multiple depends on the kernel and numerical format, and because it counts elements rather than bytes, it is a different constraint from cache-line or memory-transaction alignment. Layer pruning removes full computational stages and their associated launches and intermediates, but the rewritten graph must still satisfy shape, residual-connection, and kernel-layout requirements. Both approaches require quality validation.

10.2.1.2 Unstructured pruning

Unstructured pruning removes individual weights while preserving the overall network architecture. Some connections become redundant during training, contributing little to the final output. Pruning these weak connections reduces the nonzero count and can preserve most task quality after recovery.

Formalizing this process, let $\mathbf{W} \in \mathbb{R}^{m \times n}$ represent a weight matrix in a given layer. Pruning removes a subset of weights by applying a binary mask $\mathbf{M} \in \{0,1\}^{m \times n}$, yielding a pruned weight matrix:

$$\hat{\mathbf{W}} = \mathbf{M} \odot \mathbf{W}$$

where $\odot$ represents the element-wise Hadamard product. The mask $\mathbf{M}$ is constructed based on a pruning criterion, typically weight magnitude. A common approach is magnitude-based pruning, which removes a fraction ρ_{sparse} of the lowest-magnitude weights by defining a threshold δ_{prune} such that:

$$M_{i,j} = \begin{cases} 1, & \text{if } |W_{i,j}| > \delta_{\text{prune}} \\ 0, & \text{otherwise} \end{cases}$$

where δ_{prune} is chosen to ensure that only the largest $(1 - \rho_{\text{sparse}})$ fraction of weights remain. This method assumes that larger-magnitude weights contribute more to the network's function, making them preferable for retention.

Unstructured pruning reduces the count of nonzero parameters, but translating that reduction into physical storage savings requires an indexed sparse encoding such as Compressed Sparse Row (CSR) or coordinate list (COO), whose positional metadata can cancel the saving at low sparsity. Storing a dense tensor with zeroed entries saves no memory at all. Where the indexed formats break even in bytes and in time is a question about execution rather than about which weights to remove, and section 10.4.2.2 answers it.

10.2.1.3 Structured pruning

Where unstructured pruning removes individual weights across arbitrary tensor coordinates, **structured pruning** (Li et al. 2017) eliminates regular groups of parameters: channels, filters, attention heads, or entire layers. Because removing whole structural units contracts weight arrays into smaller, contiguous dense tensors, the remaining computation executes directly on standard Basic Linear Algebra Subprograms (BLAS) and convolution engines without specialized sparse libraries or metadata indexing overhead.

Between unconstrained irregular masks and coarse-grained channel excision lies hardware-aligned fine-grained regularity. Hardware-aware pruning strategies, such as *N:M structured sparsity*,[5] enforce fine-grained patterns that map directly onto accelerator execution datapaths. Under a *2:4 structured sparsity* constraint, every contiguous block of four weights must contain exactly two zeros and two nonzero values:

Original block (4 values): $[0.0, 1.4, 0.0, -2.1] \longrightarrow$ Compressed storage: $[1.4, -2.1]$ with 2-bit indices: $[01_2, 11$

Because every group of four weights compresses to exactly two values, the value payload halves, and a 2-bit index per kept value adds only a small, fixed metadata cost with no structural irregularity. This chapter uses the 2:4 pattern as the canonical compression example, and section 10.4.2 returns to what a sparse matrix unit does with it.

The regularity-compression trade-off spans three architectural granularities, from irregular connection masking to coarse-grained neuron dropping and full convolutional channel excision (figure 10.5). Moving from left to right trades per-weight freedom for dense tensor structure that standard hardware kernels can execute directly.

[5] **N:M structured sparsity**: Introduced commercially with NVIDIA's A100 GPU (2020), the 2:4 pattern was chosen because it halves multiply-accumulate operations while keeping position metadata small enough for the sparse Tensor Core path (NVIDIA Corporation 2020a; Choquette et al. 2021). This fixed ratio is a hardware constraint, not a mathematical optimum. The A100 Sparse Tensor Core path accelerates 2:4 sparse operands, yielding up to 2× math-throughput speedup over dense execution when kernels and layouts satisfy the constraint. Other ratios are not accelerated by this specific hardware path, illustrating how silicon design constrains which sparsity patterns translate to actual speedup.

↪ How sparse Tensor Cores use the 2-bit metadata to select matching activations and skip the zeroed multiplies is developed in section 11.4.5.3.

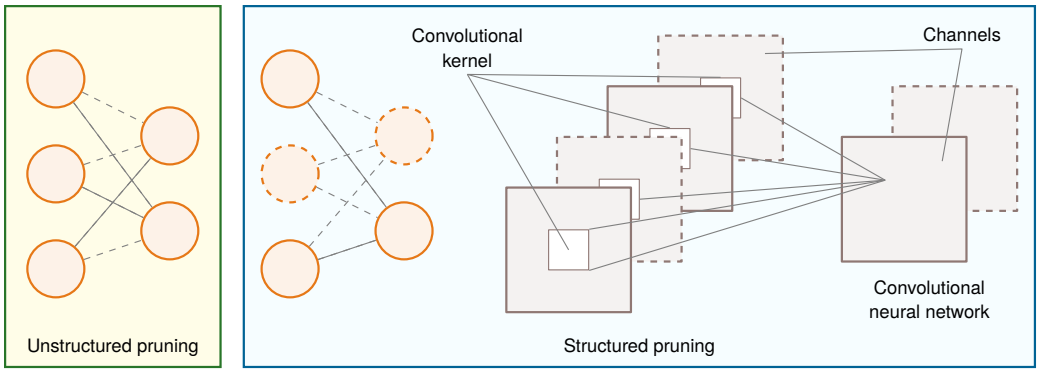

Figure 10.5: Unstructured vs. Structured Pruning: The regularity-compression trade-off across pruning granularities. Unstructured pruning (left) removes arbitrary individual connections and requires a sparse representation and matching kernel to change execution. Structured pruning of neurons (middle) or convolutional channels (right) can produce smaller dense tensors that remain compatible with standard kernels, although realized latency depends on the resulting shapes and runtime. Source: (Qi et al. 2021).

