Main Text

Chapter 1 The Causal Boundary **3**
1.1 Artificial Intelligence Beyond Glass . . . 4
1.2 From Prediction to Action . . . 6
1.3 The Question This Book Answers . . . 9
1.4 Defining the Causal Boundary . . . 11
1.5 Three Machine Classes . . . 17
1.6 The Physical AI Scope Test . . . 18
1.7 The Machine in Five Levels . . . 21

1.8 When the Responsibilities Fail Together . . . 23
1.9 Where Safety, Security, and Accountability Meet . . . 26
1.10 The Four Bedrock Laws . . . 28
1.11 The Architecture of This Book . . . 30
1.12 Fallacies and Pitfalls . . . 32
1.13 Summary . . . 33
1.14 Historical Perspective and Further Reading . . . 34

Part I: The Machine Anatomy

The Machine Anatomy **39**

Chapter 2 The Physical Body **41**
2.1 The Five Physical Budgets . . . 42
2.2 Measurement Freshness . . . 44
2.3 Kinetic Momentum . . . 48
2.4 Actuator Transmission Limits . . . 53
2.5 Thermal Duty Cycles . . . 65
2.6 Electrical Power Integrity . . . 71
2.7 Measuring a Machine's Own Limits . . . 75
2.8 Which Physical Budget Binds First . . . 79
2.9 Fallacies and Pitfalls . . . 82
2.10 Summary . . . 85
2.11 Historical Perspective and Further Reading . . . 87

Chapter 3 The Cognitive Brain **89**
3.1 The Embodied Brain . . . 90
3.2 The Classical Wall . . . 92
3.3 Learned Representations . . . 94
3.4 The Cost of a Fresh Evaluation . . . 99
3.5 Chunk Supply and Evidence Validity . . . 107
3.6 Cognitive Vulnerabilities . . . 118
3.7 Fallacies and Pitfalls . . . 122
3.8 Summary . . . 124
3.9 Historical Perspective and Further Reading . . . 125

Chapter 4 The Nervous System **129**
4.1 The Multi-Rate Bridge . . . 130
4.2 The Independence Requirement and the Two-Processor Hypothesis . . . 132
4.3 Multi-Rate Cadences . . . 136
4.4 Chunk Lease Sizing from the Stopping Budget . . . 141
4.5 Real-Time Command Transport and Bus Determinism . . . 147
4.6 Actuation Authority . . . 154
4.7 Hardware Isolation and Fault Containment . . . 157
4.8 Invariant Checking . . . 159
4.9 The Handoffs Matrix . . . 160
4.10 Fallacies and Pitfalls . . . 166
4.11 Summary . . . 167
4.12 Historical Perspective and Further Reading . . . 169

Part II: Teaching the Machine

Teaching the Machine **173**

Chapter 5 Physical Data **175**
5.1 Endogenous Experience . . . 176

5.2 Mechanics of Endogenous Covariate Shift . . . 177
5.3 Recovery and Compounding Error . . . 178
5.4 Physical Telemetry Sources and Collection Paths . . . 180
5.5 Action Label Selection across the Control Boundary . . . 183
5.6 Teleoperation Demonstration Costs . . . 189
5.7 Collection Policy Coverage . . . 196
5.8 Intervention and Recovery Data . . . 199
5.9 Cross-Embodiment Transfer . . . 204
5.10 Dataset Degradation and Physical Distribution Shift . . . 210
5.11 The Dataset Schema . . . 215
5.12 Fallacies and Pitfalls . . . 218
5.13 Summary . . . 220
5.14 Historical Perspective and Further Reading . . . 222

Chapter 6 Policy Training **225**
6.1 Dual Failure Modes of Policy Training . . . 226
6.2 Policy Training Regimes . . . 227
6.3 Reinforcement Learning and Environment Interaction . . . 242
6.4 The Simulator as a System Component . . . 246
6.5 Physical Channels of the Sim-to-Real Gap . . . 252
6.6 Real-Robot Fine-Tuning and Residual Control . . . 260
6.7 Training Failure Modes and Permission-Path Interceptors . . . 263
6.8 The Policy Manifest . . . 264
6.9 Fallacies and Pitfalls . . . 268
6.10 Summary . . . 271
6.11 Historical Perspective and Further Reading . . . 273

Chapter 7 Closed-Loop Evaluation **275**
7.1 From Clean Runs to Bounded Claims . . . 276
7.2 What a Physical Success Rate Measures . . . 277
7.3 Closed-Loop Dynamics . . . 281
7.4 Evidence Regimes . . . 287
7.5 Fixing the Trial Protocol . . . 291
7.6 Confidence from a Finite Campaign . . . 292
7.7 Trial Budgets, Stopping Rules, and Comparisons . . . 295
7.8 The Evaluation Record . . . 300
7.9 Verification Ceilings and the Exposure Wall . . . 306
7.10 Evaluation Pitfalls and Metric Masking . . . 315
7.11 Fallacies and Pitfalls . . . 317
7.12 Summary . . . 320
7.13 Historical Perspective and Further Reading . . . 322

Part III: Running the Machine

Running the Machine **327**

Chapter 8 Sensor Perception **329**
8.1 Choosing Evidence for a Spatial Decision . . . 330
8.2 Capture Physics and Calibration . . . 332
8.3 Dating and Placing the Measurement . . . 341
8.4 Bounding Observation Age . . . 345
8.5 Ingestion Overhead and Memory Bus Contention . . . 351
8.6 Spatial Error and Clearance Bounds . . . 354
8.7 Perception Failure Modes and Sensor Degradation . . . 361
8.8 The Observation Contract . . . 366
8.9 Fallacies and Pitfalls . . . 370

8.10 Summary . . . 372
8.11 Historical Perspective and Further Reading . . . 374

Chapter 9 Spatial Memory **377**
9.1 Spatial Belief Persistence and Expiry . . . 378
9.2 Estimating State from Dated Measurements . . . 380
9.3 The Spatial Memory Handoff and State Invariants . . . 386
9.4 State Epochs and Temporal Anchoring . . . 388
9.5 Coordinate Transform Expiry and Localization Drift . . . 390
9.6 Certified Spatial Assertions in Scene Memory . . . 395
9.7 Forward State Propagation and Occlusion Decay . . . 406
9.8 Observability Ceilings and Estimation Limits . . . 415
9.9 Spatial Belief Failure Modes and Map Corruption . . . 417
9.10 The Belief Record Schema . . . 420
9.11 Fallacies and Pitfalls . . . 424
9.12 Summary . . . 425
9.13 Historical Perspective and Further Reading . . . 428

Chapter 10 Grounded Intent **431**
10.1 Grounded Affordances . . . 432
10.2 Task Operators and Geometric Samplers . . . 436
10.3 Semantic Request Translation to Geometric Proposals . . . 437
10.4 The Intent Handoff and Bounded Authority . . . 446
10.5 Expiring Goals and Temporal Validity Leases . . . 448
10.6 Admissible Goal Sets . . . 452
10.7 Intent Grounding Failure Modes and Their Checks . . . 457
10.8 The Intent Lease Specification and Contract . . . 459
10.9 Fallacies and Pitfalls . . . 465
10.10 Summary . . . 467
10.11 Historical Perspective and Further Reading . . . 469

Chapter 11 Trajectory Planning **471**
11.1 Continuous Trajectory Generation . . . 472
11.2 The Planning Handoff and the Trajectory Record . . . 473
11.3 Replacement Timing and the Planning Horizon . . . 477
11.4 Kinodynamic Feasibility . . . 482
11.5 Behavior at the Seam . . . 494
11.6 Choosing a Trajectory Generator . . . 501
11.7 Trajectory Planning Failure Modes and Infeasible Seams . . . 507
11.8 The Trajectory Record . . . 509
11.9 Fallacies and Pitfalls . . . 510
11.10 Summary . . . 512
11.11 Historical Perspective and Further Reading . . . 514

Chapter 12 Safety Enforcement **517**
12.1 The Per-Tick Gatekeeper . . . 518
12.2 The Tracker Handoff and Dynamic Reference Envelopes . . . 519
12.3 Stopping Envelopes . . . 521
12.4 Authority Exhaustion and Emergency Fallback . . . 530
12.5 Safe Sets as Conditional Permission . . . 534
12.6 Refusing Proposals and Enforcing State Invariants . . . 537
12.7 The Minimal Intervention Principle and Optimization Filters . . . 539
12.8 Admission, Cyclic Checking, and Monitor Independence . . . 548
12.9 The Fallback Ladder . . . 550
12.10 Runtime Enforcement Failure Modes . . . 558
12.11 The Enforcement Record . . . 559

12.12 Fallacies and Pitfalls . . . 563
12.13 Summary . . . 565
12.14 Historical Perspective and Further Reading . . . 567

Chapter 13 Workload Placement **571**
13.1 The Silicon Substrate . . . 572
13.2 Two Paths and the Resources They Share . . . 573
13.3 Contention for Shared Resources . . . 580
13.4 Thermal and Timing Coupling . . . 585
13.5 The Boundary Contract . . . 589
13.6 Silicon Isolation Decisions . . . 591
13.7 Empirical Verification of Silicon Isolation . . . 596
13.8 The Placement Record . . . 601
13.9 Fallacies and Pitfalls . . . 604
13.10 Summary . . . 605
13.11 Historical Perspective and Further Reading . . . 607

Part IV: Governing the Machine

Governing the Machine **611**

Chapter 14 Supervisory Intervention **613**
14.1 Shared Authority . . . 614
14.2 Human Authority, Reaction Time, and Clearance . . . 616
14.3 Authority Transitions . . . 626
14.4 Transfer Without Discontinuity . . . 633
14.5 Authenticating an Intervention . . . 637
14.6 Authority Handover Failure Modes . . . 639
14.7 Trustworthy Operational Logs . . . 642
14.8 The Authority Record . . . 643
14.9 Fallacies and Pitfalls . . . 648
14.10 Summary . . . 650
14.11 Historical Perspective and Further Reading . . . 653

Chapter 15 Adversarial Verification **657**
15.1 The Claim a Fault Trial Must Test . . . 658
15.2 The Operating Envelope . . . 660
15.3 One F1 Trial from Injection to Record . . . 664
15.4 Fault Oracles and Acceptance . . . 667
15.5 Extending the Trial to the Envelope . . . 671
15.6 Deriving the Fault List . . . 673
15.7 The Qualification Ladder . . . 681
15.8 Fault Injection on Hardware . . . 686
15.9 Searching Beyond the First Trial . . . 690
15.10 Interpreting Campaign Statistics . . . 695
15.11 Fault Records for Release . . . 701
15.12 Fallacies and Pitfalls . . . 704
15.13 Summary . . . 706
15.14 Historical Perspective and Further Reading . . . 708

Chapter 16 Deployment Release **711**
16.1 The Decision to Deploy . . . 712
16.2 Physical Criteria for Release . . . 713
16.3 Safety Cases and Claims . . . 717
16.4 The Three Verdicts . . . 725
16.5 The Verdict's Standing Conditions . . . 729

16.6 Adjudicating the Safety Case . . . 733
16.7 Adversarial Review . . . 736
16.8 The Release Manifest . . . 739
16.9 Maintaining Release Through Updates . . . 743
16.10 Fallacies and Pitfalls . . . 749
16.11 Summary . . . 751
16.12 Historical Perspective and Further Reading . . . 754

Chapter 17 Responsible Physical AI **757**
17.1 Who Answered for the Cruise Collision . . . 758
17.2 Decisions Behind an Admitted Action . . . 759
17.3 Oversight a Person Can Perform . . . 760
17.4 Permission in Stages . . . 763
17.5 When Detection Depends on Who Is Detected . . . 764
17.6 Who Bears the Risk . . . 767
17.7 Data About People . . . 768
17.8 The Labor the Machine Moves . . . 770
17.9 The Approval Record . . . 771
17.10 Fallacies and Pitfalls . . . 773
17.11 Summary . . . 774
17.12 Historical Perspective and Further Reading . . . 775

Conclusion

Chapter 18 Engineering Physical AI **779**
18.1 From a Better Prediction to Useful Service . . . 780
18.2 Generalizing to Unfamiliar Systems . . . 783
18.3 The Epistemic Frontier . . . 788
18.4 Choosing the Next Capability . . . 801
18.5 Fallacies and Pitfalls . . . 805
18.6 Summary . . . 807

Preface

Who This Book Is For

This book is for senior undergraduates and beginning graduate students in computer science, robotics, electrical engineering, and machine learning, and for practicing engineers who build, deploy, or certify physical AI systems. It is written for the engineer who has watched an embodied policy succeed in simulation or a scripted demonstration and now has to ship a machine that moves mass among people, day after day. That machine must not collide with a coworker, damage a payload, burn out a motor winding, or run away on a network timeout.

The reader should understand basic programming in Python and machine learning intuition, and be comfortable with introductory Newtonian physics, linear algebra, and basic probability. The book assumes no prior book in this series. It develops physical AI concepts where they are first used and derives the timing, control, and hardware-placement relationships needed to reason about embodied workloads without requiring specialist background in nonlinear control theory or application-specific integrated circuit (ASIC) microarchitecture.

Why a Physical AI Textbook

A reasonable engineer might look at the current wave of robot foundation models and ask a skeptical question. *Is physical artificial intelligence a genuine systems discipline with durable principles, or is it simply classical robotics with a transformer bolted on, or an end-to-end neural network running on an onboard computer?*

The skepticism is fair. Much of what is written about embodied AI highlights impressive single-task demonstrations, such as a dexterous hand folding laundry or a humanoid walking through a lab. Demonstration, however, is not deployment. In the field, failure rarely comes from the raw expressiveness of the model. What fails is the system around it, as when an observation arrives 50 milliseconds too late, an action proposal demands more torque than the joint drives can deliver, or an unmodeled delay turns a braking command into an impact.

Traditional machine learning systems center on disembodied prediction. A model evaluates static inputs in an open loop and returns advisory labels, rankings, or tokens without acting directly on the world. Because a person or downstream service must still decide what to do with that output, an erroneous prediction can be discarded or recalculated before it causes harm, and systems engineering centers on balancing training cost against serving latency, memory, and throughput. Agentic machine learning systems move from single predictions to sequential action: a model formulates multi-step plans, inspects feedback, and invokes software tools in a closed loop. As long as that loop stays inside a digital environment, however, virtual time can be paused, execution can be sandboxed, and failed transactions can be rolled back.

Physical AI systems bring agency into continuous physics. When an autonomous model commands actuators, computation crosses the causal boundary into mass, momentum, friction, and heat. In continuous physics, virtual sandboxes do not exist: time cannot pause while a foundation model deliberates, and Newtonian work cannot be rolled back after an impact. A larger model cannot shorten a stopping distance, cool an electric winding, or recover clearance spent while it computed. Physical AI therefore requires an architectural discipline. Learned models propose, while an independent permission path, with its own timing and its own fallback, decides what may cross into the physical world.

This book teaches how to design, measure, and govern that machine. Its central question is what an embodied task needs around a learned model to produce useful physical service supported by

the required evidence. Readers should leave able to translate physical limits into computational budgets, design sensorimotor policies that close the loop under real-time deadlines, enforce runtime assurance independently of the learned proposer, and justify release through an assurance case that links claims to empirical evidence.

The Causal Boundary and the Four Laws

The unit of engineering in this book is the **causal boundary**, the interface where an admitted digital command becomes current in a motor winding, torque on a shaft, and physical force delivered to the world. Accuracy on a held-out dataset is not the measure of a physical AI system. The measure is whether closed-loop actions achieve task goals within verified physical limits, supported by evidence independent of the learned model's self-report, and at what cost in latency, energy, thermal margin, and compute.

Four governing laws anchor the book's architecture. Each law pairs a physical or statistical constraint with the systems mechanism required to bound it:

- **The First Law: Irreversibility.** Software cannot roll back physical consequences. Every check that admits a command must finish before the machine spends its remaining clearance, so physical limits become strict budgets in time, distance, torque, heat, and voltage.
- **The Second Law: Endogenous Data.** A physical machine's actions choose its next observations. The states a deployed policy visits are conditioned on its own previous actions, so competence is a claim bounded by the operating envelope that closed-loop evaluation actually verified.
- **The Third Law: Proposal Is Not Permission.** A learned model may propose motion; only an independent permission path may admit it. The permission path evaluates state whose age is bounded, executes within a deterministic deadline set by the plant physics, and maintains a feasible fallback that does not depend on the learned proposer.
- **The Fourth Law: Permission Must Be Earned.** Permission to operate is granted per operating condition on recorded evidence, and it expires when that evidence does.

The first of these is a physical law. The other three are design principles, the embodied counterparts to covariate shift, runtime assurance, and the assurance case. This book elevates them to bedrock laws because a production machine that violates them incurs predictable physical risks.

Two relations quantify these obligations throughout the book. **Delay is distance** governs the stopping budget: if a machine moving at velocity v takes reaction time τ_{delay} to sense, compute, and actuate before decelerating at rate a_{brake}, the total stopping distance is $d_{\text{stop}} = v \cdot \tau_{\text{delay}} + \frac{v^2}{2a_{\text{brake}}}$. Every millisecond of latency is distance spent before braking can begin. **Evidence expiration** governs the validity of state: an observation or state estimate carries an expiration timestamp derived from the plant's maximum rate of change, after which it cannot justify a safety assertion.

The machine's architecture separates five roles: the **Brain** (learned models that propose goals and motion), the **Nervous System** (deterministic communication and the independent permission path), the **Body** (drives, transmissions, windings, and power systems), the **Boundary** (register writes and sensor captures), and the **World** (continuous physical dynamics, obstacles, and people). A warehouse mobile manipulator that navigates an aisle shared with workers, opens a spring-latched door, and handles a fragile payload serves as the running reference machine in every chapter. A humanoid example at the end of each part tests whether the reasoning survives a body that couples balance, joint torque, and thermal dissipation.

What This Book Covers

The book builds understanding in physical dependency order: **anatomy, teaching, running, governing**. Each part adds responsibilities that the preceding material prepares the reader to evaluate, and reference appendices supply the supporting mathematical, control, and hardware derivations:

- **Introduction: The Causal Boundary** (chapter 1) prices delay at the causal boundary, defines the five-level machine architecture, and establishes the four governing laws.
- **Part I: The Machine Anatomy** turns the first law into physical budgets. Chapter 2 measures what the body can do before damage, chapter 3 characterizes the learned proposer and how

quickly its evidence ages, and chapter 4 derives how frequently the permission path must tick and how long a proposal may drive the actuators.

- **Part II: Teaching the Machine** applies the second law to sensorimotor learning. Chapter 5 records demonstrations with their operating conditions, chapter 6 analyzes training regimes and the dependencies they hide, and chapter 7 bounds the policy's competence through finite-trial closed-loop evaluation.
- **Part III: Running the Machine** applies the third law at runtime. It follows dated sensor measurements through perception (chapter 8), spatial memory and state estimation (chapter 9), intent grounding (chapter 10), and trajectory planning (chapter 11) to runtime enforcement (chapter 12), and tests whether real-time hardware keeps that path on time (chapter 13).
- **Part IV: Governing the Machine** applies the fourth law to operational authority. Chapter 14 governs how authority passes between the machine and an operator. Chapter 15 injects physical and computational faults to prove containment. Chapter 16 constructs the assurance case that justifies release under named conditions. Chapter 17 names who answers for each decision behind an admitted action, which human roles a person can actually perform, and which people bear the machine's risk and appear in its records.
- **Conclusion: Engineering Physical AI** (chapter 18) synthesizes the complete methodology, transfers the reasoning to an unfamiliar machine, and establishes the open research frontier.

Reference appendices provide background on machine learning foundations (Appendix A), control and dynamics (Appendix B), systems and hardware (Appendix C), sensorimotor troubleshooting (section D.6), and a unified glossary. Each appendix is organized as a lookup reference so that readers can consult a specific derivation without losing the thread of the main text.

How to Read This Book

The book is written to be read in order. Each chapter uses only ideas introduced earlier or defined where they appear, and each owns its concepts. Every chapter opens with the physical problem it solves, develops the mechanism as the answer, and closes with a summary and a handoff to the next chapter. Classical systems mechanisms (watchdog leases, safety filters, interlocks, fail-safe fallbacks, and real-time scheduling) appear as concrete solutions to physical hazards rather than as abstract theory.

Readers with a particular focus can tailor their depth after the introduction. Four tracks correspond to the primary engineering roles that collaborate on a physical AI deployment:

- **Core systems curriculum**: Follow the complete sequence from chapter 1 through chapter 18 to integrate physical limits, learning, runtime design, and operational evidence.
- **ML systems and learned runtimes**: Focus on the common foundation, sensorimotor training and evaluation (chapter 5 through chapter 7), perception and planning (chapter 8 through chapter 13), and release (chapter 16).
- **Embedded systems and silicon**: Focus on the common foundation, runtime placement (chapter 13), communication timing (chapter 4), and fault verification (chapter 15).
- **Robotics, control, and assurance**: Focus on the common foundation, state estimation and planning (chapter 9 through chapter 11), runtime enforcement (chapter 12), human intervention (chapter 14), and responsibility for the people around the machine (chapter 17).

Evidence flows from physical anatomy through training and runtime execution to operational release, and the chapter dependencies across the six divisions of the book follow that progression (figure P.1). Every arrow in the map represents a concrete record or physical bound handed forward from one engineering stage to the next.

Marginal reading aids and navigation pointers

The margins carry small visual aids beside the prose where a quantitative relationship, scale gap, or threshold is easiest to see. Each visual follows one of five recurring forms:

- **Ladders** span orders of magnitude (such as sensor ingestion bandwidths or execution loop rates).

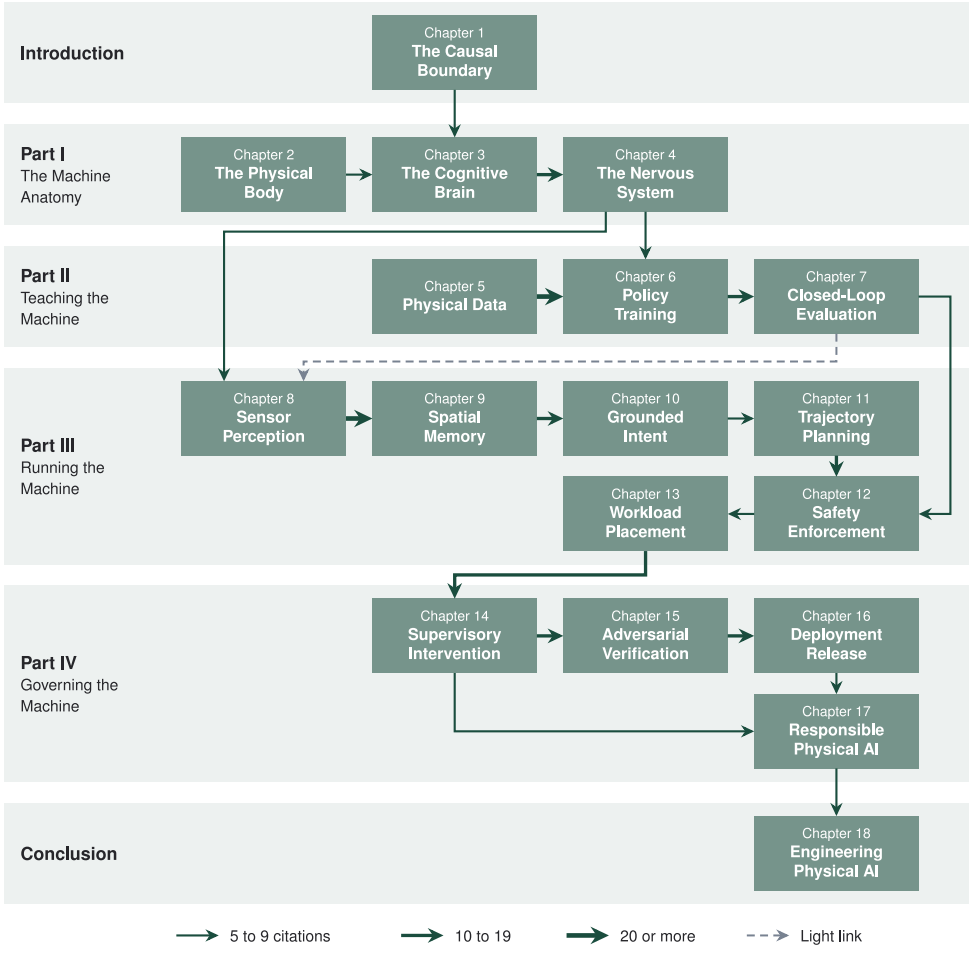

Figure P.1: Chapter Dependency Map: Arrows show chapter dependencies across the book's divisions. Solid-arrow weight follows the citation-count bands in the legend: 5–9, 10–19, and 20 or more citations; dashed arrows mark light links. Transitive links are omitted for clarity.

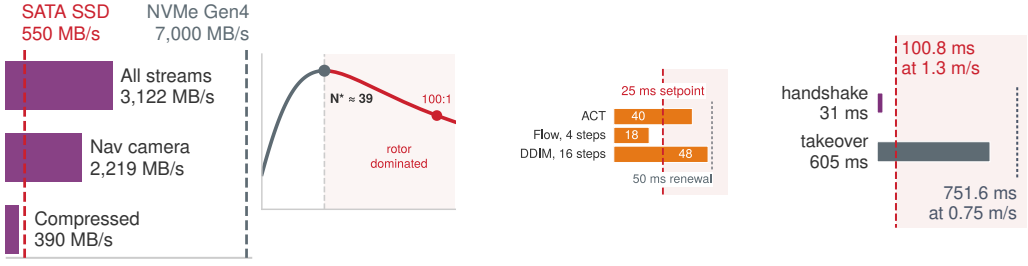
- **Threshold knees** mark the point where a physical relationship changes regime (such as reflected rotor inertia dominating gear trains or contact stiffness spiking forces).
- **Budget envelopes** set competing demands against a deadline (such as diffusion denoising steps against control periods, or operator takeover latencies).
- **Sequence strips** illustrate multi-phase timing (such as receding-horizon chunk execution or fault handshakes).
- **Causal chains** trace fault propagation from sensor error to physical consequence.



Alongside these visual notes, unnumbered **marginal navigation pointers** trace architectural connections across chapters. Three symbols distinguish whether a pointer looks back to a foundation, ahead to a downstream consumer, or across to a contrasting design:

- ↩ **Backward pointer:** Directs the reader back to the earlier chapter where a physical bound, hardware contract, or clock cadence was established.
- ↪ **Forward pointer:** Directs the reader ahead to the later chapter, or to an appendix, where the idea is developed, measured, or enforced.
- ⇄ **Contrast:** Marks a place where two chapters or machine classes treat the same problem differently.

A pointer only orients. When an argument depends on another chapter, the reference stays in the text.

What This Book Is Not

This is not a ROS 2 or middleware manual. Middleware and messaging frameworks change, whereas the physical requirements they must satisfy (bounded latency, deterministic serialization, and fault isolation) do not. The book therefore introduces real-time protocols and message queues only as mechanisms to meet stated physical deadlines. Nor is it a mechanical CAD manual or a motor design treatise, because it characterizes actuators, transmissions, and thermal limits through the software budgets they impose rather than through their mechanical fabrication. For the same reason, simulation appears here not as a benchmark leaderboard, where open-loop scores stand in for deployment, but as a tool for generating hypotheses and training data. Its claims must still be verified on the physical machine. Software agents that act solely behind digital APIs without physical actuators remain outside our scope.

A Note on Durability

Robot form factors, neural network architectures, and motor drive silicon will evolve, some before this book reaches print. The text therefore emphasizes the principles that survive those transitions: the causal boundary as the unit of engineering, the four governing laws, the separation between learned proposers and deterministic permission paths, and the discipline of grounding operational authority in empirical evidence. Current platforms and models appear throughout to make the concepts concrete, but the principles stand independently of any specific vendor, model, or hardware platform. Where a question is actively unsettled in the field, such as how best to verify generalist policies against rare corner cases, the book presents the problem as an open engineering challenge rather than settled doctrine.

An Open-Source Textbook

This book is open source. Its full text, figures, and build system are available at mlsysbook.ai/git, and contributions are welcome from every reader. That openness is deliberate. Physical AI draws on robotics, control, machine learning, and embedded systems, whose knowledge rarely sits in one place. A textbook that joins them should be available to everyone working across those boundaries, regardless of geography or institutional affiliation.

Readers help most by fixing an error, suggesting a clearer explanation, adding a worked example, or reporting where a claim does not hold on real hardware. Issues and pull requests provide the mechanism for that collaboration.

A Living Textbook

This copy is a snapshot of a book that continues to change. The field keeps moving, and so does my understanding of it, so I keep revising the online edition at **mlsysbook.ai**. The principles in this book are chosen to last. Examples, numbers, and explanations may have improved since this version was published, and the online release notes record what changed.

Prerequisites

The worked examples and derivations draw on five foundational areas. Readers should be comfortable with:

- programming in Python and working with numeric arrays;
- core machine learning concepts, including supervised training, loss functions, and inference;
- introductory Newtonian mechanics (position, velocity, acceleration, force, torque, inertia);
- linear algebra (vectors, matrices, coordinate transformations); and
- undergraduate probability and basic statistics.

Deeper background in classical control theory, real-time operating systems, or robotics kinematics is beneficial but not required; the book develops the necessary control, estimation, and real-time concepts where they are first needed. Every specialized tool is introduced from first principles at the point where a concrete systems decision depends on it.

DRAFT

0

Dedication

For my students,
who ask the question
I have not thought of yet,

and for the researchers and systems engineers
who take up the challenge of giving machines
safe and capable hands in an open physical world.

Author's Note

When a server returns an error for a page request, the reader can try again. A robot approaching an obstacle keeps moving while its computer decides whether to brake. Restarting the computation cannot recover the distance already traveled.

In a page-serving application, an unhandled exception or late result may produce a log entry, a dropped frame, or a retry button. In physical AI, software commands matter, momentum, and energy. The unit of engineering is the action crossing the causal boundary. Delay is paid in millimeters, and failure results in cracked composite, burned motor coils, or physical harm.

To build machines that survive this reality, we must give up the idea that a high-capacity network can drive a physical plant, the apparatus being controlled, directly. In the machine this book builds, the learned model proposes; only the permission path permits, and only for as long as its evidence holds.

I write these chapters as an active systems researcher exploring how the laws of computing intersect with the laws of Newtonian mechanics, thermal dissipation, and functional safety. Concrete systems tasks, hardware measurements, and first-principles napkin math guide our progression; formal continuous-control derivations and proof machinery provide optional depth in the appendices.

This book is an open, working notebook. Step across the causal boundary with me, and let us explore how to engineer machines that sense, act, and survive in the physical world.

About the Author

Vijay Janapa Reddi is the Gordon McKay Professor of Electrical Engineering and Computer Engineering at Harvard University and a Visiting Professor at ETH Zurich in the Integrated Systems Laboratory (IIS), D-ITET. He is a founding member and Vice President of MLCommons and the author of the open-source reference text *Machine Learning Systems*.

His research sits at the intersection of computer architecture, machine learning systems, and edge robotics, focusing on how computing hardware and learned software co-design to interact with the physical world. Over the past decade, his work has concentrated on democratizing applied systems through open-source education and reproducible benchmarks, connecting first-principles silicon constraints directly to accessible, bench-verified learning.

Why I Am Writing This Book: The First-Principles Systems Stance

Every textbook reflects the intellectual lineage, biases, and lens of its author. I want to make the viewpoint behind this book explicit.

I am not a classical control theorist, nor a mechanical kinematics specialist, and I do not pretend to be one. I bring the perspective of a computer systems architect and machine learning systems (MLSys) researcher going after first principles.

My intuition for this domain dates back to my undergraduate mechatronics capstone. As an electrical and computer engineering student, that capstone was the first time I had to integrate analog circuits, sensor conditioning, microcontrollers, motor drivers, mechanical linkages, and embedded software into a single working machine. It was the moment I realized that software cannot be designed in isolation from physical reality: motor coils heat up, power rails droop under sudden acceleration, and sensor measurements age the instant physical transduction occurs. For over twenty years, my work has sat at the boundary where software meets silicon and energy constraints: mobile System-on-Chip performance architecture and edge AI silicon at Google, co-founding MLCommons and MLPerf to set empirical benchmarking standards for AI accelerators, and helping start TinyML, which compresses neural networks to run on milliwatt microcontrollers.

Physical AI brings me back to that mechatronics capstone, with one difference. In classical mechatronics, we closed the loop using hand-crafted, deterministic logic: PID controllers, state machines, and analytical models. In Physical AI, we are embedding high-capacity neural networks (foundation models, diffusion policies, and learned decoders) into that exact same unforgiving loop. Their proposals may be sampled or deterministic, but neither form alone establishes that an action is safe. The engineering challenge now extends beyond making the machine move to closing the loop safely around a learned brain, using deterministic systems and safety principles.

That background shapes what I want students to understand. A model's proposed action must pass through a computing system before the physical machine can carry it out. I want readers to trace that path and ask what could prevent an action from being carried out as intended. The timing of computation, the body's capabilities, and the assumptions behind command checks all matter to that assessment. The explanations should make these interactions understandable before specialized mathematics or implementation detail is needed.

This textbook is my attempt to share that foundational systems perspective with the next generation of engineers, roboticists, and computer scientists. It is the book I wish my own students had when bridging machine learning systems to the physical world.

Research Background and Systems Path

This first-principles systems work spans three major eras. Each era extended the same hardware-to-software discipline to a tighter physical operating envelope:

- **Silicon Reality & Mobile Architecture:** Grounded in computer architecture, low-power microarchitectures, and mobile System-on-Chip (SoC) design (including edge AI silicon performance architecture at Google). This work addressed the physical realities of computing: memory bus contention under high-bandwidth camera streams, thermal throttling under strict power and thermal envelopes, and interrupt latencies under hard real-time deadlines.
- **ML Systems & The TinyML Movement:** Bridging algorithmic machine learning abstractions to silicon execution. He co-founded MLPerf to establish the global standard for benchmarking ML hardware and software, and pioneered the TinyML movement, developing the Harvard CS249r curriculum and the HarvardX TinyML program (reaching over 100,000 learners globally) to bring deep neural models onto milliwatt microcontrollers.
- **Closing the Sense-and-Act Loop in Physical AI:** Extending this systems perspective to machines whose learned models propose physical actions. The focus is on how sensing, computation, and the body's response interact, and on the conditions under which a proposed action can be executed.

The Kit and Laboratory Development

Development of the hands-on bench laboratories and the reference hardware platform (the Physical AI Kit on Arduino UNO Q Dual-Brain) is a collaboration with Dr. Andrea Mattia Garavagno, postdoctoral researcher in the Integrated Systems Laboratory (IIS), D-ITET at ETH Zurich. This work aims to translate the systems ideas in the book into firmware and software exercises that students and practitioners can reproduce and examine on the bench.

Reader Guide and Prerequisites

Physical AI: Machine Learning Systems That Sense and Act is an independent textbook for advanced undergraduate students, graduate researchers, and practicing engineers who want to build machines that sense and act. Readers may arrive from machine learning, software systems, electrical engineering, or robotics. The common goal is to connect learned behavior to physical execution and explain the conditions under which that connection can be trusted.

The Technical Starting Point

A physical AI systems engineer must reason across disciplines, but need not enter with specialist training in all of them. The starting point is programming experience, basic machine learning intuition, and introductory mechanics, supported by undergraduate mathematics. Prior study of another volume in this series is not required.

The following competencies support the worked examples. Each area supplies a practical skill that the chapters build on rather than a prerequisite in advanced theory:

- **Programming**: Read and modify a short program, follow its data flow, and interpret experimental output. The executable calculations use Python; familiarity with C or C++ helps with implementation examples but is not the entry requirement.
- **Machine learning intuition**: Distinguish training from inference, understand a learned model as a mapping fitted from data, and recognize why performance on held-out examples may differ from deployment. Experience building a large model or using a particular framework is not required.
- **Mathematics**: Work with algebra, vectors, matrices, derivatives, and elementary probability. These tools support coordinate transformations, rates of change, and uncertainty estimates. More specialized notation is introduced with the mechanism that needs it.
- **Physical reasoning**: Relate force to acceleration, speed to distance traveled, and electrical power to energy use. Introductory Newtonian mechanics supplies the starting intuition for stopping, contact, and actuator limits.
- **Experimental practice**: Interpret a measurement with its units and conditions, distinguish an assumption from an observation, and compare a calculation with a test. The book develops this practice into evidence for operating a machine.

Specialized control theory, robot kinematics, real-time scheduling, and accelerator architecture are subjects of study here, rather than a second set of admission requirements. Some derivations require a slower pass or background reading. The local appendices provide machine learning background (Appendix A), control and dynamics (Appendix B), and systems and hardware (Appendix C). When a failure spans perception, planning, and actuation, section D.6 maps the symptom to measurements that distinguish competing causes.

Learning across disciplinary boundaries

Readers from different backgrounds enter this loop from different sides. An ML practitioner starts from the consequences of a proposed action and works toward the mechanics and timing that constrain it. An embedded systems engineer starts from a hardware deadline and learns how training data and policy behavior shape the workload that must meet it. A roboticist starts from a model of the plant and examines what changes when a learned proposer supplies goals and

trajectories. Each reader brings one part of the foundation and meets the others where the system connects them.

On a first pass through a dense derivation, identify the physical quantity being bounded, the assumptions the bound needs, and the decision it changes. Then work through the example before returning to the derivation. A formal guarantee may require that deeper mathematical treatment; understanding the systems decision still begins with the concrete failure the mechanism is meant to prevent.

Curricular Reading Tracks

The sequential path is the default for learning the whole discipline. Specialist tracks select an emphasis within that path. They do not make the common physical model or the evidence limits optional.

All tracks begin with chapter 1 and the machine anatomy in chapter 2, chapter 3, and chapter 4. These establish physical budgets, learned proposals, and the independent path that decides whether a proposal may act. Later chapters repeatedly use those foundations. After that common start, readers can concentrate their deeper study along one of four role-specific tracks (table P.1).

Table P.1: Curricular reading tracks: Four structured reading tracks through this book.

Track	Primary Audience	Core Chapter Progression	Primary Systems Competency
Core systems curriculum	Students and engineers learning the full discipline	Complete sequence from chapter 1 through chapter 18	Integrate physical limits, learning, runtime design, and operating evidence
ML systems and learned runtimes	ML engineers and researchers	Common start; chapter 5 through chapter 7; chapter 8 through chapter 13; chapter 16 and chapter 18	Develop and evaluate learned behavior within physical and computational limits
Embedded systems and silicon	Embedded engineers and computer architects	Common start; evaluation limits in chapter 7; chapter 8 through chapter 13; chapter 14 through chapter 18	Keep sensing, permission, and actuation timely under interference and faults
Robotics, control, and assurance	Roboticists and control engineers	Common start; chapter 5 through chapter 7; chapter 9 through chapter 18	Integrate learned behavior with state estimation, feasible motion, and conditional guarantees

When a track omits a chapter from detailed study, its opening, worked handoff, and summary provide the context needed downstream. For example, a planning exercise still needs dated observations and a current state estimate; a release decision still needs evidence about human authority and fault response. Instructors can select technical depth while retaining those dependencies. The full sequence contains more detail than every course will cover at equal depth.

What the Book Introduces

The curriculum builds toward an end-to-end engineering judgment about a machine performing a specified task. Its parts contribute different capabilities:

1. In Part I, determine which physical budget binds, estimate what the learned proposer can supply, and derive the timing requirements that connect computation to actuation.
2. In Part II, collect demonstrations with their operating conditions, choose a training regime, and evaluate behavior in the feedback loop where actions change subsequent observations. Use failures to collect new experience and test whether a changed candidate expands competence without losing established behavior.
3. In Part III, turn measurements into dated state estimates, grounded goals, and feasible trajectories; then check proposals against physical limits and place the runtime on resources that can meet its deadlines.
4. In Part IV, design human intervention, challenge the integrated system with faults, and justify useful service within the conditions the evidence covers, assessing task performance and physical containment separately.

The conclusion synthesizes those engineering capabilities and tests whether they transfer to an unfamiliar machine. The records accumulated along the way preserve the reasoning behind a design: what was measured, what was assumed, which decision followed, and what would invalidate it. Filling in a record is useful only when the underlying engineering argument is sound.

How to Read the Numbers

The evidence behind a number determines what it can support. Four categories distinguish observations and calculations from ratings and illustrative inputs; a fifth label identifies a design choice:

- **Measured**: A calibrated observation of a particular machine. It names its instrument, its operating conditions, its sample count, and, for a distribution, the percentile it reports. Only a measured number, or a number derived from measured ones, can support a safety margin.
- **Derived**: Computed from stated inputs through a physical or statistical model. It carries that model's assumptions, input provenance, and propagated uncertainty. A result derived from illustrative inputs remains illustrative evidence.
- **Datasheet**: A manufacturer's rating under the manufacturer's conditions. It says what to expect and what to test, and it is not evidence about the unit on the bench.
- **Illustrative**: Selected to show arithmetic or scaling. It supports no margin, timeout, or release decision.

A budget or requirement, such as a lease duration or a clearance margin, belongs to none of the four. It is a design decision, labeled **chosen**, and it means something only when it is checked against the measured or derived number it must fit, as a chosen lease is checked against the derived ceiling on pre-brake delay.

A worked design in this book shows a decision procedure. When its inputs are illustrative, the decision it reaches is illustrative too. It shows how the machine's speed, lease, or verdict would be set, and it would bind a real machine only after its physical and timing premises are qualified. Some examples stipulate a supporting evidence packet to teach how successful learning or restricted service could be justified. Such branches are hypothetical throughout; their assumed trial counts and outcomes are not measurements of the book's machine.

When a number decides something, such as a speed limit, a timeout, or a release, the book keeps it as a **limit record** with six elements. The record pairs the nominal value (or distribution) and its measurement uncertainty with the operating conditions under which that value holds (payload, temperature, supply voltage, surface, concurrent workload, and firmware). Alongside the engineering margin between the operating target and the breakdown threshold, it names the runtime detector that catches an excursion while the machine runs and records the value's provenance, meaning its label and the instrument or model that produced it. A limit holds only under its stated conditions. When wear, heat, a new payload, or a new build changes them, the limit must be established again before it is reused.

Before using a worked value to justify a decision, establish both its category and the conditions attached to it, because an unlabeled value does not become a measured limit merely by appearing in a calculation. Every result holds only under the assumptions stated with its example. A statistical bound from finitely many trials depends on its sampling assumptions and proves nothing beyond them. A measured percentile describes only the tested workload rather than a true worst case. In a release argument (chapter 16 and chapter 18), each premise therefore carries an explicit status: established by qualified measurements or derivations, assumed, decided by accountable judgment, unsupported, or outside the threat model.

What We Deliberately Omit

The book develops specialist mechanisms to the depth needed for systems decisions, introducing each topic from first principles inside the chapter whose decision depends on it and stopping there. In the anatomy and learning chapters, model quantization is introduced where it sets the intent model's latency (section 3.4.2), while reinforcement learning fundamentals and the pretrain-then-post-train recipe appear when the arm learns the spring-latched door task (section 6.2.1, section 6.2.8). In the runtime chapters, perception stops at the qualified measurement and hands state estimation

to spatial memory (chapter 9). Spatial memory builds from the discrete and extended Kalman filters, multi-target tracking, and delayed updates (section 9.2) to localization and SLAM in the planning map (section 9.5.1). Task and motion planning grounds abstract goals in feasible geometry (section 10.2), while manipulator kinematics, time parameterization, and mobile-base planning build the trajectory record (section 11.2, section 11.4.5, section 11.6.1) and worst-case execution time analysis tests hardware isolation (section 13.7). Finally, the governance chapters introduce importance sampling where rare-failure rates must be estimated (section 15.10.2) and functional safety standards where the release argument is assembled (section 16.3.4).

What the book omits is the remainder of each of those fields. It does not provide an exhaustive catalog of manipulator geometries or grasp analysis, or a complete course in nonlinear or optimal control. It omits the convergence theory of reinforcement learning and the construction of large-scale SLAM back ends. It also leaves out the internals of static timing-analysis tools and a comprehensive theory of deep learning optimization, and it is not a substitute for the text of a safety standard. Specialized derivations appear where they explain a bound or trade-off, and the appendices provide supporting background.