In fully connected layers (center of figure 10.5), pruning neurons eliminates the corresponding rows and columns in adjacent weight matrices. In convolutional layers (right), pruning channels removes complete 3D filter slices. Either way the subnetwork stays dense, so the remaining systems requirement is matching the resulting tensor shapes and layouts to efficient kernels, the tile-filling condition of section 10.2.1.1.

A common approach to structured pruning ranks entire neurons or filters by the magnitude of their associated weights. A low group norm is an inexpensive proxy for low importance, not proof that the unit is dispensable. The score can use an ℓ_1-norm or ℓ_2-norm over the weights associated with each unit; groups below a selected threshold become pruning candidates. Layer-wise ranking matters because raw scales can differ across layers. The method needs no representative data pass, but computing scores, choosing a threshold, materializing the smaller graph, and validating or fine-tuning the result still incur engineering and compute cost.

Another strategy is **activation-based pruning**, which evaluates neuron or filter activations over a dataset. Units that remain weak across representative inputs become candidates for removal, subject to ablation or fine-tuning checks. This method captures input-dependent behavior rather than relying only on static weights. Its ranking can still miss rare but important inputs, depend on activation scaling, or change after upstream units are removed. Activation-based pruning therefore requires representative profiling data and validation after the selected structures are removed.

Gradient-based pruning uses loss derivatives to estimate how removing a neuron or filter would change the objective. A small first-order score suggests a candidate at the current checkpoint and on the sampled data; it does not establish permanent irrelevance or capture every interaction among units. Gradient-based criteria can combine a unit's value with its gradient to rank the expected local loss change. Mathematically, this criterion approximates the change in loss $\Delta\mathcal{L}$ when zeroing parameter w_i via a first-order Taylor expansion: $\Delta\mathcal{L} \approx |w_i \cdot \frac{\partial\mathcal{L}}{\partial w_i}|$. Weights that are either near zero or have negligible gradients exert minimal influence on the objective, making them prime candidates for excision. Unlike weight-only magnitude criteria, they require backward computation and are usually integrated into training or fine-tuning. The pruned result still needs task-level validation because the score is a local approximation.

These criteria trade measurement cost against fidelity to model behavior. Magnitude scores are inexpensive and provide a useful baseline, but they ignore the input distribution. Activation scores incorporate representative inputs and expose units that are quiet on that workload, while gradient-based scores also incorporate the local loss surface at additional training cost. None dominates across models, and none establishes that removal is harmless. A sound comparison prunes to the same structural target, applies the same recovery budget, and measures task quality after removal. It then profiles the exported graph, because a better importance score can preserve quality without producing shapes that the target runtime executes efficiently. The choice therefore depends on available data and compute, the structure being removed, and the deployment's quality margin.

10.2.1.4 Pruning trade-offs

The three pruning approaches occupy different positions on the regularity-versus-granularity trade-off. Unstructured pruning can remove individual weights and therefore express fine-grained sparsity, but accelerators need matching sparse formats and kernels to skip those zeros. Structured pruning removes channels, filters, or layers and can produce smaller dense operations that conventional hardware already supports. Dynamic pruning, which section 10.2.6 develops with the other input-dependent methods, makes the executed structure depend on each input, adding control and batching overhead in exchange for conditional allocation. The three differ in what they remove, what the runtime must support, and what recovery they need (table 10.3).

These categories describe deployed execution rather than mutually exclusive training algorithms. A structured subnetwork may be learned with a dynamic schedule and then frozen for serving; classify the artifact by what its runtime actually executes.

Table 10.3: Pruning Strategies: Unstructured pruning removes individual weights but needs sparse storage and matching kernels for deployment gains; structured pruning removes whole components that map more directly to dense hardware, while dynamic pruning adds runtime adaptation and overhead.

Aspect	Unstructured Pruning	Structured Pruning	Dynamic Pruning
Removed unit	Individual weights in the model	Entire neurons, channels, filters, or layers	Adjusts pruning based on runtime conditions
Model structure	Sparse weight matrices; original architecture remains unchanged	Model architecture is modified; pruned layers are fully removed	Structure adapts dynamically
Impact on memory	Reduces the nonzero count; storage falls only with an appropriate sparse representation	Reduces model storage by removing entire components	Varies based on real-time pruning
Impact on computation	Dense work remains unless a supported sparse path skips zeros	Reduces nominal FLOPs; latency depends on resulting shapes and kernels	Varies with routing policy and controller overhead
Hardware compatibility	Requires sparse formats and matching execution support	Produces dense subnetworks, but awkward shapes can still underutilize hardware	Requires adaptive inference engines
Fine-tuning requirement	Often used to recover accuracy after pruning	Often used after structural modification	Depends on how the routing policy and subnetworks are trained
Use cases	Targets whose runtime provides sparse formats and kernels, or storage-bound high sparsity	Real-time inference optimization, mobile/edge AI, and efficient training	Adaptive AI applications, real-time systems

10.2.1.5 Pruning schedules

The pruning schedule affects how much recovery training the network receives after capacity is removed. Two primary scheduling strategies govern weight removal: iterative pruning and one-shot pruning.

Iterative pruning Iterative pruning removes capacity gradually, alternating each structural cut with fine-tuning so that the network recovers before the next cut. Across three successive prune-and-retrain cycles, accuracy drops after each cut and recovers during the fine-tuning that follows (figure 10.6).

In the illustrative workflow, a convolutional network loses six channels with recovery between successive cuts. Rather than removing all six channels in a single pass, the pipeline removes two channels per cycle across three iterations, fine-tuning the remaining parameters after each cut. The initial cut drops accuracy from 0.995 to 0.971, but brief fine-tuning restores performance to 0.992. Two subsequent prune-and-tune cycles produce a final model at 0.991 accuracy, a 0.4 percent degradation despite a 27 percent reduction in channel count. Staging structural surgery across multiple retraining intervals allows surviving weights to adjust their representations along the loss landscape.

One-shot pruning **One-shot pruning** removes multiple architectural components in a single step, followed by an extensive fine-tuning phase to recover model accuracy. This aggressive approach

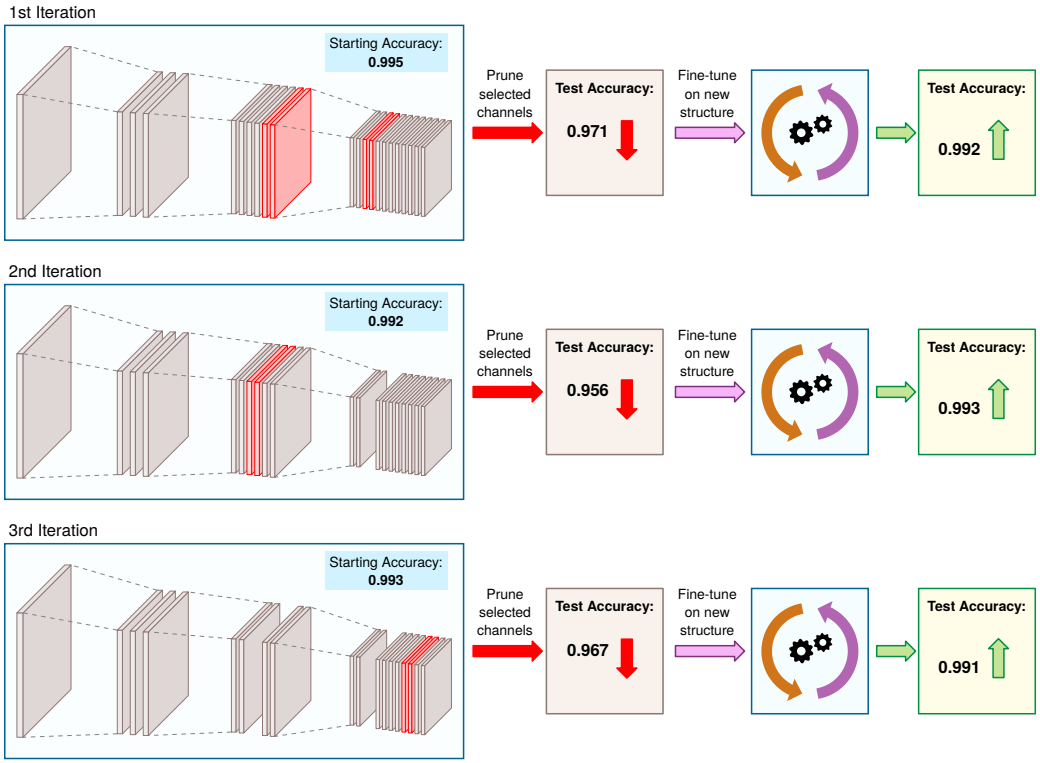

Figure 10.6: Illustrative Iterative Pruning Performance: Three rows depict successive prune-then-fine-tune cycles, each removing two of the original twenty-two channels. Accuracy drops from 0.995 to 0.971 after the first prune, recovers to 0.992 after fine-tuning, and settles at 0.991 after all three cycles, a 0.4 percent loss with 27 percent fewer channels.

compresses the model quickly but risks greater accuracy degradation, as the network must adapt to significant structural changes simultaneously.

Applying one-shot pruning to the same network illustrates the hazard of aggressive structural truncation. Removing all six highlighted channels at once (figure 10.7) causes a sharp accuracy drop from 0.995 to 0.914, from which fine-tuning recovers only partially to 0.943, leaving about a 5 percent quality penalty under the recovery procedure shown. The two figures illustrate a mechanism, not a controlled result. Both runs end with the same tensor geometry, but the iterative run also received three rounds of fine-tuning, so its better final accuracy mixes the benefit of smaller cuts with the benefit of more recovery training. A fair comparison holds the final structure and the total recovery budget fixed.

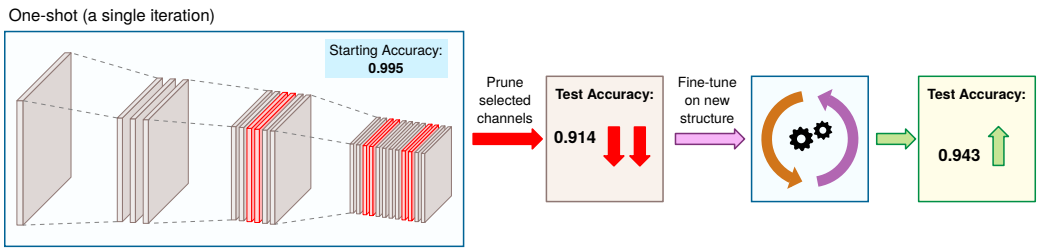

Figure 10.7: Illustrative One-Shot Pruning Impact: All six channels (27 percent) are removed simultaneously, causing accuracy to drop from 0.995 to 0.914. Fine-tuning recovers only to 0.943, a 5 percent degradation from the original accuracy.

The working rule follows from that mechanism. Start with one-shot pruning plus recovery, because it is cheapest, and accept it if the recovered model meets the quality target. Move to an iterative

schedule when it does not, which is most likely at high sparsity, where a single large cut removes capacity the network cannot rebuild in one recovery phase. Compare the two at a matched recovery budget, and spend the extra cycles only when the target accelerator can exploit the sparsity pattern that results.

10.2.1.6 Lottery ticket hypothesis (optional depth)

Standard pruning workflows assume a fully trained dense model from which weights are subsequently removed. Yet the relationship between network structure and optimization dynamics runs deeper, because pruning can reveal inherently efficient, highly trainable subnetworks embedded within the initial random parameterization.

This perspective leads to the Lottery Ticket Hypothesis[6] (LTH), which challenges conventional pruning workflows by proposing that within large neural networks, there exist small, well-initialized subnetworks ("winning tickets") that can achieve comparable accuracy to the full model when trained in isolation. Rather than viewing pruning as a post-training compression step, LTH suggests it can serve as a discovery mechanism to identify these efficient subnetworks early in training (Rachwan et al. 2022).

The discovery procedure is an iterative pruning-and-rewinding loop. After training to convergence and pruning low-magnitude connections, the surviving weights reset to their initialization state θ_0, which isolates a sparse subnetwork (figure 10.8). Repeating the cycle can isolate a sparse subnetwork that, in the reported settings, trains to accuracy comparable with the original network (Frankle and Carbin 2019). Whether the same procedure succeeds depends on architecture, scale, optimizer, and training budget.