Implementation examples expose timing, memory, communication, and actuation mechanisms. They are not tutorials for a particular robotics middleware package or simulation product. The intended result is the ability to reason about a new machine and recognize when its design needs additional specialist analysis or measurement.

A Note on AI Assistance

Working draft

This text is an evolving working draft. As I collect ideas and organize this cross-disciplinary material, these chapters represent an active work in progress. While I develop each section carefully from foundational control literature, robotics principles, and verified computation cells, I have not yet reached the stage of stress-testing these frameworks with external domain specialists. I am sharing this draft openly to organize my thoughts and invite early community feedback as the curriculum takes shape.

This book is released as an open-access, living textbook; it is not yet under contract with a commercial publisher. In digital machine learning, computation operates behind glass: an unhandled exception produces a log trace, and latency costs user patience. In Physical AI, computation commands matter, momentum, and current. Latency is paid in millimeters of uncontrolled travel, and software decisions carry direct kinetic consequences.

Crossing that boundary required reconciling two engineering traditions that rarely speak the same language. On one side stands classical robotics and control theory, built on state-space dynamics, kinematics, and formal stability proofs. On the other stands modern machine learning systems, built on statistical optimization, memory hierarchies, and massive hardware acceleration.

Bridging these disciplines is difficult because their literatures are deeply siloed. In developing this curriculum, I used generative AI as an interactive research translator and cross-domain synthesis engine. Large language models served as a lateral search tool, querying across disparate bodies of robotics, control, and systems literature to connect classical methods with modern learned representations. The tool helped surface historical precedents, identify relevant mathematical formulations across disciplines, and explore alternative pedagogical framings.

Yet an AI tool cannot test whether a control loop survives contact with physical hardware. Discovering mathematical parallels between neural networks and control theory is easy; deciding which abstractions hold under real sensor noise, actuator saturation, and hard millisecond deadlines requires human systems judgment. Translating these cross-disciplinary connections into a disciplined, first-principles textbook required months of intensive analysis, iterative drafting, and building executable models.

Authorship in this domain is stewardship: uniting two historically divided fields into a cohesive curriculum and assuming responsibility for the result. The breakthroughs belong to the control theorists, roboticists, and systems researchers cited throughout these pages. My name is on the cover so that readers and engineers have a single human being to hold accountable, someone to reach out to for debates, clarifications, and corrections.

Because physical systems carry real-world consequences, this text should be approached as an evolving working draft. While our executable Python cells verify numerical consistency and automated test suites check cross-references, I am actively refining these connections before formally stress-testing them with robotics and control specialists. I invite readers, roboticists, and control engineers to engage with these ideas, report errors on GitHub, and help refine this material as the curriculum takes shape. The principle holds with absolute finality at the physical boundary: **the tool can propose, and the tool can tutor, but only the human engineer can ratify and take responsibility.**

DRAFT

Notation

Physical AI draws on three disciplines at once. Machine learning supplies the foundation models, vision-language-action architectures, diffusion policies, and action chunking that propose what a robot should do. Robotics and control supply the mechanics that decide what it can do: articulated dynamics, the Lie group $SE(3)$, contact and friction, Lyapunov stability, control barrier functions, and actuator electromechanics. Embedded and real-time systems supply the machinery that decides when it happens, from interconnect and memory contention through zero-order hold, real-time scheduling, leases, hardware watchdogs, and functional safety.

Because each discipline developed its mathematical conventions independently over decades, combining them creates symbol collisions that cyber-physical systems engineering has long lived with. For example, writing $\nabla_\theta \pi_\theta(\mathbf{a} \mid \mathbf{q})$ when θ also denotes joint angles, or writing $\mathbf{a}_t$ for an action when $\mathbf{a}$ denotes Cartesian acceleration or barrier constraints, confuses spatial mechanics with parameter optimization and control execution authority.

The sections that follow state the cross-discipline disambiguation rules, the governing relationships of embodied systems, and the symbol tables used throughout this book. Every symbol of the series core keeps its foundational meaning: T is time, BW bandwidth, L_{lat} latency, R_{peak} peak rate, O operations, I arithmetic intensity, D_{vol} bytes moved, $\mathcal{L}$ loss, η learning rate, and $\mathcal{O}(\cdot)$ asymptotic cost. Serving and memory arithmetic on the robot's onboard computer uses those symbols, with a subscript naming the instance (BW_{mem}, O_{prefill}).

Cross-Discipline Disambiguation

When physical plant dynamics meet deep neural networks and real-time embedded hardware, common mathematical shorthand breaks down. The conventions below resolve these cross-domain collisions systematically:

Symbol	Canonical Convention	Colliding Meaning	Disambiguation Rule
θ	Learned model (policy) parameters, as in π_θ	Joint angle, trajectory polynomial $\theta(t)$, heading, azimuth, attitude or mounting error, clock offset, or thermal resistance θ_{JA}	**Bare θ is always the parameter collection of a learned model**, set italic (never bold), as the series core defines it. A geometric angle always carries a subscript that names it: θ_{joint} for one joint (θ_{motor} and θ_{link} on either side of a reducer, θ_{enc} for an encoder reading), θ_{head} for planar heading, θ_{az} for azimuth, θ_{att} for attitude error, θ_{ext} for extrinsic misalignment, θ_{tilt} for tilt from vertical, θ_{tol} for an orientation tolerance, and θ_e for the electrical rotor angle; increments keep the subscript ($\Delta\theta_{\text{joint}}$, $\delta\theta_{\text{enc}}$). Joint configurations are the generalized coordinates $\mathbf{q} \in \mathbb{R}^n$ with entries q_i, and a joint trajectory polynomial is $q(t) = \sum a_k t^k$ with boundary values q_0, q_1 (never $\theta(t)$). A clock offset is θ_{offset} (in seconds). Thermal resistance is R_{th} or $R_{\text{th,JA}}$ (in K/W), never θ_{JA}.
a vs. $\mathbf{u}_{\text{nom}}$ vs. $\mathbf{u}^*$ vs. τ	Four-stage authority chain ($\mathbf{a}_t \to \mathbf{u}_{\text{nom}} \to \mathbf{u}^* \to \tau$)	Generic "action" symbol colliding with deceleration a_{brake} or a barrier constraint row	**Disambiguate execution authority**: $\mathbf{a}_t$ is the unprivileged policy action (dimensionless/normalized); $\mathbf{u}_{\text{nom}}$ is the proposed plant control setpoint; $\mathbf{u}^* \in \mathcal{U}_{\text{adm}}$ is the certified, CBF-filtered control command; $\tau \in \mathbb{R}^n$ is realized physical actuator torque. Control commands are bold $\mathbf{u}$ (with time index $\mathbf{u}_t$). Credible linear deceleration is a_{brake} (m/s^2); stacked barrier constraints are $\mathbf{A}_{\text{cbf}}(\mathbf{x})\mathbf{u} \le \mathbf{b}_{\text{cbf}}(\mathbf{x})$, and a single constraint row is $\mathbf{a}_{\text{cbf}}(\mathbf{x})^\top \mathbf{u} \le b_{\text{cbf}}(\mathbf{x})$.

Symbol	Canonical Convention	Colliding Meaning	Disambiguation Rule
τ **vs.** τ	Actuator torque vector $\tau \in \mathbb{R}^n$ (N · m or N)	Time constants (τ_e, τ_{th}), delays (τ_{delay}, τ_{ZOH}), observation age, lease durations, or real-time task names	**Bare or bold τ is always torque** ($\tau \in \mathbb{R}^n$, scalar joint torque τ_i, component torques such as τ_{motor}, τ_{hold}, τ_{bias}), with $\tau_{\text{motor}} = K_t i_q$ at the motor. A subscripted Greek τ marks a time only for these named constants and delays: τ_{delay} (pre-brake delay, excluding Δ_{da}) and its ceiling $\tau_{\text{delay,max}}$, $\tau_e = L_{\text{phase}}/R_{\text{phase}}$ (electrical), $\tau_{\text{th}} = R_{\text{th}} C_{\text{th}}$ (thermal, with stage constants such as $\tau_{\text{th,cu}}$ and $\tau_{\text{th,case}}$), τ_{fall} (balance divergence), τ_{ZOH} (sample-and-hold delay), τ_{ev} (evidence horizon), and τ_{blend} (authority blend window). Every other interval uses Latin T or t: observation age is t_{age}, never τ; leases are T_{lease}, $T_{\text{lease,man}}$, and T_{admin}; compute and fieldbus times are T_{comp} and T_{bus}; a pure transport delay is T_d. A real-time task is named "task i", never τ_i.
x vs. s **vs. p vs.** $\mathbf{x}_p$	Mechanical plant state $\mathbf{x} = [\mathbf{q}^\top, \dot{\mathbf{q}}^\top]^\top \in \mathbb{R}^{2n}$	World state $s \in \mathcal{S}$, 3D position $\mathbf{p} = [x, y, z]^\top$, image point, or ViT image patch $\mathbf{x}_p$	**Continuous mechanical plant state is bold vector** $\mathbf{x} \in \mathbb{R}^{2n}$. Ground-truth latent world state is italic s_t (a mixed-type state, never bold). 3D Cartesian position is vector $\mathbf{p} \in \mathbb{R}^3$, including a camera-frame point $\mathbf{p}_c$ and a voxel center $\mathbf{p}_{\text{vox}}$; the translation of a rigid transform is $\mathbf{t}$. An image point in homogeneous pixel coordinates is $\tilde{\mathbf{m}} = [u, v, 1]^\top$, never $\mathbf{x}$ or $\mathbf{u}$. Vision transformer patch embeddings use explicitly subscripted $\mathbf{x}_p$ or latent feature $\mathbf{z}$.
P	Model parameter count P (series core)	Power (P_{loss}, P_{peak}), estimation covariance $\mathbf{P}$, failure probability or rate, tail-latency percentile, or 3D point $\mathbf{p}$	Use P for parameter count. Electrical/mechanical power always carries a subscript (P_{loss}, P_{peak}, P_{heat}, in Watts); the estimator's error covariance is bold matrix $\mathbf{P}$, and a generic Gaussian covariance is Σ; a per-trial probability is lowercase italic p ($p_{\text{fail}}, p_{\text{target}}$), a rate per hour is λ ($\lambda_{\text{system},h}, \lambda_{\text{target}}$), and an event probability is $\Pr(\cdot)$; percentiles are upright p50, p95, and p99 (never P_{99}); 3D Cartesian position is bold lowercase $\mathbf{p} = [x, y, z]^\top$.
B	Batch size B (series core)	Bandwidth (BW), Body frame ($\mathcal{F}_B$), bus transfer size, SPRT boundary, or input matrix $\mathbf{B}$	Batch size is B; sustained bandwidth is BW (per the single-device decomposition), with a subscript naming the path (BW_{mem}, BW_{chirp}); coordinate reference frames use calligraphic script ($\mathcal{F}_W, \mathcal{F}_B, \mathcal{F}_E$); the bytes of bus transaction k are $D_{\text{vol}\,k}$; SPRT boundaries are Λ_{up} and Λ_{lo}; state-space control input matrix is bold capital $\mathbf{B} \in \mathbb{R}^{n \times m}$.
α	Bumpless transfer blending function $\alpha(\hat{t}) \in [0, 1]$	CBF decay (γ_{cbf}), significance (α_{sig}), angular acceleration (α), copper tempco (α_{Cu}), or noise schedule ($\bar{\alpha}_k$)	Authority transfer uses scalar function $\alpha(\hat{t}) \in [0, 1]$ of normalized time $\hat{t} \in [0, 1]$; barrier linear decay uses $\gamma_{\text{cbf}} > 0$; statistical confidence significance uses $\alpha_{\text{sig}} = 1 - \text{CL}$; angular acceleration is bold vector $\boldsymbol{\alpha} \in \mathbb{R}^3$ (rad/s^2); copper resistance tempco is α_{Cu}; diffusion noise schedules use indexed $\bar{\alpha}_k$.
$\mathbf{C}$	Coriolis matrix $\mathbf{C}(\mathbf{q}, \dot{\mathbf{q}}) \in \mathbb{R}^{n \times n}$	Safe set $\mathcal{C}$, conformal prediction set, assurance claim, state-space output matrix, controllability matrix, capacitance ($C_{\text{th}}, C_{\text{bus}}$), CoM $\mathbf{c}$, or shield coverage c_h	Coriolis/centrifugal forces use matrix function $\mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})$, always written with its arguments; forward-invariant safe sets use calligraphic $\mathcal{C} \subset \mathbb{R}^{2n}$, defined on the plant state, and the conformal prediction set $\mathcal{C}$ of target grounding shares that glyph but never appears beside a safe set; the top-level claim of an assurance argument is italic C; the state-space output map is $\mathbf{H}$ (the same map as the Kalman measurement map), never $\mathbf{C}$; the controllability matrix is $\mathbf{C}_{\text{ctrb}}$; electrical/thermal capacitance uses italic C with a subscript; center of mass is bold vector $\mathbf{c} \in \mathbb{R}^3$; safety shield coverage of hazard class h uses $c_h \in [0, 1]$.
$\mathbf{A}$	Action chunk $\mathbf{A}_t$, $\mathbf{A}_{t:t+H}$, and its denoising iterate $\mathbf{A}_t^k$	Continuous LTI state matrix, barrier constraint matrix	Bold $\mathbf{A}$ with a time or denoising index is the action chunk. The continuous LTI state matrix is $\mathbf{A}_{\text{sys}}$ (its discretizations $\mathbf{A}_{\text{FE}}$ and $\mathbf{A}_{\text{BE}}$, the discrete Kalman transition $\mathbf{F}$); stacked barrier constraints use $\mathbf{A}_{\text{cbf}}$.
$\mathbf{v}$	Velocity ($\mathbf{v}$, end-effector velocity $\mathbf{v}_e$)	Measurement noise, voxel	Bold $\mathbf{v}$ is a velocity. Measurement noise is $\mathbf{v}_{\text{meas}}$ with covariance Σ_{meas} (bold $\mathbf{R}$ is reserved for rotation); a voxel is addressed by its center $\mathbf{p}_{\text{vox}}$.

Symbol	Canonical Convention	Colliding Meaning	Disambiguation Rule
K	Camera intrinsic calibration matrix $\mathbf{K} \in \mathbb{R}^{3\times3}$	Contact stiffness (k_{contact}), control gains (K_p, K_d, LQR gain), motor constants (K_t, K_e), ensembling window K, or diffusion step k	Camera intrinsics use bold matrix $\mathbf{K}$; contact stiffness is k_{contact}, with body-region stiffness k_H (N/m); feedback control gains use capitalized scalars K_p, K_d, and a state-feedback gain matrix is $\mathbf{K}_{\text{lqr}}$; motor torque/back-EMF constants use K_t, K_e (per joint K_{t_i}); temporal ensembling window length uses integer K; the number of denoising or solver evaluations per chunk is N_{eval}, never K; diffusion noise steps use lowercase index k; the Kalman gain is $\mathbf{G}_k$.
M	Articulated inertia matrix $\mathbf{M}(\mathbf{q}) \in \mathbb{R}^{n\times n}$	Mass (m, m_{eff}), memory footprint (M_{weights}, M_{KV}), or fleet size (N_{fleet})	Articulated generalized mass/inertia uses bold matrix $\mathbf{M}(\mathbf{q})$; physical body mass is lowercase italic m (kg); effective impact mass is m_{eff}; hardware memory storage uses capital M with descriptive subscript (in bytes); robot fleet size uses N_{fleet}.
T	Time (series core)	Temperature	**Bare T is always time.** A temperature always carries a subscript that names where it is measured: T_{winding} (winding), T_{core}, T_{j} (junction), T_{case}, T_{amb} (ambient), T_{limit} (rated limit), T_{trip}, T_{∞} (equilibrium), and T_0 (the reference temperature of α_{Cu}). A temperature rise is ΔT (in K); a time interval is Δt, never ΔT.
SIL (abbreviation)	Safety integrity level (IEC 61508 family), a grade of a safety function	Software-in-the-loop, the first rung of the verification ladder	**Spell out at first use in each chapter.** "SIL 2" and similar graded forms always mean safety integrity level; the verification ladder writes software-in-the-loop (SIL) only where the ladder's abbreviations MIL, SIL, PIL, and HIL appear together, and never beside a safety integrity level.

Governing Relationships

Physical intelligence operates subject to thermodynamic, mechanical, kinematic, and communications constraints. The relationships below state those constraints in the symbols this book uses. They are working relationships, not laws: the book's four bedrock laws are the ones section 1.10 states.

The sense-to-actuation delay budget

Delay converts directly into travel before any retarding force begins. The pre-brake delay τ_{delay} runs from the capture of the frame that first shows a hazard to retarding force, excluding the dispatch-to-admission interval Δ_{da}, which the stopping budget charges against its timing allowance. The stop it leaves, whose travel is $d_{\text{suffix}}(v)$, must fit inside the clear distance, and the spare that remains must pay for $v\,\Delta_{\text{da}}$:

$$\tau_{\text{delay}} = t_{\text{age}} + T_{\text{lease}} + T_{\text{tick}} + T_{\text{bus}} + T_{\text{act}}$$

$$v\,\tau_{\text{delay}} + d_{\text{suffix}}(v) + \delta_{\text{loc}} + \delta_{\text{margin}} + \epsilon_{\text{track}} \le D_{\text{clear}}$$

Inference time is spent on the proposal side of the proposal boundary. It ages the evidence behind a proposal, which the permission path checks against the proposal's expiry. It is neither a term of τ_{delay} nor part of the permission loop's period T_{tick}, because the fallback does not wait for the proposer.

The appendices regroup the same interval for two specific stop paths, and each form defines its own terms. For a stop triggered by lease expiry, $\tau_{\text{delay}} = T_{\text{lease}} + t_{\text{detect}} + T_{\text{hold}} + t_{\text{age}} + T_{\text{act}}$; for a stop triggered by a hazard detector, $\tau_{\text{delay}} = t_{\text{age}} + t_{\text{detect}} + T_{\text{compute}} + T_{\text{bus}} + T_{\text{act}}$.

Symbol	Definition	Unit	Notes
τ_{delay}	**Pre-Brake Delay**	ms	Time from capture of the frame that first shows a hazard to the onset of retarding force, excluding Δ_{da}; the machine travels $v(\tau_{\text{delay}} + \Delta_{\text{da}})$ before braking begins. Its allowed ceiling is $\tau_{\text{delay,max}}$.

Symbol	Definition	Unit	Notes
t_{age}	**Observation Age**	ms	Age of the state the permission path acts on, from the exposure midpoint at the sensor to the decision, which enters τ_{delay}. Its perception-side terms are the exposure midpoint $\frac{1}{2}t_{\text{exp}}$, sensor readout, transfer, and perception processing; a bound on it is $t_{\text{age,max}}$.
T_{lease}	**Chunk Lease**	ms	Longest interval an admitted chunk may keep driving the actuators without renewal, which enters τ_{delay}; chosen, then checked against the ceiling the stopping budget derives.
T_{chunk}	**Chunk Renewal Period**	ms	Interval between successful admissions of the chunk policy; with T_{jitter} it sets the floor of the lease rule, $T_{\text{chunk}} + T_{\text{jitter}} < T_{\text{lease}}$ (equation 4.4).
T_{jitter}	**Renewal-Jitter Allowance**	ms	Allowance for variation in the interval between successful admissions; chosen, then checked against measured renewal intervals.
T_{tick}	**Permission-Loop Period**	ms	Period of the permission loop, which enters τ_{delay} because a hazard may wait up to one period before it is checked.
T_{bus}	**Command Transport Time**	ms	Fieldbus delivery time from the permission path to the drive, which enters τ_{delay}.
T_{act}	**Actuator Response Time**	ms	Time from a delivered stop command to retarding force, including gate-drive and current rise, which enters τ_{delay}.
t_{detect}	**Detection Interval**	ms	Recognition or expiry-detection time after the decision-start epoch, not already charged to t_{age}; a term of the lease-expiry and hazard-detection forms of τ_{delay}.
T_{hold}	**Fallback Hold**	ms	Optional, separately authorized hold or fault-confirmation interval before the stop command reaches the drive; zero when the stop path has none.
t_{infer}	**Proposer Inference Time**	ms	Time for one complete evaluation of the learned proposer (prefill and decode); spent above the proposal boundary and outside the permission loop's period.
Δ_{da}	**Dispatch-to-Admission Interval**	ms	Elapsed time from perception dispatch to the admission of the candidate it conditions; evidence keeps aging through it. Not a term of τ_{delay}; its travel $v\,\Delta_{\text{da}}$ is charged against the stopping budget's timing allowance.
$T_{\Sigma,1}, T_{\Sigma,2}$	**Takeover Response Time**	ms, s	Human response plus console transport for an in-loop ($T_{\Sigma,1}$) and an out-of-loop ($T_{\Sigma,2}$) takeover; it adds to τ_{delay} while the machine waits for the person.
T_{deadline}	**Deadline**	ms, s	A duration budget a computation or handover must meet (the series symbol); qualifiers name the instance, as in $T_{\text{deadline,fallback}}$, the latest permissible wait before the fallback must begin. A deadline stated as a clock instant is lowercase, t_{deadline} or $t_{\text{deadline,stop}}$.
T_{timeout}	**Handover Timeout**	s	Timer an arbiter sets for an unacknowledged handover, $T_{\text{timeout}} = \max(0, \min(T_{\text{config}}, T_{\text{deadline,fallback}}))$, where T_{config} is the protocol ceiling.
t_{commit}	**Commitment Instant**	s	Instant after which a receding-horizon plan's prefix is committed and can no longer be replaced by a new proposal.
t_{onset}	**Hazard Onset**	s	Instant at which a hazard first becomes physically present, the reference from which detection and stopping intervals are measured.

DRAFT

Leases

A lease is authority that lapses unless it is renewed. The book uses six kinds:

Lease	Symbol	Distinction
Execution lease	remaining $T_{\text{lease,rem}}$	Any authority an admitted command source holds to keep driving the actuators without renewal; it begins at admission, and its expiry invokes the state-matched fallback.
Chunk lease	T_{lease}	The execution lease of the autonomous chunk policy, renewed by each admitted chunk; it enters τ_{delay}.
Manual lease	$T_{\text{lease,man}}$	The execution lease of a human operator in manual mode, renewed by authenticated heartbeats; it replaces the chunk lease in τ_{delay} while the operator drives.
Administrative lease	T_{admin}	The host-silence bound inside an intent lease: how long the application processor may hold a goal without renewing it.
Intent lease	expiry $t_{\text{intent_exp}}$	The record that grants a grounded target and effort ceilings, never a path; it expires at the earliest of its evidence horizon, its administrative lease, and its stopping deadline.
Hardware lease	(mechanism)	The countdown timer on the safety microcontroller that enforces any of these expiries even when the process that issued the authority has hung.

Single-device execution time

In a serial model without overlap, one evaluation of a learned proposer on the robot's onboard accelerator takes a time that splits into three terms: moving bytes through memory, executing operations, and a fixed overhead. The chunk-cadence and proposer-inference relationships below reuse these symbols, with a subscript naming the instance (BW_{mem}, O_{prefill}):

$$T = \underbrace{\frac{D_{\text{vol}}}{\text{BW}}}_{\text{Memory Time}} + \underbrace{\frac{O}{R_{\text{peak}} \cdot \eta_{\text{hw}}}}_{\text{Compute Time}} + \underbrace{L_{\text{lat}}}_{\text{Latency Overhead}}$$

DRAFT

Symbol	Definition	Unit	Notes
T	**Execution Time**	seconds	Total execution time of one evaluation; bare T is always time.
BW	**Bandwidth**	bytes/s	Sustained bytes per second across a named path; never bare B, which is batch size B.
D_{vol}	**Data Volume**	bytes	Bytes moved through memory in one evaluation; never bare D, which is dataset size.
η_{hw}	**Efficiency**	—	Fraction of the peak rate an evaluation achieves, $0 \leq \eta_{\text{hw}} \leq 1$; never bare η, which is the learning rate.
L_{lat}	**Latency**	seconds	Fixed overhead per evaluation (kernel launch, transfer setup); the subscript keeps it distinct from the loss $\mathcal{L}$.
O	**Operations**	FLOPs	Floating-point operations one evaluation executes; a subscript names the phase (O_{prefill}). Asymptotic cost is $\mathcal{O}(\cdot)$.
R_{peak}	**Peak Rate**	FLOP/s	Peak arithmetic rate of the processor at the stated precision; never bare P, which is parameter count.

Action-chunk cadence and proposer inference

Large neural policies that stream their weights from memory may exceed a kilohertz control period. Action chunking predicts an action trajectory of horizon H at a lower cognitive frequency f_{policy}, while the chunk's waypoints are consumed at f_{exec}. In the serial model with one weight-streaming pass per chunk and no additional fixed overhead, memory streaming must fit inside the chunk execution window after reserving the compute term T_{compute} of the single-device decomposition:

$$t_{\text{stream}} = \frac{M_{\text{weights}}}{\text{BW}_{\text{mem}}} \leq \frac{H}{f_{\text{exec}}} - T_{\text{compute}}$$

A decoder that streams its nonresident weights once per emitted token spends, for S_{out} emitted tokens, the inference time

$$t_{\text{infer}} \approx \max\left(\frac{O_{\text{prefill}}}{\eta_{\text{hw}} R_{\text{peak}}}, \frac{M_{\text{weights}}}{\text{BW}_{\text{mem}}}\right) + (S_{\text{out}} - 1)\frac{M_{\text{weights}}}{\text{BW}_{\text{mem}}}$$

which caps the fresh-evaluation rate at $f \leq \text{BW}_{\text{mem}}/M_{\text{weights}}$ when every evaluation streams the weights. The symbols are those of the single-device decomposition: O_{prefill} counts the prefill's operations, R_{peak} is the processor's peak rate at the activation precision, η_{hw} is the fraction of it the prefill achieves, and I is the arithmetic intensity that decides which term binds.

Symbol	Definition	Unit	Notes
H	**Horizon**	Time steps	Number of contiguous future action steps generated in a single policy forward pass ($H = 16$ on the mobile manipulator; 16 to 64 steps in the literature).
d_a	**Action Dimension**	Integer	Number of components of one action $\mathbf{a}_t$; a chunk $\mathbf{A}_{t:t+H}$ has $H \times d_a$ entries.
BW_{mem}	**Sustained Memory Bandwidth**	bytes/s	Achievable memory throughput of the SoC or accelerator memory subsystem (e.g., LPDDR5, HBM); the core's BW at the memory interface.
t_{stream}	**Parameter Streaming Time**	ms	Time required to stream non-resident model weights into execution registers.
f_{exec}	**Action Execution Rate**	Hz	Temporal consumption rate of chunked waypoints along the planned trajectory (100 Hz to 1 kHz).
S_{out}	**Emitted Token Count**	tokens	Output tokens an autoregressive decoder emits per evaluation; the core's sequence length S for the decoded part. Never D, which is dataset size.

DRAFT

Stopping, braking, and safe-set invariants

For the stopping-based safety envelope, the machine must retain enough clearance to arrest its approach before crossing the protected boundary. The relationship below specializes the resident stop to one-dimensional motion starting and ending at zero acceleration, with symmetric jerk ramps and a constant-deceleration segment. The stopping distance combines travel during the pre-brake delay with braking travel; the delay-budget inequality adds the spatial margins:

$$d_{\text{stop}}(v) = v\,\tau_{\text{delay}} + d_{\text{suffix}}(v), \qquad d_{\text{suffix}}(v) = \frac{v^2}{2a_{\text{brake}}} + \frac{v\,a_{\text{brake}}}{2j_{\text{max}}} \quad (v \geq a_{\text{brake}}^2/j_{\text{max}})$$

Symbol	Definition	Unit	Notes
d_{stop}	**Stopping Distance**	m	Distance required to bring the plant to rest from speed v.
T_{stop}	**Stopping Duration**	s	Elapsed time from braking onset to standstill in the protective-separation calculation; distinct from controller sampling period.
D_{clear}	**Clear Distance**	m	Clear distance from the machine to the boundary it must not cross; the subscript keeps it distinct from dataset size D.
v	**Speed at Detection**	m/s	Speed of the machine at the moment the hazard is detected; in stopping, pre-brake, and impact algebra, the scalar travel or approach speed v.
v_{max}	**Speed Bound**	m/s	Largest speed the machine, a tracked object, or an approaching body is credited with in a budget; the bounding speed in $\Delta t_{\text{fresh}} \leq e_{\text{max}}/v_{\text{max}}$.
a_{brake}	**Credible Deceleration**	m/s^2	Validated low tail of the deceleration the machine achieves under its stated conditions, not the datasheet peak.

Symbol	Definition	Unit	Notes
$a_{\max}$	**Profile Acceleration Bound**	$\mathrm{m/s^2}$	Largest acceleration or deceleration a planned or interpolated profile may command; for the base's resident stop it is set to a_{brake}.
a_{net}	**Net Braking Deceleration**	$\mathrm{m/s^2}, \mathrm{rad/s^2}$	Linear or angular deceleration left after a gravity or load bias torque τ_{bias} is subtracted from the actuator's braking capacity, in the direction of travel.
$d_{\text{suffix}}(v)$	**Resident Stop Distance**	m	Travel of the resident stop from speed v: $v^2/(2a_{\text{brake}})$ for constant-deceleration braking; for the jerk-limited stop of equation 11.17, that term plus the jerk ramps' $v\,a_{\text{brake}}/(2j_{\max})$ once $v \geq a_{\text{brake}}^2/j_{\max}$.
δ_{loc}	**Localization Bound**	m	Bound on localization and state-estimation error.
δ_{margin}	**Protective Clearance**	m	Fixed, nonzero protective clearance between the machine envelope and the boundary.
ϵ_{track}	**Tracking-Error Bound**	m	Bound on the deviation between the commanded and the executed trajectory, stated by the enforcement record.
v_h	**Human Walking-Speed Bound**	m/s	Walking-speed bound for a person approaching the machine, used in the form its safety standard states.
$j_{\max}$	**Jerk Limit**	$\mathrm{m/s^3}$	Maximum rate of change of deceleration; sets the jerk ramps of the resident stop in $d_{\text{suffix}}(v)$ (equation 11.17) and bounds the bumpless-transfer window τ_{blend}.

Zero-order hold and phase margin

At crossover frequencies well below the sampling frequency, holding discrete control commands constant over sampling period $T_s = 1/f_s$ contributes approximately half a sample period of delay. With fixed modeled enforcer and fieldbus delays, the relationship below estimates phase-margin erosion; its phase-lag term is in radians, so all phase margins must use the same angular unit before subtraction:

$$\tau_{\text{ZOH}} = \frac{T_s}{2}, \qquad \Delta\phi = \omega_c \left(\frac{T_s}{2} + T_{\text{comp}} + T_{\text{bus}} \right), \qquad \text{PM}_{\text{net}} = \text{PM}_{\text{plant}} - \Delta\phi > 0$$

Symbol	Definition	Unit	Notes
τ_{ZOH}	**ZOH Transport Delay**	s	Equivalent continuous delay introduced by discrete Zero-Order Hold reconstruction ($T_s/2$).
T_s, f_s	**Sampling Period and Rate**	s, Hz	Discrete controller execution period and frequency ($f_s = 1/T_s$).
T_{comp}	**Enforcer Compute Time**	s	Time the enforcer takes to evaluate its constraints within one control period; with T_{bus} it adds to the ZOH delay.
T_d	**Pure Transport Delay**	s	A fixed delay in a feedback or communication channel, contributing phase lag ωT_d at frequency ω.
ω_c	**Open-Loop Crossover Frequency**	rad/s	Frequency at which open-loop gain $\lvert L(j\omega_c)\rvert = 1$ (0 dB).
$\Delta\phi$	**Phase Lag Degradation**	rad / deg	Phase erosion at crossover ($\Delta\phi \approx 28.65^\circ \cdot (\omega_c/f_s)$ from the hold alone) depleting closed-loop stability margin.

Actuator electrical and thermal limits

Actuators are constrained by copper winding heating, DC bus rail droop, and magnetic saturation. Sustainable torque output is governed by the coupled electromechanical balance, written per joint with scalar torque:

$$V_{\text{bus}} = L_{\text{phase}} \frac{di_q}{dt} + R(T_{\text{winding}})\, i_q + K_e \omega_m, \qquad C_{\text{th}} \frac{dT_{\text{winding}}}{dt} = i_q^2 R(T_{\text{winding}}) - \frac{T_{\text{winding}} - T_{\text{amb}}}{R_{\text{th}}}, \qquad \tau = \eta_{\text{gear}} N_{\text{gear}} K_t i_q$$

Symbol	Definition	Unit	Notes
K_t, K_e	**Torque and Back-EMF Constants**	$\mathrm{N\cdot m/A}, \mathrm{V\cdot s/rad}$	Motor electromechanical coupling constants linking winding current to rotor shaft torque and rotor speed to back-EMF voltage ($K_t \approx K_e$ in SI units).
i_q	**Torque-Producing Current**	A	Quadrature-axis current of a field-oriented drive, $\tau_{\text{motor}} = K_t i_q$. Bare I is never a current, because the series core reserves it for arithmetic intensity.
I_{phase}	**Motor Phase RMS Current**	A	RMS phase current driving the stator windings of a brushless PM motor; an uppercase I with a subscript names an RMS value or rating.
i_{phase}	**Instantaneous Phase Current**	A	Signed instantaneous electrical phase current, positive from inverter node into winding; distinct from RMS phase current and torque-producing dq current.
$I_{\text{cont}}, I_{\text{peak}}$	**Continuous / Peak Current**	A	RMS current ratings bounded by winding insulation class and inverter MOSFET dissipation.
$L_{\text{phase}}, R_{\text{phase}}$	**Phase Inductance and Resistance**	H, Ω	Stator winding inductance and DC resistance; they set $\tau_e = L_{\text{phase}}/R_{\text{phase}}$.
$R(T_{\text{winding}})$	**Temperature-Dependent Resistance**	Ω	Stator copper resistance at winding temperature T_{winding}: $R(T_{\text{winding}}) = R_0[1+\alpha_{\text{Cu}}(T_{\text{winding}} - T_0)]$ with $\alpha_{\text{Cu}} = 0.00393\ \mathrm{K}^{-1}$.
R_{th}	**Thermal Resistance**	K/W	Lumped thermal resistance from stator windings to the ambient environment; path segments carry a second subscript ($R_{\text{th,JA}}$, $R_{\text{th,JC}}$, $R_{\text{th,wc}}$, $R_{\text{th,ca}}$) and add in series.
C_{th}	**Stator Thermal Capacitance**	J/K	Lumped heat capacity of the motor core, windings, and potting compound.
τ_e	**Electrical Time Constant**	s	Winding current rise time constant $\tau_e = L_{\text{phase}}/R_{\text{phase}}$; current reaches $1-e^{-1}$ of its target in τ_e.
τ_{th}	**Thermal Time Constant**	s	Actuator heating characteristic time constant ($\tau_{\text{th}} = R_{\text{th}}C_{\text{th}}$, typically 60–300 s); a single stage takes a second subscript ($\tau_{\text{th,cu}}$, $\tau_{\text{th,case}}$).
$T_{\text{winding}}, T_{\text{amb}}$	**Winding and Ambient Temperature**	K or °C	The thermal model's state and boundary temperatures; the other temperatures follow the subscript rule of the disambiguation table (T_j, T_{case}, T_{limit}, T_∞, T_0).
ΔT	**Joulean Temperature Rise**	K	Thermal rise above ambient; $\Delta T = P_{\text{loss}}R_{\text{th}}$ gives the steady-state rise for constant loss power in the lumped model. Transient rise follows the thermal balance; never a time interval.
D_{cycle}	**Actuator Duty Cycle**	$[0, 1]$	Ratio of active pulse duration to cycle period ($t_{\text{on}}/(t_{\text{on}}+t_{\text{off}})$) preventing thermal runaway.

Shielded hazards and the exposure bound

Catastrophic failure rates in embodied systems cannot be certified through stochastic testing alone. For a defined hazard class h, verified interception coverage and independently bounded residual faults constrain the system's hazard rate. Under a constant-rate Poisson exposure model, zero-failure exposure follows the Rule of Three:

$$\lambda_{\text{system},h} \le \lambda_{\text{proposal},h}(1-c_h) + \lambda_{\text{other}} \le \lambda_{\text{target}}, \qquad T \ge \frac{-\ln \alpha_{\text{sig}}}{\lambda_{\text{target}}}$$

Here T is the zero-incident operating exposure, in hours. For independent trials with a common success probability, per-trial campaigns use the same bound in probability form, $n \ge \ln \alpha_{\text{sig}} / \ln p_{\text{target}} \approx 3/(1-p_{\text{target}})$.

Symbol	Definition	Unit	Notes
$\lambda_{\text{system},h}$	**System Hazard Rate**	h^{-1}	Certified dangerous failure rate of the integrated cyber-physical machine for hazard class h.

Symbol	Definition	Unit	Notes
$\lambda_{\text{proposal},h}$	**Hazardous Proposal Rate**	h^{-1}	Arrival rate of unshielded hazardous action proposals the policy emits before the permission layer, measured against a counterfactual oracle.
c_h	**Shield Interception Coverage**	Dimensionless	Verified conditional probability that the shield intercepts a hazardous proposal of class h, evaluated over the states in which the policy errs.
λ_{other}	**Hardware and Common-Cause Rate**	h^{-1}	Independently bounded hardware-fault and common-cause hazard rate the shield cannot intercept; the floor $\lambda_{\text{system},h}$ reaches when $c_h = 1$.
λ_{target}	**Target Hazard Rate**	h^{-1}	Tolerable dangerous failure rate assigned to the safety function by risk assessment, in the band its governing standard defines.
C_{diag}	**Diagnostic Coverage**	Dimensionless	Rate-weighted fraction of hardware faults whose hazardous effect is mitigated, $\lambda_{\text{unmitigated}} = \lambda_{\text{raw}}(1 - C_{\text{diag}})$; the hardware counterpart of c_h, which covers policy proposals.
$p_{\text{fail}}, p_{\text{target}}$	**Per-Trial Probabilities**	Dimensionless	Per-trial failure probability, and the per-trial success probability a campaign must demonstrate; trial counts follow $n \geq \ln \alpha_{\text{sig}} / \ln p_{\text{target}}$.
α_{sig}	**Statistical Significance Level**	Dimensionless	Type I error threshold ($\alpha_{\text{sig}} = 1 - \text{CL}$, e.g., $\alpha_{\text{sig}} = 0.05$ for 95% confidence where $-\ln(0.05) \approx 3.0$).
β	**Type II Error Allowance**	Dimensionless	Probability of rejecting an acceptable candidate ($1 - \beta$ is the power); with α_{sig} it sets the SPRT boundaries Λ_{up} and Λ_{lo}. Diffusion schedules use indexed β_s; a KL weight β stays local to its objective.
n	**Zero-Failure Trial Count**	Trials	Required number of incident-free trials to substantiate p_{target}; for exposure measured in hours, the bound is on T instead.
Λ_m	**Sequential Log-Likelihood Ratio**	Dimensionless	After k failures in m trials, $\Lambda_m = k \ln(p_1/p_0) + (m-k) \ln \frac{1-p_1}{1-p_0}$ for per-trial failure probabilities p_0 (unacceptable) and p_1 (acceptable); SPRT stops when it leaves $(\Lambda_{\text{lo}}, \Lambda_{\text{up}})$.
$\Lambda_{\text{up}}, \Lambda_{\text{lo}}$	**SPRT Boundaries**	Dimensionless	Upper and lower stopping thresholds on Λ_m, $\Lambda_{\text{up}} \approx \ln((1-\beta)/\alpha_{\text{sig}})$ and $\Lambda_{\text{lo}} \approx \ln(\beta/(1-\alpha_{\text{sig}}))$; never bare A and B.
C	**Assurance Claim**	Proposition	Top-level safety claim of an assurance argument. Under an independent-premise probability model, its confidence $\Pr(C)$ is the product of the premise confidences for a conjunctive argument, and one minus the product of the legs' failure probabilities for a multi-legged one.

The embodied energy corollary

Untethered mobile manipulators and autonomous robots operate under strict battery energy reserves and peak thermal dissipation ceilings. Total mission energy (distinct from the ML workload's E_{total}) splits across mechanical actuation work, edge neural computation, and auxiliary sensor payloads. The compute energy expended by edge inference system-on-chip (SoC) devices decomposes into data movement and arithmetic operations according to the core energy corollary:

$$E_{\text{mission}} = E_{\text{act}} + E_{\text{total}} + E_{\text{aux}}, \qquad E_{\text{total}} \approx D_{\text{vol}} \times E_{\text{move}} + O \times E_{\text{compute}}$$

For constant loss power in the single-node thermal model, resistive heating in stator windings $P_{\text{loss}} \approx \sum i_q^2 R(T_{\text{winding}})$ sets the steady-state rise $\Delta T = P_{\text{loss}} R_{\text{th}}$. Transient heating during shorter acceleration or contact bursts follows the coupled first-order thermal balance above.

Plant State, Actuation, and Kinematics

The symbols below describe the mechanical configuration, velocities, forces, and inertia of articulated and mobile mechanisms. Units for inertia and generalized loads specialize to revolute coordinates;

mixed revolute–prismatic plants require entrywise units consistent with their generalized coordinates.

Symbol	Definition	Unit	Notes
$s_t \in \mathcal{S}$	**Physical World State**	Mixed	Ground-truth continuous state of the machine, environment, and physical contacts at time t, and the state of the decision process in the learning chapters; italic, because it mixes types.
$\mathbf{x}$	**Mechanical Plant State**	Mixed: rad or m for positions; rad/s or m/s for velocities	Generalized state vector $\mathbf{x} = [\mathbf{q}^\top, \dot{\mathbf{q}}^\top]^\top \in \mathbb{R}^{2n}$ containing positions and velocities.
$\mathbf{q} \in \mathbb{R}^n$	**Generalized Coordinates**	rad or m	Degrees of freedom describing mechanical articulation (joint angles and prismatic link extensions); entries q_i.
$\dot{\mathbf{q}} \in \mathbb{R}^n$	**Generalized Velocities**	rad/s or m/s	First time derivative of generalized coordinates.
$\ddot{\mathbf{q}} \in \mathbb{R}^n$	**Generalized Accelerations**	$\mathrm{rad/s^2}$ or $\mathrm{m/s^2}$	Second time derivative of generalized coordinates.
$\tau \in \mathbb{R}^n$	**Actuator Torque Vector**	N · m or N	Generalized forces and torques delivered by actuators at mechanical joints; a subscript names a source, as in the contact torque τ_c.
τ	**Commanded Joint Torque**	N · m	Scalar torque commanded at one joint in single-joint derivations such as the kinetic barrier; bounds and disturbances keep a subscript ($\tau_{\max}$, τ_{bias}).
$\mathbf{M}(\mathbf{q})$	**Generalized Inertia Matrix**	$\mathrm{kg \cdot m^2}$	Symmetric positive-definite mass/inertia matrix of the articulated multibody plant.
$\mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})$	**Coriolis / Centrifugal Matrix**	N · m · s/rad	Matrix satisfying $\dot{\mathbf{M}} - 2\mathbf{C}$ skew-symmetry (passivity property).
$\mathbf{g}(\mathbf{q})$	**Gravitational Torque Vector**	N · m	Generalized gravitational load acting on links as a function of configuration; a single joint's share is τ_g.
$\mathbf{J}(\mathbf{q})$	**Manipulator Jacobian**	Mixed	Linear mapping $\mathbf{v}_e = \mathbf{J}(\mathbf{q})\dot{\mathbf{q}}$ from joint rates to operational task-space velocity.
$w(\mathbf{q})$	**Yoshikawa Manipulability**	Depends on task coordinates and scaling	Singularity proximity metric $w(\mathbf{q}) = \sqrt{\det(\mathbf{J}\mathbf{J}^\top)}$ vanishing at kinematic singular configurations.
e_{bemf}	**Back-EMF Voltage**	V	Opposing voltage $e_{\text{bemf}} = K_e \omega_m$ developed across stator coils by rotor rotation.
$J_{\text{rotor}}, J_{\text{load}}$	**Rotor and Load Inertia**	$\mathrm{kg \cdot m^2}$	Moment of inertia of motor rotor shaft and coupled mechanical load.
J_{ref}	**Reflected Rotor Inertia**	$\mathrm{kg \cdot m^2}$	Effective inertia $J_{\text{ref}} = N_{\text{gear}}^2 J_{\text{rotor}}$ amplified quadratically by gearbox ratio.
J_{eff}	**Effective Joint Inertia**	$\mathrm{kg \cdot m^2}$	Total inertia seen at one joint, link and payload plus J_{ref}; the inertia in single-joint torque and acceleration budgets.
N_{gear}	**Gear Reduction Ratio**	Dimensionless	Transmission reduction ratio ($N_{\text{gear}} = \omega_m/\omega_j \gg 1$) between motor rotor and joint output shaft; never bare N.
N^*	**Optimal Inertia-Matching Ratio**	Dimensionless	Ratio $N^* = \sqrt{J_{\text{load}}/J_{\text{rotor}}}$ maximizing load angular acceleration under peak torque.
η_{gear}	**Transmission Efficiency**	Dimensionless	Mechanical power transmission efficiency ($0 < \eta_{\text{gear}} \leq 1$); never bare η, which is the learning rate.
$\tau_{\text{peak}}, \tau_{\text{hold}}$	**Continuous / Peak / Holding Torque**	N · m	Thermally continuous holding torque τ_{hold} and transient peak acceleration torque.
m	**Mass**	kg	Physical body or payload mass, lowercase italic; effective and reduced impact masses carry subscripts (m_{eff}, m_{red}).
g	**Gravitational Acceleration**	$\mathrm{m/s^2}$	Scalar magnitude of gravitational acceleration; the vector $\mathbf{g}_0$ and the configuration-dependent torque $\mathbf{g}(\mathbf{q})$ are bold.
p	**Linear Momentum**	kg · m/s	Scalar momentum mv of a moving body; distinct from the bold position $\mathbf{p}$ and from a distribution $p(\cdot)$.