[6] **Lottery ticket hypothesis**: Named for the intuition that training a large network is like buying many lottery tickets, most of which lose, while a few "winning tickets" (sparse subnetworks with favorable initializations) can train to comparable accuracy on their own. Frankle and Carbin (2019) established the hypothesis on smaller vision and fully connected networks; later work surveyed and extended the idea to larger settings (Rachwan et al. 2022). The systems implication is that some of the memory and compute spent training dense networks may be discoverable overhead, but the practical payoff depends on whether the winning subnetwork can be found before paying most of the original training cost.

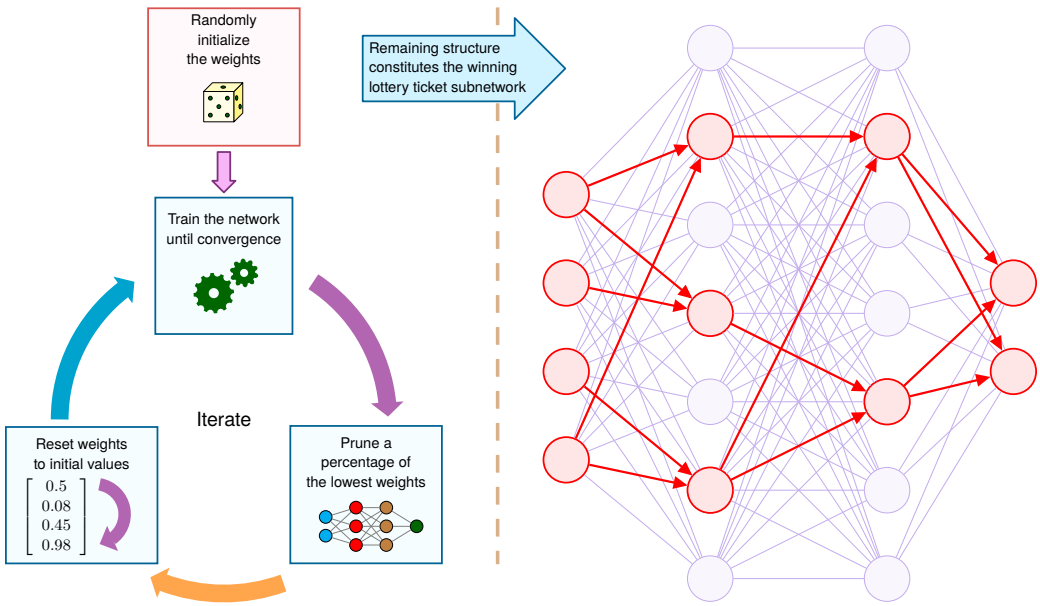

Figure 10.8: Lottery Ticket Iteration Cycle: The original procedure repeatedly trains, prunes low-magnitude weights, and resets surviving weights to their initial state θ_0. The cycle tests whether the resulting sparse subnetwork can match the dense baseline when trained in isolation; the outcome is empirical rather than guaranteed.

The Lottery Ticket Hypothesis suggests that compact, trainable subnetworks may exist inside an overparameterized initialization, which motivates direct sparse-training research. The standard discovery procedure, however, does not eliminate dense training cost. It first pays for one or more dense or partially dense runs, plus a rewind and a recovery phase per pruning cycle, to find the ticket. A winning ticket is therefore a training result. It becomes a systems win only when that total accelerator time, the final artifact size, target latency, and task quality beat the simpler alternatives: training a smaller dense model from the start, one-shot pruning with recovery, and direct sparse training.

10.2.1.7 Pruning in practice

While the Lottery Ticket Hypothesis illuminates the optimization landscape, practical serving systems care only about executable artifacts. Framework-level pruning is useful only when it materializes concrete hardware savings: a smaller dense tensor, a hardware-aligned structured sparse matrix, or an indexed sparse layout paired with matching runtime kernels. Training-time pruning often begins as mask application. The original tensor remains resident in memory, while a binary mask zeros selected weights during forward propagation. That mechanism guides gradient flow during recovery, but it delivers zero memory reduction or latency improvement on its own. Measurable efficiency gains emerge only after the masked structure is exported into the physical artifact loaded by the inference engine.

This artifact boundary is where the unstructured and structured strategies part ways. An exported unstructured mask still needs a sparse storage format and a matching kernel, whereas exported structured pruning is already a smaller dense graph. The systems audit therefore has three concrete steps. Identify what was pruned, identify the format the runtime receives, and verify that the target hardware has kernels that make the sparsity useful.

In practice, BERT-style transformers[7] have been pruned by removing redundant attention heads or intermediate dimensions, while separate distillation methods such as DistilBERT and TinyBERT train smaller dense student models that retain much of BERT's performance (Sanh et al. 2019; Jiao et al. 2020). Pruning decides which weights exist, and every weight it keeps is still stored and multiplied at full size. A second way to shrink an existing layer keeps every weight position but stores the matrix as a product of two thin matrices, which suits layers whose weights carry less information than their dimensions suggest.

↪ Benchmark protocols that separate structured from unstructured pruning and specify the hardware and sparse-kernel support behind any measured speedup are developed in section 12.9.1.3.

7 **BERT pruning**: BERT's 12 attention heads per layer can contain substantial redundancy. Michel et al. (2019) found on MultiNLI that many heads could be removed without a statistically significant performance change. The removable fraction depends on the layer and task, so deployment pruning must measure both task quality and whether the resulting structure reduces runtime work.

10.2.2 Low-rank factorization

Fetching and multiplying a full 4096×4096 weight block from DRAM spends 93.75 percent of its memory traffic and arithmetic on directions that barely change the layer's output when a rank-128 subspace already captures almost all of the transformation's variance. Deep network weight matrices often show this rapid singular-value decay, and **structured approximation** exploits it by decomposing dense $M \times N$ weight tensors into products of low-rank matrices or tensor factors that require only a fraction of the original scalar parameters (6.25 percent in the rank-128 case). Low-rank matrix factorization and multi-linear tensor decompositions translate this algebraic redundancy into reduced memory traffic and lower arithmetic cost. In the camera pipeline, the candidates are MobileNetV2's pointwise convolutions, which are matrix multiplications over channels, and factoring one trades fewer multiply-accumulates against an extra kernel and an intermediate tensor, the trade-off developed below.