Symbol	Definition	Unit	Notes
r	**Wheel Radius**	m	Rolling radius of a driven wheel, which converts wheel torque to floor force and speed to wheel rate ($\omega = v/r$); the barrier relative degree r appears only in barrier analysis.
ω	**Angular Speed**	rad/s	Magnitude of a rigid body's angular velocity ω; not the crossover frequency ω_c.
v	**Base Forward Speed**	m/s	Forward linear speed of the mobile base along its heading, the speed input of the unicycle model; not the speed at the instant a hazard is detected.
$\dot{\theta}_{\text{head}}$	**Base Heading Rate**	rad/s	Rate of change of a mobile base's heading angle, the turn input of the unicycle model.
$\dot{y}$	**Base Lateral Velocity**	m/s	Lateral velocity of a mobile base in the plane.
$\dot{x}$	**Base Longitudinal Velocity**	m/s	Forward velocity of a mobile base in the plane.
v	**Body Speed**	m/s	Magnitude of the linear velocity of a moving body or machine; the scalar speed, with the vector velocity bold.
$\dot{\tau}$	**Commanded Joint Torque Slew**	$\text{N}\cdot\text{m/s}$	Time derivative of the torque at a single joint; for constant effective inertia it equals J_{eff} times the joint jerk.
τ_{cont}	**Continuous Torque**	$\text{N}\cdot\text{m}$	Largest motor torque a winding can sustain indefinitely at its temperature limit under the stated cooling; set by heat rejection, and at the engineering ceiling it gives the installed rating.
i_d	**Direct-Axis Current**	A	Current of a field-oriented drive along the rotor field, which produces no torque and is normally regulated to zero; not the torque-producing quadrature current.
ω_e	**Electrical Angular Speed**	rad/s	Rotor speed times the pole-pair count; the electrical frequency of the drive, not the mechanical shaft speed.
θ_e	**Electrical Rotor Angle**	rad	Mechanical rotor angle times the pole-pair count, the angle a field-oriented drive uses to rotate between stator and rotor frames.
θ_{enc}	**Encoder Angle**	rad	Joint angle an encoder reports; a sample index appears as a subscript, as in θ_{enc_k}.
FK	**Forward Kinematics Map**	Function	Map from joint positions to the positions of points on the robot's links in the base frame.
n	**Generalized Coordinate Count**	Dimensionless	Number of generalized coordinates of a mechanism, its degrees of freedom (the joints of a serial arm); the plant state has twice this many entries.
θ_{head}	**Heading Angle**	rad	Heading of a planar mobile base in the unicycle model, the direction its forward speed points.
v_{conv}	**Conveyor Speed**	m/s	Speed of the belt that carries a workpiece past the pick station; not the bound on a takeaway conveyor, v_{conv}.
ϕ_{drive}	**Driven-Wheel Load Fraction**	Dimensionless	Fraction of a vehicle's total weight carried by its driven wheels; it scales the traction ceiling on braking deceleration.
q	**Joint Coordinate**	rad or m	One entry of the generalized coordinates $\mathbf{q}$, a single joint's angle or extension.
q	**Joint Position**	rad or m	Position of a single joint along its axis, an angle for a revolute joint and a length for a prismatic one; its time derivatives are $\dot{q}$ and $\ddot{q}$.
θ_{joint}	**Joint Angle**	rad	Angle of one revolute joint, a scalar; the joint-space vector is $\mathbf{q}$.
$\dot{q}$	**Joint Velocity**	rad/s or m/s	Velocity of one joint, a scalar; the vector of all joints is $\dot{\mathbf{q}}$.
ω	**Joint Angular Speed**	rad/s	Angular speed of a single arm joint; a subscript zero marks the initial value.
$\ddot{q}$	**Joint Acceleration**	rad/s^2 or m/s^2	Acceleration of one joint, a scalar; the vector of all joints is $\ddot{\mathbf{q}}$.
j_{joint}	**Joint Jerk**	rad/s^3	Jerk of one joint's trajectory, the third time derivative of its position; a scalar for one joint.

Symbol	Definition	Unit	Notes
n	**Joint Count**	Dimensionless	Number of joints of a manipulator, the length of its joint-position vector; it shares its glyph with the zero-failure trial count of the validation chapters.
i	**Joint Index**	Index	Position of one joint axis of a manipulator, from one to the number of joints.
τ_{motor}	**Motor Torque**	$\mathrm{N \cdot m}$	Torque a motor produces at its shaft before the transmission, the torque constant times the torque-producing current; the joint output is τ_{out}.
τ_{out}	**Joint Output Torque**	$\mathrm{N \cdot m}$	Torque a joint delivers at the transmission output: the transmission efficiency η_{gear} times the gear ratio N_{gear} times the motor torque τ_{motor}.
τ_{fric}	**Joint Friction Torque**	$\mathrm{N \cdot m}$	Total friction torque of a joint, referred to its output link.
$\tau_{\max}$	**Joint Torque Limit**	$\mathrm{N \cdot m}$	Largest torque the actuator of one joint can deliver, indexed by joint; it bounds τ at the same joint and is not the transient burst rating.
$\boldsymbol{\tau}_{\max}$	**Joint Torque Upper Limit**	$\mathrm{N \cdot m}$	Per-joint upper bounds on the torque the actuators can deliver, as a vector; the vector counterpart of the scalar $\tau_{\max}$.
$\dot{\boldsymbol{\tau}}$	**Joint Torque Slew**	$\mathrm{N \cdot m/s}$	Time derivative of the joint torque vector; it couples to jerk through the derivative of the manipulator equation.
$\dot{\mathbf{q}}_{\max}$	**Joint Velocity Limit**	rad/s or m/s	Per-joint bounds on the magnitude of the generalized velocities; a planned trajectory and every admitted command must stay within them.
$\mathbf{e}$	**Joint Tracking Error**	rad or m	Vector of differences between the desired and the measured joint positions; not the state estimation error, which shares the glyph.
r_{arm}	**Lever Arm Length**	m	Distance from a rotating joint to the point it carries, which converts a joint rotation into tool travel; a scalar length.
σ	**Jacobian Singular Value**	Mixed	Singular value of the manipulator Jacobian $\mathbf{J}$, the tool speed a unit joint rate produces along one singular direction; units follow the Jacobian rows.
λ	**Inverse Kinematics Damping**	Mixed	Damping length that damped-least-squares inverse kinematics adds to bound the joint step near a singularity; it enters squared, and along a singular direction the gain never exceeds one over twice its value. The ridge-regression analogue of weight decay.
λ_{pm}	**Permanent-Magnet Flux Linkage**	$\mathrm{V \cdot s}$	Magnetic flux from the rotor magnets that links each stator winding; with the pole-pair count it sets the torque constant.
$\mathbf{f}$	**Plant Dynamics Function**	Function	Vector field of a plant's equations of motion, giving the state rate from the state, the control input, and the plant parameters; not the unforced drift part of control-affine dynamics, which shares its glyph.
m	**Plant Parameters**	Record	Physical and hardware properties of the machine in one trial or rollout, such as tolerances, wear, payload mass, state of charge, and calibration; not the mass m of a body.
$\dot{\mathbf{x}}$	**Plant State Rate**	Dimensionless per unit time	Time derivative of the mechanical plant state; the decorated form of the plant state, and not the Cartesian velocity of the tool, which shares its glyph.
$\mathcal{X}$	**Plant State Space**	Set	Set of all states the mechanical plant can occupy, positions together with velocities.
ω_m	**Rotor Angular Speed**	rad/s	Angular speed of a motor rotor about its axis; it sets the back-EMF, and on a direct-drive hub motor it equals the wheel's angular speed.
N_{poles}	**Rotor Pole-Pair Count**	Dimensionless	Number of magnetic pole pairs on a motor rotor; multiplying the mechanical rotor speed by it gives the electrical frequency of the drive.
v_q	**Quadrature-Axis Voltage**	V	Voltage the inverter of a field-oriented drive applies along the quadrature axis, the axis that produces torque.
θ_{tilt}	**Tilt Angle**	rad	Angular deflection of a body from vertical; zero when the body is upright.

Symbol	Definition	Unit	Notes
$\dot{\tau}_{\max}$	**Torque Rate Limit**	$\mathrm{N}\cdot\mathrm{m/s}$	Largest rate of change of joint output torque a drive accepts. Divided by the effective joint inertia it bounds joint jerk.
K_{joint}	**Transmission Torsional Stiffness**	$\mathrm{N}\cdot\mathrm{m/rad}$	Torsional stiffness of the transmission between rotor and output link, the compliance that couples motor to load.
ω_z	**Yaw Rate**	rad/s	Angular velocity of a body about its vertical axis, one component of the body angular velocity ω.

Contact Mechanics and Centroidal Dynamics

Contact turns a free-moving body into a constrained one. The symbols here describe the forces a contact can transmit, the friction cone that bounds them, and the centroidal quantities that sum them over the whole robot.

Symbol	Definition	Unit	Notes
$\mathbf{S} \in \mathbb{R}^{n\times(n+6)}$	**Actuation Selection Matrix**	Matrix	Matrix $[\mathbf{0}, \mathbf{I}]$ projecting generalized forces onto actuated joints in floating-base systems.
$\mathbf{f}_k \in \mathbb{R}^3$	**Contact Force Vector**	N	Physical contact force exerted by environment on contact patch k ($\mathbf{f}_k = [\mathbf{f}_{k,\parallel}^\top, f_{k,\perp}]^\top$); always indexed by the contact.
f_n	**Finger normal force**	N	Normal force one finger of a grasp presses against the object at its contact.
$\mathbf{f}_t$	**Finger tangential force**	N	Tangential friction force one finger of a grasp carries at its contact, bounded by the friction cone times f_n.
$\mathbf{J}_{\mathbf{c}_k}(\mathbf{q})$	**Contact Point Jacobian**	Mixed	Mapping joint velocities to contact patch Cartesian linear velocity: $\dot{\mathbf{p}}_k = \mathbf{J}_{c_k}(\mathbf{q})\dot{\mathbf{q}}$.
$f_{k,\perp}$	**Normal Contact Force**	N	Unilateral compressive force ($f_{k,\perp} = \mathbf{f}_k^\top \hat{\mathbf{n}}_k \geq 0$) perpendicular to contact plane.
$\mathbf{f}_{k,\parallel}$	**Tangential Contact Shear**	N	Friction traction force tangential to contact plane ($\mathbf{f}_{k,\parallel} = \mathbf{f}_k - f_{k,\perp}\hat{\mathbf{n}}_k$).
μ	**Coulomb Friction Coefficient**	Dimensionless	Static/kinetic coefficient bounding friction cone: $\|\mathbf{f}_{k,\parallel}\| \leq \mu f_{k,\perp}$.
$\mathbf{c} \in \mathbb{R}^3$	**Center of Mass (CoM)**	m	Spatial coordinates of the total articulated body mass centroid ($\mathbf{c} = \frac{1}{m}\sum m_i \mathbf{p}_i$).
$\mathbf{h}_{\text{lin}}$	**Centroidal Linear Momentum**	$\mathrm{kg}\cdot\mathrm{m/s}$	Total plant linear momentum ($\mathbf{h}_{\text{lin}} = m\dot{\mathbf{c}}$), governed by $\dot{\mathbf{h}}_{\text{lin}} = \sum \mathbf{f}_k + m\mathbf{g}_0$, with gravitational acceleration $\mathbf{g}_0$.
$\mathbf{h}_{\text{ang}}$	**Centroidal Angular Momentum**	$\mathrm{kg}\cdot\mathrm{m}^2/\mathrm{s}$	Angular momentum about CoM: $\dot{\mathbf{h}}_{\text{ang}} = \sum(\mathbf{p}_k - \mathbf{c}) \times \mathbf{f}_k + \tau_k$.
$\mathbf{p}_{\text{ZMP}} \in \mathbb{R}^2$	**Zero Moment Point (ZMP)**	m	Ground-plane point where net horizontal tipping moment vanishes; must reside in $\mathrm{Conv}(\{\mathbf{p}_k\})$.
$e \in [0,1]$	**Coefficient of Restitution**	Dimensionless	Kinematic velocity rebound ratio during non-smooth impact ($\dot{q}^+ = -e\dot{q}^-$).
k_{contact}, k_H	**Contact Stiffness**	N/m	Elastic stiffness of a structural contact, and of the human body region H in an impact (with its effective mass m_H), in the form ISO/TS 15066 states.
m_{eff}	**Effective Impact Mass**	kg	Apparent normal mass at a specified contact point and configuration. For a single frictionless normal impact, it is the reciprocal of the positive scalar Delassus coefficient formed from the contact normal Jacobian and generalized inertia matrix (section B.7).
m_{red}	**Reduced Impact Mass**	kg	Two-body reduced mass of a collision, $m_{\text{red}} = (1/m_{\text{eff}} + 1/m_H)^{-1}$, which sets the transferred energy.
F_{unbraked}	**Unbraked Impact Force**	N	Transient collision force peak ($F_{\text{unbraked}} = v_{\max}\sqrt{k_H m_{\text{red}}}$) governed by ISO/TS 15066.
a_{arm}	**Arm Stopping Deceleration**	$\mathrm{m/s}^2$	Deceleration the arm must achieve after braking onset to stop within the latch force limit.

Symbol	Definition	Unit	Notes
m_H	**Body Region Mass**	kg	Effective mass of a human body region, here the hand, in the ISO/TS 15066 body model.
F_{cmd}	**Brake Command Contact Force**	N	Contact force against the latch at the instant the brake command issues, after the contact loop responds; distinct from a commanded traction force.
F_{cmd}	**Braking Onset Contact Force**	N	Contact force reached against the latch plate at physical braking onset.
$\dot{\mathbf{h}}_{\text{ang}}$	**Centroidal Angular Momentum Derivative**	$\mathrm{N \cdot m}$	Time derivative of the centroidal angular momentum, the net external moment about the center of mass: contact-force moments plus the contact torques.
$\dot{\mathbf{h}}_{\text{lin}}$	**Centroidal Linear Momentum Derivative**	N	Time derivative of the centroidal linear momentum, the net external force on the robot: the sum of contact forces plus mass times gravity.
v_{approach}	**Contact Approach Speed**	m/s	Speed at which the robot approaches and strikes a contact surface; contact force rises at stiffness times this speed.
$\dot{x}$	**Contact Direction Velocity**	m/s	Velocity of the robot's contact point along the contact direction.
F_{contact}	**Contact Force**	N	Force between the robot and the environment at a contact, along the contact direction; the per-point vector is $\mathbf{f}_k$.
T_c	**Contact Loop Response Time**	s	Time the contact-control loop takes to respond after its tripwire fires.
$\hat{\mathbf{n}}$	**Contact Normal**	Dimensionless	Unit vector normal to the contact plane at one contact, pointing into the robot; indexed by contact.
x	**Contact Normal Position**	m	Position of a tool or link along the contact normal, whose change from first contact is the contact penetration in the spring contact model.
i	**Contact Point Index**	Index	Position of one contact point among the contacts of a grasp.
$\mathbf{r}$	**Contact Point Offset**	m	Position of a grasp contact relative to the reference point of the grasped object, the moment arm of its force; indexed by contact.
x	**Contact Point Position**	m	Position of the robot's contact point along the contact direction.
τ	**Contact Point Torque**	$\mathrm{N \cdot m}$	Moment the environment exerts on the robot at one contact patch, the torque part of the contact wrench; indexed by contact. Not the joint torque vector τ, which shares the glyph.
F_{trip}	**Contact Tripwire Force**	N	Contact force at which the permission path ends an attempt on the machine, set below the structural damage limit.
$\mathbf{w}$	**Contact Wrench**	Varies	Force and moment the environment applies at a contact, stacked into one vector; force rows in newtons, moment rows in newton-meters. Privileged in simulation.
$\mathbf{w}_{\max}$	**Contact Wrench Ceiling**	Varies	Largest contact force and torque an intent lease permits at the tool, stacked as a wrench; units mix newtons and newton-meters.
x_{des}	**Desired Contact Position**	m	Setpoint position of the robot's contact point along the contact direction.
$\dot{x}_{\text{des}}$	**Desired Contact Velocity**	m/s	Setpoint velocity of the robot's contact point along the contact direction.
k_{eff}	**Effective Series Stiffness**	N/m	Stiffness of a contact whose two sides deflect in series, the reciprocal of the sum of their compliances; the softer side dominates.
$\mathbf{F}_{\text{ext}}$	**External Wrench**	Mixed	Force and moment the environment applies at the end effector, in newtons for the force and newton-meters for the moments; it maps into joint torques through the transposed manipulator Jacobian.
τ_{ext}	**External Contact Torque Vector**	$\mathrm{N \cdot m}$	Joint torques produced by external contact forces acting on the manipulator.
τ_{ext}	**External Joint Torque**	$\mathrm{N \cdot m}$	Torque the environment applies at one joint's output; the scalar counterpart of the external contact torque vector τ_{ext}.

Symbol	Definition	Unit	Notes
$\mu_{\min}$	**Friction Coefficient Floor**	Dimensionless	Lowest friction coefficient a braking or contact premise assumes the surface provides; an unobserved oil spill can invalidate it.
$f_{\max}$	**Grasp Force Ceiling**	N	Largest grasp contact force the object tolerates without crushing or deforming.
$f_{\min}$	**Grasp Force Floor**	N	Smallest grasp contact force that holds the object against slip; the grasp must stay between this floor and $f_{\max}$.
$\mathbf{G}$	**Grasp Map**	Matrix	Linear map from contact forces to the wrench they exert on the grasped object; indexed by contact when one contact is meant; not the Kalman gain.
$h_{\mathbf{cg}}$	**Center-of-Gravity Height**	m	Height of a vehicle's center of gravity above the floor; it sets the tip-over ceiling on deceleration.
$\mathbf{g}_0$	**Gravity Vector**	$\mathrm{m/s^2}$	Gravitational acceleration as a vector pointing down with the magnitude of surface gravity; the scalar is the gravitational acceleration, and it is not the vector of gravitational joint torques.
x	**Impedance-Controlled Position**	m	Measured position of the point an impedance controller regulates; its deviation from x_{des}, times the stiffness, is the spring term.
$\dot{x}$	**Impedance-Controlled Velocity**	m/s	Measured velocity of the regulated point, the time derivative of x.
$x_{\mathbf{des}}$	**Impedance Equilibrium Position**	m	Virtual rest point of the emulated spring that an impedance controller pulls the controlled point toward.
$\dot{x}_{\mathbf{des}}$	**Impedance Equilibrium Velocity**	m/s	Velocity of the virtual equilibrium; its difference from $\dot{x}$, times the damping, is the damper term.
E_k	**Kinetic Energy**	J	Energy a moving body carries, one half its mass times its speed squared (plus rotational terms where stated); not the standard's limit on energy transferred to a person.
z_c	**Center-of-Mass Height**	m	Height of a body's center of mass above its support or contact point; it sets the natural frequency of the linear inverted pendulum, $\sqrt{g/z_c}$, and is not a camera-frame coordinate.
δ	**Penetration Depth**	m	Depth by which one body penetrates or compresses another at a contact, measured along the contact normal; penalty and compliant contact models compute normal force from it. Shares its glyph with the Huber threshold of the training chapters.
$\dot{\delta}$	**Penetration Rate**	m/s	Time rate of change of the penetration depth δ at a contact; zero at the instant of maximum compression.
$v_{\mathbf{latch}}$	**Latch Approach Speed**	m/s	Speed at which the arm presses into the cage-door latch plate; the enforcement and release chapters use the same latch scenario.
$F_{\mathbf{lim}}$	**Latch Force Limit**	N	Structural force limit of the door latch the arm pushes against.
$k_{\mathbf{latch}}$	**Latch Plate Stiffness**	N/m	Spring stiffness of the cage-door latch plate the arm compresses.
$d_{\mathbf{lead}}$	**Leading Support Distance**	m	Horizontal distance from a vehicle's center of gravity forward to its leading ground support; it shrinks when an arm extends forward.
C	**Intrusion Distance**	m	Distance a body part can intrude past the sensing field before detection; a term of the ISO/TS 15066 protective separation distance.
S_h	**Person Approach Travel**	m	Distance a person travels toward the robot during the robot's reaction and stopping time; a term of the ISO/TS 15066 protective separation distance.
Z_d	**Person Position Uncertainty**	m	Position uncertainty of the person from the sensing system; a term of the ISO/TS 15066 protective separation distance.

Symbol	Definition	Unit	Notes
d_{budget}	**Known-Component Stop Distance**	m	Stopping travel that the known components of the stopping budget add up to at a given speed on a dry floor: delay travel, braking, jerk ramps, and fixed overheads; the clear distance minus it is the spare the stopping claim holds in reserve.
v_n^-	**Pre-Impact Normal Velocity**	m/s	Normal contact velocity just before an impact, negative while the bodies approach; the restitution law links it to the post-impact velocity.
v_n^+	**Post-Impact Normal Velocity**	m/s	Normal contact velocity just after an impact, equal to minus the restitution coefficient times the pre-impact normal velocity.
k_{robot}	**Robot Structural Stiffness**	N/m	Stiffness of the manipulator side of a contact, its pads, linkages, and joint elasticity acting as one series spring; it combines in series with the stiffness of the struck body.
a_{slip}	**Slip Acceleration Bound**	m/s^2	Bound on the residual acceleration of a tracked object slipping relative to its carrier; it widens the evidence horizon of a target estimate.

Geometry, Transformations, and Perception

Every measurement a robot uses arrives in some frame, and every command leaves in another. These symbols name the frames, the rigid transforms between them, and the camera models that project the world onto a sensor.

Symbol	Definition	Unit	Notes
$SE(3)$	**Special Euclidean Group**	Lie Group	Group of 3D rigid-body spatial transformations (translations and rotations: $\mathbb{R}^3 \rtimes SO(3)$).
$SO(3)$	**Special Orthogonal Group**	Lie Group	Group of 3×3 proper orthogonal rotation matrices ($\mathbf{R}^\top \mathbf{R} = \mathbf{I}, \det(\mathbf{R}) = +1$).
$\mathcal{F}_W, \mathcal{F}_B, \mathcal{F}_E$	**Coordinate Reference Frames**	Reference	Fixed World frame ($\mathcal{F}_W$), mobile robot Base/body frame ($\mathcal{F}_B$), and End-effector frame ($\mathcal{F}_E$).
$\mathbf{p} \in \mathbb{R}^3$	**Cartesian 3D Position**	m	Position vector $[x, y, z]^\top$ expressing point coordinates in a stated frame.
$\mathbf{t} \in \mathbb{R}^3$	**Rigid-Transform Translation**	m	Translation part of a rigid transform between two frames (the offset of one frame's origin in the other).
$\mathbf{R} \in SO(3)$	**Directional Cosine Matrix**	Matrix	3×3 orthonormal matrix parameterizing spatial attitude and orientation.
$\mathbf{q}_{\text{quat}} \in \mathbb{H}$	**Unit Quaternion**	Dimensionless	Hypercomplex orientation vector $[w, x, y, z]^\top$ satisfying $\|\mathbf{q}_{\text{quat}}\| = 1$.
$\mathbf{T} \in SE(3)$	**Pose**	Matrix	Rigid-body pose of a named frame, such as a grasp, the tool center point, or a target ($\mathbf{T}_{\text{grasp}}$, $\mathbf{T}_{\text{TCP}}$); the transform between two frames is $\mathbf{T}_{AB}$ below.
$\mathbf{T}_{AB} \in SE(3)$	**Homogeneous Transform**	Matrix	4×4 matrix $\begin{bmatrix} \mathbf{R}_{AB} & \mathbf{t}_{AB} \\ \mathbf{0}^\top & 1 \end{bmatrix}$ mapping coordinates from frame B into frame A.
$\omega, \alpha \in \mathbb{R}^3$	**Angular Velocity & Acceleration**	$\text{rad/s}, \text{rad/s}^2$	Spatial angular velocity and angular acceleration vectors of a rigid body.
$\mathbf{r}_{P/O} \in \mathbb{R}^3$	**Sensor Lever-Arm Vector**	m	Displacement vector from body rotation origin O to displaced sensor location P; its length, or a link's lever arm, is the scalar r_{arm}.
$\mathbf{F}, \mathbf{E}$	**Fundamental and Essential Matrices**	Matrix	Two-view epipolar constraint $\tilde{\mathbf{m}}_2^\top \mathbf{F} \tilde{\mathbf{m}}_1 = 0$ with $\mathbf{E} = [\mathbf{t}]_\times \mathbf{R}$; the subscript keeps it distinct from the transition matrix $\mathbf{F}$.

Symbol	Definition	Unit	Notes
$\mathbf{K} \in \mathbb{R}^{3\times3}$	**Pinhole Camera Intrinsics**	Pixels	Calibration matrix $\begin{bmatrix} f_x & 0 & c_x \\ 0 & f_y & c_y \\ 0 & 0 & 1 \end{bmatrix}$ parameterizing focal lengths and principal center.
$\mathbf{K}^{-\top}$	**Inverse-transpose intrinsic matrix**	Matrix	Transpose of the inverse of the camera intrinsic matrix $\mathbf{K}$, which carries an essential matrix into the pixel-coordinate fundamental matrix.
$\mathbf{p}_c = [X_c, Y_c, Z_c]^\top$	**Camera-Frame 3D Coordinate**	m	Metric coordinates of a spatial point in the optical camera frame (Z_c is optical depth).
$[u, v]^\top$, $\tilde{\mathbf{m}}$	**Image Plane Pixel Coordinates**	Pixels	Discrete sensor pixel coordinates ($u \sim f_x \frac{X_c}{Z_c} + c_x$, $v \sim f_y \frac{Y_c}{Z_c} + c_y$), italic as scalars; the homogeneous image point is $\tilde{\mathbf{m}} = [u, v, 1]^\top$, never bold $\mathbf{u}$.
t_{exp}	**Exposure Duration**	ms	Integration time of one camera frame; the frame's timestamp belongs at its midpoint, $t_{\text{exp}}/2$ after exposure starts.
T_{inv}	**Belief Invalidation Horizon**	ms	Time since the last supporting evidence after which a belief can no longer be shown to lie inside its task tolerance; a belief expires at $t_0 + T_{\text{inv}}$.
d_{free}	**Free-Space Depth**	m	Distance from a hull's surface to the nearest cell that is occupied, unknown, or expired, read from an ESDF built with all three treated as obstacles; the budget motion may spend there (section 9.6.1).
t_{row}	**Rolling Shutter Row Readout**	µs	Exposure time delta between adjacent CMOS sensor scanlines; row y starts at $t(y) = t_{\text{start}} + y\, t_{\text{row}}$.
$\Delta\mathbf{x}(y)$	**Rolling Shutter Distortion**	m	Kinematic skew displacement $\Delta\mathbf{x} = \mathbf{v} \cdot y \cdot t_{\text{row}}$ induced by high-velocity platform motion.
$\mathbf{tsdf}(\mathbf{p}_{\text{vox}})$	**Truncated Signed Distance**	$[-1, +1]$	Normalized volumetric distance $\text{tsdf}(\mathbf{p}_{\text{vox}}) = \text{clamp}(d(\mathbf{p}_{\text{vox}})/\mu_{\text{tsdf}}, -1, 1)$ of the voxel centered at $\mathbf{p}_{\text{vox}}$ to the nearest surface.
μ_{tsdf}	**TSDF Truncation Band**	m	Metric thickness of the spatial surface interface band stored in voxel memory.
$D_t(\mathbf{p}_{\text{vox}}), W_t(\mathbf{p}_{\text{vox}})$	**TSDF Accumulated Volume**	Mixed	Running weighted signed distance and accumulated visibility weight at the voxel centered at $\mathbf{p}_{\text{vox}}$.
$e_0, e_{\max}$	**Initial and Ceiling Error**	m	Position error of an estimate when its evidence is fresh, and the largest error the task tolerates; E_0 and $E_{\max}$ stay energies.
r_{tol}	**Positional Task Tolerance**	m	Radius within which a target estimate must lie for the task to succeed; paired with the orientation tolerance θ_{tol}.
$\mathcal{G}_{\text{goal}}$	**Geometric Goal Set**	Subset of $SE(3)$	Admissible terminal poses within the positional and angular tolerances of the task; the spatial component of an intent lease $\mathcal{I}_{\text{intent}}$.
d	**Distance to Target**	m	Straight-line distance from the measured end-effector position to the admitted target, $\|\mathbf{p}_{\text{target}} - \mathbf{p}_0\|$, in the intent-lease reachability test; distinct from the hidden width d.
θ_{att}	**Attitude Error**	rad	Angular error in an estimated attitude, which leaks gravity into the horizontal acceleration.
θ_{az}	**Azimuth Angle**	rad	Angle of a direction measured in the horizontal plane about the vertical axis; the book may state values in degrees.
$\mathbf{T}^{\text{cam}}_{\text{base}}$	**Base-to-Camera Transform**	Matrix	Rigid transform mapping camera coordinates into the robot base frame.
$\mathbf{p}_{\text{body}}$	**Body-Frame Point**	m	Position of a perceived point expressed in the robot body frame, the camera-frame point carried through the extrinsics.
Σ_{body}	**Body-Frame Point Covariance**	m^2	Covariance of a perceived point's position error in the robot body frame, the spatial covariance an observation contract carries; rotated camera-frame covariance plus the extrinsic term, not the covariance of a state estimator.

Symbol	Definition	Unit	Notes
$\mathbf{R}_{bc}$	**Camera Extrinsic Rotation**	Dimensionless	Rotation part of a camera's extrinsic calibration, taking camera-frame vectors into the body frame; the rotation block of $\mathbf{T}_{bc}$.
$\mathbf{T}_{bc}$	**Camera Extrinsic Transform**	Matrix	Rigid transform of a camera's extrinsic calibration, mapping camera-frame coordinates into the body frame; mixed rotation and translation blocks.
Σ_c	**Camera-Frame Point Covariance**	m^2	Covariance of a point's position error in the camera's optical frame, after unprojection of its pixel and depth measurement; rotated into the body frame by $\mathbf{R}_{bc}$.
x	**Cartesian X Coordinate**	m	First Cartesian component of a three-dimensional position.
y	**Cartesian Y Coordinate**	m	Second Cartesian component of a three-dimensional position.
z	**Cartesian Z Coordinate**	m	Third Cartesian component of a three-dimensional position.
C_{inset}	**Clearance Inset**	m	Separation a consumer holds between an estimated obstacle position and the machine's envelope so the true obstacle stays the required clearance away, except with a stated tail probability; a field of the observation contract.
σ_z	**Depth Standard Deviation**	m	Standard deviation of the depth a stereo or range sensor reports for one point; for stereo it grows with the square of the range.
σ_d	**Disparity Standard Deviation**	pixels	Standard deviation of the disparity a stereo matcher measures; it feeds the stereo depth term σ_z.
ϕ	**Elevation Angle**	rad	Angle of a direction above the horizontal plane; not the encoder parameters of a variational autoencoder, which render the same glyph.
Σ_{ext}	**Extrinsic Calibration Covariance**	m^2	Covariance of a sensor's calibrated mounting extrinsic.
θ_{ext}	**Extrinsic Misalignment Angle**	rad	Angular error of a sensor's extrinsic calibration relative to its true mounting.
f	**Focal Length**	pixels	Focal length of a pinhole camera in pixels, the scale from normalized image coordinates to pixels; a rectified pair shares one value.
f_x	**Horizontal Focal Length**	pixels	Camera focal length in pixels along the horizontal image axis, one entry of the intrinsics.
t_{start}	**Frame Exposure Start Time**	s	Instant at which the first row of a rolling-shutter frame begins its exposure.
t_{readout}	**Frame Readout Time**	s	Time a camera takes to read its pixels out after exposure.
t_{capture}	**Evidence Capture Instant**	s	Instant, on a monotonic clock, at which the sensor evidence behind an observation or proposal was captured; observation age and proposal validity are measured from it.
t_0	**Evidence Epoch**	s	Capture instant of the most recent measurement that constrained a stored belief; republishing or predicting never advances it.
t_{fresh}	**Fresh Evidence Time**	s	Capture time of the fresh physical evidence that renews a belief's evidence epoch t_0.
t_{now}	**Current Time**	s	Wall-clock time at which a consumer evaluates a stored record; evidence age is the current time minus t_0.
t_{age}	**Dispatch Observation Age**	s	Elapsed time from the sensor exposure midpoint to dispatch of the processed observation. Current consumer evidence age additionally includes elapsed time after dispatch.
$\mathcal{C}_{\text{free}}$	**Free Configuration Space**	Set	Configurations at which the robot touches no obstacle, the configuration space minus the obstacle set.
ρ	**Inverse Depth**	$1/\mathrm{m}$	Reciprocal of a point's depth along the optical axis, the parameterization that lets a landmark at infinity enter an estimator at zero; linear in disparity.
d	**Obstacle Separation Distance**	m	Distance between the machine and the nearest obstacle or boundary at a given time, the signal a clearance predicate scores; written as a function of time.

Symbol	Definition	Unit	Notes
L	**Occupancy Log-Odds**	Dimensionless	Natural logarithm of the odds of a voxel's occupancy probability, the quantity an occupancy map stores per cell; indexed by step, with the prior at step zero.
$\mathbf{p}_{\text{meas}}$	**Measured Tracked Position**	m	Measured Cartesian position of the tracked point, which the tracking error compares against the reference.
t_{last}	**Last Measurement Time**	s	Capture time of the most recent measurement that updated a track or map cell.
$\sigma_{v,0}$	**Initial Velocity Standard Deviation**	m/s	Standard deviation of the velocity error of an estimate, here at the onset of occlusion.
σ_u	**Pixel Standard Deviation**	Pixels	Standard deviation of a measured image position, in pixels; the image-plane noise that propagates into depth and position error.
c_x	**Principal Point Column**	Pixels	Horizontal pixel coordinate of the principal point, where the optical axis meets the image.
c_y	**Principal Point Row**	Pixels	Vertical pixel coordinate of the principal point, where the optical axis meets the image.
b	**Stereo Baseline**	m	Distance between the optical centers of a stereo camera pair; depth is focal length times baseline over disparity.
d	**Stereo Disparity**	Pixels	Horizontal pixel offset between the images of one scene point in the two views of a rectified stereo pair; not a travel distance or a sightline range, which share the glyph.
z	**Target Range**	m	Distance from a camera to the target it observes, measured along the viewing direction; stereo depth error grows with its square.
$\mathbf{p}_{\text{target}}$	**Target Position**	m	Position of the target an end effector is commanded toward, in the robot base frame; a decorated form of the Cartesian position.
E	**Position Error Bound**	m	Worst-case position error of a target estimate as a function of the time elapsed since its evidence was captured; it grows while the target is occluded.
e	**Position Error Envelope**	m	Conservative bound on the position error of a target estimate along one coordinate axis of the base frame; written with the axis index.
z	**Range Observation**	Record	One range observation a sensor returns at a time step; indexed by step, with the history as the sequence of them.
$\mathcal{M}$	**Spatial Memory Map**	Set	Occupancy map in spatial memory that stores the obstacle geometry around the machine; not a decision-process tuple.
$\mathbf{R}_{AB}$	**Transform Rotation Block**	Matrix	Rotation block of the homogeneous transform from frame B to frame A, its upper-left three-by-three part.
$\mathbf{t}_{AB}$	**Transform Translation Block**	m	Translation block of the homogeneous transform from frame B to frame A, the position of the origin of frame B expressed in frame A.
$\mathbf{J}_{\text{unproj}}$	**Unprojection Jacobian**	Mixed	Jacobian of a camera-frame point with respect to its pixel coordinates and depth; it carries measurement covariance into Cartesian covariance. Not the manipulator Jacobian $\mathbf{J}$.
f_y	**Vertical Focal Length**	Pixels	Camera focal length expressed in pixels along the vertical image axis.
$\mathbf{T}_{wb}$	**World-from-Body Transform**	Matrix	Rigid transform giving the pose of the vehicle body frame in the world frame; it maps body coordinates into world coordinates.
$\mathbf{p}_{\text{world}}$	**World-Frame Point**	m	Position of an observed point expressed in the world frame; compare $\mathbf{p}_c$, the same point in the camera frame.
Σ_{depth}	**Perception Depth Covariance**	m^2	Covariance of the three-dimensional position error of a point lifted from stereo, lidar, or depth data; a matrix, not the scalar depth variance.
c	**Speed of Light in Vacuum**	m/s	About 3×10^8 m/s, the upper limit on how fast a signal crosses a chip or link; on-chip wires carry signals at a fraction of it.

Control, Observers, and Safety Filters

The control symbols follow state-space convention. A plant has a state, an input, and a measured output; an observer estimates the state from that output; and a safety filter, such as a control barrier function solved as a quadratic program, edits the input before it reaches the actuators.

Symbol	Definition	Unit	Notes
$\mathbf{A_{sys}}, \mathbf{B}$	**Linear State-Space Matrices**	Matrix	Continuous LTI plant: $\dot{\mathbf{x}} = \mathbf{A}_{\text{sys}}\mathbf{x} + \mathbf{B}\mathbf{u} + \mathbf{w}$, observed output $\mathbf{y} = \mathbf{H}\mathbf{x} + \mathbf{v}_{\text{meas}}$ through the measurement map $\mathbf{H}$ below.
$\mathbf{w}(t), \mathbf{v_{meas}}(t)$	**Process and Measurement Noise**	Vector	Zero-mean Gaussian noise vectors with covariance matrices $\mathbf{Q} \succeq 0$ and $\Sigma_{\text{meas}} \succ 0$; bold $\mathbf{R}$ is reserved for rotation.
$\mathbf{F}, \mathbf{H}$	**Transition and Measurement Maps**	Matrix	Discrete state transition $\hat{\mathbf{x}}_{k\|k-1} = \mathbf{F}\hat{\mathbf{x}}_{k-1\|k-1}$ and measurement map $\mathbf{y}_k = \mathbf{H}\mathbf{x}_k + \mathbf{v}_{\text{meas}}$ of a Kalman filter.
$\mathbf{G}_k$	**Kalman Gain**	Matrix	Weight on the innovation $\nu_k = \mathbf{y}_k - \mathbf{H}\hat{\mathbf{x}}_{k\|k-1}$ in the update step; bold $\mathbf{K}$ is reserved for camera intrinsics.
$\mathbf{P} \in \mathbb{R}^{n \times n}$	**Estimation Error Covariance**	Matrix	Symmetric positive-definite matrix $\mathbb{E}[(\mathbf{x}-\hat{\mathbf{x}})(\mathbf{x}-\hat{\mathbf{x}})^\top]$ ($\mathbf{P}(t)$ continuous, $\mathbf{P}_{k\|k}$ discrete) evolving via matrix Riccati equation; $\mathbf{P}_{\text{est}}$ where an LQR cost matrix is also in scope.
$\mathbf{O_{obs}}, \mathbf{O_{NL}}$	**Observability Matrices**	Matrix	Kalman observability matrix $[\mathbf{H}^\top, (\mathbf{H}\mathbf{A}_{\text{sys}})^\top, \ldots]^\top$ and nonlinear Lie matrix $[d\mathbf{h}, d L_{\mathbf{f}}\mathbf{h}, \ldots]^\top$; calligraphic $\mathcal{O}(\cdot)$ stays asymptotic cost. The dual controllability matrix is $\mathbf{C}_{\text{ctrb}}$.
$\mathbf{C_{ctrb}}$	**Controllability Matrix**	Mixed	Kalman block matrix formed from the input matrix and its products with powers of the system matrix; full row rank characterizes unconstrained LTI controllability.
$\partial\mathcal{C}$	**Safety Boundary Manifold**	Boundary	Zero level set $\{\mathbf{x} \mid h(\mathbf{x}) = 0\}$, the boundary of the safe set $\mathcal{C}$, separating nominal operation from irreversible hazard.
$h(\mathbf{x}), h$	**Control Barrier Function (CBF)**	Scalar	Continuously differentiable function whose 0-superlevel set is the safe set $\mathcal{C}$. Written $h(\mathbf{x})$ on the plant state, and as the function head h when it takes other arguments or is differentiated ($\dot{h}$, $L_{\mathbf{f}}h$, $h(\theta_{\text{clear}}, \omega)$).
$\mathcal{C} \subset \mathbb{R}^{2n}$	**Forward-Invariant Safe Set**	Set	Superlevel set $\mathcal{C} = \{\mathbf{x} \mid h(\mathbf{x}) \geq 0\}$ of plant states where safety invariants are strictly maintained; a qualifier names a variant ($\mathcal{C}_{\text{contact}}$, $\mathcal{C}_{\text{discrete}}$).
$\mathbf{f}(\mathbf{x}), \mathbf{g}(\mathbf{x})$	**Control-Affine Drift and Input Fields**	Vector, Matrix	The control-affine model $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}) + \mathbf{g}(\mathbf{x})\mathbf{u}$ of barrier analysis; these letters hold only inside that model, where the gravity torque $\mathbf{g}(\mathbf{q})$ and contact forces $\mathbf{f}_k$ do not appear.
$L_{\mathbf{f}}h(\mathbf{x})$	**Lie Derivative along Drift**	Barrier units/s	Directional gradient derivative $\nabla h(\mathbf{x})\mathbf{f}(\mathbf{x})$ along unforced plant dynamics; its units are those of the barrier divided by time.
$L_{\mathbf{g}}h(\mathbf{x})$	**Lie Derivative along Control**	Vector	Directional control effectiveness gradient $\nabla h(\mathbf{x})\mathbf{g}(\mathbf{x})$.
r	**Barrier Relative Degree**	Integer	Number of differentiations required before control input $\mathbf{u}$ appears ($L_{\mathbf{g}}L_{\mathbf{f}}^{r-1}h \neq 0$).
$h_{\text{kinetic}}(\mathbf{x})$	**Kinetic Inset Barrier Function**	Scalar	Relative-degree-1 barrier: $h_{\text{kinetic}}(\mathbf{x}) = h(\mathbf{x}) - v^2/(2a_{\text{brake}})$ incorporating stopping distance.
$\kappa(\cdot), \kappa$	**Class-$\mathcal{K}$ Rate Function**	Scalar function	Extended class-$\mathcal{K}$ function in the barrier condition $\dot{h} \geq -\kappa(h)$, written as the function head κ when applied; the book uses the linear choice $\kappa(h) = \gamma_{\text{cbf}}h$.
γ_{cbf}	**Linear Barrier Decay Rate**	s^{-1}	Coefficient of the linear class-$\mathcal{K}$ choice, $\dot{h} + \gamma_{\text{cbf}}h \geq 0$; bare γ is the reinforcement-learning discount factor.
$\mathbf{u_{nom}} \in \mathcal{U}_{\text{adm}}$	**Nominal Control Command**	N·m / rad	Unverified control candidate proposed across the proposal boundary by the learned policy.
$\mathbf{u}^* \in \mathcal{U}_{\text{adm}}$	**Certified Control Action**	N·m / rad	Privileged, safety-filtered control command resolved by the real-time active-set CBF-QP.