10.2.2.1 Matrix factorization

Low-rank matrix factorization (LRMF) approximates weight matrices with lower-rank representations. Given a weight matrix $\mathbf{W} \in \mathbb{R}^{m \times n}$, LRMF identifies factor matrices $\mathbf{U} \in \mathbb{R}^{m \times k}$ and $\mathbf{V} \in \mathbb{R}^{n \times k}$ such that:

$$\mathbf{W} \approx \mathbf{U}\mathbf{V}^T$$

where the approximation rank $k \ll \min(m, n)$. This decomposition is typically computed via singular value decomposition (SVD),[8] retaining only the k largest singular values. Writing the truncated decomposition as $\mathbf{W} \approx \mathbf{P}_{kk}\mathbf{Q}_k^T$ and splitting the singular values evenly between the two factors gives $\mathbf{U} = \mathbf{P}_{kk}^{1/2}$ and $\mathbf{V} = \mathbf{Q}_{kk}^{1/2}$. During inference, computing the layer output as $\mathbf{h} = \mathbf{U}(\mathbf{V}^T\mathbf{x})$ replaces a single large matrix-vector product with two sequential, smaller multiplications. The primary systems question is whether the reduction in parameter footprint and arithmetic operations compensates for the overhead of staging an intermediate activation and dispatching an additional kernel.

8 **Singular value decomposition (SVD)**: The Eckart-Young theorem (1936) proves that retaining the top k singular values yields an optimal rank-k approximation in the Frobenius and spectral norms. The key systems trade-off is whether the high, one-time compute cost of this factorization, $\mathcal{O}(mn \cdot \min(m, n))$, is amortized by the memory and bandwidth savings from using the smaller model in repeated inference calls.

> Systems Perspective 10.1: The bandwidth-compute trade-off
>
> Low-rank factorization can reduce both arithmetic and bandwidth demand when the retained rank is small, though it adds a second factor operation and possible kernel-launch overhead.

Storing a 4096 by 4096 matrix requires 67.1 MB (at FP32). Fetching this matrix for a single inference imposes substantial memory traffic, especially when execution is limited by physical memory bandwidth.

Factoring the matrix at rank $k = 128$ requires storing two smaller matrices (4096 by 128 and 128 by 4096), totaling only 4.2 MB, a 16× reduction in stored values. When inference uses the two factors directly, matrix-vector arithmetic also falls from $\mathcal{O}(mn)$ to $\mathcal{O}(k(m+n))$ for small k. The deployment speeds up only if the two factor operations and their intermediate traffic cost less than the original dense kernel. Explicitly materializing $\mathbf{UV}^T$ would add $\mathcal{O}(mkn)$ work and defeat the purpose.

This bandwidth-compute trade-off exemplifies the memory wall at the operator level. When batch sizes are small, execution is bottlenecked by the time required to fetch weight bytes from DRAM rather than the time required to perform multiply-accumulate operations. In production serving engines, evaluating the factored representation avoids full-rank materialization entirely. The original $m \times n$ weight matrix $\mathbf{W}$ becomes the product of a tall factor $\mathbf{U}$ ($m \times k$) and a wide factor $\mathbf{V}^T$ ($k \times n$) (figure 10.9).

↪ The AI memory wall, the regime in which arithmetic throughput outpaces the memory bandwidth that feeds it, is developed in section 11.5.1.

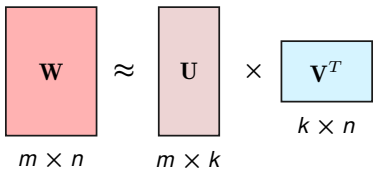

Figure 10.9: Low-Rank Factorization: A weight matrix $\mathbf{W}$ of size $m \times n$ is approximated by two smaller factors, $\mathbf{U}$ ($m \times k$) and $\mathbf{V}^T$ ($k \times n$). Storage falls from $m \times n$ to $m \times k + k \times n$ parameters, while one dense operation becomes two factor operations.

LRMF applies directly to fully connected projection layers and to flattened convolutional weight tensors. The storage and arithmetic savings derived above are only half of the accounting on a real accelerator. The intermediate activation vector $\mathbf{z} = \mathbf{V}^T\mathbf{x}$ must be staged in on-chip SRAM or round-tripped through memory, and dispatching two separate kernels incurs launch latency unless the operations are fused. Furthermore, if the approximation rank k is small or unaligned with hardware tile dimensions (such as 16×16 systolic arrays), the hardware compute units operate well below peak throughput. Selecting rank k therefore balances memory footprint and bandwidth reduction against approximation error, kernel dispatch overhead, and hardware tile utilization.

↪ How a matrix is tiled onto a fixed-size systolic array, and why a dimension just past the tile width drops utilization sharply, is developed in section 11.7.5.

10.2.2.2 Tensor decomposition (optional depth)

Tensor decomposition extends low-rank approximation to multidimensional arrays, such as four-dimensional convolutional kernels ($d_{\text{out}} \times d_{\text{in}} \times K_h \times K_w$) and multi-head attention weights. Matrix factorization could compress such a tensor only after unfolding it into a matrix, which discards which axis was which. Tensor decompositions instead keep each axis separate by representing the tensor through multilinear products of lower-dimensional factors. A three-dimensional tensor $\mathcal{Y} \in \mathbb{R}^{I \times J \times T}$, for example, decomposes into three rank-k factor matrices ($\mathbf{A}$, $\mathbf{B}$, and $\mathbf{C}$), and outer products of the slice vectors $\mathbf{a}_i$, $\mathbf{b}_j$, and $\mathbf{c}_t$ reconstruct entry y_{ijt} (figure 10.10).

Formats trade parameter reduction against contraction complexity. **CP decomposition** (canonical polyadic decomposition) is the form drawn in figure 10.10. It expresses the tensor as a sum of k rank-one components, $\mathcal{Y} \approx \sum_{s=1}^{k} \mathbf{a}_s \otimes \mathbf{b}_s \otimes \mathbf{c}_s$, where $\mathbf{a}_s$, $\mathbf{b}_s$, and $\mathbf{c}_s$ are column s of $\mathbf{A}$, $\mathbf{B}$, and $\mathbf{C}$ (Lebedev et al. 2015), giving maximal parameter reduction but often unstable rank optimization. **Tucker decomposition** keeps a small dense core tensor multiplied along each mode by a factor matrix, $\mathcal{Y} \approx \mathcal{G} \times_1 \mathbf{A} \times_2 \mathbf{B} \times_3 \mathbf{C}$, where $\times_{n_{\text{mode}}}$ multiplies along axis n_{mode} of the tensor. **Tensor-train (TT)** stores a many-axis tensor (the order of a tensor is its number of axes) as a chain of small third-order cores, which avoids the exponential growth of Tucker cores with the number of axes.

Tensor decomposition applies to convolutional filters, attention projections, and embedding tables. Its barrier is execution cost, because accelerators are specialized for dense matrix multiplication (GEMM). Contracting decomposed tensors needs transposition kernels or many small contractions,

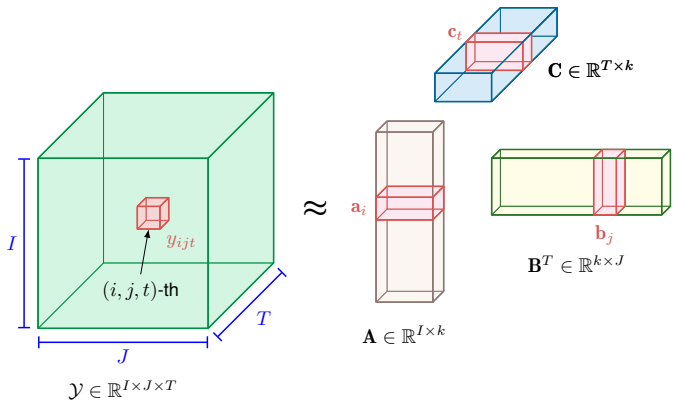

Figure 10.10: Tensor Decomposition: A three-dimensional tensor $\mathcal{Y} \in \mathbb{R}^{I \times J \times T}$ is approximated by factor matrices **A**, **B**, and **C**. The highlighted factor vectors $\mathbf{a}_i$, $\mathbf{b}_j$, and $\mathbf{c}_t$ combine across rank k to reconstruct the entry y_{ijt}. Extending low-rank approximation from two dimensions to three carries the storage and computation argument into convolutional layers. Source: (Gholami et al. 2022).

and without fused contraction kernels the data movement and launch latency can erase the arithmetic savings. LRMF and tensor decomposition differ in the data structures they apply to, the compression they achieve, and what they ask of the execution engine (table 10.4).

Table 10.4: Matrix and Tensor Factorization: LRMF applies to two-dimensional matrices, while tensor decompositions extend low-rank representations to multidimensional tensors; realized storage and latency depend on rank choice and kernel support.

Feature	Low-Rank Matrix Factorization (LRMF)	Tensor Decomposition
Applicable Data Structure	Two-dimensional matrices	Multi-dimensional tensors
Compression Mechanism	Factorizes a matrix into two or more lower-rank matrices	Decomposes a tensor into multiple lower-rank components
Common Methods	SVD; Alternating Least Squares (ALS), which fits one factor at a time	CP Decomposition, Tucker Decomposition, Tensor-Train (TT)
Compute cost	Depends on the factorization method, selected rank, and kernels	Depends on the decomposition, selected ranks, optimization procedure, and tensor-contraction kernels
Storage Reduction	Reduces storage from $\mathcal{O}(mn)$ to $\mathcal{O}(mk+kn)$	Depends on the decomposition and selected ranks; stores factor matrices and, for some methods, a core tensor
Inference execution	Replaces one dense operation with two factor operations	Introduces tensor contractions whose latency depends on available kernels
Primary Use Cases	Fully connected layers, embeddings, recommendation systems	Convolutional filters, attention mechanisms, multi-modal learning
Implementation Complexity	Easier to implement, often involves direct factorization methods	More complex, requiring iterative optimization and rank selection

In production pipelines, practitioners frequently combine these structured approximations, applying LRMF to large linear projections and embedding tables while targeting multi-dimensional convolutional layers with tensor decompositions. Under the D·A·M taxonomy, structured approximation alters the Algorithm to relieve Machine memory-capacity and bandwidth bottlenecks. When fetched weights dominate serving latency, reducing weight bytes can reduce that component of execution time. Added factor operations, intermediate tensors, and launch overhead must still be counted; they can offset the saving in either a memory-bound or compute-bound workload.

Pruning and factorization both modify the parameterization of an existing model, and neither can replace an operator that suits the target poorly. If the original operator choices, kernel dimensions, or memory access patterns are ill-suited to the target accelerator, removing or factoring weights cannot substitute more efficient primitives. When deployment limits demand a different topology altogether, the compression objective shifts from subtracting weights to training a compact model to behave like the original.

10.2.3 Knowledge distillation

The camera pipeline's MobileNetV2 does not have to learn its task from labels alone. A ResNet-50 trained for the same task needs 102.4 MB of FP32 weights and 8.2 GFLOP per image against MobileNetV2's 14 MB and 600 MFLOP (table 10.1), far too much arithmetic for the phone's frame budget, yet its output distribution carries information that labels do not. Knowledge distillation trains a compact *student* network, here MobileNetV2, to reproduce the output behavior and representations of an overparameterized *teacher*, here ResNet-50 (Hinton et al. 2015; Sanh et al. 2019). While the term borrows from chemical purification,[9] the systems mechanism is algorithmic. Distillation transfers dark knowledge across architectures, amortizing a one-time training phase across millions of lower-latency inference queries.

[9] **Distillation**: The name borrows from the chemical process of separating a mixture. In model compression, the student learns from a teacher's softened output distribution or internal representations rather than copying its parameters. Soft targets can encode relationships among classes, but the student learns only what its objective and training data expose. The metaphor is useful but not literal, since the temperature parameter comes from softmax scaling, and the size-quality trade-off depends on the student, data, objective, and training procedure (Hinton et al. 2015). Deployment savings come from the student architecture, not from the metaphor itself.

> **Definition 10.3: Knowledge distillation**
>
> ***Knowledge distillation*** is a model-compression technique that trains a smaller *student* model to match the behavior of a larger, pretrained *teacher* model.
>
> 1. **Significance**: Distillation moves cost from repeated inference to an additional training phase. A student can be substantially smaller than its teacher while retaining useful task performance; DistilBERT, for example, reports 40 percent fewer parameters, 60 percent faster inference, and 97 percent of BERT's language-understanding performance (Sanh et al. 2019). This trade-off is valuable when the student-training cost is amortized across many deployed queries.
> 2. **Distinction**: Unlike pruning, which removes parameters from an existing architecture, and quantization, which lowers numerical precision, distillation trains a new dense architecture. The student inherits behavior from the teacher's output distribution or intermediate representations rather than inheriting the teacher's full parameter count or layer structure.
> 3. **Common pitfall**: A frequent misconception is that distillation is lossless compression. In reality, the student is bounded by its own capacity, the quality of the teacher, and the match between the distillation data and deployment distribution; a student can faithfully reproduce teacher errors as well as teacher knowledge.