DRAFT

Symbol	Definition	Unit	Notes
$\mathbf{r}$	**Reference Position**	m	Commanded Cartesian position reference the plant tracks, $\mathbf{r}(t)$; the feedback tracker bounds the tracked point's position error by $\|\mathbf{p}(t)-\mathbf{r}(t)\| \le \epsilon_{\text{track}}$, with both positions expressed in the same frame. Whole-body clearance requires a declared output map or metric that bounds swept-volume displacement. Elsewhere bold $\mathbf{r}$ is local (a moment arm, ellipsoid semi-axes).
$\alpha(\hat{t})$	**Bumpless Transfer Blend**	$[0,1]$	C^2 quintic polynomial $6\hat{t}^5-15\hat{t}^4+10\hat{t}^3$ of normalized time $\hat{t}\in[0,1]$, ramping between prior and candidate controllers.
α'	**Blend slope**	Dimensionless	Derivative of the bumpless-transfer blend weight α with respect to normalized progress.
τ_{blend}	**Blending Transition Window**	s	Duration of bumpless transfer; for two fixed, latched acceleration commands, bounded by $\tau_{\text{blend,min}} = 1.875\|\Delta\mathbf{u}\|/j_{\max}$. Torque or position commands require their own compatible command-rate bounds.
K_p, K_d, K_i	**PID / Feedback Gains**	Mixed	Proportional, derivative, and integral gains for joint-level or operational-space error stabilization.
$\mathbf{K}_{\text{lqr}}, \mathbf{Q}_x, \mathbf{R}_u$	**LQR Gain and Weights**	Matrix	State-feedback gain $\mathbf{u}^* = -\mathbf{K}_{\text{lqr}}\mathbf{x}$ and the state and control weights of the quadratic cost; the subscripts keep them distinct from intrinsics, process noise, and rotation.
N_{mpc}	**MPC Prediction Horizon**	Control steps	Number of predicted discrete control steps in the finite-horizon MPC formulation; distinct from physical-trial count and learned action-chunk horizon.
$\mathbf{D}_{\text{virt}}, \mathbf{K}_{\text{virt}}$	**Virtual Damping & Stiffness Matrices**	Matrix	Target compliance matrices in impedance control: $\tau_{\text{safe}} = -\mathbf{D}_{\text{virt}}\dot{\mathbf{q}} - \mathbf{K}_{\text{virt}}\Delta\mathbf{q} + \mathbf{g}(\mathbf{q})$.
q_c	**Acceleration Noise Spectral Density**	m^2/s^3	Continuous power spectral density of the zero-mean white acceleration noise per axis in a constant-velocity motion model; sets how fast the predicted position uncertainty grows.
$\mathcal{W}$	**Admissible Disturbance Set**	Set	Set of disturbance values a falsification search may inject; the search is bounded to it.
$\mathbf{u}$	**Admitted Control Command**	Per interface	Control command the permission path applies to the actuators after admitting, clipping, or replacing a policy proposal; indexed by step. Not $\mathbf{u}_{\text{nom}}$ (before the filter) or $\mathbf{u}^*$ (the filter's projection).
ω	**Angular Frequency**	rad/s	Frequency of a sinusoidal signal, the free variable of a frequency response; evaluated at the crossover frequency when a delay's phase lag is charged to the phase margin.
$\mathbf{A}_{\text{BE}}$	**Backward Euler Transition Matrix**	Matrix	Discrete-time transition matrix that backward (implicit) Euler integration produces, the inverse of the identity minus the system matrix times the step; unconditionally stable but numerically dissipative.
b_{cbf}	**Barrier Constraint Bound**	Varies	Bound on the right side of one affine control-barrier constraint, one entry of $\mathbf{b}_{\text{cbf}}$; its unit follows the barrier function rate.
$\mathbf{a}_{\text{cbf}}$	**Barrier Constraint Normal**	Varies	Normal vector of a single affine control-barrier constraint on the control input, equal to $-L_{\mathbf{g}}h$ transposed; one row of $\mathbf{A}_{\text{cbf}}$.
$\dot{h}$	**Barrier Function Rate**	m/s	Time derivative of the control barrier function along the closed-loop dynamics, the rate in the barrier condition; a dot is not an allowed decoration on h, so it has its own entry.
λ	**Barrier Projection Multiplier**	Varies	Lagrange multiplier of the barrier half-space constraint in the CBF-QP projection; starred at the optimum, where it is zero when the nominal command is already safe.
E	**Belief Error Bound**	Varies	Upper bound on the discrepancy between a stored belief and the true state after a given elapsed time without new evidence; the unit is that of the stored quantity (meters for a position, radians for an angle).

Symbol	Definition	Unit	Notes
t_{start}	**Bumpless Transfer Start Instant**	s	Instant at which a bumpless-transfer blend begins, the zero of its normalized progress; other chapters use the same letters for exposure or sweep starts, different quantities.
u	**Channel Command**	Varies	Scalar command of one actuator channel, such as the base acceleration or one joint torque; the unit is the channel's command unit. Scalar per-channel form of $\mathbf{u}$.
$\mathcal{K}$	**Class-K Function Set**	Set	Class of continuous strictly increasing functions that are zero at zero; named in "extended class-K function."
$\mathbf{u}$	**Control Command**	Per interface	Control command vector sent toward the actuators, whatever its source or stage; indices name instances. The stages are $\mathbf{u}_{\text{nom}}$ and $\mathbf{u}^*$.
$\mathbf{u}$	**Control Input**	Per interface	Control input applied to the plant, the command a controller or safety filter sends to the actuators; units depend on the command interface (torques, setpoints).
m	**Control Input Dimension**	Count	Number of components of the control input vector; not the mass m.
$\mathbf{u}_{\min}$	**Control Input Lower Limit**	Per interface	Per-component lower limit of the control input the actuators can deliver.
$\mathcal{U}$	**Control Input Set**	Set	Set of control inputs the controller may choose from, a subset of the input space; the actuator box and the barrier-feasible subset are narrower sets inside it.
$\mathbf{u}_{\max}$	**Control Input Upper Limit**	Vector	Per-component upper limit of the control input the actuators can deliver.
t	**Control Step Index**	Dimensionless	Position of one discrete control step, or setpoint, in a robot's control timeline; a subscript on per-step quantities, bare in expressions such as a clipped next step.
$\mathbf{K}_d$	**Derivative Gain Matrix**	Matrix	Derivative feedback gains acting on the tracking error rate in joint-space PD or PID control; its diagonal entries are the per-joint derivative gains.
C	**Differentiability Class**	Set	Functions whose derivatives up to the order written as the superscript exist and are continuous; C^2 means continuous position, velocity, and acceleration of a blended trajectory.
f	**Discrete Plant Dynamics**	Function	Discrete-time map from the current state and applied command to the next state; the deterministic counterpart of the plant's transition kernel.
$L_{\mathbf{f}}$	**Drift Lie Derivative Operator**	Operator	Rate of change of a scalar function of the state under the unforced dynamics; it is applied repeatedly for higher-order derivatives.
v_{drift}	**Drift Speed Bound**	m/s	Bound on the unobserved speed at which a target drifts relative to its last measured position; not the bound on the state-estimate drift, v_{drift}.
v_{drift}	**Drift Velocity Bound**	m/s	Bound on the unmodeled velocity at which an unobserved estimate drifts from the true state.
v_{conv}	**Conveyor Speed Bound**	m/s	Largest speed at which the takeaway conveyor carries a target; the bound used when sizing a catch window, not the belt speed v_{conv} of a single pick.
$\hat{\mathbf{x}}$	**Estimated Plant State**	Mixed	Estimate of the mechanical plant state reconstructed from sensor observations; its error covariance is a separate symbol.
$\hat{\mathbf{p}}$	**Estimated Position**	m	Position of a point that a filter propagates under its nominal model.
$\hat{\mathbf{v}}$	**Estimated Velocity**	m/s	Velocity of a body that a filter propagates under its nominal model.
T	**Finite Time Horizon**	s	Length of the finite window from time zero to the horizon over which an optimization, rollout, test, or temporal-logic operator is evaluated; not the wall-clock time to complete a unit of work.

Symbol	Definition	Unit	Notes
$\mathbf{A_{FE}}$	**Forward Euler Transition Matrix**	Matrix	Discrete-time transition matrix that forward Euler integration produces, identity plus the system matrix times the step; its spectral radius exceeds one for an undamped oscillator at any step size.
h	**Hermite Basis Function**	Function	Cubic Hermite basis polynomial that weights an endpoint position or velocity in spline interpolation; indexed by two digits.
j	**Imaginary Unit**	Dimensionless	Square root of minus one, written j by the engineering convention rather than i.
v	**Inductive Voltage**	V	Voltage across a coil, the inductance times the rate of change of its current.
g	**Inequality Constraint Function**	Varies	Constraint function of an optimization problem, whose nonpositive values define the feasible set; it appears in the interior-point barrier.
$L_{\mathbf{g}}$	**Input Lie Derivative Operator**	Operator	Lie derivative along the input matrix field, mapping a scalar function of the state to its sensitivity to the control input.
s	**Integration Time Instant**	s	Time instant running over an integration interval, the dummy variable when the interval ends at the time t; it keeps the integrand's time distinct from the upper limit.
t'	**Integration Dummy Time**	s	Dummy time variable of integration inside a time integral, distinct from its limits; a primed time would be a decorated quantity, so this entry names the bound variable.
s	**Laplace Variable**	$1/\mathrm{s}$	Complex frequency variable of the Laplace transform, standing for differentiation in time; read as the imaginary unit times the angular frequency for sinusoidal motion.
$\lambda_{\max}$	**Largest Eigenvalue**	Varies	Largest eigenvalue of a symmetric matrix, applied to that matrix; its unit is that of the matrix entries.
$\mathbf{P}$	**LQR Cost-to-Go Matrix**	Varies	Symmetric solution of the regulator algebraic Riccati equation (the discrete one in discrete-time LQR), whose quadratic form is the optimal LQR cost-to-go; shares its glyph with the estimation error covariance.
$\mathbf{u}_{0:N_{\mathbf{mpc}}-1}$	**MPC Control Sequence**	Varies	Sequence of control inputs over a model-predictive-control horizon, one per step, that the optimizer chooses; only the first is applied before the next re-solve.
$\mathbf{h}$	**Nonlinear Output Function**	Varies	Output function of a nonlinear state-space model, mapping the state to the measurement vector $\mathbf{y}$; not the barrier function nor the bias forces of the floating-base equations.
L	**Open-Loop Transfer Function**	Dimensionless	Open-loop transfer function of a feedback loop, evaluated along the imaginary axis for frequency response; never the loss.
$\mathbf{K}_p$	**PID Proportional Gain Matrix**	Varies	Proportional gain matrix of multi-joint PD or PID feedback, the stiffness acting on the position error.
$\mathbf{y}$	**Measurement Vector**	Varies	Measurement vector a sensor or detector reports at one step.
ν	**Measurement Innovation**	Varies	Difference between a measurement and the measurement the predicted state implies; its normalized square is the NIS.
$\Sigma_{\mathbf{meas}}$	**Measurement Noise Covariance**	Varies	Covariance of the noise on a sensor measurement vector, such as a pixel position with depth or a Kalman filter measurement; units are those of the measurement squared.
$\Delta t_{\mathbf{asym}}$	**Path Delay Asymmetry**	s	Difference between the forward and reverse one-way delays of a clock-synchronization exchange, which biases the estimated clock offset by half its value; two-way time transfer assumes it is zero.
$\hat{\mathbf{x}}_{k\mid k-1}$	**Predicted State Estimate**	Vector	State estimate at step k predicted from measurements through the previous step, before the measurement update; the step index is part of the symbol.
$\mathbf{P}_{k\mid k-1}$	**Predicted Error Covariance**	Matrix	Error covariance at step k predicted from measurements through the previous step, before the update; the conditioned form of the estimation error covariance.
$\hat{\mathbf{x}}_{k-1\mid k-1}$	**Previous Updated State Estimate**	Vector	State estimate at the previous step after that step's update, the input to the next prediction.

Symbol	Definition	Unit	Notes
$\mathbf{P}_{k-1\|k-1}$	**Previous Updated Error Covariance**	Matrix	Error covariance at the previous step after that step's update, the input to the next prediction.
$\mathbf{Q}$	**Process Noise Covariance**	Matrix	Covariance of the process noise vector; the predict step adds it to the error covariance.
$\hat{\mathbf{x}}$	**State Estimate**	Vector	Estimate of the state vector that a recursive estimator maintains; conditioned forms with the step index baked in have their own symbols.
$\mathbf{K}_p$	**Proportional Gain Matrix**	Matrix	Matrix of proportional feedback gains acting on the tracking error vector in joint-space PD or PID control; its diagonal entries are the per-joint proportional gains, and it is not the camera calibration matrix.
$\mathcal{U}_{\text{safe}}$	**Safe Control Set**	Set	Set of control inputs that satisfy every active barrier constraint and the actuator limits at the current state; it is empty when saturation leaves no command that keeps the barrier condition, which selects a fallback.
$\mathcal{X}_{\text{safe}}$	**Safe State Constraint Set**	Set	Set of plant states that satisfy the state constraints of a model predictive control problem, such as joint limits and obstacle margins; polyhedral, and not the barrier safe set.
d_{safe}	**Safe Separation Distance**	m	Smallest separation from an obstacle that a clearance requirement allows.
s	**Signal Trajectory**	Function	Trajectory of a system's real-valued signals over continuous time, the trace a temporal logic formula is evaluated on; two trajectories are told apart by subscripts.
ϕ	**Signal Temporal Logic Formula**	Record	Signal temporal logic formula a signal must satisfy, such as a safety invariant or a reachability deadline; subscripts index subformulas.
f	**Signal Temporal Logic Predicate Function**	Function	Real-valued function of a signal whose sign decides an atomic temporal-logic predicate; its unit is the physical unit of that predicate's margin, and it is indexed per predicate.
ρ	**Signal Temporal Logic Robustness**	Function	Signed margin by which a signal satisfies (positive) or violates (negative) a temporal logic formula at a time; it carries the units of the atomic predicates when they agree and is dimensionless after a declared normalization. Not a correlation coefficient.
δ	**Small Change**	Operator	Small change, increment or error in the quantity it prefixes; the companion of the finite change for first-order changes.
δ	**Small Perturbation**	Operator	Small change or error in the quantity it prefixes, treated to first order, as in a perturbation of a signal or a time; not a labeled localization bound that also renders δ.
a	**Polynomial Trajectory Coefficient**	Varies	Coefficient of one power of time in a polynomial joint trajectory segment, indexed by the power it multiplies; its unit is the joint unit divided by seconds to that power, and it is not an acceleration.
k	**Setpoint Sample Index**	Index	Position of one discrete setpoint sample in a sampled trajectory.
Δt_{step}	**Setpoint Step Interval**	s	Time between consecutive setpoints of an action chunk, the spacing at which the controller consumes them; the reciprocal of the action execution rate.
d_s	**State Space Dimension**	Dimensionless	Number of continuous coordinates in the task-relevant state.
$t_{\text{stop_end}}$	**Stop Completion Instant**	s	Instant, on the permission clock, at which the matched stop of an admitted trajectory record reaches rest; the commitment instant plus the stopping duration.
$t_{\text{deadline,stop}}$	**Stopping Deadline**	s	Latest instant at which authority can be revoked and a worst-case stop still ends within the verified clearance.
L_{lip}	**Policy Lipschitz Bound**	Varies	Lipschitz bound of a learned policy over a stated operating domain, the largest ratio of action change to state change; it gives no guarantee unless established for that domain, and times the sensor error bound it bounds the action error.
$\mathbf{r}$	**Task Tolerance Semi-Axes**	m	Principal semi-axes of the ellipsoid within which terminal position error must lie; the vector of r values.

DRAFT

Symbol	Definition	Unit	Notes
r	**Task Tolerance Semi-Axis**	m	Semi-axis of the task tolerance ellipsoid along one coordinate axis, written with the axis index.
$\mathcal{X}_f$	**Terminal Invariant Set**	Set	Plant states from which an invariant fallback control law keeps the system safe indefinitely, the required endpoint of a receding horizon. On an embodied system a validated stop that reaches rest within verified clearance realizes it.
$\mathbf{e}$	**Tracking Error Vector**	Vector	Commanded reference state minus measured state of a feedback controller, acted on by $\mathbf{K}_p$. Not the error feedback residual, which shares the glyph.
$\dot{\mathbf{e}}$	**Tracking Error Rate**	Vector	Time derivative of the tracking error vector, the velocity error of a feedback controller; multiplied by $\mathbf{K}_d$ in PD control, so a step in it produces a torque step.
δ	**Unit Impulse Function**	s^{-1}	Dirac delta, the idealized unit impulse of zero width and unit area; with time as its argument it carries inverse seconds.
$\mathbf{P}_{k\|k}$	**Updated Error Covariance**	Matrix	Error covariance at a step after incorporating that step's measurement, the posterior counterpart of $\mathbf{P}$.
$\hat{\mathbf{x}}_{k\|k}$	**Updated State Estimate**	Vector	State estimate at a step after incorporating that step's measurement, the posterior estimate of a Kalman filter.
d	**Derivative Operator**	Operator	Differential operator of an ordinary derivative, written over the differential in a Leibniz quotient. Prefer writing the derivative so the d sits before a variable.
Δ	**Finite Change**	Operator	Finite change in the quantity it prefixes, between two states, configurations, or points in time. Differs from the increment fused into named entries such as ΔT.
s	**Path Coordinate**	Dimensionless	Scalar coordinate along a geometric path, from zero at its start to one at its end, that a timing law maps to time; not a Laplace variable.

DRAFT

Learned Policies for Robotics

Learned policies propose actions rather than issue them. The symbols below cover how those policies are trained and sampled, including diffusion denoising, action chunking, and vision-language-action models, and how their imitation and reinforcement-learning objectives are written.

Symbol	Definition	Unit	Notes
π_θ	**Policy**	Distribution	Deep policy network parameterized by weights θ (italic), mapping observation tensors to action distributions.
$\mathbf{o}_t$	**Multimodal Observation**	Mixed	Synchronized tokenized sensor packet (RGB images, depth latents, joint encoders, tactile arrays).
$\mathbf{a}_t \in \mathcal{A}$	**Cognitive Policy Action**	Normalized	Unprivileged action emitted by neural policy π_θ (normalized joint delta, target pose, or gripper command).
K	**Ensembling Window Length**	Time steps	Number of overlapping past chunks blended in receding horizon execution ($K \leq H$).
$N_{\mathbf{eval}}$	**Decoder Evaluation Count**	Count	Dependent forward passes of a generative action head per chunk (denoising or ODE-solver steps); distinct from the ensembling window K and the step index k.
$\mathbf{z} \in \mathbb{R}^{d_z}$	**Latent Style / State Embedding**	Dimensionless	Compressed semantic representation or CVAE latent style variable in ACT policies.
$\bar{\alpha}_k$	**Diffusion Schedule Parameter**	$[0, 1]$	Cumulative noise variance schedule parameter $\bar{\alpha}_k = \prod_{s=1}^{k}(1-\beta_s)$ at diffusion step k.
$\epsilon \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$	**Diffusion Gaussian Noise**	Tensor	Standard normal Gaussian noise corrupted onto clean action trajectories.
$\epsilon_\theta(\mathbf{o}_t, \mathbf{A}_t^k, k)$	**Noise Prediction Network**	Tensor	Neural network predicting added noise in Denoising Diffusion Probabilistic Models (DDPM).

Symbol	Definition	Unit	Notes
$\mathbf{A}^k$	**Noised Action Chunk**	Tensor	Action chunk after k forward-diffusion steps, $\sqrt{\bar{\alpha}_k}\,\mathbf{A}^0 + \sqrt{1-\bar{\alpha}_k}\,\epsilon$; the denoising iterate the reverse process refines.
$\mathcal{L}_{\text{diff}}(\theta)$	**Diffusion Matching Loss**	Scalar	Mean-squared error objective: $\mathbb{E}[\|\epsilon - \epsilon_\theta(\mathbf{o}_t, \mathbf{A}_t^k, k)\|^2]$ optimized across denoising steps.
$\mathcal{L}_{\text{ACT}}(\theta, \phi)$	**ACT Variational Objective**	Scalar	CVAE objective combining trajectory reconstruction $\mathcal{L}_{\text{recon}}$ with latent KL-regularization $\beta\mathcal{D}_{\text{KL}}$.
$q_\phi(\mathbf{z} \mid \mathbf{o}, \mathbf{A})$	**CVAE Recognition Encoder**	Distribution	Variational encoder in Action Chunking with Transformers parameterizing latent distribution $\mathcal{N}(\mu, \Sigma)$; ϕ here is the encoder's parameter set.
t_{div}	**Divergence Instant**	s	Time at which the autonomous policy's rollout begins to leave its supported states before a takeover; the start of the interval excluded from imitation targets.
e_{div}	**Trajectory Divergence Residual**	m	Signed lateral gripper-position error between measured and planned kinematics in the declared fixture frame for the latch example.
δ_{tol}	**Divergence Tolerance**	m	Positive threshold for the declared trajectory-divergence residual; expressed in that residual's physical unit.
r	**Reward**	Scalar	Per-step reward $r(s, \mathbf{a})$ that policy search maximizes; the stage cost of control is its negative. The barrier relative degree r also renders r but appears only in barrier analysis.
g	**Residual Gate**	$\{0, 1\}$	Deterministic, independently evaluated gate $g(s)$ that admits a learned residual correction only inside the certified contact region and is zero elsewhere.
N	**Trial Count**	Trials	Number of physical trials (rollouts) in a learning or evaluation campaign, which sets its wall-clock cost; distinct from the zero-failure trial count n.
ϵ	**Single-Step Imitation Error**	$[0, 1]$	Bounded probability of an unforced policy error during an individual execution step; bold $\boldsymbol{\epsilon}$ is diffusion noise, the conformal miscoverage rate is ϵ, and other error bounds carry a subscript (ϵ_{track}).
S	**Behavioral-Cloning Horizon**	Control steps	Episode length in control steps over which imitation error compounds; not the action-chunk horizon H, not a duration T, and not the token sequence length S.
$\mathcal{O}(S^2\epsilon)$	**Compounding Covariate-Drift Bound**	Task cost	Worst-case excess cost of fixed-archive behavioral cloning, which grows quadratically over a rollout of S control steps with per-step error ϵ.
$\mathbf{W}_{\text{patch}}, \mathbf{E}_{\text{pos}}$	**ViT Projection & Positional Bias**	Matrix	Convolutional/linear patch projection matrix and spatial coordinate position embedding tensors.
$\mathbf{Z}$	**Multimodal Fused Token Stream**	Tensor	Concatenated token sequence $[\mathbf{z}_{\text{vision}}, \mathbf{z}_{\text{text}}, \mathbf{z}_{\text{proprio}}]$ ingested by embodied transformer backbones.
M_{KV}	**KV-Cache Memory**	bytes	Autoregressive key-value cache memory footprint at the embodied batch size $B = 1$ ($2 \times N_L \times d \times S \times s_{\text{elem}}$ with full multi-head attention); the core's quantity.
$\mathcal{I}_{\text{intent}}$	**Intent Lease**	Tuple	$(\mathcal{G}_{\text{goal}}, [t_{\text{adm}}, t_{\text{intent_exp}}], \mathbf{w}_{\max})$: the admitted goal set, its validity interval, and its effort ceilings; it names a target, never a path. Calligraphic $\mathcal{L}$ stays the loss.
$t_{\text{intent_exp}}$	**Intent-Lease Expiry**	s	$t_{\text{intent_exp}} = \min(t_0 + \tau_{\text{ev}},\, t_{\text{adm}} + T_{\text{admin}},\, t_{\text{deadline,stop}})$, where $t_{\text{deadline,stop}}$ is the instant by which a stop must begin; see the lease table above.
τ_{ev}	**Evidence Horizon**	ms	Time for which a target estimate stays within its task tolerance without fresh evidence.
$\mathcal{C}$	**Conformal Prediction Set**	Set	Calibrated set of referent candidates that cannot be excluded at miscoverage rate ϵ; a singleton admits the referent, and a larger set refuses. It shares the glyph of the safe set $\mathcal{C}$, but the two never appear together.
ϵ	**Conformal Miscoverage Rate**	Probability	Allowed marginal probability that the conformal prediction set misses the true referent under the calibration procedure's exchangeability assumptions; coverage is at least $1 - \epsilon$.

Symbol	Definition	Unit	Notes
T_{wait}	**External Wait**	Seconds	Time the machine spends waiting for a remote operator's response during a handover or intervention.
ϵ_N	**Aggregated Surrogate Loss**	Dimensionless	Best-in-class surrogate imitation loss on the states the learner visited, aggregated over the rounds so far; differs from the error measured on expert-visited states.
$\hat{\pi}$	**Aggregation Learned Policy**	Function	Policy trained in one round of corrective dataset aggregation, one of the sequence the bound selects from; carries a round index in the appendix.
H_{exec}	**Chunk Execution Horizon**	Count	Number of actions of each predicted chunk the controller executes before the policy is queried again; at most the chunk horizon.
i	**Chunk Step Index**	Index	Position of one step within an action chunk, counted from zero.
α_{CQL}	**Conservative Penalty Weight**	Dimensionless	Weight of the conservative penalty that pushes down values of unsupported actions in conservative Q-learning.
$\mathcal{A}$	**Continuous Action Space**	Set	Set of continuous actions a robot policy may emit, a subset of real space of the action dimension.
$\mathbf{a}$	**Continuous Action Vector**	Varies	Continuous action vector of the robot's decision process, written without a step index: the argument of a policy, value function, reward, or action distribution, or an action recorded from a demonstrator. A star marks the demonstrated action; it lives in $\mathcal{A}$.
Q_ϕ	**Critic Action-Value Estimate**	Function	Return a learned critic predicts for a state and an action; the action counterpart of the critic's state-value estimate.
t_{pass}	**Decoder Pass Time**	s	Time of one dependent forward pass of a generative action head, one denoising or ODE-solver step; summed over the decoder evaluations in the proposer inference time.
p	**Demonstration Action Distribution**	Distribution	Conditional distribution of the actions demonstrators took given an observation, the target a behavioral cloning decoder models; its mean minimizes squared error and can fall between modes (mode averaging).
$\mathcal{D}_{\text{demo}}$	**Demonstration Dataset**	Set	Recorded observation-action pairs that an imitation loss averages over.
$\hat{\mathbb{E}}$	**Empirical Timestep Average**	Operator	Sample average over the timesteps of a batch of rollouts, the estimate of an expectation.
m	**Ensembling Decay Rate**	Dimensionless	Decay factor per chunk index of exponential temporal-ensembling weights; its size sets how fast newer chunks enter the blend.
$\hat{\pi}$	**Imitation-Learned Policy**	Function	Policy learned from expert demonstrations or expert-labeled states, compared against the expert policy; indexed by aggregation round in DAgger.
β	**Latent KL Weight**	Dimensionless	Weight on the KL divergence between the latent posterior and prior in a conditional variational autoencoder objective; not the RLHF reference penalty coefficient.
q	**Latent Posterior Distribution**	Distribution	Distribution over the latent style variable that a conditional VAE encoder infers from a demonstration chunk and its observation; compared with p in the KL term.
M	**Mixture Component Count**	Dimensionless	Number of components of a mixture distribution.
m	**Mixture Component Index**	Index	Position of one component of a mixture distribution, from one to the component count M; it indexes the weight, mean, and covariance of a mixture density network.
μ_m	**Mixture Component Mean**	Varies	Mean vector of one component of a Gaussian mixture, output by a mixture density network for the given input.
Σ_m	**Mixture Component Covariance**	Varies	Covariance matrix of one component of a Gaussian mixture, output by a mixture density network for the given input.
t_{enc}	**Observation Encoding Time**	s	Time to encode one observation, visual backbone and proprioception, once per policy proposal; the first term of the proposal latency.

Symbol	Definition	Unit	Notes
$\mathbf{o}_{t-H_{\text{hist}}:t}$	**Observation History Window**	Varies	Sliding window of the robot's most recent onboard observations, from the history length before the current step up to the current step; one row per observation step.
H_{hist}	**Observation history length**	Steps	Number of past steps the observation history window holds before the current one.
$\mathbf{a}$	**Robot Action**	Vector	Action vector a learned robot policy emits, written without a step index as the argument of a policy, value function, or action distribution; the same quantity as the cognitive policy action, which carries the step index.
$\mathbf{o}$	**Robot Observation**	Vector	Observation vector a robot policy receives from its sensors, written without a step index.
a_{req}	**Requested Action Tap**	Record	First stream of the four-stream action tap, the raw policy or operator request before kinematic mapping.
$\mathbf{a}'$	**Successor Action Vector**	Vector	Continuous action vector taken in the successor state of a transition, the next action a Bellman backup evaluates.
k	**Return Step Offset**	Index	Number of control steps after the current step at which a reward arrives, the summation index of a discounted return.
T	**Rollout Horizon**	Dimensionless	Number of control steps in one executed rollout, the index of its final state; a step count, not a duration.
θ_{old}	**Rollout Policy Parameters**	Vector	Parameters of the policy that collected the current batch of rollouts, frozen while the updated parameters are optimized; the denominator policy of the probability ratio.
$\mathcal{L}^{\text{CLIP}}$	**PPO Clipped Surrogate Objective**	Dimensionless	Clipped surrogate objective that proximal policy optimization maximizes, the empirical mean of the smaller of the ratio-weighted advantage and its clipped counterpart; a whole-batch objective, not the per-token term of the language model variant.
s_{priv}	**Privileged Simulator State**	Record	Ground-truth simulator quantities such as friction and contact wrenches that a deployed policy cannot measure; a subset of the physical world state exposed by the simulator.
ξ	**Simulation Parameter Vector**	Varies	Physical parameters that define one simulated environment: link masses, centers of mass, friction, joint damping, transport delays, and sensor noise; sampled in domain randomization, with the nominal point marked by a zero subscript.
$\mathbf{z}_{\text{proprio}}$	**Proprioceptive Token Embeddings**	Vector	Token embeddings of the robot's joint and force state fed to an embodied transformer; one block of the fused multimodal token stream.
p_{data}	**Static Data Distribution**	Distribution	Fixed data distribution from which a static benchmark draws its held-out examples.
$\mathbf{z}_{\text{text}}$	**Text Token Embeddings**	Vector	Token embeddings of the language instruction fed to an embodied transformer, one block of the fused token stream.
$\mathbf{z}_{\text{vision}}$	**Vision Token Embeddings**	Vector	Token embeddings an embodied transformer computes from camera images, one block of the fused token stream.
p_{patch}	**Patch Size**	Pixels	Side length of one square image patch a vision transformer tokenizes, typically 14 or 16 pixels.
$\mathbf{z}$	**Patch Token Embedding**	Vector	Latent token embedding a vision transformer forms from one image patch.
V_ϕ	**Critic Return Estimate**	Dimensionless	Remaining-return estimate a learned critic network predicts for an interaction history; the baseline of PPO, which GRPO replaces with the group mean reward.
s	**Decision Process State**	Record	Complete environment state of a decision process, including interaction history and variables the agent cannot observe. A record, not a number.
u	**Deviation Disadvantage**	Dimensionless	Largest extra expected cost of one deviation from the reference action followed by reference recovery, at any state the learner can reach; an assumption about the task, in normalized cost units.

Symbol	Definition	Unit	Notes
γ	**Discount Factor**	Dimensionless	Factor by which a reward arriving one step later is weighted in the return, between zero and one; one means undiscounted.
p	**Environment Transition Distribution**	Distribution	Distribution the environment induces over the next state given the current state and the action taken.
$\hat{A}$	**Estimated History Advantage**	Dimensionless	Estimate of how much an action taken after a given interaction history beats the policy value at that history.
Q	**Expected History-Action Return**	Function	Expected remaining return under a policy after taking a given action at a given interaction history and then following the policy.
V	**Expected Remaining Return**	Function	Expected remaining return under a policy from a given interaction history at a decision step; written with the policy as a superscript.
J	**Expected Return Objective**	Function	Expected return of a policy as a function of its parameters, the objective reinforcement learning maximizes. Not the imitation cost sum J.
J	**Expected Task Cost Sum**	Function	Expected sum over the horizon of the normalized immediate task costs a policy incurs; the imitation bounds compare it for a learner and the reference. Not monetary.

Embedded Real-Time Systems, Power, and Hardware Safety

Response-time analysis keeps the Liu–Layland letters of its literature, but only inside that model and only with a task index i, j, or k. The letters are C_i (worst-case execution time), B_i (blocking), I_i (interference), J_i (release jitter), T_i (period), R_i (worst-case response time), and D_i (relative deadline, which is T_{deadline} of task i in the series' terms). They combine as in $R_i = C_i + B_i + I_i \le D_i$. Outside that model these letters keep their table meanings.

DRAFT

Symbol	Definition	Unit	Notes
$L_{\text{bus}}, R_{\text{bus}}$	**Power Rail Inductance / ESR**	$\mu\text{H}, \text{m}\Omega$	Parasitic inductance and equivalent series resistance of the power harness feeding the inverter; with C_{bus} they set the droop ΔV_{droop} under a current step.
C_{bus}	**DC Bus Bulk Capacitance**	μF	Inverter decoupling capacitor bank buffering transient inductive voltage collapse.
t_{queue}	**Memory Bus Queue Delay**	ms	Contention latency $\sum_k D_{\text{vol}\,k}/\text{BW}_{\text{peak}} + N_{\text{conflict}}\Delta t_{\text{conflict}}$ across shared SoC crossbars.
Δt_{fresh}	**Telemetry Freshness Bound**	ms	Maximum allowable age of sensor telemetry before an interlock trips: $\Delta t_{\text{fresh}} \le e_{\max}/v_{\max}$.
θ_{offset}	**Clock Offset**	µs	Offset of one clock from another, estimated from a timestamp exchange as $\theta_{\text{offset}} = [(t_2 - t_1) - (t_4 - t_3)]/2$; its one-way path delay is T_{prop}.
σ_{jitter}	**Timing Jitter**	µs	Standard deviation of a nominally periodic event's timing about its schedule.
T_{blackout}	**Synchronization Blackout**	s	Interval during which a node receives no synchronization message and free-runs on its own clock.
t_{acq}	**Acquisition Epoch**	s	Instant a sensor transduced one observation, such as a camera frame's exposure midpoint or an encoder latch; the evidence epoch of a belief is the latest acquisition epoch among the measurements that constrained it.
t_{off}	**Actuator Recovery Time**	s	Recovery duration between actuator bursts in one duty cycle; the burst itself is t_{on}.
t_{on}	**Actuator Burst Time**	s	Duration an actuator runs at burst power in one duty cycle; pairs with the recovery time t_{off}.
v_{aisle}	**Aisle Travel Speed**	m/s	Speed the mobile base is set to travel in a warehouse aisle, chosen below the derived dry-floor speed ceiling; it is the speed at detection in the aisle stopping budget.

Symbol	Definition	Unit	Notes
t_{recv}	**Arrival Timestamp**	s	Instant a sensor sample arrives in host memory, when its direct memory access transfer completes; later than the capture timestamp by exposure, readout, transport, and transfer.
D_{avail}	**Available Braking Distance**	m	Clear distance minus the localization bound and the protective clearance margin; the distance braking and blind travel may use.
a	**Available Deceleration**	m/s^2	Deceleration a machine actually has, the smaller of its credible braking deceleration and the traction limit, friction coefficient times g.
$\Delta t_{\text{conflict}}$	**Bank Conflict Penalty**	s	Time one memory bank or row conflict adds to a queued transfer, about a precharge plus an activation.
d_{blind}	**Blind Travel Distance**	m	Distance a machine travels during the pre-brake delay, before retarding force begins: speed at detection times that delay.
R_{brake}	**Brake Chopper Resistance**	Ω	Resistance of the absorption resistor a dynamic brake chopper switches across the bus; must dissipate the peak regenerated power at the clamp voltage.
d_{brake}	**Braking Distance**	m	Distance a machine travels from brake onset to rest, speed squared over twice the credible deceleration; excludes travel during the pre-brake delay.
t_{capture}	**Capture Timestamp**	s	Midpoint of the sensor's exposure or firing window, the instant the observation describes; the letter t carrying index zero.
T_{case}	**Case Temperature**	°C	Temperature of a motor or package case.
$\tau_{\text{th,case}}$	**Case Thermal Time Constant**	s	Thermal time constant of the motor case stage of a multi-node motor thermal model.
V_{clamp}	**Chopper Clamp Voltage**	V	Bus voltage at which a dynamic brake chopper switches its absorption resistor across the bus; above the full-charge voltage and below the converter and switch ratings.
ϵ_{sync}	**Clock Conversion Bound**	s	Bound on the error of converting a sensor's capture timestamp to the clock of the safety microcontroller that hosts the permission path; measured from offset tails, path asymmetry, and drift, and added to the observation age at dispatch.
b_{clk}	**Clock Conversion Intercept**	s	Intercept of the affine mapping that converts a capture-clock time to the safety microcontroller's clock.
a	**Clock Conversion Slope**	Dimensionless	Slope of the affine mapping that converts a capture-clock time to the safety microcontroller's clock; near one, the drift between the clocks.
T_{comm}	**Console Communication Time**	s	Time the operator console and link add to a takeover: video transport to the operator plus the returning protocol exchange; shares its glyph with the gradient communication time of training, a different quantity.
λ	**Constant Hazard Rate**	h^{-1}	Constant rate of hazardous failures per operating hour of a machine, the rate a failure-free test exposure bounds from above; assumes the flat middle of the bathtub curve.
V_{uvlo}	**Converter Lockout Voltage**	V	Input voltage at which a DC-DC converter shuts off (undervoltage lockout); bus droop below it resets the computation the converter supplies.
T_0	**Copper Reference Temperature**	°C	Temperature at which a winding has its reference resistance, the base of the copper temperature coefficient.
α_{Cu}	**Copper Temperature Coefficient**	K^{-1}	Fractional rise in a copper winding's resistance per kelvin; about 0.00393 per kelvin for annealed copper at 20 °C.
$\tau_{\text{th,cu}}$	**Copper Thermal Time Constant**	s	Thermal time constant of the winding copper stage in a multi-node motor thermal model.
$R_{\text{th,ca}}$	**Core-to-Ambient Thermal Resistance**	K/W	Convective thermal resistance from a motor's stator core to the ambient air; it rises when an enclosure removes airflow.

DRAFT

Symbol	Definition	Unit	Notes
T_{∞}	**Equilibrium Winding Temperature**	°C	Temperature a winding approaches asymptotically under a constant loss power: ambient plus loss power times the thermal resistance in the first-order model.
$V_{\mathbf{bus}}$	**DC Bus Voltage**	V	Voltage of the DC bus that feeds a motor inverter.
$V_{\mathbf{rail}}$	**DC Rail Voltage**	V	Voltage of the shared DC power rail that feeds the compute and the motor inverters; the bus of V_{bus} is the inverter's side of it.
$V_{\mathbf{droop}}$	**Drooped Supply Voltage**	V	Supply voltage a core sees at the bottom of a droop event.
$V_{\mathbf{final}}$	**Final Bus Voltage**	V	DC bus voltage at the end of a regenerative stop when the bus capacitance alone absorbs the returned energy; a screening endpoint, since exceeding a component rating means the stop needs another energy path.
$t_{\mathbf{prop}}$	**Gate Propagation Delay**	s	Propagation delay of a logic gate as a function of its supply voltage; the alpha-power law makes it grow as the supply approaches the transistor threshold voltage.
$P_{\mathbf{heat}}$	**Heat Dissipation Power**	W	Power the hardware at one signal handoff dissipates as heat, the energy-and-heat limit of the handoff matrix; from under a watt on the safety microcontroller to tens of watts on the proposer accelerators.
$t_{\mathbf{deadline}}$	**Deadline Instant**	s	Clock instant by which an observation or action must be complete.
$T_{\mathbf{deadline,fallback}}$	**Fallback Deadline**	s	Latest permissible wait after a handover request before the fallback must begin, from the stopping inequality at the current speed and clearance; it clips the handover timeout ceiling T_{config}.
$T_{\mathbf{config}}$	**Handover Timeout Ceiling**	s	Configured protocol ceiling on the handover timeout, which the clearance-derived $T_{\text{deadline,fallback}}$ may shorten but never extend.
$a_{\mathbf{enf}}$	**Enforced Command Tap**	Record	Third stream of the four-stream action tap, the command the permission check admitted.
$V_{\mathbf{initial}}$	**Initial Bus Voltage**	V	DC bus voltage at the moment a regenerative deceleration begins; the worst case is a full pack, when the battery refuses charge.
$V_{\mathbf{nom}}$	**Nominal Supply Voltage**	V	Nominal regulated supply voltage of a core rail.
I_{max}	**Inverter Current Limit**	A	Largest current an inverter bridge lets flow, set to protect its transistors and the stator.
$I_{\mathbf{load}}$	**Load Current**	A	Current the loads draw from a bus node.
T_{j}	**Junction Temperature**	°C	Temperature of a silicon die at its transistor junctions; written as a function of time when it relaxes after a power step. A temperature always carries a subscript, since the bare letter is time.
$R_{\mathbf{th,JC}}$	**Junction-to-Case Thermal Resistance**	K/W	Thermal resistance from a silicon junction to the case of its package.
$R_{\mathbf{th,JA}}$	**Junction-to-Ambient Thermal Resistance**	K/W	Lumped thermal resistance from a silicon junction to the ambient air, the sum of the junction-to-case, interface-material, and chassis paths; not the motor stator-to-ambient path.
Ω	**Ohm Unit**	Unit	SI unit of electrical resistance, written upright after a prefix as in milliohms.
n	**Periodic Task Count**	Dimensionless	Number of periodic tasks in a real-time task set; it sets the Liu and Layland utilization bound, which falls toward the natural logarithm of two as the count grows.
$t_{\mathbf{MCU}}$	**Microcontroller Clock Time**	s	Time read on the safety microcontroller's monotonic clock.
$a_{\mathbf{cmd}}$	**Mapped Command Tap**	Record	Second stream of the four-stream action tap, the kinematically mapped command before it crosses to the safety microcontroller.
$a_{\mathbf{meas}}$	**Measured Response Tap**	Record	Fourth stream of the four-stream action tap, the plant response measured by joint encoders and current shunts.