Data selection used the teacher's soft targets as training data (section 9.5.4); here they become a compression mechanism. Teacher models transfer semantic knowledge through nonzero probabilities assigned across non-target classes. Whereas a one-hot ground-truth label assigns a probability of one exclusively to the correct class, a teacher's distribution keeps the inter-class correlations known as **dark knowledge**, revealing that an input classified as a cat (85 percent) shares subtle semantic features with a dog (10 percent) and a fox (5 percent) (figure 10.11).

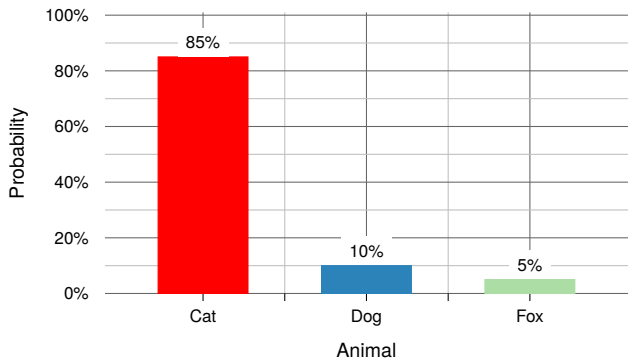

Figure 10.11: Soft Target Distribution: The teacher's relative confidence levels indicate which classes are semantically similar (for example, cat vs. dog), providing a much richer supervision signal than a binary "correct" label.

Training a student model requires balancing teacher imitation against ground-truth task supervision. Operationally, the workflow requires four decisions before training begins: selecting a teacher with the desired behavior, designing a student whose dense architecture satisfies the target accelerator's memory and compute budget, generating soft targets over the training corpus, and choosing the temperature and loss weights that govern optimization. In the resulting dual-path pipeline, an input sample x passes through both the teacher and the student, temperature-scaled soft predictions ($T_{\text{distill}} > 1$) feed the distillation loss, and unscaled student predictions ($T_{\text{distill}} = 1$) are scored against ground-truth hard labels (figure 10.12).

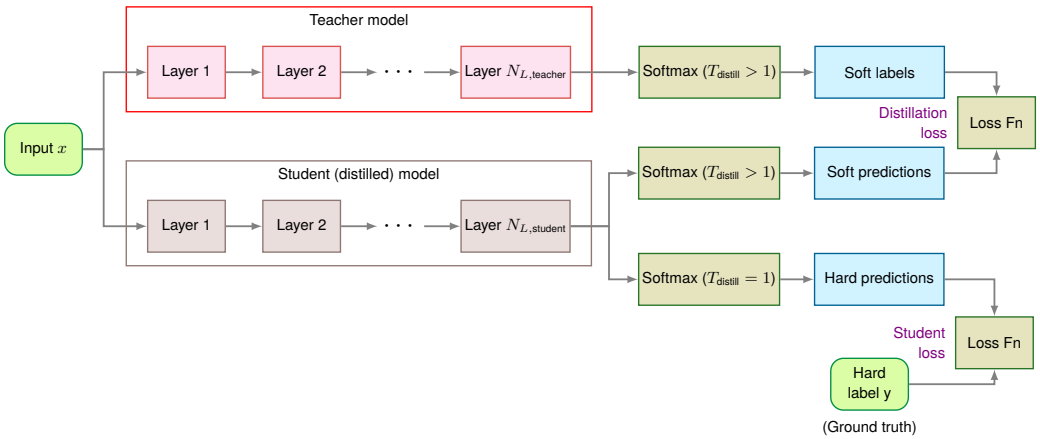

Figure 10.12: Knowledge Distillation Workflow: An input sample passes through both the teacher and the student network. The teacher produces soft labels via temperature-scaled softmax, while the student output is compared against both the soft labels (distillation loss) and the hard labels (student loss).

Deploying the distilled student requires verifying more than top-1 accuracy. Because a student can inherit the teacher's systematic biases and miscalibrations as readily as its useful representations, verification must measure calibration error, subgroup behavior, and executed latency on the target hardware.

10.2.3.1 Distillation mathematics

Standard softmax normalization converts raw model logits z_i into probabilities. Introducing a **temperature parameter**[10] T_{distill} softens the resulting probability distribution across output classes:

$$p_i^{(T_{\text{distill}})} = \frac{\exp(z_i/T_{\text{distill}})}{\sum_j \exp(z_j/T_{\text{distill}})}$$

A higher T_{distill} flattens the softmax distribution and exposes more of the dark knowledge carried in relative class probabilities, such as a teacher assigning a small but nonzero probability to dog and near-zero probability to truck when classifying an image of a cat. The total distillation loss $\mathcal{L}_{\text{distill}}$ balances standard cross-entropy with the Kullback-Leibler (KL) divergence against the teacher's softened distribution:[11]

$$\mathcal{L}_{\text{distill}} = (1-\gamma_{\text{KD}})\mathcal{L}_{\text{CE}}(\mathbf{p}_{\text{student}}, \mathbf{y}) + \gamma_{\text{KD}} T_{\text{distill}}^2 \mathcal{D}_{\text{KL}}(\mathbf{p}_{\text{teacher}}^{(T_{\text{distill}})} \| \mathbf{p}_{\text{student}}^{(T_{\text{distill}})})$$

Here $\mathbf{p}_{\text{teacher}}^{(T_{\text{distill}})}$ and $\mathbf{p}_{\text{student}}^{(T_{\text{distill}})}$ are the probability vectors computed at temperature T_{distill}, $\mathbf{y}$ is the one-hot ground-truth label vector, and $\gamma_{\text{KD}} \in [0,1]$ balances the hard-label and soft-target objectives. The scaling factor T_{distill}^2 ensures that the gradient magnitude of the distillation loss remains commensurate with the hard cross-entropy loss. Dividing logits by T_{distill} scales the derivative of the softmax probabilities by $1/T_{\text{distill}}$, and the gradient of the KL divergence with respect to the student's logits scales as $1/T_{\text{distill}}^2$ in the high-temperature limit. Multiplying by T_{distill}^2 prevents the teacher's supervisory gradient from vanishing relative to the hard-label loss as T_{distill} increases. This formulation defines response-based distillation, matching final output distributions. Modern

[10] **Temperature (softmax)**: The term comes from the Boltzmann distribution in statistical mechanics. Dividing logits by a temperature above one produces a softer distribution and can expose relative probabilities among non-target classes. At T_{distill}=1, the expression is standard softmax; increasing the temperature reduces logit gaps but does not guarantee that the revealed probabilities help the student. The useful amount of softening depends on logit scale, teacher calibration, student capacity, loss weighting, and the accompanying T_{distill}^2 factor. Temperature is therefore selected empirically rather than fixed to a universal range.