Symbol	Definition	Unit	Notes
$t_{\mathbf{adm}}$	**Lease Admission Instant**	s	Instant at which the permission path admits an intent lease, the start of its validity interval.
$t_{\mathbf{plan_exp}}$	**Nominal Plan Expiry**	s	Instant, on the permission clock, at which the nominal setpoints of an admitted trajectory record end; never executed when the matched stop begins at commitment.
$t_{\mathbf{age},\max}$	**Observation Age Budget**	s	Configured upper bound on observation age above which a consumer refuses a state.
$t_{\mathbf{age},\max}$	**Maximum Observation Age**	s	Largest observation age a consumer tolerates before acting on the observation is no longer safe or stable; the phase-margin ceiling in the control chapters and the freshness threshold in the memory and machine-learning chapters.
$T_{\mathbf{mission}}$	**Mission Duration**	s	Duration of one mission of a mobile robot, the unit of operation over which a per-mission failure probability is allocated.
$E_{\mathbf{mission}}$	**Mission Energy**	J	Total energy a machine draws to complete one physical mission; distinct from the machine-learning workload's total energy.
$T_{\mathbf{sensory}}$	**Operator Sensory Time**	s	Time an operator needs to perceive a takeover stimulus, the perceptual stage of a simple reaction (Model Human Processor perceptual cycle).
$T_{\mathbf{cognitive}}$	**Operator Cognitive Time**	s	Time an operator needs to decide on a response to a takeover stimulus, the cognitive stage of a simple reaction (Model Human Processor cognitive cycle).
$T_{\mathbf{motor}}$	**Operator Motor Time**	s	Time an operator needs to move the controls once a response is chosen, the motor stage of a simple reaction; not the electrical time of a motor.
$t_{\mathbf{stabilize}}$	**Operator Stabilization Instant**	s	Time after a takeover at which the operator's corrections settle into a steady return toward the nominal corridor.
$\theta_{\mathbf{tol}}$	**Orientation Tolerance**	rad	Largest angular orientation error a task accepts.
N	**Observed Cycle Count**	Dimensionless	Number of operating cycles, each one observation of the monitored quantity, over which exceedances are counted.
k	**Observed Trial Failure Count**	Dimensionless	Number of failures observed among the trials of a test campaign, fixed-sample or sequential.
$\mathcal{D}$	**Operational Test Distribution**	Distribution	Declared joint distribution of trial conditions an evaluation campaign samples, the population its success probability describes; each stratum of a stratified test matrix is its own distribution, and it is not a dataset.
$T_{\mathbf{pre}}$	**Pre-Trigger Window Duration**	s	Length of the ring-buffer window before an intervention trigger that the logger freezes and keeps; sized from the out-of-loop takeover latency and rounded up to whole seconds.
$\tau_{\mathbf{delay},\max}$	**Pre-Brake Delay Ceiling**	s	Largest pre-brake delay that still lets the machine stop within its clearance: clearance minus margins and braking distance, divided by speed; the ceiling the lease rule subtracts the loop, transport, actuator, and observation times from.
$T_{\mathbf{compute}}$	**Stop Decision Compute Bound**	s	Bound on the stop-decision computation and any still-required input transfer that a hazard-triggered stop spends inside the pre-brake delay; a budget term, not operations over a sustained rate.
T_{Σ}	**Supervisory Takeover Latency**	s	Total time from a takeover demand to the first checked human command: the human sensory, cognitive, and motor times plus console transport and handshake; the generic form of the in-loop and out-of-loop design values.
$T_{\mathbf{lease,rem}}$	**Remaining Execution Lease**	s	Time left on the active execution lease, the lease length minus the time elapsed since its last accepted renewal; a field of the per-tick evidence tuple.

DRAFT

Symbol	Definition	Unit	Notes
L	**Replacement Latency**	s	Time from the capture of the observation a candidate trajectory rests on to that candidate's admission into the execution queue; a latency, not a period, and not the loss that bare L names.
$\mathcal{H}$	**Signal Handoff**	Record	One of the five canonical signal handoffs of the machine, from sensing to perception through enforcer to actuator, at which interface limits are budgeted; written with its position.
ϵ_{sync}	**Synchronization Error Bound**	s	Bound on the error of converting a timestamp from one node's clock to another's; the clock-conversion error of the observation contract, not an estimated clock offset.
T_{prop}	**PTP Propagation Delay**	s	One-way network path delay between two clocks, estimated from a symmetric two-way Precision Time Protocol exchange.
i	**Real-Time Task Index**	Index	Position of one periodic task in a real-time task set, the index of its period, deadline, and execution time; written bare when the text names the task.
B	**Task Blocking Time**	s	Longest time a real-time task can wait for a lower-priority task to release a shared resource; written with its task index, and under the priority ceiling protocol at most one lower-priority critical section.
c_{start}	**Read-Start Sequence Count**	Dimensionless	Value of a sequence-lock counter that a reader loads before copying the shared slot; the read is valid only if it is even and equals the end count.
c_{end}	**Read-End Sequence Count**	Dimensionless	Value of a sequence-lock counter that a reader loads after copying the shared slot; a change from the start count means a writer preempted the copy and the snapshot is torn.
t_{RCD}	**Row Activation Delay**	s	Minimum time from activating a DRAM row to the first column access to it, the row-to-column delay (JEDEC tRCD).
t_{RP}	**Row Precharge Time**	s	Minimum time a DRAM bank needs to close its open row by precharge before another row can be activated (JEDEC tRP); a row conflict costs it plus the row activation delay.
λ_{raw}	**Raw Hardware Fault Rate**	h^{-1}	Rate of hazardous hardware faults before any diagnostic mitigates them, the sum of the component fault rates; usually quoted in failures in time.
L_{10}	**Rated Fatigue Life**	Dimensionless	Cumulative load-cycle count at which 10% of a population of identical components is expected to have failed; the subscript ten is part of the symbol.
I_{source}	**Source Current**	A	Current arriving at a bus node through the source path of battery, harness, and switches; it differs from the load current during a transient, and the bus capacitance supplies the difference.
V_{source}	**Source Voltage**	V	Unloaded voltage of the supply that feeds a bus node through the source path; minus the drop across the rail resistance and inductance it gives the bus voltage.
R_0	**Reference Winding Resistance**	Ω	Winding resistance at the reference temperature, the base of copper's linear resistance law.
T_{core}	**Stator Core Temperature**	K or °C	Temperature of the stator core in a two-node motor thermal model.
S_p	**Protective Separation Distance**	m	Minimum distance a speed-and-separation monitor must keep between a person and a robot; the sum of the human travel, robot reaction travel, robot stopping travel, intrusion, and the two uncertainty terms of ISO/TS 15066.
S_r	**Robot Reaction Travel**	m	Distance a robot travels during its reaction time before stopping begins; a term of the protective separation distance.
S_s	**Robot Stopping Travel**	m	Distance a robot travels while stopping; a term of the protective separation distance.
Z_r	**Robot Position Uncertainty**	m	Position uncertainty of the robot; a term of the protective separation distance.
m	**Sequential Trial Count**	Dimensionless	Number of trials a sequential test has observed so far, the index of its running log-likelihood ratio.

Symbol	Definition	Unit	Notes
X	**Tail-Risk Observation**	Varies	Monitored physical quantity whose rare large values a tail model describes, such as a contact load or a control-loop latency, treated as a random variable; in the unit of the quantity monitored, and indexed for one independent observation.
x	**Tail-Risk Observation Level**	Varies	Level of the monitored quantity at which its distribution or density is evaluated, or one observed value of it; the lower cutoff of a power-law tail is marked by a zero subscript.
ξ	**Tail Shape Parameter**	Dimensionless	Shape parameter of an extreme value tail model, positive for a power-law tail, zero for an exponential tail, and negative for a bounded tail; shared by the generalized extreme value and generalized Pareto models.
x_F	**Tail Support Upper Endpoint**	Varies	Right endpoint of the support of the monitored quantity's distribution, possibly infinite; in the unit of the monitored quantity.
ϵ	**Target Exceedance Probability**	Dimensionless	Per-sample probability of a catastrophic exceedance that a design margin is sized against; a probability per sampled cycle, not a rate per operating hour.
I	**Task Interference Time**	s	Processor time that higher-priority tasks and interrupt handlers take from a real-time task within its response window. Written with its task index; it depends on the response time itself, so it is found by a fixed-point recurrence.
T	**Task Period**	s	Interval between successive releases of a periodic real-time task, written with its task index.
D	**Task Relative Deadline**	s	Longest time after its release by which a job of a real-time task must complete, written with its task index. The series-wide deadline is T_{deadline}.
U	**Task Set Utilization**	Dimensionless	Share of processor time a set of periodic real-time tasks demands, the sum over tasks of C/T.
C	**Worst-Case Execution Time**	s	Worst-case execution time of one real-time task in response-time analysis; used only inside that analysis and only with a task index.
R	**Worst-Case Response Time**	s	Longest time from a real-time task's release to its completion; used only with a task index.
t_{start}	**Tracking Start Instant**	s	Instant, on the permission clock, at which nominal tracking of an admitted trajectory record begins; the first of the record's four deadlines.
t_{skew}	**Timestamp Skew**	s	Skew between the time stamps of two records or clocks. The book writes it with the finite-change prefix, Δt_{skew}.
t_{last}	**Track Last Update Time**	s	Time of the most recent observation associated with a track.
t_{current}	**Current Wall-Clock Time**	s	Wall-clock time at which a monitor evaluates staleness; a point in time, like t, fixed at the moment of the check.
T	**Failure Observation Interval**	s	Length of the time interval over which failures are counted under the Poisson failure model; a generic window, not the length of one job.
λ	**Component Failure Rate**	h^{-1}	Rate at which one component fails; the system-wide rate is the component count times this rate under independent, identical components.
$\lambda_{\text{unmitigated}}$	**Unmitigated Hardware Fault Rate**	h^{-1}	Rate of hardware faults whose hazardous effect no diagnostic mitigates, the rate compared with the target hazard rate.
T_{lower}	**Watchdog Earliest Service Time**	s	Time after the last reload before which a windowed watchdog rejects a service attempt as too early, the lower end of its service window. With T_{upper} it bounds the valid window.
T_{upper}	**Watchdog Latest Service Time**	s	Time after the last reload by which a windowed watchdog must be serviced, past which it trips the safe state.

Symbol	Definition	Unit	Notes
T_{trip}	**Throttle Trip Temperature**	°C	Junction temperature at or above which a hardware thermal governor reduces the processor clock; paired with a lower clear temperature for hysteresis.
V_{th}	**Transistor Threshold Voltage**	V	Gate-source voltage at which a transistor begins to conduct. The headroom between supply and threshold sets gate delay in the alpha-power law.
α	**Velocity Saturation Exponent**	Dimensionless	Technology-dependent exponent of the alpha-power law, by which drain current grows with gate overdrive above threshold; it falls from 2 for a long channel toward 1 as carrier velocity saturates.
$R_{\text{th,wc}}$	**Winding-to-Core Thermal Resistance**	K/W	Conductive thermal resistance from a motor winding to its stator core; in series with the core-to-ambient resistance it makes the total R_{th}.
I	**Winding Current**	A	Electric current flowing through a motor winding, which heats it at the rate of current squared times resistance.
I	**Conductor Current**	A	Electrical current flowing through a power-distribution conductor; resistive loss is its square times the conductor resistance.
P_{loss}	**Winding Loss Power**	W	Resistive power dissipated in the motor windings.
T_{limit}	**Winding Temperature Limit**	°C	Largest winding temperature the insulation class and derating policy allow.
µ	**Micro Unit Prefix**	Prefix	SI prefix for one millionth, written before a unit such as seconds; it only scales the unit after it and is never a quantity, a service rate, or a mean.
V	**Supply Voltage**	V	Voltage that powers a digital circuit and that voltage and frequency scaling lowers; dynamic power scales with V^2.
$L_{\text{parasitic}}$	**Parasitic Loop Inductance**	H	Unintended inductance of the current loop that feeds an accelerator core rail; it turns current slew into voltage droop.

Deep Learning Foundations and Edge Serving

Embodied robotic platforms increasingly run large multimodal foundation models, such as vision-language-action (VLA) backbones and cross-attention policy decoders, alongside deterministic real-time control stacks. Serving these models on an embedded edge computer requires tracking both the neural architecture dimensions and the memory footprint those dimensions occupy:

Symbol	Definition	Unit	Notes
d_{head}	**Attention Head Dimension**	Integer	Per-head hidden dimension in attention layers.
d	**Hidden Dimension**	Integer	Hidden feature (model) width d of a transformer layer or representation; the distance to a target, also d, is d and appears only in the intent-lease reachability test.
$p(\cdot)$	**Distribution**	Distribution	Probability mass or density $p(x)$, conditional $p(y \mid x)$, or an observation model $p(\mathbf{o} \mid s)$; lowercase avoids the collision with P (parameter count).
$\Pr(E)$	**Event Probability**	Dimensionless	Probability of an event E, as in $\Pr(\text{error by step } t)$; use $p(\cdot)$ for distributions.
$d_{\text{in}}, d_{\text{out}}$	**Layer Input and Output Widths**	Integer	Number of input and output features of a dense layer, which holds $d_{\text{in}} d_{\text{out}}$ weights.
η	**Learning Rate**	Scalar	Step size for the optimizer; never bare for hardware efficiency, which is η_{hw}.
$\mathcal{L}$	**Loss Function**	Scalar	The objective minimized during training; a subscript or superscript names the objective ($\mathcal{L}_{\text{MSE}}$, $\mathcal{L}_{\text{chunk}}$, $\mathcal{L}^{\text{CLIP}}$).
θ	**Model Parameters**	Vector	Trainable parameter vector or weights θ of a learned model, such as a policy.
N_L	**Number of Layers**	Integer	Total number of layers in a network.

Symbol	Definition	Unit	Notes
S	**Sequence Length**	tokens	Input context or sequence length S in tokens. The behavioral-cloning horizon S also renders S but counts control steps; the two never share an equation.
M_{weights}	**Weight Memory**	bytes	Memory occupied by model weights ($P \times$ bytes-per-parameter).
s_{elem}	**Element Storage Size**	bytes/element	Bytes per stored tensor element at the deployed precision.
I	**Arithmetic Intensity**	FLOP/byte	Operations per byte moved from off-chip memory, O/D_{vol}; it decides whether an evaluation is bound by memory or by compute.
N_{eff}	**Effective Sample Size**	Dimensionless	Number of independent observations that carry the same information about a mean as a serially correlated stream.
e	**Environment Parameters**	Record	External physical variables of one trial or rollout, such as floor friction, illuminance, obstacle geometry, and air temperature; written non-bold, so a record rather than a vector.
ϕ	**Evaluation Predicate**	Function	Binary predicate that maps a realized trial trajectory to its task outcome, zero or one.
z_ϵ	**Exceedance Return Level**	Varies	Level of the monitored quantity exceeded with the target probability per sampled cycle; its subscript is that exceedance probability.
u	**Exceedance Threshold**	Varies	High threshold on a performance metric above which peaks-over-threshold modeling fits exceedances; it carries the metric's units (meters for a distance overshoot).
H	**Generalized Pareto Distribution**	Function	Cumulative distribution function of the excess over a high threshold, parameterized by a scale and a tail shape.
$\tilde{\sigma}$	**Generalized Pareto Scale**	Varies	Scale parameter of the generalized Pareto distribution fitted to exceedances over a threshold.
$p_{\text{fail, upper}}$	**Failure Upper Confidence Limit**	Dimensionless	One-sided upper confidence limit on the per-trial failure probability from a finite campaign.
p	**Hypothesized Trial Failure Probability**	Dimensionless	Per-trial failure probability a sequential probability ratio test specifies under one of its two hypotheses, indexed 0 for the unacceptable null and 1 for the acceptable alternative.
h	**Hazard Class Index**	Dimensionless	Index of one defined hazard class.
N_{fleet}	**Fleet Robot Count**	Dimensionless	Number of robots in a deployed fleet; not the accelerator count of a data center fleet.
Σ	**Gaussian Covariance Matrix**	Matrix	Covariance matrix of a multivariate Gaussian; entries carry the products of the component units.
μ	**Gaussian Mean Vector**	Vector	Mean vector of a multivariate Gaussian, paired with Σ.
O_{prefill}	**Prefill Operations**	FLOP	Arithmetic operations one evaluation's prefill executes over all of its input tokens; the compute-bound phase of a fresh evaluation, and an instance of the operation count.
f	**Proposer Evaluation Rate**	Hz	Rate of fresh proposer evaluations when every evaluation streams the weights.
σ	**Softmax Function**	Function	Function that maps a vector of logits to a probability vector that sums to one; normalization by construction, not calibrated confidence, and not the sigmoid.
x	**Model Input**	Record	Input of one example, the data a model receives to produce a prediction; its label partner is $\mathbf{y}$. Not a scalar feature x_i of a neuron.
$\hat{y}$	**Model Prediction**	Dimensionless	Scalar prediction a model outputs for one example, compared with its label by the loss; the vector of class probabilities is $\hat{\mathbf{y}}$.
$\mathbf{z}$	**Logit Vector**	Vector	Unnormalized score for every class that a classifier outputs before softmax; its entries are z.
z	**Output Logit**	Dimensionless	Raw score a model outputs for one class before the softmax, indexed by class as z_i.
$\mathcal{L}_{\text{val}}$	**Validation Loss**	Scalar	Loss a trained model incurs on held-out validation data; the outer objective of neural architecture search, never the training loss.
$\mathbf{W}$	**Weight Matrix**	Matrix	Matrix of learned weights one layer multiplies its input by, or the kernel tensor of a convolution layer; a subscript names the layer, as in $\mathbf{W}_1$.

DRAFT

Symbol	Definition	Unit	Notes
$\mathbf{J}$	**Function Jacobian**	Matrix	Matrix of partial derivatives of a differentiated function's outputs with respect to its inputs; not the manipulator Jacobian of a robot arm.
$\mathbf{0}$	**Zero Matrix or Vector**	Matrix	Matrix or vector whose entries are all zero; bold, so it is not the scalar zero.
H	**Image Height**	pixels	Number of pixel rows in an image or its segmentation mask; shares its glyph with horizons but counts rows.
W	**Image Width**	pixels	Number of pixel columns in an image or its segmentation mask.
$\mathbb{I}$	**Indicator Function**	Function	Function equal to one when its condition holds and zero otherwise.
$\mathcal{D}_{\mathrm{KL}}$	**KL Divergence**	nats or bits	Expected extra code length from encoding one distribution with a code built for another; asymmetric, so $\mathcal{D}_{\mathrm{KL}}(p\|q) \neq \mathcal{D}_{\mathrm{KL}}(q\|p)$, and distillation uses the teacher-to-student order.
H	**Shannon Entropy**	bits	Average uncertainty of a probability distribution, the expected negative log probability of its outcomes; the log base sets the unit, base two for bits and natural log for nats.
H	**Statistical Hypothesis**	Record	A hypothesis about a population: H_0 the null, H_1 the alternative, and $H_{(i)}$ the hypothesis with the i-th smallest p-value. A record, not a number.
$z_{1-\alpha_{\mathbf{sig}}/2}$	**Significance Critical Quantile**	Dimensionless	Standard-normal quantile at one minus half the significance level, the two-sided critical value of a release test; about 1.96 at a significance level of 0.05.
s'	**Next Decision-Process State**	Record	State a decision process moves to after an action is taken in the current state, as in the transition law $p(s' \mid s, a)$; the successor of the current state.
s	**Policy Observed State**	Record	State or observation a policy conditions its choice of action on, the conditioning argument in $\pi_\theta(a \mid s)$.
a	**Policy Action**	Record	Action a policy chooses given the state it observes, the chosen argument in $\pi_\theta(a \mid s)$; agentic rollouts use their own rollout-action symbol.
ρ	**Policy Probability Ratio**	Dimensionless	Ratio of a sampled token's probability under the current policy to its probability under the behavior policy that generated it; clipped to an interval of half-width ϵ_{clip} around one.
ϵ_{clip}	**Ratio Clipping Width**	Dimensionless	Half-width of the interval around one to which the clipped surrogate limits the probability ratio; between zero and one.
Q^π	**Policy History-Action Return**	Dimensionless	Expected remaining return under the current policy after taking a given action at a given interaction history and then following that policy, written $Q^\pi(h_k, a_k)$.
V^π	**Policy Remaining Return**	Dimensionless	Expected remaining return under the current policy from a given interaction history, written $V^\pi(h_k)$; the baseline the advantage subtracts.
A^π	**Policy History Advantage**	Dimensionless	Return of a given action at a given interaction history minus the remaining return at that history, $A^\pi(h_k, a_k) = Q^\pi(h_k, a_k) - V^\pi(h_k)$.
d_π	**State Distribution**	Distribution	Average distribution of states a policy visits over the horizon; the per-step form carries a superscript, d_π^t.
d_{π^*}	**Reference State Distribution**	Distribution	Average distribution of states the reference policy visits over the horizon; the reference-policy counterpart of d_π.
τ	**Trajectory**	Record	Ordered record of the states, actions, and observations of one delegated task, $\tau = (s_0, a_0, o_1, \ldots, s_H)$; a record, not a number.
K	**Class Count**	Count	Number of classes a classifier distinguishes, or vocabulary entries it scores; the length of its softmax output.
y	**Example Label**	Record	Label paired with one input, treated as a random variable; a bold form is the label written as a vector.

Latin matrices and vectors are set in bold (**W**, **x**); scalars, dimensions, indices, and individual matrix entries stay italic (N, d, i, W_{ij}). The generic parameter symbol θ is the one conventional exception and stays italic. Local matrix algebra follows the same bold rule: matrix operands are bold (**A**, **B**, **C**), as in general matrix multiply (GEMM) $\mathbf{C} = \alpha\mathbf{AB} + \beta\mathbf{C}$. The bold form marks a matrix operand and is distinct from the italic scalar batch size B, which remains batch size in scalar contexts.

A GEMM's scalar dimensions are M, N, and K (**A** is $M \times K$, **B** is $K \times N$). Asymptotic cost is written $\mathcal{O}(\cdot)$, which keeps it distinct from the operation count O.

Evaluation and Statistical Evidence

A physical trial is expensive, so the evaluation chapters count carefully. These symbols name the trials themselves, the samples a metric is computed over, and the threshold exceedances that tail estimates are built from.

Symbol	Definition	Unit	Notes
n_{cal}	**Calibration Example Count**	Count	Number of held-out calibration examples, and so of nonconformity scores, used to set a conformal prediction threshold. Not the quantization calibration set.
N	**Evaluation Sample Count**	Count	Number of examples in the evaluation set over which an accuracy or calibration metric is computed; it sets the sampling error. Not the training set size D.
X	**Discrete Random Variable**	Record	Discrete random variable, the uncertain quantity whose outcomes a distribution describes; uppercase for the variable, lowercase for one of its outcomes.
c	**Trial Condition**	Record	Condition of one physical trial: initial plant state, environment parameters, plant parameters, computational configuration, and termination protocol; drawn from the operational test distribution.
n	**Trial Index**	Index	Position of one physical trial within a learning campaign, counted from one.
p	**Trial Success Probability**	Dimensionless	True probability that one trial succeeds under the declared evaluation protocol and test distribution.
N_u	**Threshold Exceedance Count**	Count	Number of trials whose performance metric exceeds the threshold.
y	**Threshold Excess**	Varies	Amount by which the monitored quantity exceeds the threshold, one recorded exceedance; it carries the unit of the monitored quantity. Its random-variable form is Y.
Y	**Threshold Excess Variable**	Varies	Excess of the monitored quantity over the threshold, conditional on exceeding it, treated as a random variable.

Units and Precision

- Physical units: This book uses SI (metric) units throughout, including meters, kilograms, seconds, watts, and °C, consistent with standard engineering and scientific practice. Where source data was originally reported in imperial units, the book converts to SI and notes the original values parenthetically. A space always separates the number from the unit (for example, 100 ms, 2 TB/s).
- Data and memory: This book uses **decimal SI prefixes only**: KB = 10^3 bytes, MB = 10^6, GB = 10^9, TB = 10^{12}. Binary-prefixed units do not appear in prose; model sizes, activation footprints, throughputs, and transfer volumes are reported in decimal units (for example, 2 TB/s, 102 MB). Hardware memory capacities are the one exception: they keep the vendor's nameplate figure and label. A device modeled here with a binary 80 GB capacity holds 80×2^{30} bytes; usable capacity and allocation headroom remain separate.
- Compute: The notation distinguishes operation counts from rates. Total work uses FLOPs (for example, GFLOPs, TFLOPs), while throughput uses FLOP/s with decimal prefixes (for example, GFLOP/s, TFLOP/s).
  - 1 TFLOP = 10^{12} FLOPs
  - 1 TFLOP/s = 10^{12} FLOPs per second
  - Arithmetic intensity conventionally uses FLOP/byte as a unit ratio (floating-point operations per byte moved). This is a ratio unit, not a total-work symbol or throughput symbol.

- Power: Power carries a subscript (P_{avg}, P_{device}, P_{cluster}); bare P remains parameter count.
- Latency percentiles: Written p50, p95, and p99 in upright type, inside math as well as in prose.
- Currency: Dollar amounts use the dollar sign (`$`); unless otherwise noted, dollar-denominated costs are U.S. dollars (USD).
- Precision:
  - **FP64**: Double precision (8 bytes)
  - **FP32**: Single precision (4 bytes)
  - **TF32**: TensorFloat-32 (19-bit Tensor Core compute mode; inputs and storage remain FP32)
  - **FP16**: Half precision (2 bytes, standard range)
  - **BF16**: Brain float (2 bytes, wide dynamic range)
  - **FP8**: Quarter precision (1 byte, E4M3 or E5M2 format)
  - **FP4**: 4-bit floating-point format
  - **INT8**: 8-bit integer (1 byte)
  - **INT4**: 4-bit integer; lower integer precisions follow the same uppercase `INTn` pattern (for example, INT3, INT2)

Quick Reference: Resolving Collisions

Throughout this book, two single-letter symbols recur in both machine learning equations and hardware performance budgets. The most frequent symbol collisions across the machine learning, control, and embedded systems literatures are resolved as follows:

Symbol	ML Meaning	Systems Meaning	Book Convention
B	**Batch Size**	Bandwidth	**Batch Size**. Use BW for bandwidth.
P	**Parameters**	Peak FLOP/s	**Parameters**. Use R_{peak} for peak rate.

DRAFT

As a general principle, ML conventions take precedence for single letters, while systems concepts get subscripts or multi-letter symbols. This preserves compatibility with the ML literature while distinguishing the robotics and embedded systems meanings used in this book.

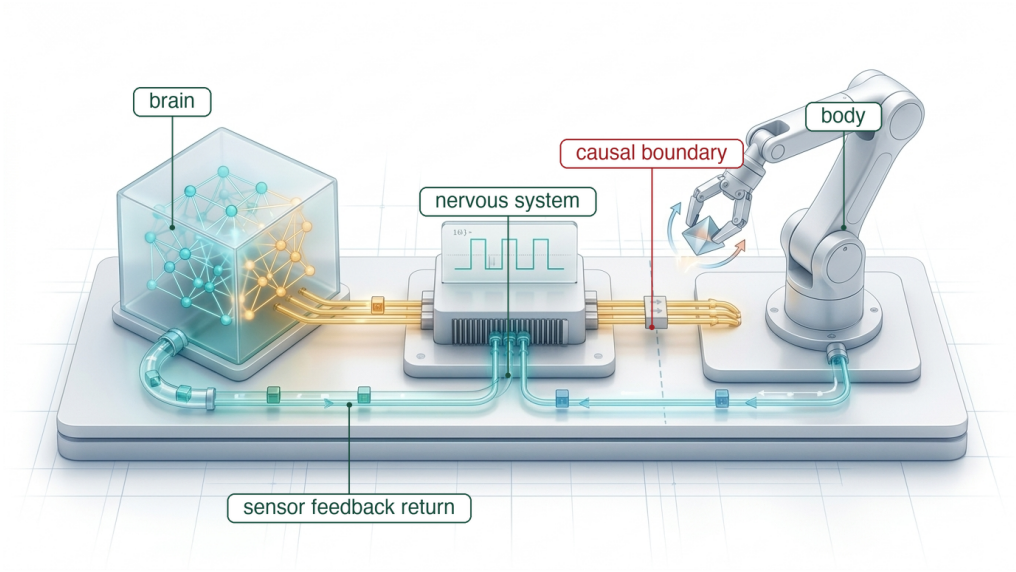
The Causal Boundary

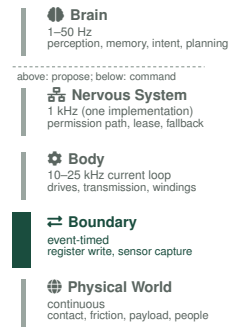


1.1 Artificial Intelligence Beyond Glass
1.2 From Prediction to Action
1.3 The Question This Book Answers
1.4 Defining the Causal Boundary
1.5 Three Machine Classes
1.6 The Physical AI Scope Test
1.7 The Machine in Five Levels
1.8 When the Responsibilities Fail Together
1.9 Where Safety, Security, and Accountability Meet
1.10 The Four Bedrock Laws
1.11 The Architecture of This Book
1.12 Fallacies and Pitfalls
1.13 Summary
1.14 Historical Perspective and Further Reading

Purpose

Why can a better prediction still produce a worse physical action?

A learned model can recognize a task correctly and still act too late to stop a moving machine or prevent excessive contact force. Once a command produces motion or heat, replacing the prediction cannot undo the work already delivered. The engineer must therefore connect model quality to the body's limits, the time available to respond, and the evidence supporting the next action. An independent permission path must be able to refuse a proposal and carry out a feasible fallback even when the model stalls. At the causal boundary, where commands become physical work, irreversibility makes these responsibilities part of the system's architecture.



Learning Objectives

- Trace how machine learning systems evolved from disembodied prediction through digital agency to physical embodiment, and explain why that progression gives data, compute, evaluation, and deployment physical stakes
- Explain why an action that crosses the causal boundary requires reasoning about consequences that software rollback cannot undo
- Calculate how response delay consumes a moving machine's stopping clearance
- Apply the scope test to distinguish physical AI from advisory learning and classical control
- Distinguish learned proposals from permission to execute them in the five-level machine
- Diagnose how perception, response timing, and missing redundancy interacted in the Tempe collision
- Relate the four laws to their established names in the field and to the book's four parts

1.1 Artificial Intelligence Beyond Glass

When an image classifier mislabels a warehouse photograph on a server, a downstream filter can discard the label before any machine moves; when a mobile robot's policy misjudges aisle clearance and drives its wheel motors, the chassis is already accelerating toward the rack. Across offline advisory prediction, digital agency, and physical embodiment, computation acquires different consequences as its outputs enter an action loop, and physical AI diverges from the other two in how agency, time, and recovery behave (table 1.1).

In the offline or advisory case, a model delivers predictions against a static dataset before any downstream action closes a feedback loop. Whether classifying an image, predicting customer churn, estimating a bounding box, or ranking search results, the model operates in open loop. Its input distribution is exogenous, because the predictions it emits do not alter the process that generates later test examples. Because those requests arrive independently, throughput-oriented serving can batch many inputs together ($B \gg 1$) across pipeline stages, performing many arithmetic operations for every byte of weights fetched from memory (its arithmetic intensity). The advisory model exercises no agency of its own. Before a person or downstream service acts on the output, an incorrect label or irrelevant search result can be ignored, filtered, or recalculated without having done physical work.

The emergence of agentic machine learning marked an architectural transition from passive, single-shot prediction to active, sequential decision-making. Endowed with reasoning loops and test-time deliberation, an agentic model formulates multi-step plans, maintains internal state across execution traces, and autonomously invokes external tools. These tools execute database queries, call web APIs, run generated code in execution environments, and coordinate software subagents. In this regime, the execution loop is closed. An action taken at step t alters the state of the software environment, so subsequent observations o_{t+1} depend directly on prior decisions a_t. The system possesses genuine agency.

Within a controlled software environment, this agency can operate inside a protective envelope, "behind the glass." Such environments can grant agentic systems three structural privileges, though external services and consequential tool calls may fall outside that envelope:

- **Elastic virtual time**: A controlled software environment can wait while the model computes. Whether an agent requires 200 ms or 30 s of test-time compute to plan its next tool call, the environment can hold its simulated state until the action is emitted. External services continue evolving on their own clocks.
- **Transactional rollback and sandboxing**: Tool execution can occur within isolated containers, virtual machines, or transactional databases. When an action produces an error inside this envelope, software exceptions catch the fault, database transactions roll back, or the container restarts from a clean snapshot. These mechanisms cannot undo consequences already delivered outside it.

- **Discrete symbolic interfaces**: Actions are structured strings, JSON schemas, or API payloads whose syntax and validity can be verified by deterministic compilers and linters before execution.

Physical artificial intelligence represents the arrival of agency in the physical world. A physical AI system does not invoke a software API inside a virtual sandbox; its outputs cross the **causal boundary** into physical actuators. A learned model's output becomes a setpoint (the target value a low-level controller drives toward), the setpoint becomes electrical current in a motor phase winding (one of the stationary copper coils whose current turns the motor), and the current becomes electromagnetic torque. The torque accelerates physical mass through gearboxes, linkages, and contact surfaces sharing space with people and objects. That physical embodiment strips away every digital privilege:

- **Continuous time**: Physical time advances under Newtonian mechanics regardless of processor state. The **physical plant**, the apparatus being controlled such as a robot's wheeled base or arm, does not pause while a neural network deliberates. In a moving robot, computational latency is not a software delay. A machine moving at speed v that takes a time τ_{delay} to begin braking covers $v\,\tau_{\text{delay}}$ toward an obstacle under unguided momentum. Delay is physical distance.
- **Mechanical and thermodynamic irreversibility**: Physical state transitions admit no software rollback. Once software commands current through an inverter (the power electronics that switch a DC supply into the motor's phase currents), electromagnetic force accelerates mass, dissipating irreversible Joule heat ($P_{\text{phase}} = I_{\text{phase}}^2 R_{\text{phase}}$ in each phase winding) and altering mechanical contact states. Kinetic energy ($E_k = \frac{1}{2}mv^2$) cannot be garbage-collected, and a mechanical impact cannot be undone by restoring a checkpoint. A command that has moved a machine can be answered only by another physical action, which itself consumes time, clearance, and energy.
- **Single-batch, hard real-time execution**: On the running machine, each new action proposal depends on observations shaped by prior motion, so the live loop does not accumulate independent observations into a throughput batch ($B = 1$). Control loops must also meet hard real-time deadlines across several coupled timescales: motor current loops at tens of kilohertz, loops near a kilohertz that check motion and regulate contact force, learned policies renewing at tens of hertz, and slower models interpreting the scene a few times per second. Section 1.7 gives the running machine's rates. A missed deadline does not degrade user experience; it can destabilize the physical plant.

Losing these privileges forces an architectural response. Deep neural networks are statistical function approximators, vulnerable to distribution shift, sensor noise, and hallucination, so they cannot be granted unmediated authority over physical actuators. Physical AI therefore separates proposal from permission. High-capacity learned models act only as *proposers* in an unprivileged tier (the Brain). An independent, deterministic *permission path* (in the Nervous System) checks each proposal against the machine's physical limits and *admits* (accepts for execution) only the proposals that pass. It also keeps an executable fallback ready on isolated real-time hardware. The permission path does all of this before any action crosses the causal boundary into the plant (the Body).

Table 1.1: Three deployment regimes of machine learning systems: The selected arrangements progress from offline advisory prediction to digital agency to physical embodiment. The unit of engineering shifts from advisory prediction to digital tool execution, and finally to irreversible physical action across the causal boundary.

Deployment Regime	Execution Substrate	Primary Output	Environmental Coupling	Time Semantics	Failure & Recovery	Safety & Authority Model
Offline/advisory prediction	Cloud servers / accelerators	Advisory prediction (label, score, token)	Open-loop (static dataset, exogenous data)	Batchable in the selected serving case	Discard or recompute before downstream action	Advisory; downstream software or human decides

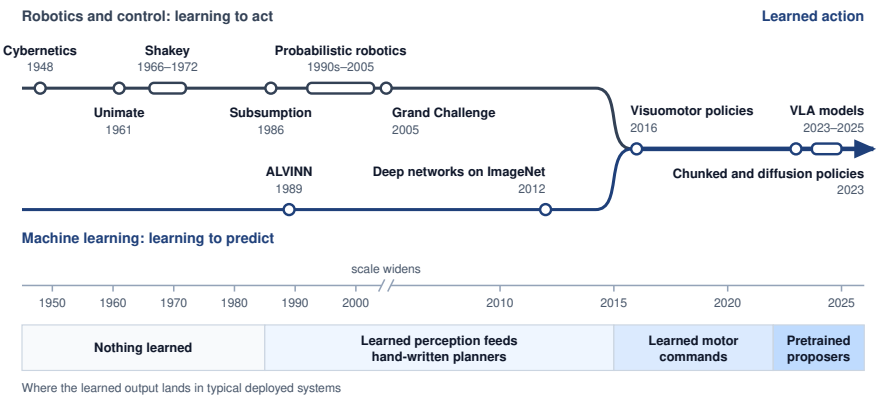


Figure 1.1: From prediction to action: Robotics and control (top) learned to act on the physical world, and machine learning (bottom) learned to predict from data; the two lines merge in learned action. The band beneath the time axis shows where the learned output lands in typical deployed systems of each era, from no learned component, to learned perception feeding hand-written planners, to learned motor commands, to pretrained models that propose motion. The time axis widens after 2005.

Deployment Regime	Execution Substrate	Primary Output	Environmental Coupling	Time Semantics	Failure & Recovery	Safety & Authority Model
Agentic ML	Digital software environments	Tool execution (API payload, code snippet)	Closed-loop in software (actions alter state)	Elastic virtual time in controlled environments	Software exception, container restart, DB rollback	Sandboxed permission; API scopes and virtual gates
Physical AI	Embodied physical plant	Physical force and motion (current, torque)	Closed-loop in physics (actions alter world)	Inexorable continuous time; delay is distance	Irreversible work; energy dissipation; damage	Proposal vs. permission; deterministic runtime veto

Physical AI did not arrive solely through the scaling of language models. It represents the convergence of two long-standing engineering traditions: robotics and control, which learned to act reliably on a physical world that pushes back, and machine learning, which learned to extract representations from data at scale. Over eighty years, the learned model has moved step by step from the periphery of the machine toward its actuators, and each step shifted what the surrounding systems architecture had to guarantee. That history explains what physical AI inherits from classical control and digital learning, and why its central systems challenge is new.

1.2 From Prediction to Action

The acting line begins with feedback. Wiener's cybernetics described animals and machines alike as systems that measure the result of their own action and use it to correct the next one (Wiener 1948), and control theory soon learned to estimate a moving system's state from noisy measurements (Rudolph Emil Kalman 1960). The first industrial robots needed little of this at the level of the task. In 1961 a Unimate arm began stacking hot die-cast parts at General Motors by replaying step-by-step commands stored on a magnetic drum (Computer History Museum 1961). Nothing in that program could notice a person in the arm's path, so protecting people meant keeping them out of its reach. The machine acted, but it did not perceive, and nothing in it was learned. Robotics and control learning to act and machine learning mastering prediction run as the upper and lower lanes of figure 1.1 until they merge.

Shakey, developed at SRI from 1966 through 1972, joined perception to planning (Nilsson 1984). It took camera images and range-finder readings, kept a model of its surroundings, and used a planner called STRIPS to compose sequences of actions that would achieve a stated goal. This organization, later summarized as sense-plan-act (S·P·A), treats acting as the last step of a computation. Shakey moved slowly, and its designers treated its motion as running asynchronously to the programs

directing it (Nilsson 1984). The world was assumed to wait while the computer thought. Shakey also carried a detail that anticipates this book's architecture. When one of its catwhiskers touched an obstacle, the robot stopped by a reflex action beneath the planner.

Brooks inverted that organization. His subsumption architecture built control from layers of simple, asynchronous behaviors, each coupling sensing to action. Higher layers could suppress the outputs of lower ones, but the lower layers continued to run as higher ones were added (Brooks 1986). A fast layer that keeps working while a slow one is busy or wrong is an ancestor of the permission path this book develops. Neither organization, however, made perception or dexterous motion easy to write by hand, and the planners and behavior layers alike stalled on exactly the skills a toddler has. That difficulty has a name. **Moravec's paradox**[1] observes that sensorimotor skills people perform with little conscious effort can be difficult to reproduce computationally, which is why learning became attractive for physical tasks.

↪ The sense-plan-act paradigm, and the failure taxonomy it organizes, is developed in Appendix D.

Learning had already entered the loop. In 1989 ALVINN, a small neural network, mapped camera and laser range images to the direction a vehicle should steer, and followed real roads under some field conditions (Pomerleau 1989). Through the 1990s robotics also made uncertainty explicit. Probabilistic robotics represents what a machine believes about itself and its surroundings as probability distributions, updated as actions and measurements arrive (Thrun et al. 2005). The DARPA Grand Challenge tested these ideas at scale. In the first race, in 2004, no vehicle covered more than a small fraction of the desert course. In 2005 five vehicles finished, and the winner, Stanford's Stanley, relied predominantly on machine learning and probabilistic reasoning (Thrun et al. 2006). In systems of this kind, learning mostly estimated what the world was like, and hand-written planners and controllers decided what to do. A decade later, the DARPA Robotics Challenge Finals asked robots to work at a simulated disaster site, driving a vehicle, opening a door, turning a valve, and climbing stairs. The organizers deliberately degraded the communications link to the remote human operators, so that each robot had to carry out parts of every task under supervised autonomy rather than direct teleoperation (Krotkov et al. 2017). Even at that stage, a person remained close to the loop.

1 | **Moravec's Paradox**: Moravec (1988) observed that computers could be made to perform at an adult level on intelligence tests or at checkers far more easily than they could be given a one-year-old's perception and mobility, and he traced the gap to evolutionary age, since sensorimotor skill was refined over a far longer history than abstract reasoning. For a physical machine the hard part is therefore the part that touches the causal boundary, perceiving a changing world and acting on it before a deadline, which is where learning and this book both concentrate.

Deep learning then changed how much a machine could perceive. In 2012 a deep convolutional network trained on GPUs classified ImageNet photographs with error well below the previous state of the art (Krizhevsky et al. 2012), and learned detectors spread into the perception systems of robots and automated vehicles. The architecture around them usually stayed modular, with a learned percept feeding a planner written as rules or as an optimization. The learned outputs were still predictions, yet no person stood between them and the brakes. The Tempe vehicle examined in section 1.8 was a machine of this kind.

↪ ALVINN's missing recovery examples, and the compounding error they expose, are developed in section 5.3.

Learning reached the actuator itself in the following years. Levine and colleagues trained convolutional networks that mapped raw camera images directly to the torques at a robot's motors, for tasks such as screwing a cap onto a bottle (Levine et al. 2016). Grasping systems learned from hundreds of thousands of their own attempts, gathered by groups of robot arms working in parallel (Levine et al. 2018; Kalashnikov et al. 2018). Deep reinforcement learning (training a network by trial, error, and a numerical reward) in simulation produced controllers for a legged robot and a dexterous hand that transferred to hardware (Hwangbo et al. 2019; OpenAI et al. 2019). With that step the data changed character. A robot that learns from its own attempts chooses the states it will see, so its training data depends on its own behavior.

Imitation learning, which trains a policy to reproduce recorded demonstrations, made human demonstration a practical route to new manipulation skills, and two ideas shaped the policies now in use. Action chunking predicts a short sequence of future actions from each observation, a design its authors motivated partly by the way a cloned policy's errors compound over time (Zhao et al. 2023). Diffusion policies generate action sequences by iterative denoising, which lets one policy represent the several different ways a demonstrator might complete the same task (Chi et al. 2025). The learned output had become a short plan of future motion, executed by controllers beneath it.

The latest step changed where learned proposals come from. In digital software systems, foundation models matured as agentic reasoning engines capable of decomposing abstract goals, generating plans, and invoking external tools. Bringing that agentic reasoning into physical embodiment required grounding multimodal representations in spatial geometry, continuous dynamics, and motor coordination. Large multitask datasets collected on many robots prepared the ground (Brohan,

Brown, Carbajal, Chebotar, Dabis, et al. 2023; Open X-Embodiment Collaboration et al. 2024), and between 2023 and 2025 several groups showed that a model pretrained on web-scale images and text can be fine-tuned to emit robot actions directly. These **vision-language-action (VLA) models** share one mechanism. A pretrained vision-language backbone encodes the camera images and an instruction, and an action head converts the backbone's output into motor commands. The head either decodes actions as discrete tokens, the way a language model decodes words (Brohan, Brown, Carbajal, Chebotar, Chen, et al. 2023; Kim et al. 2024), or produces a continuous *action chunk*, a short sequence of future setpoints from one inference (Black et al. 2024). A backbone with billions of parameters cannot run at a controller's rate, so recent designs split the work across rates. A slow model interprets the scene, and a fast action model or on-robot decoder emits chunks that controllers execute (Bjorck et al. 2025; Gemini Robotics Team 2025b). These systems are dated instances of one step, in which a pretrained general-purpose backbone, rather than a policy trained for one task on one robot, proposes the motion. The sizes and rates their authors report are collected later in table 3.2. The running machine adopts the same hierarchy with two proposers: an *intent model*, the slow vision-language model that reads the scene and chooses the goal, and a *chunk policy*, the fast learned policy that emits action chunks toward that goal. Their rates are fixed on its machine card (section 1.4.2). Because a general-purpose learned model can now propose motion for a general-purpose machine, deciding which component may *permit* that motion becomes a design question for every machine that adopts one.

↪ The memory-bound cost of splitting the work between a slow intent model and a fast chunk policy on the running machine is developed in section 3.5.2.