[11] **KL divergence**: Introduced by Solomon Kullback and Richard Leibler in 1951, $\mathcal{D}_{\text{KL}}(p\|q)$ quantifies the extra bits needed to encode samples from distribution p using a code optimized for q. The key asymmetric consequence: $\mathcal{D}_{\text{KL}}(\text{teacher}\|\text{student})$ penalizes the student heavily for assigning zero probability to teacher-probable outputs, forcing the student to maintain broad coverage of the teacher's distribution, including low-probability "soft labels" that carry the teacher's learned uncertainty. Distillation can affect calibration, which must be evaluated separately.

pipelines also employ feature-based distillation, training intermediate student layers to directly match the teacher's hidden representations or attention maps using mean squared error or cosine distance to guide gradient updates across deep backbones.

Efficiency gains and trade-offs Distillation's primary deployment advantage over unstructured pruning is that it produces a smaller dense model. Standard accelerators achieve peak throughput on contiguous matrix multiplications; unstructured sparse models incur irregular memory access and index decoding overheads that often negate theoretical FLOP reductions unless sparsity is extreme. A compact dense student maintains coalesced memory access and executes vendor-optimized dense GEMM kernels. However, parameter reduction alone does not guarantee lower latency, because operational intensity, layer depth, attention sequence length, and memory bandwidth limits still govern runtime. DistilBERT, for example, is about 60 percent faster (roughly 1.6×) primarily because it removes half of BERT's transformer layers (Sanh et al. 2019). The gap from the ideal 2× reflects work that halving the layers does not remove, such as the embedding layer, the task head, and fixed per-request overheads.

Distillation composes with pruning and quantization in multi-stage compression pipelines, and the order matters. Quantization usually comes last, because its calibration must see the weight and activation distributions of the final structure. Pruning first and then distilling makes the pruned network itself the student, so distillation doubles as the recovery training after the cut. Section 10.5.3 applies this order to the camera pipeline and to a modeled BERT pipeline. Structural compression can also happen earlier than fine-tuning. Gordon et al. (2020) show that BERT pruned during pretraining transfers to downstream tasks, so the structural step need not wait for a task-specific model.

These operational gains trade inference efficiency for substantial training overhead. Distillation requires running inference across the teacher model to generate soft targets and backpropagating loss through the student across millions of tokens. For large models, this auxiliary training phase consumes significant accelerator FLOPs and memory bandwidth, whereas post-training quantization, introduced later in this chapter, needs only a pass over a small calibration set. Compression effectiveness is also bounded by student capacity and teacher fidelity. An undersized student lacks the capacity to absorb the teacher's distribution, while an inaccurate or uncalibrated teacher imparts its own systematic errors to the student. Selecting an optimization strategy therefore requires evaluating task accuracy, parameter footprint, serving latency, and total training cost together, the comparison that table 10.11 in section 10.5 makes for distillation, pruning, and quantization.

Distillation still needs a student architecture, and the student's own design decides how much of the frame budget remains for everything else. Efficient architecture design and neural architecture search build that student to be efficient on the target by construction.

10.2.4 Efficient architecture design

Hardware-aware design begins before compression. If the target device cannot keep convolution kernels fed, cannot store activations without spilling, or cannot meet the power budget at the chosen input resolution, pruning and quantization only treat symptoms. The architecture itself must expose the kind of work the hardware can execute efficiently. That means choosing layer shapes, scaling rules, and operator patterns with memory bandwidth, parallelism, and energy as first-class constraints rather than post-hoc deployment checks. The efficient families of chapter 6, among them MobileNetV2's depthwise separable factorization, are best read here as responses to a measured deployment bottleneck rather than as a catalog of architectures.

10.2.4.1 Efficient design principles

The first design step is to identify what the trace shows as the limiting resource. A model can miss its target because every layer is too expensive, because one convolution family dominates arithmetic, because activations or parameters do not fit the memory hierarchy, or because the candidate architecture ignores the platform's preferred operators. Table 10.5 organizes the common responses by the bottleneck they address rather than by model family.

Table 10.5: Hardware-Aware Design Principles: A profiling trace should determine which architectural response is appropriate. MobileNet responds to redundant convolutional computation with depthwise separable convolutions, DenseNet and SqueezeNet respond to memory pressure with feature reuse and parameter reduction, and hardware-aware NAS incorporates measured platform behavior directly into the search objective.

Observed bottleneck	Architectural response	Example networks
Over-budget model scaling	Adjust depth, width, and resolution together so the model stays within the latency, memory, and power envelope.	EfficientNet
Redundant computation	Replace expensive dense operations with factorized or grouped operations that preserve useful channel mixing at lower arithmetic cost.	MobileNet, ResNeXt
Memory pressure	Reduce parameter storage or reuse features, then check peak activation lifetimes; feature reuse can retain a larger working set.	DenseNet, SqueezeNet
Platform mismatch	Include measured device latency, operator support, and power behavior in the architecture search or design loop instead of optimizing FLOPs alone.	MobileNetV3, MnasNet

These responses interact. Reducing convolutional FLOPs with depthwise separable convolutions helps only if the target runtime has efficient kernels for the resulting operators. Shrinking a model with parameter-reduction layers helps only if activation storage or memory traffic was part of the measured problem. Hardware-aware design therefore does not replace profiling; it moves profiling information earlier, into the architecture itself.

10.2.4.2 Scaling optimization