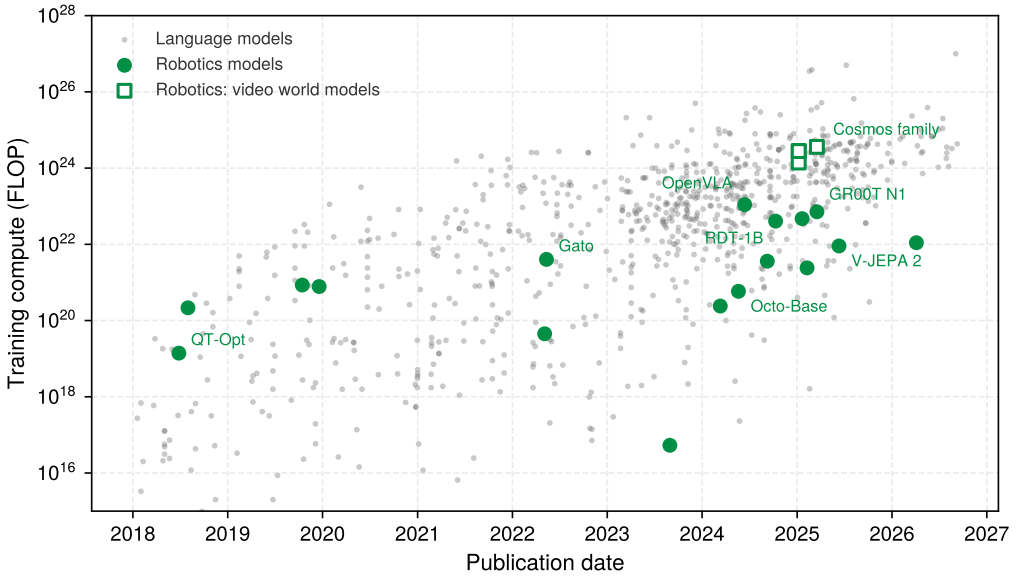

Figure 1.2: Robot models train on a sliver of frontier compute: Estimated training compute, on a logarithmic axis, of the models the Epoch AI database tags as language models (gray) and as robotics models (green), from 2018. Robotics models that generate video of the world rather than actions are drawn as open squares and labeled by family. The open robot action policies sit orders of magnitude below the largest language models of the same year; on this record, the scaling that drove language models has not been applied to learned action. Compute values are Epoch's estimates (Epoch AI 2026).

The scale of that transfer from web-scale pretraining is easy to overstate. In the Epoch AI database, the open robot action policies trained on hundreds to thousands of times less compute than the largest language models of their year (figure 1.2) (Epoch AI 2026). The gap is about 350 times less for a 2024 vision-language-action model and about 7,000 times less for a 2025 open robot foundation model, and only 25 robotics models in the database carry a compute estimate at all. Physical AI is therefore not a smaller copy of the language-model scaling story. Its learned proposers are bounded by what can be collected from machines acting in the world and by what can run on the machine itself, two constraints that Parts I and II of this book treat as first-class.

The name *physical AI* is recent, and industry usage since 2024 applies it broadly to almost any AI that perceives and acts in the physical world (NVIDIA 2026c). The history above runs through

two research traditions that cover much of the same ground. **Embodied AI** descends from Brooks's argument that intelligent behavior arises from a body situated in and interacting with its environment rather than from abstract representation alone (Brooks 1991). **Cyber-physical systems** name the integration of computation and networking with physical processes (Lee 2008), and they carry the timing and verification discipline of embedded engineering (Lee and Seshia 2017). Embodied AI supplies much of the learning this book uses, and cyber-physical systems supply much of its timing and verification practice. The book's subject is where the two meet at an actuator, and the definition given below is deliberately narrower than industry usage, narrow enough that the scope test in section 1.6 can apply it to a given machine.

Read as one story, this history moves the learned model step by step toward the actuator, as the band beneath the time axis of figure 1.1 records. At first nothing was learned. Then learned percepts fed hand-written planners, learned policies emitted motor commands, and finally pretrained general-purpose models began to propose motion for many kinds of machine. At each step, a guarantee that separation or human inspection used to supply had to move inside the machine. The familiar concerns of machine learning systems engineering come along, and each acquires physical stakes. Data stops being a fixed corpus because the machine's own actions choose what it will observe next. Compute stops being a matter of throughput and cost alone because a late answer is paid for in stopping distance. Evaluation stops being a score on held-out examples because the competence that matters appears only in the closed loop. Deployment stops being a routine version rollout because a release grants a machine authority over motion near people. When a learned output becomes an irreversible action, none of these concerns can be settled inside the model. They belong to the whole machine, and they meet at the boundary where its commands become physical work.

1.3 The Question This Book Answers

That convergence is why the problem now faces the whole field rather than a few robotics specialists. The central question of this book is why a better prediction can still produce a worse physical action, and what the rest of the machine must supply so that a learned proposal becomes useful work within justified limits. The book's answer is an argument in four linked steps. The body's physical limits bound what any proposal may ask for. The learned proposer's competence holds only over the states that its data and closed-loop evaluation covered. For both reasons, an independent permission path, rather than the model itself, must decide what may execute at each tick. The evidence gathered about the whole machine then bounds the operating conditions under which that permission is granted. The argument first requires a shared vocabulary. That vocabulary covers the causal boundary and the cost of delay at it, the scope of physical AI, a five-level model of the machine that separates proposal from permission, and the four laws that organize the rest of the book.

One machine carries the argument through every chapter. A warehouse mobile manipulator must collect an object from a conveyor, open a spring-latched cage door, and carry its load through an aisle shared with people. These tasks join abilities often studied separately. The machine must recognize an unfamiliar object, choose a grasp, coordinate its arm and base, and respond when contact or the scene differs from expectation. Learning makes varied behavior possible; engineering must turn that behavior into useful, repeatable physical work.

This book develops the ability to design, teach, integrate, evaluate, and maintain such a machine within justified operating limits. Its recurring warehouse machine is an illustrative engineering design, not a report of a qualified deployment. The same task connects physical budgets, learning experiments, runtime decisions, and evidence for service. When the evidence is incomplete, the engineer must identify what measurement, new experience, or design change would support the next capability.

Consider the base approaching the end of a storage rack while its model processes a camera image. A worker steps into the aisle before the next proposal returns. The computer can still discard that proposal, but the robot has continued moving throughout the calculation, so choosing an action requires reasoning about both the prediction and the physical state in which it will execute. Three things must therefore hold together: the model must recognize a useful action, the execution mechanism must judge it while the observation remains relevant, and the body must be able to deliver the admitted motion or a feasible alternative. A stronger prediction alone cannot recover

clearance already consumed during computation, which is why the engineering problem leads from physical limits to the architecture that checks each proposed action.

Building such a machine requires contributions from four disciplines that normally work apart. Machine learning supplies perception and action proposals. Computer systems determine how quickly those proposals compute and move across memory (Williams et al. 2009). Mechanics and control establish which motions the plant can physically sustain. Embedded systems enforce the real-time scheduling and bus rules that connect a proposal to an actuator. All four responsibilities meet at a single runtime question: whether the proposed action may execute under the machine's current conditions. This book develops the reasoning needed to make and justify that decision.

DRAFT

Definition 1.1: Physical artificial intelligence

Physical artificial intelligence is the engineering of closed-loop machines in which learned models influence, without synchronous human approval, physical actions that change subsequent observations.

1. **Significance**: Model performance becomes a property of an operating machine. Its actions must fit the plant's physical limits and the time available to respond.
2. **Distinction**: The scope test later in this chapter combines a learned model, consequential physical feedback, and delegated authority. Neither a model used only for advice nor an automated machine without a learned component meets all three criteria.
3. **Common pitfall**: Treating the body as a peripheral device for a model. A useful proposal still needs an independent permission decision based on the current state, physical limits, and available fallback.

The argument starts where the definition does, with the difference between a proposed action and its physical effect. A short stopping calculation then puts a number on what delay costs at the causal boundary. A documented collision later in the chapter shows these responsibilities failing together, and four laws then distill them.

1.4 Defining the Causal Boundary

That difference between a proposed action and its physical effect separates advisory computing from physical AI. An advisory model that renders an inference on a dashboard or returns a JSON payload across a network has no direct electrical or mechanical coupling to physical actuators: an operator or downstream software filter can inspect, validate, or discard its output before any physical energy is expended. Digital errors are not benign (an operator who acts on flawed guidance can cause serious damage), but advisory software cannot directly alter physical state. Once an automated system acquires the delegated authority of definition 1.1 to turn a computed proposal directly into physical motion, safety arbitration cannot remain an external afterthought. It must live inside the machine architecture, at the causal boundary between digital intent and physical consequence.

1.4.1 From a proposed action to motion

In modern computational frameworks, executing `action_chunk = policy(observation)` produces a floating-point tensor. That tensor represents an uncommitted proposal; converting it into physical motion requires an entire chain of intermediate controllers, bus interfaces, and power electronics. The causal boundary is the exact interface through which an admitted digital command begins driving physical change in the plant.

A learned policy typically proposes a trajectory of future joint positions, target velocities, or motor torques. Those numerical arrays remain purely informational descriptions until a low-level controller validates, accepts, and begins executing them. The internal representation and predictive horizon of such action sequences are developed in section 3.5.1; here the systems distinction is between proposing an action and authorizing its irreversible consequences.

That authorization is governed by the permission path, an independent mechanism defined in section 1.7 that alone holds the authority to pass commands to motor drives. The permission path verifies whether a proposed trajectory satisfies physical kinematic constraints, obeys velocity and acceleration bounds, and can complete safely within current time allowances. Once admitted, trajectory setpoints feed into dedicated motor controllers. A position loop compares each setpoint with the measured joint position and computes a correction, and a current controller sets the motor current that produces the torque the correction needs.

Consider an electric motor driven by pulse-width modulation. A software write updates a compare register in a microcontroller timer, which sets how long each power switch stays on in every switching period. The resulting on-off pattern drives the inverter's transistor switches, which turn the DC supply into current in the stator windings (the stationary coils). That current sets up a magnetic field that pulls on the magnets of the rotor (the spinning part) to produce torque, which accelerates the

↪ The bus timing and jitter bounds on command transport from the permission path to the drives are developed in section 4.5.

rotor shaft, transmission gears, and mechanical payload. The progression is asymmetric. Rewriting a planned setpoint in memory requires negligible energy and can be undone before the next clock cycle, but modifying a command that has already energized a winding requires physical work performed against mechanical inertia over finite time. A subsequent command can apply brakes or reverse drive current, but that corrective maneuver requires its own physical distance and must obey strict actuator limits.

Definition 1.2: Causal boundary

Causal boundary is the interface through which a digital command produces physical forces, currents, or flows.

1. **Significance**: A proposal can be rejected before it changes the plant. Once executed, it can alter the environment, dissipate energy, and change subsequent observations.
2. **Distinction**: Restoring a command in memory does not restore the machine's prior physical state. Recovery requires another physical action, with its own limits and consequences.
3. **Common pitfall**: Assuming that canceling a software task stops the motion it initiated. The machine needs a feasible stopping or holding response even when its proposer stops computing.

Offline supervised learning evaluates models against static datasets where predictions never influence future test inputs. An embodied robot cannot rely on this decoupling. When the mobile base steers its chassis, its onboard cameras immediately capture a different visual field. When its manipulator nudges a carton, the object's spatial coordinates and contact forces change. When the vehicle cruises along an aisle, its closing distance to personnel shifts in real time. The closed-loop feedback introduced in section 1.2 applies directly to the learned model, because an acting machine reshapes the very environment that produces its future training and inference inputs.

In any embodied system, the environment evolves through closed-loop dynamics: the subsequent physical state s_{t+1} and incoming sensory observation $\mathbf{o}_{t+1}$ depend directly on the action $\mathbf{a}_t$ issued by the policy inference:

$$s_{t+1} = f(s_t, \mathbf{a}_t), \quad \mathbf{o}_{t+1} \sim p(\mathbf{o} \mid s_{t+1})$$

Here f represents the physical plant and environmental dynamics (formulated without process noise for this introductory overview), and p denotes the observation model transforming underlying physical states into discrete sensor measurements. Because each state transition feeds the next observation, a flawed action proposal can steer the machine into configurations its training data never covered. In those out-of-distribution states the model's outputs degrade further, and the machine departs faster from its nominal trajectory. Advisory output stops at an informational interface. In physical AI the loop closes through the permission path, the motor actuators, and the plant, so the model's own actions irreversibly reshape the observations $\mathbf{o}_t$ it receives next (figure 1.3).[2] Imitation learning formalizes this compounding divergence as **covariate shift**. Whereas independent errors in open-loop prediction simply add up across the task horizon S (the number of control steps the task lasts), a single mistake in closed-loop execution can push the machine into an unfamiliar state that causes elevated error rates across every remaining step of the rollout, so the expected cost of mistakes can grow quadratically with the horizon, $\mathcal{O}(S^2\epsilon)$, rather than linearly (Ross et al. 2011). Section 5.2 develops the mechanics of this endogenous covariate shift. Contractive feedback controllers (stabilizing low-level tracking loops that pull perturbed states back toward the reference trajectory) or well-damped passive mechanics can absorb minor trajectory errors, although verifying behavior over long horizons still requires closed-loop evaluation rather than static offline benchmark scoring.

1.4.2 The running machine

To trace how a proposed action crosses the causal boundary on the warehouse mobile manipulator of section 1.3, the book needs one set of numbers that every later chapter can share. With them, the

2 **Recovery Data (ALVINN)**: The neural network that steered Carnegie Mellon's Navlab autonomous van directly from camera imagery confronted this challenge in early trials: because human test drivers kept the van centered in the driving lane, training logs contained no examples of recovering from the road shoulder, causing the system to veer off whenever it drifted off center. To synthesize recovery demonstrations without hazardous trials, Pomerleau (1991) transformed recorded road images using synthetic lateral shifts and calculated corresponding steering corrections back toward the lane center. While synthetic shifts work for simple geometric offsets, a physical policy must still be trained over the states its own actions visit.

↪ Corrective aggregation and the intervention data that defend a policy against covariate shift are developed in section 5.8.

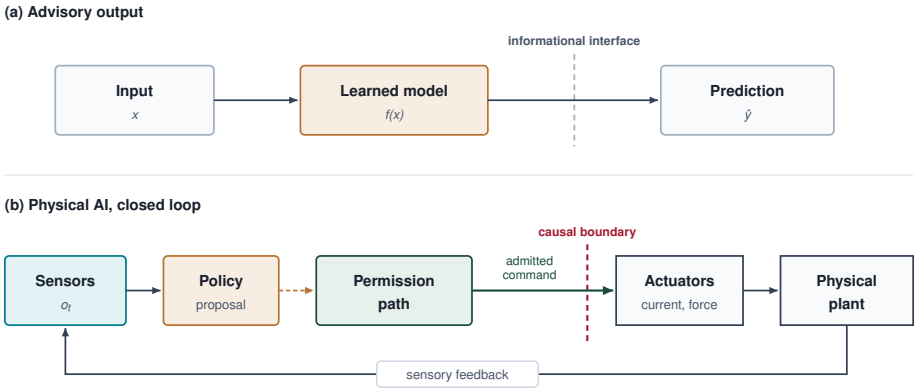

Figure 1.3: The closed causal loop: Advisory output (top) stops at an informational interface. In physical AI (bottom), permitted model proposals reach hardware registers, where electrical current produces force and motion. Those actions alter the environment and subsequent sensor observations.

stop chapter 2 derives, the timing chapter 4 budgets, and the evidence Part IV demands all describe the same robot. Table 1.2 fixes the fifteen parameters of the machine that later derivations use most, each with the evidence label the reader guide defines (measured, derived, datasheet, or illustrative, or chosen for a design decision). The stopping budget that follows uses five of them, the drive limit, the credible deceleration, the clear distance, the pre-brake delay, and the chunk lease inside that delay. This chapter needs only those five and, in one pitfall, the in-loop takeover time. The other rows use ideas (the jerk-limited stop, the intent model's prefill and decode, human takeover studies) that the section named in each row's Basis column develops. They appear here so that every chapter reads the same values. Subsequent worked examples cite the values by parameter name. For complete hardware specifications, the machine data sheet in section C.14.1 catalogs every other input alongside its programmatic registry key.

Table 1.2: The running machine's card: The fifteen parameters of the warehouse mobile manipulator that later calculations use most. A derived value built on illustrative inputs is illustrative evidence. Values print from the MLSysIM registry when the book is built.

Parameter	Value	Category	Basis
Loaded mass m	368 kg	Derived	Base, arm, and a full tote rack; an upper bound (section 2.1)
Drive limit $v_{\max}$	1.5 m/s	Illustrative	Class profile of a warehouse base
Aisle speed v_{aisle}	1.3 m/s	Chosen	Set below the dry-floor speed ceiling (section 12.3.1)
Credible deceleration a_{brake}	2 m/s^2	Illustrative	Loaded, on a dry floor whose grip supplies a friction coefficient $\mu \geq 0.204$ if all the weight bears on the driven wheels, or 0.250 at the share the drive motors allow; tip-over is unchecked until the center of gravity is measured (section 2.3.1)
Stop jerk bound $j_{\max}$	7.11 m/s^3	Derived	Stipulated for the jerk-limited stop, whose deceleration bound is $a_{\max} = a_{\text{brake}}$ (section 11.5.2)
Rack-end clear distance D_{clear}	1.10 m	Illustrative	Clearance the stop must fit inside
Pre-brake delay τ_{delay}	133.6 ms	Derived	Observation age, chunk lease, tick, bus cycle, and brake onset (section 8.4.1); excludes the dispatch-to-admission interval, which the spare pays for (section 13.6.2)
Permission tick T_{tick}	1 ms	Derived	Period of the chosen permission-loop rate (section 4.3.1)
Chunk lease T_{lease}	60 ms	Chosen	Longest an admitted chunk may drive without renewal (section 4.4)
Setpoint step Δt	25 ms	Chosen	Spacing of the chunk policy's setpoints (section 3.5.1)

Parameter	Value	Category	Basis
Chunk replan period	50 ms	Derived	A whole number of setpoint steps
Intent-model latency	336 ms	Derived	Prefill plus decode on the application processor (section 3.4.1)
Intent-model rate	2 Hz	Chosen	Largest rate whose period covers the latency
In-loop takeover $T_{\Sigma,1}$	605 ms	Derived	Slow-bound human reaction plus console video and handshake (section 14.2.2)
Out-of-loop takeover $T_{\Sigma,2}$	4.47 s	Derived	Take-over time of the 90th-percentile study condition plus video and handshake

With these parameters fixed, every later design problem on this platform starts from the same physical foundation. It asks which margin a commanded action approaches and whether the machine can execute an assured protective response before that margin is exhausted. The first margin to price is stopping clearance, and four rows of the card, the drive limit, the credible deceleration, the clear distance, and the pre-brake delay, are enough to price it.

1.4.3 Delay consumes stopping clearance

When the loaded warehouse base cruises down an aisle at speed v and a worker steps out from behind a rack, stopping requires clearance across two distinct phases. The first is the distance the base travels before braking forces engage. The second is the distance it travels while mechanical braking brings its momentum to zero. Assuming steady initial velocity v, uniform deceleration a_{brake} once brakes engage, and a stationary obstacle, the elementary stopping distance satisfies the kinematic budget:

$$d_{\text{stop}} = \underbrace{v\tau_{\text{delay}}}_{\text{travel during response delay}} + \underbrace{\frac{v^2}{2a_{\text{brake}}}}_{\text{mechanical dissipation}} \leq D_{\text{clear}} \tag{1.1}$$

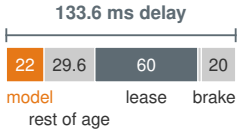
Here v denotes initial forward speed, τ_{delay} represents total pre-brake response latency, a_{brake} is the sustained braking deceleration, and D_{clear} is the usable line-of-sight clearance. The pre-brake delay τ_{delay} spans the time from when an obstacle first appears in a sensor exposure to the physical onset of retarding force. Specifically, it sums the age of the sensor observation upon handoff and the unexpired lease duration of any currently executing motion chunk (the lease is the longest an admitted chunk may drive before the permission path must act again). It also adds one discrete permission-path evaluation tick (the period at which the permission path re-checks the motion it has admitted), one bus communication cycle (the time to carry a command to the motor drives), and mechanical brake onset latency.

The lease belongs in the worst case even though the permission path re-checks every tick, because of what that check can see. Each tick tests the admitted chunk against limits the permission path already holds (the chunk's freshness, its lease, and the kinematic bounds, measured against the wheel and joint encoders). The permission path has no camera pipeline of its own. On the detection path this budget models, evidence that a worker has stepped out therefore reaches the brakes only through the learned perception path and a replacement proposal. If the proposer stalls or fails to answer the worker, the most recently admitted chunk keeps driving until its lease expires, and only then does the permission path command the stop. The term deliberately excludes one interval, the dispatch-to-admission interval (the time while the learned policy computes a replacement proposal and the permission path admits it). Its length depends on where the proposer and the permission path run and how they communicate, which are decisions this chapter has not yet made. Section 13.6.2 therefore allocates it, and the finished budget pays for it from the spare this elementary budget leaves.

The budget has two terms that grow differently with speed: travel during the delay grows linearly ($v\tau_{\text{delay}}$), and travel while shedding kinetic energy grows with the square of speed ($v^2/(2a_{\text{brake}})$). Equating them gives the crossover speed $v^* = 2a_{\text{brake}}\tau_{\text{delay}}$. Below v^*, delay travel is the larger term; above it, braking travel dominates. Shortening sensing, computation, and signaling reduces the delay term, while lowering speed reduces both terms: halving speed halves the delay travel and

quarters the braking travel. Which change saves more clearance depends on the reductions available, not on term dominance alone. Solving equation 1.1 for v gives the fastest speed whose stop fits inside a verified clear distance, a ceiling section 2.3.2 derives with the allowances this elementary form omits.

Every input to the budget comes from the running machine. Its speed, deceleration, clear distance, and pre-brake delay are rows of the machine card (table 1.2), and the five terms of that delay come from the same MLSysIM registry, so the notebook's givens are the ones every later chapter refines.



The learned backbone is 22 ms of the 133.6 ms delay; the lease costs more.

Napkin Math 1.1: Does the base stop inside its clearance?

Problem: The loaded base cruises toward a rack end at its drive limit, and a worker may step out at the end of the rack. The permission path must stop the base inside the rack-end clear distance on the machine card. Does the elementary stopping budget of equation 1.1 fit, which term dominates, and how much of the delay belongs to the learned model?

Variables:

- Speed $v = 1.5$ m/s, the drive limit (illustrative).
- Credible deceleration $a_{\text{brake}} = 2$ m/s², loaded on a dry floor (illustrative).
- Clear distance $D_{\text{clear}} = 1.10$ m (illustrative).
- Pre-brake delay $\tau_{\text{delay}} = 133.6$ ms (derived). It is the sum of five registry terms. The first is the observation age of the camera frame that first shows the worker, 51.6 ms, which includes the 22 ms perception backbone (the rest is half the exposure, sensor readout, transfer, image processing, and the handoff to the proposer, itemized in section 8.4.1). The second is the chunk lease of 60 ms, the longest an admitted command may drive before the permission path must act. The remaining terms are one permission tick of 1 ms, one bus cycle of 1 ms, and a brake onset of 20 ms. It excludes the dispatch-to-admission interval, for the reason given with equation 1.1.

Math:

$$\tau_{\text{delay}} = 51.6 + 60 + 1 + 1 + 20 = 133.6 \text{ ms}$$

$$v\tau_{\text{delay}} = 1.5 \text{ m/s} \times 0.1336 \text{ s} = 200.4 \text{ mm}$$

$$\frac{v^2}{2a_{\text{brake}}} = \frac{(1.5 \text{ m/s})^2}{2 \times 2 \text{ m/s}^2} = 562.5 \text{ mm}$$

$$d_{\text{stop}} = 200.4 + 562.5 = 762.9 \text{ mm} \leq D_{\text{clear}} = 1100 \text{ mm}, \quad D_{\text{clear}} - d_{\text{stop}} = 337.1 \text{ mm}$$

$$v^* = 2a_{\text{brake}}\tau_{\text{delay}} = 2 \times 2 \text{ m/s}^2 \times 0.1336 \text{ s} \approx 0.53 \text{ m/s}$$

Result: The elementary budget fits, with 337.1 mm to spare. The drive limit sits above the crossover speed, so braking dominates: it needs 2.8× the travel of the delay, and the delay adds 35.6 percent to the braking distance. At half speed, 0.75 m/s, delay travel halves to 100.2 mm while braking quarters to 140.6 mm, for a stop of 240.8 mm.

Systems insight: The learned model's backbone accounts for 22 ms of the delay, or 33 mm of travel; the chunk lease alone costs 90 mm. Each added millisecond of delay anywhere in the chain costs 1.5 mm at this speed, so a slower but more accurate model is a distance cost the budget must absorb. The spare is not yet a safety margin. Section 12.3.1 adds the localization bound, a protective margin, tracking error, and the longer stop of a jerk-limited brake (one that limits jerk, the rate of change of deceleration, by ramping its braking up instead of stepping it). Together they exceed the clear distance at the drive limit, which is why the card sets the aisle speed at 1.3 m/s.

The running machine's drive limit lies well above the crossover speed the notebook computed (figure 1.4), so braking, not delay, sets most of its stop, and the sum still clears the dashed clear-distance line before any later allowance is added. These values are representative parameters and a

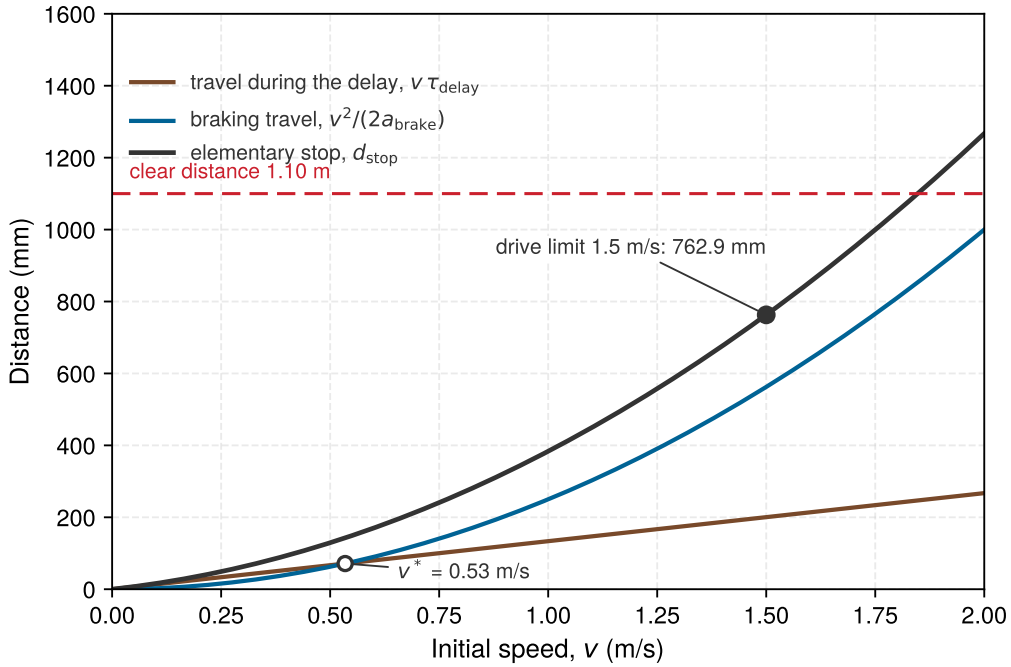


Figure 1.4: Delay travel and braking travel against speed: The elementary stopping budget of the loaded base, split into travel during the 133.6 ms pre-brake delay, which grows linearly with speed, and braking travel at 2 m/s², which grows with its square. The two terms are equal at the crossover speed v^*; above it braking dominates. At the 1.5 m/s drive limit the elementary stop fits inside the 1.10 m clear distance, before the allowances that later chapters add.

derived latency profile, not measured stopping distances for a real chassis, but they already show the two levers a designer holds. Shortening response latency contracts the linear term, whereas lowering cruising speed contracts both, the braking term quadratically. Selecting a model purely on offline accuracy overlooks the first lever, because added inference latency is added travel.

The budget just computed models one particular detection path, and naming it shows which learned computation it charges. The worker is seen by the learned perception stack, so the perception backbone sits inside the observation age. The chunk policy's own compute time does not appear, because the lease, not the policy, bounds how long an admitted chunk may keep driving once the proposer falls silent. A machine can also carry a second, independent protective path with its own sensing, timing, power, and fallback logic, such as a certified safety scanner wired to the drives. A stop that path triggers bypasses perception dispatch and the lease entirely. The backbone and lease terms leave its delay, and its own sensing and switching latency take their place, while the braking travel and the allowances stay. Under that decoupled architecture, the protective path's latency, rather than the execution time of the neural network, governs the protective stop. Industrial automated guided vehicles (AGVs) implement this separation today, with safety standards mandating certified safety scanners that halt the machine before human contact, independent of fleet management or guidance computers (International Organization for Standardization 2023b). This book layers learned sensorimotor proposers atop deterministic safety kernels and analyzes the architectural contracts required between them.

↪ The scanner path's own timing budget, and how the software stopping budget maps onto certified safety functions, are developed in section 12.9.3.

Deploying this budget in real-world facilities requires several additional physical allowances. Beyond the allowances the notebook's systems insight names (localization, a protective margin, tracking error, and the longer jerk-limited stop), real-world controllers must also account for unmodeled initial acceleration and degraded tire-floor traction. Dynamic obstacles complicate the clearance budget even further: if a pedestrian walks toward the mobile robot at speed v_h, the relative closing distance contracts during both the pre-brake delay and the mechanical deceleration phase. For this reason, functional safety standards mandate adding a pedestrian approach-speed allowance

to the vehicle's own braking distance (International Organization for Standardization 2024a). Later chapters formalize these dynamic constraints and allocate delay budgets across compute hardware. Even before they do, a learned policy's behavior is acceptable only inside the real-time envelope that plant momentum sets.

1.4.4 Irreversibility and recovery

The stopping budget prices one consequence of irreversibility. The other is what recovery becomes. A database transaction that aborts restores the state it started from, but a gripper that has permanently deformed a workholding fixture, or a winding whose insulation has degraded from overheating, has no earlier state to return to. Recovery on a physical machine is therefore a new trajectory, not a reversal.

Corrective commands can brake the motors, release a grasp, or plan a diversion, but each is itself motion, limited by the torque the actuators can deliver, by friction, and by the speeds and accelerations the drives can reach. Which limit governs depends on what the machine is doing. For the mobile base it is stopping clearance under momentum. When the arm closes its jaws on a fragile component or braces against an assembly fixture, it is contact force, the flex of the gears and belts between motor and gripper (transmission compliance), and heat in the windings. Because recovery is constrained motion, the permission path must check before it admits an action that a feasible recovery from the resulting state will still exist; checking afterward is too late.

1.5 Three Machine Classes

↪ The contact loads a transmission delivers to a gripped part or a latch, the arm's limiting quantity here, are developed in section 2.4.4.

As the warehouse mobile manipulator travels down an aisle, its primary engineering challenge is kinetic: preserving enough clearance to stop safely before an obstacle. When the same robot presses against a door latch, the governing constraint shifts to contact mechanics, regulating interaction forces to avoid damaging the mechanism or the workpiece. When holding a suspended payload stationary, the machine performs zero mechanical work, yet its actuators must sustain continuous stall torque without exhausting thermal headroom or browning out the shared electrical supply. Because each phase of the task spends a different physical margin, the book names three machine classes by the margin each one spends (figure 1.5).

The first class, **mass-dominated mobility** (Class 1), spends stopping clearance. A mobile base, delivery vehicle, or aerial drone carries significant momentum and cannot halt instantaneously. Forward velocity, control and sensing latency, and available braking deceleration or reverse thrust jointly dictate the spatial clearance required to arrest or redirect its motion.

The second class, **contact-dominated manipulation** (Class 2), spends force and deformation margin. When an articulated arm presses against a stiff fixture, minute position displacements can generate destructive contact forces over fractions of a millimeter. Physical contact is both the means of task success (seating a part or opening a latch requires deliberate force) and the immediate hazard. The engineering task is to supply the wrenches (the combined forces and torques) needed to complete the assembly while guaranteeing that contact forces never exceed the mechanical yield limits of the payload or the manipulator.

The third class, **energy- and thermal-dominated operation** (Class 3), spends heat and electrical supply margins. Supporting a heavy load or resisting gravity demands sustained motor current, driving continuous Joule heating in actuator windings even when joints remain stationary. Concurrent peak current draws from drive inverters, compute accelerators, and sensor payloads can induce voltage sag across a shared DC bus. The system must sustain these thermal and electrical loads across the entire operational profile while reserving sufficient energy and thermal headroom to execute a safe protective abort.

These three classes identify dominant physical constraints rather than mutually exclusive hardware categories. A practical robot transitions across all three regimes throughout a single task. The running machine integrates a wheeled base, an articulated arm, navigation lidar, and wrist cameras. An end-to-end learned policy can coordinate simultaneous base trajectories and arm proposals (Fu et al. 2024), but the integrated machine must enforce the safety envelopes of every regime concurrently. A fixed-base arm still faces thermal and bus-voltage limits during prolonged holding, just as a wheeled base encounters contact constraints when docking against a workstation.

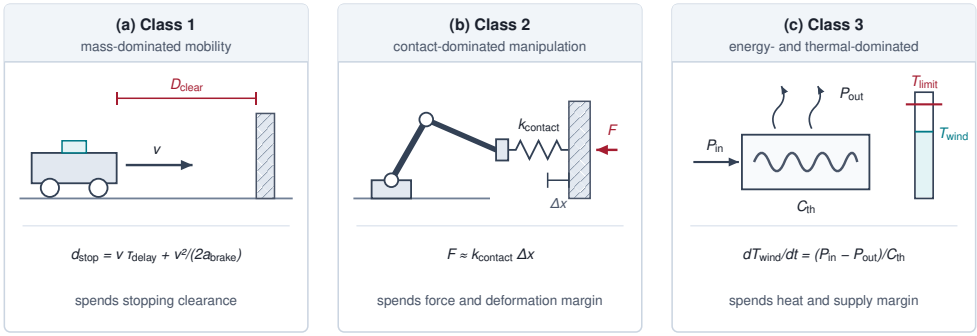

Figure 1.5: Three machine classes: Each class is named for the constraint that dominates it and the margin it spends: (a) mass-dominated mobility (Class 1) spends stopping clearance, set by momentum and braking; (b) contact-dominated manipulation (Class 2) spends force and deformation margin, set by contact stiffness and the strength of the object and mechanism; and (c) energy- and thermal-dominated operation (Class 3) spends heat and supply margin, set by Joule heating, thermal capacitance, and power delivery.

Systems Perspective 1.1: The humanoid crucible

A humanoid robot exposes the tight coupling across all three regimes. Catching a shifted load perturbs dynamic balance, requiring an immediate recovery step that demands peak joint torque. That torque surge draws heavy current from the shared DC bus and injects rapid thermal energy into the joint windings. If the power distribution network sags or thermal protection limits current, the recovery step fails and the machine falls. Shielding the onboard computing stack from reset does not by itself supply the transient mechanical energy needed to stabilize the body. The part-ending humanoid examples throughout this book test how each systems principle survives these tightly coupled physical demands.

↪ The multi-contact balance mechanics a humanoid's recovery step depends on are developed in section B.9.

Identifying whether a task spends stopping clearance, contact force, or thermal headroom tells the engineer which physical budget binds, regardless of how the controller is implemented. Whether the machine also requires the proposal-and-permission architecture of physical AI, rather than a classical feedback loop or an offline tool, depends on a separate test of how its decisions are generated and authorized.

1.6 The Physical AI Scope Test

A robotic arm in a fulfillment center can follow a fixed motion profile under a proportional-integral-derivative (PID) controller (a classical hand-tuned feedback law that corrects in proportion to the present error, its accumulated sum, and its rate of change). It can also execute an offline trajectory pre-screened and loaded by a human technician, or stream joint torques directly from a learned policy running on real-time sensor frames. While all three regimes actuate identical electric motors and gear trains, they impose different architectural obligations on the computing system. The scope test establishes the operational boundaries that define physical AI throughout this book.

The scope of physical AI is defined by the simultaneous intersection of three structural criteria:

1. **Learned Statistical Model:** The system relies on a policy, perception encoder, or world model whose runtime behavior emerges from training data rather than an inspectable closed-form specification, as seen in deep neural networks or diffusion policies (Chi et al. 2025). Correctness cannot be formally proven across all state configurations from source code alone; engineers must establish operational validity empirically across a defined operating domain. By contrast, a linear plant model fitted through classical system identification,[3] where parameter uncertainty yields provable stability margins, falls outside this category. A high-capacity neural policy falls within it.
2. **Consequential Physical Feedback:** The system's actions alter the material state of the surrounding physical world, and those state changes directly govern what its sensors measure in

[3] **System Identification**: The control-engineering practice of fitting low-order dynamic models to measured input-output time series. When this fitting establishes bounded parameter uncertainty under stated modeling assumptions, control engineers can use those bounds to prove stability guarantees before deploying the controller. Modern high-dimensional neural networks lack tractable closed-form uncertainty bounds and therefore require empirical verification across explicitly specified operating domains.

subsequent time steps under classical mechanics, thermodynamics, or electromagnetism. The environment cannot be paused or rolled back, and energy dissipated into it cannot be recalled.

3. **Delegated Authority:** The system's outputs reach execution without synchronous human approval for each control cycle. In a machine that also meets the second criterion, that execution is actuation, so the authority is physical. A learned component holds this authority whenever its output (a raw percept, a semantic state estimate, or a proposed motion trajectory) can propagate to live actuators without such approval. The learned network need not write directly to motor driver registers; the system possesses delegated authority whenever learned signals actively shape downstream actuation commands. Adding downstream safety checks or deterministic rate limiters does not vacate this authority, provided accepted proposals still drive hardware motion.

Together, these three criteria delineate the domain of physical AI. The three-set Venn diagram in figure 1.6 formalizes this boundary, locating physical AI at the central intersection where a learned model, consequential physical feedback, and delegated authority converge. Each pairwise overlap holds systems that meet only two of the three criteria. Advisory systems place a learned model inside a physical process, as when a technician inspects learned toolpaths before loading them onto a mill, but a person still approves each action. Digital autonomy executes learned outputs without human approval, as in an automated trading engine, but its actions land in software rather than in physics. Classical control closes a physical feedback loop automatically, as in a PID speed governor, but relies on an analytical control law rather than a learned model. Excluding these pairwise overlaps restricts the design problem to systems where statistical uncertainty collides directly with physical irreversibility.

A learned model alone does not make a machine a physical AI system. Consider an offline trajectory generator that optimizes smooth paths using a learned diffusion model. If a manufacturing engineer must inspect, validate, and load those toolpaths onto a CNC mill prior to cutting metal, the statistical model operates only as an advisory tool. The human retains ultimate physical authority. Similarly, a vision model that highlights defects on an assembly line display assists human inspection without closing the physical loop.

Conversely, delegated authority does not require end-to-end neural control. Most production autonomous systems adopt modular architectures where deep neural networks handle perception while deterministic trajectory planners compute actual actuator setpoints. These systems satisfy the delegated-authority test through perception: if an unvetted object detection or bounding-box estimate triggers an automated swerve or emergency braking maneuver, the learned representation directly dictates plant dynamics. The autonomous test vehicle in the Tempe collision examined in section 1.8 is such a machine: changing classifications in its modular perception fed the path predictions that decided whether it would brake.

Shared autonomy falls within physical AI whenever a learned sub-system modifies live motion before a human operator can intervene. In a robotic surgical console equipped with learned haptic virtual fixtures, for example, the assistive policy exerts real forces on the master tool manipulators to guide the surgeon around delicate anatomical structures. Even if the surgeon holds administrative responsibility for the procedure, high-bandwidth force cues alter physical tissue contact well within normal human neurological reaction latency (typically 150 ms to 250 ms). Because the machine enforces learned spatial guidance dynamically without requiring the surgeon to review and acknowledge each micro-correction, it exercises delegated authority over physical motion.

When classifying an ambiguous machine, engineers must evaluate each of the three criteria independently. Implementing an independent deterministic veto, such as an analog brake relay triggered by a certified safety lidar, does not strip a machine of delegated authority, because learned proposals still govern all nominal motion up to the intervention threshold. In contrast, requiring a human operator to screen and authorize every trajectory command before transmission reliably removes that authority. Once a design satisfies all three criteria, it qualifies as physical AI, and its computing architecture must respect the hard timing and causal boundaries established in section 1.4.

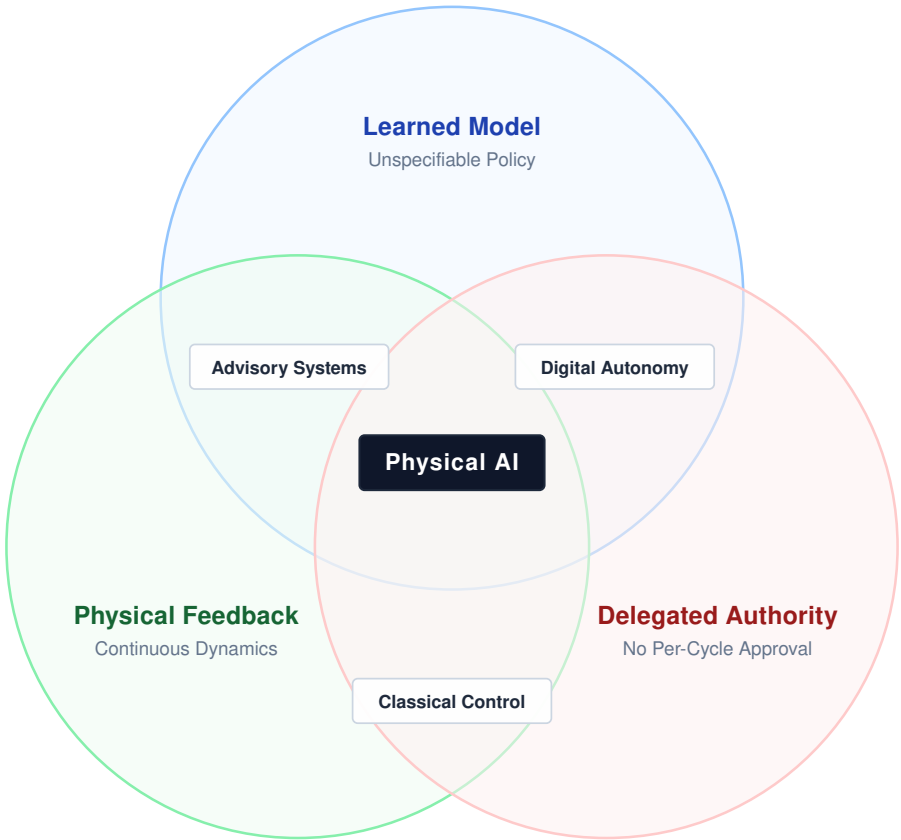

Figure 1.6: The physical AI scope test: Physical AI combines a learned component, consequential physical feedback, and delegated authority to let learned outputs reach actuation without human approval. An independent veto belongs inside this intersection because accepted proposals can still move the plant. The pairwise overlaps locate advisory systems, digital autonomy, and classical control.

Checkpoint 1.1: Binding budgets and the scope test

- ☐ **Delay vs. braking**: Explain why response delay and active braking consume separate portions of stopping clearance, and identify which one dominates above the crossover speed.
- ☐ **Stopping budget estimate**: Using the machine card, estimate how far the elementary stop at the 1.5 m/s drive limit grows if the 60 ms chunk lease doubles, and determine whether it still fits inside the 1.10 m clear distance.
- ☐ **Binding margins**: Identify the relevant physical margin when the warehouse machine travels, presses a latch, and holds a load.
- ☐ **Scope criteria**: Apply all three scope criteria to a new machine, including one whose learned output passes through an independent veto.

Satisfying the scope test binds statistical uncertainty directly to hardware consequences. To design systems that operate safely under these demands, computer systems engineers must map how timing, state estimation, and control authority distribute along the execution path from raw sensor frames to physical actuator motion.

1.7 The Machine in Five Levels

When the running machine's chunk policy stalls mid-aisle, something other than the policy must still be able to stop the base. When the policy emits a chunk that would carry the arm through a coworker's hand, something other than the policy must refuse it. An embodied machine therefore needs an architecture that prevents learned models from writing directly to the actuators they could damage, while still letting those models guide physical behavior.

The Body establishes what motion, force, and mechanical power the hardware can physically sustain. The Brain generates learned proposals intended to operate within those capabilities. Mediating between them, the Nervous System coordinates communication and control, preserving both the temporal margin and the hardware authority required to intercept and refuse an inadmissible command. Adding the interface where commands become current and the environment the machine acts on gives a five-level model that runs from learned computation down to the physical world:

1. **The Brain (Level 1):** The learned models that interpret sensory observations and propose candidate goals, trajectories, or torques. Generating a proposed trajectory or sequence of setpoints confers no intrinsic authority to execute it.
2. **The Nervous System (Level 2):** The deterministic communication buses, real-time schedulers, and control loops that bridge proposals to physical execution. Its permission path evaluates, filters, or rejects proposals against fresh sensory evidence and invariant physical limits, and it executes a fallback shown feasible from the current state under the stated sensing, plant, and response-time assumptions when the proposer falters.
3. **The Body (Level 3):** The physical plant, including motor drives, transmissions, electromagnetic windings, structural linkages, and energy storage, that delivers mechanical action.
4. **The Boundary (Level 4):** The hard physical and electrical interface where digital registers translate into actuator voltages or currents, and where physical phenomena register across sensor transducers as raw measurements.
5. **The World (Level 5):** The external physical environment (surfaces, payloads, obstacles, ambient lighting, and human collaborators), which evolves continuously under the laws of physics regardless of whether the machine measures it.

The list orders the levels by abstraction, from learned computation down to physics, not along the path a command travels. A command leaves the Nervous System, crosses the Boundary at a register write, and only then drives current through the Body's windings. The Boundary is listed after the Body because it gathers the transducers at both edges of the machine, the register writes that energize the windings and the sensor captures that turn light, force, and motion into numbers. Those are the places where the machine exchanges energy and information with the World. The actuation half of this level is the causal boundary defined earlier in the chapter. The proposal boundary, defined below, is not a level at all. It is the line between the Brain and the Nervous System that separates proposing from permitting.

A concrete physical AI implementation often maps this hierarchy across distinct computational tiers. Learned proposers run on high-throughput accelerator hosts (such as an application processor paired with a GPU or neural processing unit). The permission path executes on an independent real-time microcontroller or dedicated real-time operating system (RTOS) core. The current loops that regulate motor-phase current run directly on dedicated motor drives. This architectural isolation is rooted in strict timing guarantees and fault-containment boundaries rather than specific silicon families or nominal operating system labels.

Governance does not constitute a sixth level in this real-time control hierarchy. Instead, it serves as the operational and lifecycle envelope enclosing all five. Governance determines which entity holds valid command authority, what verification evidence licenses the machine to operate, and when that license lapses and must be renewed. Governance transitions unfold across the human and operational timescales of safety interventions, policy rollouts, and maintenance releases, rather than the millisecond rhythms of real-time control loops.

↪ The loaded test of the two-processor split that realizes this isolation is developed in section 13.7.

↪ The authority state machine that hands each actuator channel to exactly one owner during a transfer is developed in section 14.3.

Definition 1.3: Proposal boundary

Proposal boundary is the line between a learned model, which may only propose an action, and the **permission path**, an independent mechanism with bounded latency that the model cannot delay or corrupt and that alone may permit the action to reach an actuator. The permission path validates every proposal against fresh sensory evidence, the stopping envelope (the state space from which the machine can safely decelerate to a halt prior to obstacle collision), and a fallback trajectory shown feasible from the current state. On the running machine, the algorithmic admission checks remain an unrated performance layer (one not certified to a functional-safety rating) above separate certified protective functions. Section 12.9.3 explains that distinction. If any condition is violated, the permission path rejects the proposal within the established response bound.

1. **Significance**: Prevents learned model outputs from directly manipulating actuators. This architectural protection remains dependable only as long as the permission path's independent sensing, dynamic models, and fallback maneuvers remain physically valid.
2. **Distinction**: Even a deep reinforcement learning policy trained to emit joint torques possesses zero raw actuator-write authority; its output remains a mere proposal until explicitly admitted by the permission path.
3. **Common pitfall**: Treating the permission path as a cosmetic post-processing filter or output clamp, rather than an autonomous supervisory mechanism capable of seizing control when the learned proposer hangs, violates deadlines, emits pathological values, or falls silent.

The proposal boundary determines who holds the authority to approve an action, whereas the causal boundary marks the physical interface where an admitted command alters the state of the plant. The Nervous System bridges this divide, verifying proposals against hard constraints before energizing the drives.

Readers steeped in classical control theory will recognize this design as a supervisory architecture. Specifically, the proposal boundary implements runtime assurance. In classic Simplex architectures, a complex, high-performance controller (here, the learned policy) is paired with a certified baseline controller, coordinated by decision logic that determines which subsystem drives the plant (Seto et al. 1998; Sha 2001). The lineage table in section 1.10 (table 1.3) maps this book's terms to their established names once the four laws are stated.

↪ Runtime assurance for physical AI, which pairs the learned proposer with a resident protective controller and an output selector, is developed in section 12.1.

Hardware fault isolation alone does not guarantee safety, because architectural independence also constrains the permission path's sensor inputs. The learned detection path used in the stopping budget prices response delay, but its lease cannot protect against a perception error that produces timely, unsafe proposals. If an enforcement monitor validates a proposed trajectory using the very same learned perception pipeline that synthesized it, a single perception error will corrupt both components simultaneously. The sensing pipelines that grant execution authority must therefore maintain distinct failure modes from the learned models they supervise.

Across the five stacked levels in figure 1.7, characteristic operating rates span four orders of magnitude. The continuous physical World sits at the bottom, followed by the event-timed Boundary, the 10–25 kHz current loops of the mechanical Body, and the 1 kHz permission loop of the Nervous System. At the top, the hierarchical Brain operates from 40 Hz setpoints to 2 Hz intent models. The prominent gap between Brain and Nervous System marks the foundational proposal boundary: components above this line may only formulate proposals, while only deterministic subsystems below it possess the authority to command physical actuators. The operating frequencies charted across the levels reflect the reference architecture analyzed throughout this book, rather than immutable physical constants for every robotic platform. Subsequent chapters derive these timing budgets directly from task dynamics and mechanical plant characteristics. What remains fundamental across all physical AI systems is the proposal boundary that severs learned computation from unchecked execution authority.

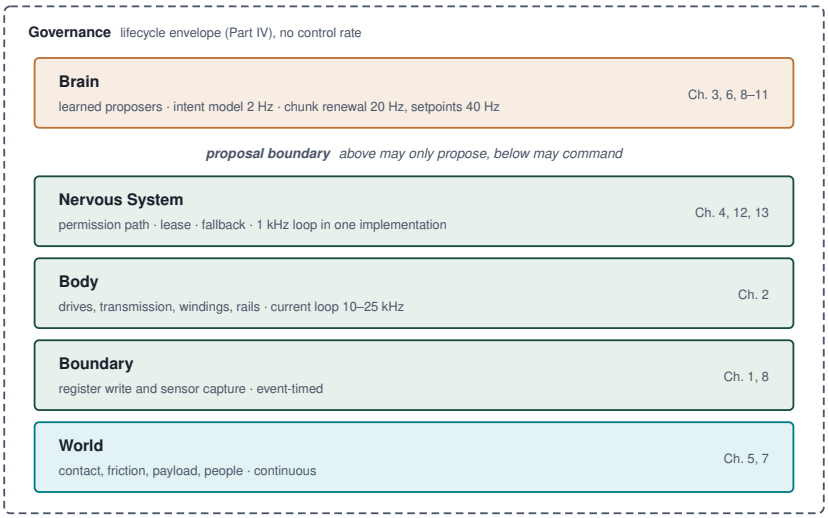

Figure 1.7: The five-level machine: Each band carries its pinned rate and the chapters that work on it. The wider gap between Brain and Nervous System marks the proposal boundary, above which a component may only propose. A chapter-opening stack with no level highlighted marks a governance chapter. The permission-loop rate shown is one implementation.

Deploying capable physical AI requires balancing expressive policy proposals with deterministic execution guarantees. This separation of concerns does not demand rejecting every imperfect proposal out of hand; real-time intervention mechanisms can project a trajectory onto safe constraints or smoothly blend corrections, preserving task progress while respecting physical invariants. Systems evaluation must therefore disentangle what the learned proposer achieves in isolation, how effectively the integrated machine executes under routine supervisory filtering, and whether the fallback mechanisms themselves introduce secondary hazards.

Distributing responsibilities across these five levels gives the rest of the book its structure. It also gives a way to diagnose real failures by asking which level failed, rather than reducing every physical malfunction to a deficiency in neural network weights.

↪ The minimal-intervention optimization filters that project a proposal onto its constraints are developed in section 12.7.

1.8 When the Responsibilities Fail Together

A warehouse model that recognizes an obstacle too late cannot recover the clearance already consumed. In a road vehicle, the same timing problem can combine with tracking errors, delayed intervention, and missing redundancy. The 2018 Tempe collision provides a documented example of these interacting failures; it does not establish that one prescribed hardware architecture would have prevented them. The National Transportation Safety Board (NTSB) attributed the crash primarily to the vehicle operator's distraction. The design choices traced below explain why the automated system had made that single, unmonitored person the last line of defense.

On a March night in 2018, a modified Volvo XC90 operating Uber Advanced Technologies Group's developmental automated driving system (ADS) struck and fatally injured a pedestrian pushing a bicycle across a road in Tempe, Arizona (National Transportation Safety Board 2019).[4] The vehicle carried a roof-mounted lidar, forward and side radars, surround cameras, and GPS antennas, all routed to ADS compute and data-storage racks in the cargo bay (figure 1.8). The ADS first detected the pedestrian 5.6 s before impact, but detection alone did not provide a correct path prediction (National Transportation Safety Board 2019). The failure ran through perception and path prediction, a response rule that withheld braking, and a human operator the design relied on as its last countermeasure.

4 **Reading the Tempe Record**: Times in this section count backward from impact at T, as the event table of NTSB/HAR-19/03 does, and speeds are those the ADS itself recorded (National Transportation Safety Board 2019). The report also cautions that communication delay leaves unclear exactly when the planned slowdown began. Reading each time as an interval before impact, rather than as a clock time, is what lets it be converted into distance traveled at the recorded speed, the conversion this section applies.

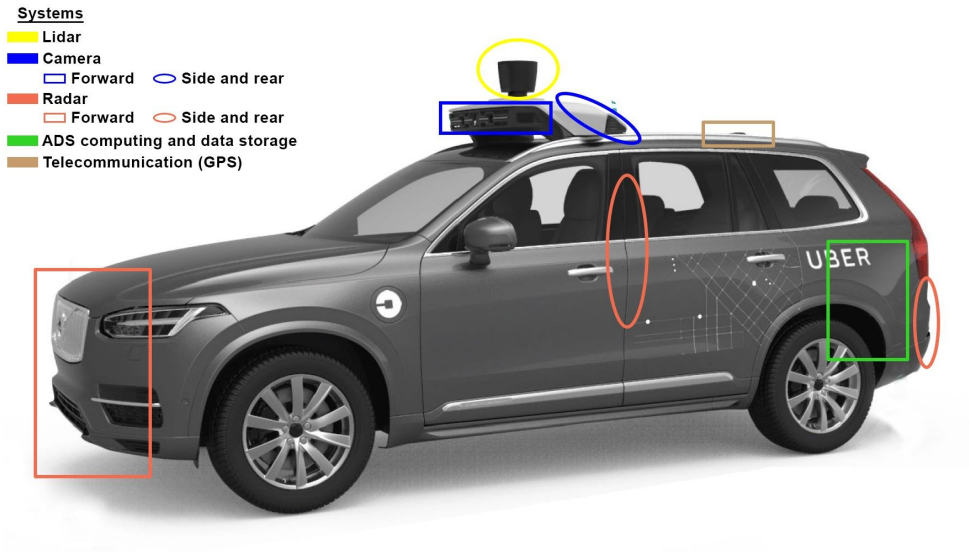

Figure 1.8: Tempe test vehicle sensor locations: The NTSB diagram identifies the developmental ADS vehicle's lidar, camera, radar, computing, and telecommunications locations. (Source: NTSB, public domain).

1.8.1 Tracking history loss under classification churn

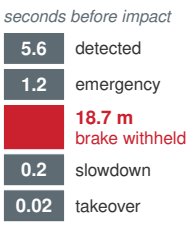
Despite continuing to track the detected object, the ADS did not brake in response to it because its classification kept shifting among vehicle, bicycle, and other before $T-1.2$ s (National Transportation Safety Board 2019). Whenever the classification changed, the ADS path predictor did not use the object's earlier locations, and for an "other" object it could assume a static path.[5] The loss of earlier locations matters because successive positions provide evidence of motion across the roadway; a changing semantic label must not silently discard that evidence. Because each relabeling shortened the track, the resulting path predictions did not place the pedestrian in the SUV's lane until $T-1.2$ s (National Transportation Safety Board 2019).

1.8.2 Action suppression and lost stopping distance

The ADS included an action-suppression interval intended to reduce responses to false alarms while the system checked the situation and allowed operator intervention (National Transportation Safety Board 2019). That software choice directly consumed time available for a physical response: at $T-1.2$ s, with the vehicle traveling at 43.2 mph, the ADS recognized an emergency and entered its one-second action-suppression period with braking withheld. At $T-0.2$ s, suppression ended with the vehicle at 40.5 mph. The ADS then initiated a plan for gradual slowdown and sounded an alert; it did not request emergency braking. The NTSB notes that communication delay leaves unclear whether that slowdown began before the operator disengaged the ADS at $T-0.02$ s (National Transportation Safety Board 2019).

The first term of the warehouse stopping budget applies directly. Averaging the two recorded speeds over the 1 s of suppression, the vehicle traveled about 18.7 m while emergency braking was withheld, distance that no later action could recover. The speed still fell during that second because a slowdown for the planned right turn at the next intersection was already under way; what the suppression withheld was the emergency response (National Transportation Safety Board 2019). The emergency itself was defined by a chosen limit. The ADS treated a situation as an emergency when avoiding a collision required more than 7 m/s² (0.71 g) of deceleration or a jerk[6] beyond its limit, and it capped its own automated braking at that deceleration. Police determined that the vehicle could decelerate at an average of 0.92 g, about 9.0 m/s², on that road surface (National Transportation Safety Board 2019). The difference between a chosen permission limit and a physical one is the distinction the book's numbers keep throughout. The calculation stops short of a counterfactual stop, because the report does not establish when a different design would have begun braking. Detection,

[5] **Tracking-History Loss**: The NTSB record states only that a changed classification caused the predictor to omit the object's earlier locations; it does not describe a Kalman-filter reset or a zero-velocity initialization, so neither should be read into it (National Transportation Safety Board 2019). The consequence follows from the omission alone. Each relabeling shortened the evidence window from which motion is estimated, so an object crossing the lane began again, after each change, as one with no recorded history of crossing.



Recognition came seconds after detection; suppression then spent 18.7 m with the brake withheld.

correct path prediction, hazard recognition, and physical braking are distinct events; reporting the first detection time alone conceals the failures between them.

War Story 1.1: The disabled safety redundancy (2018)

Context: On March 18, 2018, a developmental ADS on a 2017 Volvo XC90 struck and killed a pedestrian crossing a road in Tempe, Arizona (National Transportation Safety Board 2019).

Mechanism: As traced above, classification changes discarded the object's tracking history, and the one-second suppression withheld braking until only a gradual slowdown was planned. The design did not use maximum braking solely to mitigate an unavoidable collision (National Transportation Safety Board 2019).

Impact: The vehicle struck and fatally injured the pedestrian. The late gradual-slowdown plan could not recover the lost stopping opportunity.

Response: The NTSB determined that the probable cause was the vehicle operator's failure to monitor the driving environment and the ADS because she was visually distracted throughout the trip by her personal cell phone. It found three contributing factors at Uber ATG, all a consequence of an inadequate safety culture: inadequate safety risk assessment procedures, ineffective oversight of vehicle operators, and a lack of adequate mechanisms for addressing operators' automation complacency. The impaired pedestrian's crossing outside a crosswalk and the Arizona Department of Transportation's insufficient oversight of automated vehicle testing also contributed. The NTSB further found that deactivating the Volvo collision warning and automatic emergency braking, which Uber ATG had done over possible radar interference, removed a layer of safety redundancy, and it recommended stronger safety risk management for testing automated vehicles (National Transportation Safety Board 2019).

Systems lesson: Classification uncertainty, a delayed response rule, and reliance on an inattentive operator can combine. The design made the operator the primary countermeasure in an emergency, yet no mechanism monitored her attention in real time: authority rested on evidence nobody collected. A design needs timely hazard assessment and a response that can mitigate impact when avoidance is no longer possible; the investigation does not prescribe a particular hardware architecture.

The investigation supports a broader architectural requirement. A developmental ADS needs safety redundancy and a timely mitigation path even when perception or path prediction fails, and simulation tests by Volvo that the NTSB cites suggest that the factory emergency braking might have prevented or mitigated this collision. The report does not establish when a separate permission path would have triggered or where it would have stopped the vehicle.[7]

Tempe illustrates failure *before* impact, where classification changes and a software suppression delay prevented timely braking. The 2023 Cruise robotaxi incident marks the opposite pole *after* impact. A hit-and-run driver's car threw a pedestrian into the path of the driverless vehicle, which braked hard but struck her and stopped. It then began a pullover toward a minimal-risk condition[8] and, because its sensing did not detect a person beneath the vehicle, moved about 20 ft (6.1 m) at up to 7.7 mph while she was pinned beneath it. This account comes from a review commissioned by the company's boards, whose focus was the company's disclosures to regulators (Quinn Emanuel Urquhart and Sullivan, LLP 2024).

Neither failure reduces to an inaccurate model. The first spent stopping distance before braking began, and no later action could recover it. The second chose motion after the impact without fresh evidence about the space it moved through. Together they show what must hold before the machine acts and what a fallback may do once harm has begun. Both also had to be reconstructed afterward from records of what the machine perceived and when, so accountability, like safety, depends on the path that authorizes motion.

6 **Jerk Limit**: Jerk, met in the stopping notebook as the rate of change of deceleration, is measured in m/s^3. A jerk limit makes a brake ramp its deceleration up instead of stepping it, which spares occupants, loads, and transmissions a shock but costs stopping distance, because full deceleration arrives later. The warehouse machine's card carries a jerk bound for the same reason, and the machine's finished stopping budget pays for the ramp.

↪ The stopping envelope, which charges every interval of delayed braking against the clear distance, is developed in section 12.3.

7 **Safety-Critical Standards**: Three standards divide the ground. ISO 26262 addresses hazards caused by faults in a vehicle's electrical and electronic systems (International Organization for Standardization 2018); ISO 21448, safety of the intended functionality (SOTIF), addresses hazards that arise when a function works as designed but performs insufficiently, as perception can (International Organization for Standardization 2022); and UL 4600 sets out the safety case for autonomous products with no human driver to fall back on (UL Standards & Engagement 2023). Tempe falls on the SOTIF side, since the recorded failures were in classification and path prediction rather than in a faulted component, and none of the three prescribes a processor architecture. Section 16.3.4 maps the standards that govern the running machine.

8 **Minimal-Risk Condition**: In automated driving, the stable, usually stopped, state a system brings a vehicle to when a trip cannot or should not continue. Reaching it can itself require motion, as a pullover to the curb does, and in the Cruise case that motion was the harm. A fallback trajectory therefore needs the same permission check as any other proposal, judged against fresh evidence about the space it will move through.

↪ The Cruise pullover, and the fallback rule that forbids renewed motion while the space beneath the vehicle is unverified, are developed in section 12.9.1.

↪ Who answered for the Cruise collision, and the decisions behind an admitted action that no per-tick log records, are developed in section 17.1.

Checkpoint 1.2: Forensics of boundary and authority failures

Verify how the Tempe mechanisms connect to the architecture:

- ☐ **Classification changes and path prediction**: Explain how classification changes caused the ADS path predictor to omit earlier object locations, despite continued tracking.
- ☐ **Software suppression vs. kinematic clearance**: Distinguish the $T - 1.2$ s recognition time from the one-second suppression period, and explain why the gradual-slowdown plan at $T - 0.2$ s could not restore the time already spent.
- ☐ **Safety redundancy**: Explain why disabling factory collision warning and emergency braking removed a layer of protection from a developmental ADS.

1.9 Where Safety, Security, and Accountability Meet

Tempe and Cruise both turned on what the machine knew when it moved or failed to brake, and both had to be reconstructed afterward from what it had recorded. The same three questions (whether the evidence behind a motion was sound, whether anything could refuse it, and whether the decision can be traced) also describe an attack and an audit. In enterprise software and distributed systems, safety, security, and accountability usually live in separate tiers. Security defends network boundaries with cryptographic tokens, reliability frameworks mitigate component failures through retries and circuit breakers, and accountability records transactions to append-only databases. In physical AI, all three converge on the causal boundary, the interface where software commands meet physical actuators. Consider the running machine crossing a warehouse aisle. It needs a valid stopping decision whether its forward cameras are obscured by dirt, an attacker has injected spoofed packets onto its internal Controller Area Network (CAN) bus, or a vision-language-action policy has hallucinated an unobstructed path. In each case the hazard is kinetic, a collision with racking or a worker. Because momentum cannot be rolled back like a failed database transaction, admission control cannot simply confirm who dispatched a command. It must determine whether executing that command now would violate the machine's physical limits.

An ordinary environmental change challenges this boundary as directly as an attack. The running machine's credible deceleration of 2 $\mathrm{m/s^2}$ rests on the premise, stated on its card, that the floor supplies a friction coefficient of at least 0.204. When the floor cannot supply the friction the brakes ask for, traction rather than the brakes caps deceleration, and braking distance grows in inverse proportion to the available friction. A film of spilled hydraulic fluid can drop tire-floor friction from about 0.60 on the aisle's dry concrete to 0.05 (an illustrative pair). A vehicle that brakes at the traction limit would see its braking distance grow by a factor of 12. The running machine asks far less of a dry floor than it supplies, but 0.05 falls below its premise. Its credible deceleration therefore no longer holds, and every clearance envelope and speed profile computed from that deceleration a moment earlier is invalid. The learned planner, processing camera streams that do not reveal the transparent slick, may continue to output an aggressive velocity command with high nominal confidence. Safety verification cannot treat the model's internal confidence as proof of physical feasibility. The machine needs independent, real-time evidence from the plant and its surroundings to detect the divergence. Such evidence includes wheel-slip telemetry, disagreement between commanded and inertial-measurement-unit (IMU) acceleration, and motor current transients. The machine can then restrict motion using a response feasible under the updated traction estimate. If the machine has already consumed the clearance that response needs, detection can support harm mitigation but cannot establish collision avoidance.

Security threats target this same permission machinery by corrupting the evidence used to authorize motion. An adversary does not need to crack cryptographic keys or modify model weights to destabilize a physical agent; distorting the sensory inputs that inform admission decisions is sufficient. Projecting structured light patterns onto camera lenses, spoofing ultra-wideband (UWB) localization beacons, or injecting rogue packets into sensor buses can deceive the controller into approving destructive commands, even while the neural network executes its inference pipeline without numerical fault. Isolating the proposer from the permission path offers little defense if both subsystems ingest the same corrupted telemetry. Securing the causal boundary therefore

requires validating the evidence itself. The validation consists of cross-checking heterogeneous sensor streams (for example, corroborating camera-based visual odometry against wheel encoders and inertial sensors), enforcing cryptographic message authentication across bus transceivers, and maintaining fail-operational plausibility checks that reject sensor readings deviating from physical conservation laws.

In digital systems, a cryptographic capability token or access control list entry grants authority to modify a file regardless of processor load or ambient conditions. In physical AI, **physical authority is state-dependent**. Cryptographic credentials establish identity and organizational rights to request an action, but physical admissibility depends entirely on the instantaneous operational state of the machine and its workspace. A joint velocity command of 2 rad/s may represent a routine transit when an industrial manipulator operates in open free space, yet that identical command becomes unacceptable if the arm is within 2 mm of a mechanical hard stop or a human coworker. Evaluating physical authority requires testing the proposed action against instantaneous kinematics, payload inertia, motor thermal headroom, and state estimation uncertainty. Admission control must also remain coupled to an executable fallback. If the permission gate rejects a proposed command because the machine approaches an operational boundary, the controller must immediately dispatch a dynamically feasible contingency maneuver, such as controlled regenerative braking or a compliant hold that yields to contact. The maneuver halts or redirects the plant without exceeding mechanical stress limits.

↪ A well-formed packet that carries a false measurement becomes a fault trial in the injection campaign developed in section 15.6.3.

Accountability demands an audit trail that reconstructs the causal chain connecting sensory evidence to physical outcomes. When an embodied machine causes a collision or near-miss, post-incident analysis requires timestamp and clock-conversion uncertainty small enough to distinguish the relevant sensing, admission, dispatch, and physical-response events across multiple data streams. These streams include the raw observations ingested by the planner and the action proposed by the learned policy. They also include the state estimates and dynamic constraints evaluated by the admission gate, the filtered command dispatched to the motor drives, and the measured response from joint encoders and force-torque sensors. Command logs record the intended trajectory, while sensor telemetry measures the plant's actual mechanical response. Recording dispatched setpoints alone does not confirm that an actuator executed them; an open-circuit fault, a tripped thermal breaker, or mechanical gearbox jamming will cause the physical plant to diverge immediately from commanded behavior. Both streams must be logged against synchronized hardware clocks (such as the IEEE 1588 Precision Time Protocol) so that investigators can distinguish between a planning failure, an admission gate error, and an electromechanical actuator breakdown. Reconstruction is necessary but does not by itself say who answers for an action. The decisions that set the machine's envelope, its staffing, and its permission to operate are made before any tick, and they have to be recorded on purpose (section 17.2).

Safety, security, and accountability ultimately converge on three unified demands at the permission path guarding the causal boundary:

↪ **Protocol:** The IEEE 1588 Precision Time Protocol exchange that aligns these clocks is developed in section C.7.

1. **Fresh, authenticated physical state**: The permission gate must operate on telemetry fresh enough to bound physical uncertainty and robust enough against tampering or degradation to justify admitting an action.
2. **Deterministic authority to intervene**: The admission mechanism needs uncompromised physical authority to veto or clamp infeasible proposals and inject safe contingency maneuvers, regardless of the learned model's internal confidence or identity.
3. **Synchronized causal telemetry**: The system must keep an immutable record of what was proposed, what state was evaluated, what commands were dispatched, and how the machine responded.

The incidents above map onto these demands. Tempe's predictor discarded evidence it already had, and the factory emergency braking that could have intervened independently had been disabled; Cruise moved without fresh evidence about the space beneath it. Both investigations then depended on the third demand, the recorded telemetry from which the events were reconstructed. The permission path is therefore where a physical machine's safety, security, and accountability obligations are discharged, and anchoring probabilistic proposals to checks against physical limits

is what lets learned capability operate within justified bounds. What those checks must respect, and why, is the subject of four laws.

↪ The operational log that survives physical failure, from which an investigator reconstructs each admitted action, is developed in section 14.7.

1.10 The Four Bedrock Laws

Every check on the permission path answers to constraints that neither a learned policy nor a software supervisor can negotiate away. Whether the warehouse machine is braking for a coworker in an aisle, pressing a spring-latched cage door, or carrying an unmodeled payload, it must respect the mechanical limits of its plant, adapt to dynamic environments altered by its own motion, and arbitrate between speculative model outputs and physically safe actuation. Four bedrock laws organize these engineering responsibilities, each anchoring a major part of this book:

1. **The first law: irreversibility.** Software cannot roll back physical consequences. In pure digital systems, an erroneous transaction can be aborted and state restored from a checkpoint. In physical space, however, work performed on a plant is thermodynamic and permanent. A motor command that collides with a fixture, tears a cable, or fractures a fragile payload cannot be retracted. Every admissibility check must therefore complete before the machine consumes its remaining clearance margin. As the stopping distance budget demonstrates, processing latency directly expends physical clearance, forcing the mechanical actuators to brake over an ever-shrinking distance. Reversing a drive voltage may eventually return an arm to its starting coordinates, but it cannot mend cracked structural material or recover energy lost to friction and heat. Part I translates this physical reality into kinetic budgets for the robot's body and deterministic timing constraints for its low-level controllers.
2. **The second law: endogenous data.** In classic offline machine learning, data samples are drawn independently from a stationary distribution. In embodied systems, data generation is endogenous. Every control action alters the physical state and determines what sensors will observe next. If an arm nudges an object during an approach, the object shifts; if a mobile base drifts off its nominal path, the subsequent visual frames deviate from the training demonstrations. Single-step prediction accuracy on an offline benchmark cannot guarantee closed-loop behavior, because minor execution errors compound across the task horizon, the covariate shift met with the closed causal loop (section 1.4.1). Part II frames data collection, model training, and policy evaluation as a continuous improvement cycle: diagnose behavioral failures, curate targeted recovery demonstrations, retrain candidate policies, and systematically evaluate both performance gains and unintended regressions. Empirical evidence from past rollouts bounds what can be claimed about present capability; only qualified new experience can expand that envelope.
3. **The third law: proposal is not permission.** A learned model operates only as a proposer, never as an unconstrained executor. An architecturally independent permission path (a runtime safety filter or an assurance monitor, for example) must arbitrate every proposed control command before that command reaches hardware actuators. Granting permission requires three prerequisites: fresh state estimates from verified sensors, an explicit check that the command respects every physical safety envelope, and an immediately executable fallback maneuver if the proposal is delayed, missing, or unsafe. This separation of authority must remain robust against system faults, so a runaway or stalled model thread must never be allowed to delay, starve, or corrupt the deterministic safety logic guarding the plant. Part III constructs the real-time execution runtime around this division between speculative proposal and independent, bounded permission.
4. **The fourth law: permission must be earned.** An embodied machine earns permission to operate only as far as empirical evidence supports its performance under stated conditions. Flawless execution across a handful of laboratory trials does not justify autonomy across diverse surface friction, variable payloads, degraded lighting, or sensor degradation. Every deployment safety case must explicitly demarcate the system's operational design domain (ODD),[9] articulate the environmental assumptions underlying those boundaries, and specify fail-safe degradation policies whenever runtime conditions drift beyond verified bounds. The 2018 Tempe collision showed the cost of ignoring this boundary. The system architecture relied on an in-vehicle safety operator as the primary emergency countermeasure, yet lacked any mechanism to monitor whether the operator was actually attending to the roadway

[9] **Operational Design Domain (ODD)**: The automated-driving term for the stated environmental and operating conditions (roadway types, speed ranges, weather, lighting) under which a system is designed to work, and the starting scope of a UL 4600 safety case (UL Standards & Engagement 2023). This book applies the concept to the payloads, surface friction, operating speeds, and disturbances covered by the machine's empirical testing. Operating outside that tested domain has no evidence behind it, which is why section 5.7.1 organizes the operating domain as an explicit scenario table against which collected training data are audited.

(National Transportation Safety Board 2019). Part IV formalizes command authority, fault injection testing, and release criteria so that epistemic and physical uncertainty bound what the machine is permitted to do.

Of these four, only the first is a physical law. Irreversibility follows from Newtonian mechanics and thermodynamics. Work performed on a plant transfers energy and raises entropy, and no software architecture can undo that transition. The remaining three are engineering design principles, distilled from decades of systems engineering, industrial robotics, and aerospace failures. A team could build an architecture that violates them, for example by piping unvalidated network outputs straight to motor amplifiers, but it would incur severe and predictable risks. The book elevates all four to bedrock laws because it treats them as mandatory constraints for any production embodied system.

None of these three architectural principles is entirely novel. Each has a rich foundation in computer systems, control theory, and safety-critical engineering. Table 1.3 maps this book's terminology to the established literature, alongside the canonical sources and documented real-world failures each principle distills, including the Tempe and Cruise incidents. Where the book's terms introduce tighter operational precision, as when tying state freshness directly to the dynamic stopping budget, the book retains specialized systems phrasing. When searching broader engineering literature, the classical terms serve as the standard index.

Table 1.3: Lineage of the four laws: Each law and key term of this book against the field's established name, its canonical source, and a documented failure it distills. Only the first law is physical; the other three are design principles, which is why each has an independent literature. Runtime assurance enters with the proposal boundary, and section 1.14 traces its lineage together with the safety filter and the assurance case.

Book's law or term	Kind	Established name in the field	Canonical source	Documented failure it distills
First law: irreversibility (the causal boundary)	Physical	Irreversible work on the plant; the reaction-plus-braking stopping budget	Mechanics; section 2.3	Tempe (2018): the one-second action suppression let the vehicle travel about 18.7 m with emergency braking withheld (National Transportation Safety Board 2019)
Second law: endogenous data	Design principle	Covariate shift; compounding error in imitation learning	Ross, Gordon, and Bagnell (Ross et al. 2011)	A learning result rather than an accident: a cloned policy's errors can compound with the task horizon (section 5.2)
Third law: proposal is not permission (proposal boundary, permission path)	Design principle	Runtime assurance and its Simplex architecture; safety filter	Sha (Sha 2001); Hsu, Hu, and Fisac (Hsu et al. 2024)	Therac-25: software took over protection that hardware interlocks had provided (Leveson and Turner 1993); Mars Pathfinder (1997): through priority inversion, lower-priority work delayed a deadline-critical bus task until the scheduler's completion check reset the computer (Reeves 1997)
Fresh evidence (an input to every permission check)	Design principle	Age of information	Kaul, Yates, and Gruteser (Kaul et al. 2012)	While not a pure staleness failure, Tempe (2018) shows the neighboring hazard of discarded evidence: each object reclassification dropped historical tracks, forcing path prediction to compute trajectories on truncated sensor history (National Transportation Safety Board 2019)
Fourth law: permission must be earned	Design principle	Assurance case; operational design domain (ODD)	UL 4600 (UL Standards & Engagement 2023)	Tempe (2018): the design made the operator the primary countermeasure in an emergency, yet nothing monitored her attention in real time (National Transportation Safety Board 2019); Cruise (2023): a post-collision pullover moved the vehicle without evidence that the space beneath it was clear, because its detection system did not identify the pedestrian there (Quinn Emanuel Urquhart and Sullivan, LLP 2024)

The proposal boundary is where all four laws meet in one architecture. Irreversibility requires that every check complete before a command alters the plant, and endogenous data prevents offline training metrics from certifying a proposer in the closed loop. For these reasons, the third law (proposal is not permission) places that check on an independent permission path that the model cannot delay or corrupt. The fourth law (permission must be earned) then confines admitted proposals to the operating conditions that empirical evidence has verified. Scaling up model capacity does not relax these constraints; on the contrary, it intensifies physical pressure on the system. Although general machine learning methods deliver superior performance as compute expands (Sutton 2019), the running mobile machine must supply its onboard compute within a finite electrical and thermal budget. Every additional neural layer, attention head, or diffusion step draws against fixed physical allocations of memory bandwidth, electrical power, and thermal dissipation. Inference latency on the stopping path is travel that braking cannot recover. On the running machine at its drive limit, each millisecond costs 1.5 mm of clearance, as the stopping notebook showed. This compute, thermal, and temporal ceiling forms the physical wall confronting every learned proposer.

↪ The memory-bandwidth and latency bottlenecks confronting onboard learned proposers are developed in section 3.4.

Finally, rejecting an inadmissible command must have an explicit physical realization. In traditional software, an unhandled exception or failed assertion can simply terminate a thread. On a moving robot, halting a software process leaves physical momentum untouched. A refusal is meaningful only if the execution runtime immediately dispatches an admissible fallback (a dynamic braking maneuver, a compliant hold, or a controlled stop) that the physical body can safely execute within its remaining stopping clearance. Translating the four laws and their runtime mechanisms into an engineered system takes the four parts of this book, each producing records that later parts rely on.

1.11 The Architecture of This Book

Moving a learned proposal, such as the running machine's trajectory to open a warehouse cage door, from an abstract task requirement to safe, justified physical operation requires a disciplined four-stage progression. The engineer must first bound what the hardware plant can physically achieve and characterize what the learned proposer has demonstrated under rigorous testing. The engineer must then build an isolated runtime monitor to intercept live proposals and establish the operational conditions under which continued execution remains justified. Each stage corresponds to one of the four laws. The system of records illustrated in figure 1.9 formalizes this progression, capturing operating assumptions and empirical evidence so that downstream runtime decisions can inspect and rely on them. Conceptually, these records trace two converging pipelines. One strand establishes offline physical limits and verified competence; the second processes online sensor observations and real-time candidate actions. Both pipelines converge at the permission decision, where the system admits or rejects a proposed trajectory. In section 18.1, this architecture synthesizes both strands to resolve the book's central challenge of engineering dependable, high-performance physical systems out of unverified learned models and unforgiving mechanical hardware.

A record is a machine-checkable artifact that downstream safety and runtime decisions can verify and trust. The initial stopping calculation (notebook 1.1) already sketches the first record in the chain: a limit record, with the six elements the reader guide introduces (nominal value, operating conditions, uncertainty, margin, runtime detector, and provenance). Its nominal value is the derived stopping distance under stated operating conditions of loaded payload mass, dry concrete, a stationary obstacle, and constant approach speed. Because those inputs are illustrative scalars rather than calibrated distributions, however, its uncertainty remains unquantified. The apparent buffer between the obstacle and the machine is therefore only an arithmetic difference between provisional figures rather than a verified safety margin. The calculation also lacks a runtime detector (no sensor yet monitors whether floor traction drops or cargo shifts outside the assumed envelope, section 2.7.3), and its provenance rests on baseline assumptions rather than calibrated hardware logs. An ungrounded calculation becomes operational engineering evidence only when all six fields are populated and backed by empirical data. Every numbered box across the four part bands in figure 1.9 establishes a machine-checkable record of this rigor for a distinct architectural decision.

Part I, The Machine Anatomy, translates physical irreversibility into rigid architectural limits. Chapter 2 profiles the mechanical plant to quantify its physical budgets (measurement freshness,

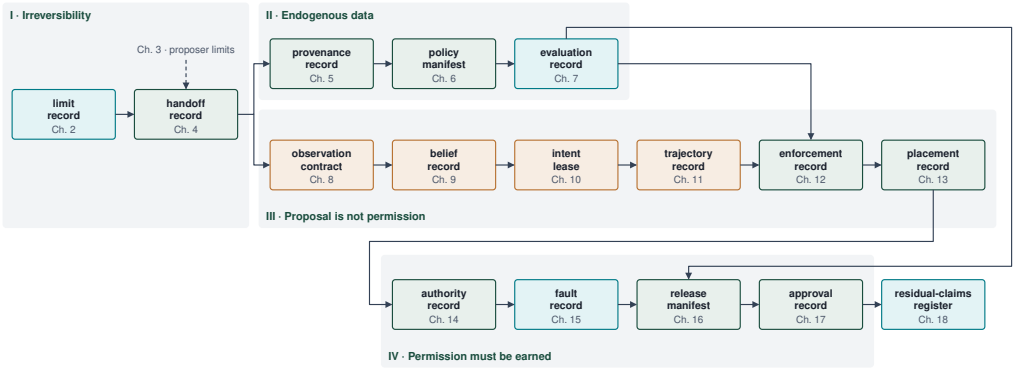


Figure 1.9: The spine of the book: Each part is led by one law, and each chapter of Parts I to IV except The Cognitive Brain (Chapter 3) produces a record that a later one consumes. What the plant can do and what the proposer has shown it can do run as one strand, what the proposer proposes now as another, and the two meet at the permission decision.

stopping distance, deliverable torque, winding heat, and supply voltage). Chapter 3 measures the throughput and inference latency of the learned proposer to determine what it can deliver before deadlines expire. Chapter 4 links compute to the actuators across deterministic buses, structuring a permission path whose timing guarantees derive from the plant's stopping requirements. Together, the limit record and handoff record make every physical and temporal assumption explicit. Part II, Teaching the Machine, confronts the reality that physical actions continuously alter future sensor observations. Chapter 5, chapter 6, and chapter 7 build the evidentiary chain required to collect demonstrations, train control policies, and bound policy performance to a declared operational design domain. Across this pipeline, the provenance record, policy manifest, and evaluation record document both the empirical competence demonstrated by the model and the operational boundaries where its statistical guarantees break down.

Part III, Running the Machine, enforces at runtime the separation between proposing an action and permitting it to execute. From chapter 8 through chapter 13, the chapters trace candidate commands through the online runtime. They qualify sensor measurements in observation contracts and maintain state estimates in a belief record. They bound a goal with an intent lease (a time-limited grant of a target, never of a path, and distinct from the chunk lease that bounds one motion segment). They check candidate trajectories against real-time physical constraints before admission and dispatch, then test whether the hardware keeps the permission path independent. Part IV, Governing the Machine, enforces the principle that permission must be earned. Chapter 14, chapter 15, and chapter 16 govern how authority transfers between the machine and a human operator, how fault injection tests whether protective responses hold, and how deployment decisions are assembled into release manifests. Chapter 17 then names who answers for each decision behind an admitted action. It also tests whether each human role the design relies on is one a person can perform, and it counts the people who bear the machine's risk and appear in its records. Finally, chapter 18 brings the framework to bear on an unfamiliar machine, synthesizing what an engineering team can construct and formally justify while identifying the residual risks that require further mitigation. Across these parts, the warehouse mobile manipulator introduced here provides a single concrete machine on which to ground each architectural decision. Its records render design assumptions fully inspectable, though an engineer must remember that assembling a record documents an explicit claim rather than guaranteeing its physical truth. The system record register in section C.14.2 catalogs all sixteen records, noting their producing chapters and the specific invariants they bind, while the machine card in section 1.4.2 specifies the foundational physical parameters of the robot itself. Together, this four-stage route forms a repeatable discipline for making learned behavior dependable in physical space, guarding against the common misconceptions that arise when digital assumptions are carried across the causal boundary.

1.12 Fallacies and Pitfalls

The misconceptions that follow arise when assumptions from pure software engineering, statistical learning, or classical control theory are imported into embodied machines. In digital systems, an erroneous state can typically be trapped, rolled back, or restarted. Across the causal boundary, however, software outputs become physical forces that alter the world irrevocably. Preventing physical harm requires hard deterministic guarantees that learning objectives, human operators, and asynchronous recovery routines cannot provide on their own.

Fallacy: *Safety constraints can be trained into the policy.*

Engineering teams often attempt to enforce physical safety by adding penalty terms, barrier penalties, or negative rewards to the training objective. While penalty shaping suppresses undesirable actions over the training distribution, it provides no mathematical guarantee on the actions emitted during deployment. Deep neural networks remain uncalibrated function approximators when exposed to out-of-distribution inputs, sensor degradation, or novel environmental dynamics. A statistical loss function optimizes expected performance, but safety requires hard invariants that hold on every control cycle. For this reason, deterministic safety enforcement must sit downstream of the policy, operating as an independent permission path that filters proposed commands before they reach actuator driver registers, exactly where the third law places the boundary gate.

Pitfall: *Treating human supervisory intervention as instantaneous in shared-autonomy systems.*

In shared-autonomy designs, such as a robotic surgical tool providing haptic guidance from a learned anatomical model, system designers sometimes treat the human operator as a failsafe catch-all. This assumption ignores the physiological limits of human reaction time, which ranges between 150 ms and 250 ms for simple tactile or visual reflexes and grows under cognitive load. Once console video and a handshake are added, the running machine's card budgets an in-loop takeover at 605 ms. Over that interval, an actuator running on a 1 kHz control loop can execute hundreds of unchecked cycles, generating enough force to tear soft tissue or damage a mechanical workpiece before the operator can intervene. Delegating authority to a human supervisor does not eliminate the machine's capacity for harm during the supervisory lag. The permission path must enforce local force, velocity, and displacement envelopes autonomously, preserving the established physical envelopes under their operating assumptions without relying on timely human overrides.

Pitfall: *Assuming software latency merely degrades performance gracefully.*

In purely digital systems, inference latency or scheduler jitter increases response time or degrades service quality. In physical systems, timing is a functional correctness requirement. If a learned policy stalls, whether from accelerator kernel contention, memory allocation pauses, or network serialization delays, allowing its previous command to persist across subsequent control cycles turns stale intent into physical danger. For example, a mobile manipulator that repeats its last forward-velocity command during a 100 ms inference hiccup can collide with an unmapped obstacle. Actuation commands must therefore carry bounded temporal validity, enforced by hardware or real-time software watchdogs. When that validity window (the chunk lease of the stopping budget) expires without a verified update, the low-level controller must begin a fallback within its established response budget. The selected stop or hold must remain feasible for the current mechanism, state, and surviving resources.

Fallacy: *Assuming physical actuation is reversible through subsequent software compensation.*

Transactional software architectures rely on rollbacks and compensation routines to undo erroneous operations. In embodied systems, thermodynamics and materials science break this equivalence. If a robotic arm applies excessive torque to a workpiece, issuing a reverse motor command cannot unbend plastically deformed metal, repair fractured composite, or recover the electrical energy dissipated as heat in the motor windings ($I^2_{\text{phase}} R_{\text{phase}}$). Anomaly detection routines that react after physical contact can only truncate ongoing damage; they cannot undo the mechanical work already transferred across the causal boundary. Preventive verification, such as checking proposed trajectories against workspace boundaries, torque limits, and kinetic energy caps before dispatch, must serve as the primary defense. Reactive recovery strategies remain necessary for unexpected

disturbances, but they function as a secondary backstop rather than a substitute for preventive enforcement.

1.13 Summary

Physical AI converges two historically distinct engineering disciplines: classical robotics and modern machine learning. As learned models move progressively closer to direct actuator control, the boundary between digital computation and physical reality sharpens at the causal boundary, the interface where an admitted command becomes an irreversible physical effect. In purely software systems, state rollbacks and retries can recover from algorithmic faults; in the physical world, software cannot undo kinetic energy, momentum, or impact. Safe recovery requires an executable, physically feasible countermeasure.

Physical dynamics also do not pause while neural networks compute. Because a machine continues to travel during sensing and processing delays, safety requires deterministic admission checks upstream of any consequential actuation. As the warehouse mobile manipulator's stopping budget and the Tempe collision show, prediction quality offers no protection once response delay has spent the clearance. The architecture resolves this tension by separating proposal from permission and giving an independent, bounded-latency permission path the authority to refuse. Four laws, one physical and three design principles, organize the framework the rest of the book develops, while the elementary stopping budget and its crossover speed form this chapter's quantitative core (table 1.4).

Table 1.4: Key equations of the causal boundary: The elementary stopping budget and its crossover speed, with the place each is derived.

Equation	What it bounds or decides	Derived
$d_{\text{stop}} = v\tau_{\text{delay}} + \frac{v^2}{2a_{\text{brake}}} \leq D_{\text{clear}}$	Whether a moving machine can stop within its observed clearance: distance traveled during response delay plus braking distance, prior to allowances added in later chapters	equation 1.1
$v^* = 2a_{\text{brake}}\tau_{\text{delay}}$	The crossover speed at which delay distance equals braking distance; below v^*, delay travel is larger, while above it, braking travel is larger	From equation 1.1, section 1.4.3

Key Takeaways: Engineering across the causal boundary

- **Useful behavior requires an integrated machine**: Physical AI combines learned decision-making, physical dynamics, and delegated mechanical authority. Delivering reliable autonomous operation requires co-designing task competence with physical body limits, real-time compute runtimes, and the operational evidence supporting deployment.
- **Response delay consumes physical margin**: The elementary stopping budget $d_{\text{stop}} = v\tau_{\text{delay}} + v^2/(2a_{\text{brake}}) \leq D_{\text{clear}}$ partitions stopping distance into latency-induced travel and mechanical braking. Below the crossover speed $v^* = 2a_{\text{brake}}\tau_{\text{delay}}$, response delay dominates stopping distance; above v^*, braking deceleration dominates. For the warehouse mobile manipulator at its drive limit, pre-braking travel adds 35.6 percent to braking distance. The decisive delay belongs to whichever path triggers the protective response, which can operate independently of the learned proposer's inference time.
- **Proposal and permission serve distinct architectural roles**: The learned proposer (the Brain) generates goal-directed actions, while an independent permission path admits, modifies, or rejects them before they cross the causal boundary. Safety enforcement relies on validated sensor inputs, physical kinematic envelopes, strict real-time deadlines, and verifiable fallback maneuvers.
- **Evidence governs safe operation and systematic refinement**: Four laws structure this book. Irreversibility is a physical law; the other three (endogenous data, proposal is not permission, and permission must be earned) are design principles that translate covariate

shift, runtime assurance, and the assurance case into systems practice. Together they link physical hardware, embodied learning, real-time execution, and operational governance, establishing verified service within defined operational envelopes while identifying the targeted evaluations needed to expand them.

Before judging whether a proposed action is right, an engineer should establish what physical response would remain if the proposal were wrong, stale, or never arrived, and whether the machine still holds the clearance, the time, and the authority to carry that response out. A design that cannot answer from its own measured limits has handed safety to prediction quality, and the stopping budget showed that prediction quality cannot buy back clearance once delay has spent it. The answer therefore starts from what the plant can do under stated conditions, never from what the model believes.

1.14 Historical Perspective and Further Reading

In physical artificial intelligence, moving learned models directly into the actuation loop creates severe timing and safety hazards. The engineering principles that resolve these challenges originate in embedded systems, real-time control, and safety engineering. General-purpose computing treats execution time as a mere performance optimization, assuming that correctness depends solely on logical input-output relationships. Cyber-physical systems theory overturned this assumption, holding that physical dynamics and computational processes must be modeled jointly because a command dispatched at the wrong time is physically incorrect (Lee 2008). This insight forms the foundation of the causal boundary. Similarly, separating command proposal from execution permission stems from runtime assurance architectures. The Simplex architecture demonstrated that an industrial control system could safely run an unverified, high-performance controller if paired with a certified baseline controller and deterministic switching logic capable of taking back the plant before safety boundaries were violated (Seto et al. 1998; Sha 2001). Modern safety filters in embodied machine learning generalize this design, validating neural network proposals against mathematical certificates of safe states (control barrier functions or reachability envelopes, which chapter 12 develops) before granting actuator permission (Hsu et al. 2024).

Many foundational safety principles in physical systems emerged from forensic investigations of catastrophic failures. The Therac-25 radiation therapy disasters demonstrated the fatal peril of replacing mechanical interlocks with software routines (Leveson and Turner 1993). When race conditions bypassed software checks, the machine administered lethal radiation overdoses, proving that software reliability does not imply system safety. Systems-theoretic safety subsequently recast accidents not as isolated component breakdowns, but as failures of the overall control structure to enforce safety constraints on the interactions among components, feedback loops, and human operators (Leveson 2011). This shift led directly to the assurance case, a structured argument demonstrating that concrete evidence satisfies defined safety claims within explicit operating environments (Kelly 1998). The UL 4600 standard adopted this structure as its central framework for autonomous products (UL Standards & Engagement 2023), abandoning arbitrary road-testing mileage in favor of verifiable, claim-based arguments. Public accident records, particularly the National Transportation Safety Board investigation of the 2018 Tempe autonomous vehicle collision (National Transportation Safety Board 2019), remain the field's most complete documentation of how safety arguments unravel when classification changes, a response delay chosen in software, and reliance on a human fallback interact in the field.

- **Cyber-physical systems** (Lee 2008). Lee articulates why classical computing abstractions fail when computation interacts with physical processes. General-purpose computer architectures deliberately abstract away time, treating execution speed as a performance consideration rather than a correctness specification. Lee demonstrates that for physical interactions, the timing of an actuation command is inseparable from its physical meaning, providing the conceptual foundation for treating the causal boundary as an explicit systems interface.
- **Runtime assurance** (Sha 2001). Sha's paper on the Simplex architecture is the place to see how the switching logic decides when to take the plant back from the unverified controller, and

why that logic must be simpler than what it supervises. It is the pattern behind this book's separation of proposal from permission.

- **Therac-25** (Leveson and Turner 1993). Leveson and Turner's forensic analysis traces the specific race conditions and the development and reporting practices that let the overdoses recur, detail the summary above omits. It remains the essential case study in why protective functions need justification independent of the software they supervise.
- **Systems-theoretic safety** (Leveson 2011). Leveson introduces the STAMP accident model, reframing safety as a continuous control problem rather than a collection of component failure probabilities. Accidents occur when the control structure fails to enforce safety constraints across component interactions, sensor delays, and feedback loops. This text provides the theoretical basis for enforcing safety invariants as dynamic runtime constraints rather than static design assumptions.
- **The Tempe investigation** (National Transportation Safety Board 2019). The National Transportation Safety Board report on the fatal 2018 Tempe autonomous vehicle crash offers the most thorough empirical record of an embodied AI safety failure. The report details how classification changes that discarded tracking history, a one-second action suppression meant to limit responses to false alarms, the separate deactivation of the vehicle's factory emergency braking over possible radar interference, and reliance on an operator whose attention nothing monitored combined in the collision. The event timeline and sensor telemetry provide vital reading for anyone building real-time perception-action loops.

What's Next: From the causal boundary to physical limits

A permission decision needs a physical limit against which to judge the proposed action. Chapter 2 begins Part I with the five budgets the permission path must check before it commits torque (measurement freshness, stopping distance, deliverable torque, winding heat, and supply voltage) and asks which binds first for a given maneuver, under what stress, and on what evidence. Each budget ends as a limit record, the six-element form this chapter sketched from its stopping calculation. Chapter 3 then examines the learned proposer's capabilities and timing, and chapter 4 uses both sets of constraints to design the handoff and independent permission path. The progression starts with what the machine can sustain and ends with how computation may safely request it.

1

The Machine Anatomy

Every physical AI system acts through a body with limited capacity to move, stop, exert force, and dissipate heat. The first law of section 1.10 holds that this apparatus cannot take back the work it delivers, and Part I turns that law into numbers. It asks how quickly the machine's evidence ages, how far the machine travels before it stops, how much torque its drives can deliver, and how much winding heat and supply-voltage drop they tolerate. The Body establishes what motion the hardware can physically support. The Brain, the learned proposer, establishes what computation can supply and how long its answers stay true. The Nervous System must therefore connect them within the time the stopping budget allows. Following this physical order lets the engineer derive an architectural requirement before selecting its implementation.

Principle 1: The irreversibility law

Invariant: Once a permitted command crosses the causal boundary, the energy it delivers becomes motion, strain, or heat that no software action can recall. At steady speed, during a pre-brake delay τ_{delay} the machine travels $v\,\tau_{\text{delay}}$ before any response begins. A stop therefore requires $d_{\text{stop}} \leq D_{\text{clear}}$, with every term of d_{stop} taken from a measured limit of this machine under stated conditions (section 2.3).

Implication: Each part of the machine carries budgets in time, distance, torque, heat, and voltage. The checks needed to admit a command must finish before its execution and inside those budgets. A design is admissible only when it can say which budget binds first, how that budget was established, and what the machine does when it is exhausted.

- **The Physical Body (chapter 2):** Decides which physical budget binds first and how its value was established, and produces the limit record from which every later record descends.
- **The Cognitive Brain (chapter 3):** Decides what a learned proposer can deliver on time and what memory and latency that costs, and derives the machine's two-speed split, a slow intent model above a fast chunk policy. It produces no record of its own; its proposer limits, and the payload every proposal must carry, enter the handoff record.
- **The Nervous System (chapter 4):** Decides where the permission path must run to stay independent of the proposer, how often it must check, and how long a proposal may drive the actuators. It produces the handoff record together with the header that every proposal carries. The independence it requires leads it to adopt a two-processor split as the hypothesis the machine is built on; whether that split holds on real silicon is decided in chapter 13.

Part I hands forward three linked artifacts across these chapters. On the physical side, chapter 2 establishes the limit record, the six-element form in which every budget that can end in damage states its operating conditions and its evidence category. The chapter then fills that form on the running machine for the credible deceleration behind the stopping distance, the drive torque that must deliver it, and the input lockout of the converter on the shared drive bus. Against those physical bounds, chapter 3 characterizes the proposer's supply by pricing how many future setpoints one chunk covers, how long a new chunk takes, and how quickly the evidence behind it ages, showing why a chunk keeps the arm supplied without keeping that evidence fresh. Joining demand and supply, chapter 4 produces the handoff record: the lease the permission path derives from the stopping budget, the tick at which it checks, the handoffs between proposer and permission path,

and a worked budget that couples all three chapters on the running machine. That worked example selects a candidate configuration. Qualification still requires bounds on each interval, including dispatch to admission, evidence that the protective response remains physically available, and loaded tests showing that the permission path's isolation from the proposer holds. Part II inherits both records as preconditions on the demonstrations the machine collects while its permission path is watching.

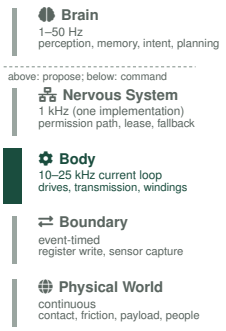
Purpose

Why can a correctly chosen action still demand more than the machine's body can deliver?

A mobile manipulator can recognize an obstacle correctly and still strike it if its body cannot stop within the remaining distance. The same machine can hold a payload without moving while its motor windings overheat, or lose its controller when a sudden demand for current pulls the supply voltage too low. These failures arise from limits that prediction accuracy alone cannot reveal. Physical AI engineering requires connecting a proposed action to the motion, heat, and electrical demand it creates, then establishing which limit the assembled machine reaches first. Measurements must also establish the conditions under which those limits hold, because a change in payload, floor surface, cooling, or battery state changes what the machine can deliver. The body's limits therefore govern what the permission path may admit before a command crosses the causal boundary and produces irreversible physical work.



Learning Objectives

- Calculate observation freshness limits from measurement age and the machine's allowable motion
- Calculate stopping distance and the admissible speed ceiling from pre-brake delay, credible deceleration, and clearance overheads
- Evaluate actuator and transmission choices against response limits, reflected inertia, and mechanical impedance
- Estimate sustainable motor duty cycles from heat generation, cooling, and operating conditions
- Budget electrical supply margins for simultaneous actuation, computation, and regenerative braking
- Specify the elements of a limit record that states a measured limit's conditions, uncertainty, margin, runtime detector, and evidence category
- Evaluate maneuver-specific binding budgets from qualified evidence and justify holding up the permission supply through covered faults

2.1 The Five Physical Budgets

Every action a learned model proposes ultimately manifests as electrical current flowing through a motor winding, and from that instant physics governs execution. Machine learning practice rarely contends with this transition. Policies trained in simulation typically interact with idealized plants where commanded torque appears instantaneously, heat never accumulates in windings, and direct current (DC) bus voltages never sag under load. A physical machine honors none of these simplifications. The **physical body** is the coupled assembly of actuators, mechanical transmissions, structural linkages, power electronics, and sensors that translates digital commands into mechanical motion. Its physical dynamics bound what even a mathematically optimal policy can achieve. An emergency brake command requires finite time to develop mechanical retarding force and clearance distance to dissipate kinetic energy. Similarly, commanding a manipulator to hold a heavy payload motionless draws continuous phase current, dissipating resistive heat into the stator even though the joint does zero mechanical work.

The proposal boundary in section 1.7 assigns the permission path responsibility for admitting action, and the body provides the concrete physical envelopes that make that gating decision meaningful. Before committing a command to hardware registers, the permission path must evaluate five physical budgets. It must confirm that the sensor observation remains fresh, that the moving machine can stop within available clearance, that the actuator can deliver the required torque trajectory, that the winding can tolerate the resulting thermal rise, and that the electrical bus can support the transient current demand. These mechanisms form a direct causal chain. Sensor and pipeline latencies consume allowable stopping distance. Arresting momentum demands delivered actuator torque. Generating that torque dissipates heat in motor coils and pulls current from a shared power rail. For any given maneuver, the governing systems question is which of these physical budgets binds first, under what operational stress, and on what empirical evidence.

1. **Measurement freshness** (t_{age}): The observation must remain valid until the mechanical plant responds. Latency accumulated across sensor exposure, data transport, neural inference, and low-level drive dispatch consumes allowable tracking margins as the physical world continues to move.
2. **Kinetic momentum** (E_k, p): A moving machine carries kinetic energy ($E_k = \frac{1}{2}mv^2$) and linear or angular momentum ($p = mv$). Bringing the plant to rest demands applying retarding force over finite distance and time; safe operating velocity must therefore preserve a stopping envelope well within available physical clearance.
3. **Actuator bandwidth and reflected inertia** ($N_{\text{gear}}^2 J_{\text{rotor}}$): Winding inductance and supply voltage limit the rate at which torque can change. A gearhead with reduction ratio N_{gear} multiplies

delivered torque by N_{gear}, but it also scales the motor rotor's inertia J_{rotor} by N_{gear}^2 as seen at the joint output (section 2.4.3), which constrains instantaneous acceleration.

4. **Thermal capacity** ($\hat{T}_{\text{wind}}$): Resistive losses ($P_{\text{loss}} = i_q^2 R_{\text{eff}}$, with R_{eff} the winding's effective loss resistance) deposit thermal energy directly into the stator windings and inverter switching stages. Heat dissipation limits sustained continuous torque, while the thermal mass of the coils constrains the magnitude, duration, and repetition rate of transient torque bursts.
5. **Electrical power integrity** (V_{rail}): Onboard compute clusters and motor inverters draw from a shared DC power rail. Peak motor accelerations must not drag the bus voltage below digital logic thresholds, while regenerative braking must provide an electrical sink so returned kinetic energy does not overvoltage the bus.

Under the **simultaneous admission invariant**, motion permission requires a non-negative margin in every budget before the permission path commits torque to hardware registers. Each margin must be checked in its own units; time, distance, torque, temperature, and voltage are separate constraints, not interchangeable quantities:

$$
\begin{aligned}
t_{\text{age}} &\leq \Delta t_{\text{fresh}}, \\
d_{\text{stop}} &\leq D_{\text{clear}}, \\
|\tau| &\leq \tau_{\text{out,max}}, \\
\hat{T}_{\text{wind}} &\leq T_{\text{limit}}, \\
V_{\text{rail,min}} &\geq V_{\text{uvlo}}.
\end{aligned}
$$

Here τ is requested torque and $\tau_{\text{out,max}}$ is the maximum deliverable output torque under current electrical and thermal conditions. The estimated winding temperature $\hat{T}_{\text{wind}}$ must remain below its limit, while the lowest rail voltage $V_{\text{rail,min}}$ must remain above the undervoltage-lockout threshold V_{uvlo} at which the supply regulator shuts down. The fifth line checks only undervoltage. Permission must also require regenerative braking to stay below the qualified upper operating-voltage limit of the supplied components, with an available absorption or dissipation path. Two lines state their budgets in derived form. The kinetic budget appears as the stopping distance it demands, $d_{\text{stop}} \leq D_{\text{clear}}$. The actuator line checks only torque magnitude, because the slew-rate limit that winding inductance and reflected inertia impose enters the stopping line instead, through the brake-onset term of the pre-brake delay τ_{delay}. All five inequalities must hold simultaneously. A surplus in four budgets cannot compensate for a deficit in the fifth. A fresh observation cannot prevent a stop from overrunning if kinetic energy exceeds available clearance, and abundant battery energy cannot prevent an actuator from burning out if thermal dissipation limits are violated.

> Systems Perspective 2.1: Why physical limits bound physical AI architecture
>
> The permission path requires concrete bounds on physical behavior, not abstract software promises. Accepting a torque command does not guarantee that the inverter can deliver the requested current against the back electromotive force (back-EMF) the spinning motor induces in its own windings, nor does cutting motor power guarantee that friction will arrest the plant before it breaches a clearance zone. The five physical budgets bridge this gap, tying software proposals to verifiable, empirical responses under declared operating conditions.

The warehouse mobile manipulator that this book follows draws on all five. Loaded to at most 368 kg and moving at its 1.5 m/s drive limit (illustrative; see the Reader Guide), it carries 414 J of kinetic energy through aisles it shares with people. Each budget establishes an empirical operating boundary on the assembled machine under declared thermal and electrical stress. Each ends the chapter as a limit record, the six-element record that section 1.11 sketched from the stopping notebook: a value, the conditions under which it holds, its uncertainty, the margin defended, a runtime detector, and the provenance of its evidence. The first budget is the age of the measurement on which every command rests, which runs from physical transduction, well before any software process receives the raw sensor data.

2.2 Measurement Freshness

Software benchmarks in machine learning frequently report latency as isolated accelerator execution time, for example 18.5 ms for the vision backbone of the arm's wrist-camera grasp path on an edge neural processing unit (NPU), a different pipeline from the navigation backbone that the stopping budget of section 1.4.3 charges. This narrow focus fosters the illusion of an agile 54.1 Hz control loop. In physical AI systems, however, that compute kernel represents only one intermediate segment in an end-to-end silicon-to-plant dataflow pipeline. A sensor measurement begins decaying the moment physical transduction occurs; what governs physical performance is its total age when torque actually appears at the actuator joint. That physical age spans the entire interval from the moment photons strike a photodiode array, magnetic flux sweeps past a Hall sensor, or strain deflects a piezoresistor to the moment motor inverter switches build stator magnetic flux that alters link acceleration. If a perception policy evaluates an obstacle bounding box in 18.5 ms, while exposure integration, sensor readout, Peripheral Component Interconnect Express (PCIe) transport, kernel scheduling, fieldbus dispatch, and motor current rise consume an additional 16.5 ms at the median, the true physical age of the observation when the joint accelerates is 35 ms. The distribution tail extends farther still.

Throughout that capture-to-onset window, the physical environment continues to evolve unobserved. In distributed data systems, read-after-write consistency windows govern whether a client observes stale or linearized state. In physical AI, the physical plant acts as an autonomous, unpausable concurrent writer: spatial position $\mathbf{p}(t)$ evolves along continuous trajectories at velocity $\mathbf{v}(t)$. An observation age t_{age} converts directly into unobserved physical displacement $\Delta\mathbf{p} \approx \int_0^{t_{\text{age}}} \mathbf{v}(t)\,dt$. High-speed machines inevitably act on historical state.

The rate of world-state change dictates how long a measurement remains valid before acting on it introduces intolerable error. Let $e_{\max}$ denote the maximum acceptable error in a tracked state, such as a joint angle or the position of a part on a conveyor, and let $v_{\max}$ denote the fastest credible velocity at which that state can evolve. The freshness deadline Δt_{fresh} is the upper bound on measurement age before a control action based on that measurement becomes invalid, defined by the inequality

$$\Delta t_{\text{fresh}} \leq \frac{e_{\max}}{v_{\max}} \tag{2.1}$$

Definition 2.1: Freshness deadline

Freshness deadline (Δt_{fresh}) is the largest age, counted from the capture of a measurement to the onset of the actuator's response, that the measurement of a moving target may reach before the target's motion alone spends the allowable position error $e_{\max}$ (equation 2.1).

1. **Significance**: It converts a spatial tolerance into a time budget that every stage from exposure to torque onset must share. A 12 mm tolerance on a target moving at 0.20 m/s leaves 60 ms for sensing, inference, transport, and current rise together.
2. **Distinction**: Unlike an inference-latency budget, which times one stage, the deadline bounds the age at onset; unlike a control-loop period, it is set by the target's speed and the tolerance rather than by the loop rate. When the machine moves toward a stationary obstacle instead, the same age becomes the first term of the pre-brake delay τ_{delay} and is paid as blind travel $v\tau_{\text{delay}}$ in the stopping distance.
3. **Common pitfall**: Treating the deadline as a property of the sensor or the model. It changes whenever the target moves faster or the tolerance shrinks, so a pipeline qualified on a slow conveyor can miss on a faster one without any change in its own timing.

↪ The same deadline applied to a stored belief, which lapses once its region falls out of view, is developed in section 9.7.

The running machine meets this bound at its pick station, where the arm grasps a mug from a moving conveyor. The belt carries the mug at speeds up to $v_{\text{conv}} = 0.20$ m/s, and the gripper mechanism tolerates $r_{\text{tol}} = 15$ mm of position error. Initial handle-pose estimation already consumes $e_0 = 3$ mm of this margin. Consequently, the mug's physical motion may spend at most $e_{\max} = r_{\text{tol}} - e_0 = 12$ mm, with $v_{\max} = v_{\text{conv}}$. Notebook 2.1 evaluates this resulting deadline against the ages

an integrated camera-to-joint pipeline delivers in practice. The deadline governs any target that moves while its observation ages. For moving workpieces, it limits motion-induced tracking drift under bounded relative velocity and valid initial observations. Sensing and state-estimation noise consume separate slices of the tolerance budget, just as e_0 does here. Conversely, when the robot approaches a stationary obstacle, such as a person standing in a warehouse aisle, the target does not move. Instead, the mobile base drives toward the person during the latency interval. Observation age then converts directly into unguided vehicular travel before braking begins, which section 2.3 charges against the kinetic stopping envelope.

2.2.1 Transduction physics, quantization noise, and Nyquist limits

If a 12-bit magnetic encoder jumps by a single count between two 1 ms servo ticks, backward differencing reports a sudden 88°/s velocity spike. If an unshielded cooling fan vibrates an inertial unit above half its sampling rate, the vibration folds into the low-frequency band and looks like chassis acceleration. Every sensor trades error tolerance against time: it must resolve the physical state of interest, and the analog filtering, sampling, or serial scanning needed to extract a clean signal must fit inside the freshness deadline. Four physical mechanisms set this trade:

1. **Optical Encoders and Velocity Quantization Noise:** An encoder measures joint position in discrete angular increments. An n-bit encoder discretizes the continuous 2π rad circle into an angular resolution of $\delta\theta_{\text{enc}} = \frac{2\pi}{2^n}$. For an 18-bit absolute optical encoder, $\delta\theta_{\text{enc}} \approx 2.4 \times 10^{-5}$ rad (0.0014°); for a 12-bit magnetic encoder, $\delta\theta_{\text{enc}} \approx 1.53 \times 10^{-3}$ rad (0.088°). Feedback controllers, which compute each command from the measured difference between the desired and the actual state, estimate joint velocity from successive position samples across a discrete control cycle Δt:

   $$\dot{\theta}_{\text{enc}_k} \approx \frac{\theta_{\text{enc}_k} - \theta_{\text{enc}_{k-1}}}{\Delta t}$$

   Backward differencing acts as an effective high-pass filter, scaling high-frequency position fluctuations by $1/\Delta t$. Under an idealized model where successive quantization errors are independent and uniformly distributed across one encoder count, each sample has variance $(\delta\theta_{\text{enc}})^2/12$. Differencing two independent samples sums their variances to $(\delta\theta_{\text{enc}})^2/6$, yielding a velocity-error standard deviation of $\sigma_{\dot{\theta}_{\text{enc}}} = \frac{\delta\theta_{\text{enc}}}{\sqrt{6}\,\Delta t}$. At a 1 kHz servo update rate ($\Delta t = 1$ ms), a single-count jump on a 12-bit encoder (1.53 mrad) registers as an abrupt velocity spike of 1.53 rad/s (88°/s). If routed directly into velocity feedback loops or neural policy state inputs, these discrete impulses cause severe torque chatter and excite mechanical resonances. Downstream low-pass filters or state observers (models that infer a quantity such as velocity from a stream of measurements) smooth this quantization noise, but filter group delay introduces phase lag, consuming milliseconds of the freshness budget.
2. **Inertial Measurement Units (IMUs) and Nyquist Aliasing:** An inertial measurement unit measures linear acceleration and angular velocity. Sampling must isolate macroscopic body dynamics from high-frequency structural vibration. Under the Nyquist-Shannon sampling theorem (Nyquist 1928; Shannon 1949), continuous signals require a sampling frequency strictly greater than twice their highest spectral component ($f_s > 2f_{\text{max}}$). Mechanical sources, including gear mesh harmonics, cooling fans, and motor inverter switching, generate vibrations reaching kilohertz frequencies. Without adequate analog anti-aliasing filters before the analog-to-digital converter (ADC), structural vibrations above the Nyquist frequency fold back into baseband frequencies (1–20 Hz). The state estimator, which combines sensor readings into an estimate of the machine's motion, cannot distinguish these aliased artifacts from genuine chassis acceleration, introducing cumulative drift into dead-reckoning integrations. Raising downstream software loop rates cannot reconstruct information already corrupted at the sensor hardware interface.
3. **Tactile Sensor Arrays and Scanning Bandwidth:** Tactile arrays measure contact pressure across a robot gripper using discrete sensing elements called taxels. To minimize cabling across robotic wrists, hardware architectures multiplex taxels across shared row and column lines. Scanning these elements sequentially forces an entire frame to span the multiplexing period. This serial scan time adds directly to the measurement age and limits the bandwidth

for detecting rapid contact events, such as the onset of localized slip. Increasing the taxel density without scaling the underlying ADC readout rate produces older tactile observations.

4. **Cameras and Rolling-Shutter Readout:** A rolling-shutter CMOS camera exposes and transfers pixel rows sequentially, so a single frame spans its entire readout duration. Image timestamps must therefore anchor to a defined reference, such as the exposure midpoint of a designated row, rather than the frame-arrival interrupt.

Across all four mechanisms, a measurement begins aging at physical transduction, milliseconds before any software driver receives a buffer. Bounding how much of the freshness deadline remains at actuation therefore requires tracing the signal across every stage between transduction and motor current.

↪ Rolling-shutter distortion on the navigation camera, and its compensation before images enter the state estimator, is developed in section 8.2.

2.2.2 The end-to-end sense-to-actuation latency pipeline

A measurement's physical age begins at **capture**, the moment of physical transduction, rather than when an operating system process first receives the data buffer. Three subsequent boundary events demarcate the pipeline from transduction to mechanical work. *Dispatch* is when perception publishes dated perceptual evidence to the action proposer. *Admission* is when the real-time permission path validates and accepts a proposal built using that evidence. *Onset* is when electrical current in the motor stator windings begins driving physical acceleration at the joint. The four events recur throughout the book, and table 4.1 later budgets the intervals between them for the running machine. For the freshness deadline, capture and onset form the bounding endpoints, and the deadline limits the cumulative delay between them.

An illustrative camera-to-joint pipeline reveals how latency compounds across physical and digital boundaries (table 2.1). Between capture and dispatch, the CMOS sensor integrates exposure and reads out raw scanlines over MIPI CSI-2.[1] Direct memory access (DMA) transfers the frame into host memory, and the vision backbone executes. In this representative architecture, the policy network executes in the same inference pass as the backbone, spanning the dispatch boundary. Between dispatch and admission, inter-process communication (IPC) transmits the proposed trajectory to the safety microcontroller, a dedicated real-time processor that executes the deterministic permission path. Between admission and onset, an EtherCAT fieldbus[2] delivers target setpoints to individual motor drives, where power-inverter gate drivers switch to ramp up stator current. Neural inference occupies one of the eight stages. Under memory bus contention and scheduling delays, the peripheral system stages expand the latency tail substantially more than the neural network execution itself.

Systems engineers sometimes estimate worst-case pipeline latency by summing the 99th-percentile (p99) latencies of individual stages. However, the percentile of a sum does not equal the sum of the percentiles.[3] In embedded system-on-chip (SoC) architectures, shared hardware resources couple stage delays. For example, PCIe DMA bursts during camera readout contend for memory-controller bandwidth with neural accelerators, while CPU cache evictions during kernel message passing induce thread scheduling jitter. The end-to-end distribution of sense-to-torque latency must therefore be profiled empirically on the integrated hardware platform under concurrent production workloads. Furthermore, an empirical percentile remains a statistical measurement; it does not replace the formal worst-case bounds required for hard real-time safety guarantees. Under continuous inference load, each stage in table 2.1 carries its own tail, and the two bottom rows separate the arithmetic column sums from the end-to-end age the system actually delivers.

Table 2.1: Illustrative sense-to-actuation latency decomposition: Stage and system-level timings show why the arithmetic sum of stage percentiles is not the end-to-end tail. The example's p99.9 of 68.4 ms exceeds the 60 ms freshness deadline of the mug on the pick-station conveyor, although its median fits.

Pipeline Stage	Physical Mechanism / Contention Source	p50 (ms)	p99 (ms)	Max (ms)
1–2. Sensor Exposure & Readout	60 Hz rolling shutter exposure midpoint	11.2	16.6	16.7
3–4. Host Transport & DMA	PCIe DMA transfer into host memory	1.4	3.2	6.8
5. Vision Backbone & Policy	Onboard accelerator inference (memory throttling tail)	18.5	24.1	38.4

[1] **MIPI CSI-2 (Camera Serial Interface 2)**: The Mobile Industry Processor Interface camera link carries raw frames from the image sensor to the system-on-chip and marks the start and end of each frame with short packets. Latching a hardware timestamp on the frame-start packet ties the frame to a fixed offset from its exposure rather than to the moment software first sees it, which is what lets transduction time, not arrival time, anchor the age budget.

[2] **EtherCAT**: An industrial Ethernet fieldbus in which one frame passes through every drive on the segment, each node reading and writing its own slice of the frame as it passes. Frame length and node count, not contention for the wire, fix the cycle time, which is why the fieldbus row of table 2.1 has equal p50 and p99. Section 4.5.3 sizes that cycle for the running machine.

[3] **Quantile Convolution**: In general, the quantile of a sum of delays does not equal the sum of their individual quantiles ($Q_p(X+Y) \neq Q_p(X) + Q_p(Y)$). Even when stages are independent, adding their p99 values is not a worst-case bound, and shared buses and queues correlate the stages so that the end-to-end tail must be measured across the whole pipeline.

Pipeline Stage	Physical Mechanism / Contention Source	p50 (ms)	p99 (ms)	Max (ms)
6. OS Scheduling & IPC	Kernel preemption and mailbox hand-off to safety microcontroller	0.6	2.1	12.3
7. Fieldbus Transmission	Deterministic EtherCAT cyclic packet exchange	1	1	2
8. Actuator Current Rise	Gate driver switching and stator flux buildup	2.3	3	4.5
Arithmetic Stage Sum	Sum of each column's stage values; not an end-to-end quantile	**35**	**50**	**80.7**
End-to-End Age	System-level profile, capture to onset; max bounded within the illustrative profile	**35**	**46.2**	$\leq$ **80.7**

The 50 ms sum of individual stage percentiles overstates the system-level p99 latency of 46.2 ms because pipeline stages rarely experience worst-case contention simultaneously. For the same reason, the sum of the stage maxima enters the end-to-end row only as an upper bound within the stated illustrative profile and conditions. A measured maximum needs a separately justified allowance or bound before it can support a hard real-time deadline. Coupling pushes the other way. Stages that slow down together, because they contend for the same memory controller or scheduler, fatten the end-to-end tail toward the stage sum, while stages that vary independently usually leave that sum pessimistic, as here. The end-to-end median in the table is set equal to the stage-median sum, a simplification of the illustrative profile that a measured one need not share. Notebook 2.1 evaluates how this illustrative profile behaves against the conveyor's physical deadline.

Napkin Math 2.1: The freshness deadline

Problem: The arm grasps a mug riding the pick-station conveyor, acting on camera observations of the handle. Suppose the grasp path had the illustrative age profile of table 2.1. Does it deliver those observations within the freshness deadline, and how far does the mug move at the median and at the tail of the observation age?

Variables:

- Grasp tolerance $r_{\text{tol}} = 15$ mm, of which the initial estimate spends $e_0 = 3$ mm (illustrative)
- Conveyor speed $v_{\max} = v_{\text{conv}} = 0.20$ m/s (illustrative)
- Median backbone time 18.5 ms, median end-to-end age 35 ms, and p99.9 age 68.4 ms (illustrative profile of table 2.1)

Math:

1. **Deadline**: $e_{\max} = r_{\text{tol}} - e_0 = 12$ mm, so $\Delta t_{\text{fresh}} = e_{\max}/v_{\max} = 12$ mm / 0.20 m/s $= 60$ ms (equation 2.1).
2. **Backbone alone**: 18.5 ms is less than 60 ms, so the one stage a benchmark times fits with room to spare.
3. **Median chain**: 0.20 m/s $\times$ 35 ms $= 7$ mm of mug travel, 5 mm inside the tolerance.
4. **Tail**: 0.20 m/s $\times$ 68.4 ms $= 13.7$ mm, 1.7 mm past the tolerance.

Result: Inference and the median chain both meet the deadline, but the stated p99.9 age exceeds it. The profile therefore does not establish that 99.9 percent of grasps meet the freshness deadline.

Systems insight: The whole path from exposure to torque onset spends the freshness deadline, not the model alone, and its tail, not its median, decides whether the grasp holds. When the machine instead drives toward a stationary obstacle, the same age enters the pre-brake delay τ_{delay} as its first term and is paid as blind travel $v\,\tau_{\text{delay}}$, the first term of the stopping distance that section 2.3 sets against the clear distance.

Excessive feedback delay can also degrade closed-loop tracking or destabilize motor control loops,[4]

[4] **Transport Delay and Feedback Stability**: Transport delay makes a controller act on historical state. Whether delayed corrections destabilize the loop depends on the plant, controller, and total response. Section B.5.5 develops the phase-margin calculation; delay alone does not establish a particular oscillation or damage outcome.

but the freshness calculation requires no frequency-domain model: at the latency tail, the mug has already moved beyond mechanical capture tolerance. System architectures must therefore preserve the observation's true physical capture timestamp. Hardware timers synchronized through **IEEE 802.1AS**, the generalized Precision Time Protocol (gPTP),[5] or hardware capture strobes associated with the MIPI CSI-2 receiver provide a common physical timebase. The sensor's exposure and readout characteristics determine how that hardware timestamp maps to the measurement midpoint. Once latched, this capture timestamp accompanies the observation through every subsequent compute kernel.

At the admission boundary, the real-time permission path computes the observation's total elapsed age, $t_{\text{age}} = t_{\text{current}} - t_{\text{transduction}}$, and adds the bounded remaining admission-to-onset interval for fieldbus dispatch and motor current rise. Capture and clock-synchronization uncertainty must also fit the qualified age budget. The permission path rejects the proposed trajectory update if its projected onset age exceeds the freshness deadline. Rejecting a stale trajectory replacement does not require cutting motor torque immediately; an executing command may continue while its qualified physical margin remains valid. If that margin expires before fresh, valid observations arrive, the permission path triggers a qualified fallback maneuver within the remaining stopping distance (Brooks 1986).

[5] **IEEE 802.1AS (gPTP)**: The generalized Precision Time Protocol of IEEE 802.1AS is a profile of the IEEE 1588 Precision Time Protocol (IEEE 2020a) for time-sensitive Ethernet networks (IEEE 2020b). It synchronizes clocks by exchanging packets timestamped in hardware at the network interface, which keeps the operating-system scheduler's jitter out of the measurement. The age $t_{\text{age}} = t_{\text{current}} - t_{\text{transduction}}$ means something only when the camera, the host, and the drives read one timebase; an offset between their clocks enters the freshness budget as an error that no timestamp reveals.

> **Systems Perspective 2.2: The publish timestamp anti-pattern**
>
> A widespread architectural bug in robotics systems is timestamping sensor observations inside user-space publishers, such as a Robot Operating System 2 (ROS 2) node transmitting over Data Distribution Service (DDS) middleware. Latching timestamps in application software discards the duration of sensor exposure, rolling-shutter integration, sensor readout, DMA transfers, and kernel queueing. The latency budget therefore loses stages 1 through 4 of table 2.1 (exposure, readout, transport, and DMA), along with any kernel queueing before the publisher runs. Hardware strobes must latch timestamps directly at the physical silicon interface (such as MIPI CSI-2 Start-of-Frame interrupts or Ethernet physical-layer transceiver timestamps synchronized via IEEE 802.1AS) before data enters operating-system queues.

Bounding measurement age ensures that control policies act on valid observations rather than historical artifacts, but freshness alone cannot guarantee collision avoidance. Throughout that capture-to-onset interval, the body continues moving under unguided momentum, consuming physical clearance before braking can begin. Halting that physical mass requires dissipating its stored kinetic energy across real distance, an irreversible mechanical process governed by momentum rather than processor clock rates.

2.3 Kinetic Momentum

When the loaded mobile manipulator drives down a warehouse aisle at its 1.5 m/s drive limit and a pedestrian steps out from behind a rack 1.10 m ahead, the capture-to-onset age from section 2.2 becomes unguided travel toward the pedestrian. Even after the brake command arrives, halting the base is not instantaneous: the moving chassis carries linear momentum ($p = mv$) and stores kinetic energy ($E_k = \frac{1}{2}mv^2$) that must be dissipated across real space through mechanical work ($W = \int F\,dx$). Stopping distance grows linearly with pre-brake delay but quadratically with velocity, so above the crossover speed of the elementary stopping budget, the braking term rather than the delay dominates the stop.

2.3.1 Kinematic stopping distance and pre-brake delay

As in the elementary stopping budget, a stop divides into two phases, pre-brake delay and active braking. During the pre-brake delay τ_{delay}, the vehicle travels forward without any retarding force. This latency accounts for the age of the sensory observation when perception hands it downstream, followed by the communication transit, safety validation, and actuator-onset intervals required before mechanical braking begins. It excludes the dispatch-to-admission interval, in which the proposer and the permission path turn that observation into an admitted command, because section 12.3.1 charges that interval separately. An independent protective response need not wait for a motion

planning proposal; safety enforcement can trigger immediately along a fast-path monitor. The safety budget must trace whichever concrete execution path initiates braking. Furthermore, if an obstacle can enter the path between sensing cycles, the budget must include an allowance for camera exposure and sampling intervals. The budget conservatively credits zero retarding force during this total pre-brake delay and assumes approximately constant forward speed v, which gives the blind travel distance

$$d_{\text{blind}} = v\,\tau_{\text{delay}}$$

Once the selected braking mechanism engages, the system enters the active braking phase. Mechanical work done by the retarding braking force F_{brake} over the physical braking distance d_{brake} must dissipate the machine's stored kinetic energy, $W = \Delta E_k$. How that retarding force arises depends on the physical hardware. A powered motor stop requires functioning drive inverters, sufficient bus-voltage headroom, and a circuit capable of absorbing or dissipating returned electrical power. A mechanical brake, by contrast, operates independently of electrical power but carries distinct engagement latencies and thermal dissipation limits. In any safety certification, the credible deceleration must reflect the specific mechanism available during the fault scenario under analysis.

↩ The two-phase stopping budget is established in section 1.4.3.

In an embodied machine, stored kinetic energy includes rotating powertrain components as well as the translating chassis. A component spinning at angular velocity ω stores rotational energy $\frac{1}{2}J\omega^2$, where its moment of inertia J (in $\text{kg}\cdot\text{m}^2$) measures resistance to rotational acceleration. It plays the same role that mass plays in translational energy $\frac{1}{2}mv^2$. A transmission with **gear ratio** N_{gear} turns the motor shaft N_{gear} times for every revolution of the wheel, multiplying motor torque by N_{gear} while dividing speed by N_{gear}. The machine's total kinetic energy sums the translational energy of the chassis and payload ($E_{k,\text{trans}} = \frac{1}{2}mv^2$) and the rotational energy of its wheels, gearboxes, and motor rotors ($E_{k,\text{rot}} = \sum_i \frac{1}{2}J_{\text{rotor}_i}{\omega_{m_i}}^2$). Because a drive with gear ratio N_{gear_i} spins its rotor at angular speed $\omega_{m_i} = N_{\text{gear}_i}\frac{v}{r}$, the rotor's rotational kinetic energy reflects into the translational frame scaled by the square of the gear ratio:

$$E_{k,\text{total}} = \frac{1}{2}mv^2 + \sum_i \frac{1}{2}J_{\text{rotor}_i}\left(N_{\text{gear}_i}\frac{v}{r}\right)^2 = \frac{1}{2}\left(m + \sum_i \frac{{N_{\text{gear}_i}}^2 J_{\text{rotor}_i}}{r^2}\right)v^2$$

This formulation reveals that the effective translational inertia of the machine is $m_{\text{eff}} = m + \sum_i \frac{{N_{\text{gear}_i}}^2 J_{\text{rotor}_i}}{r^2}$. For a platform decelerating to rest under sustained retarding force $F_{\text{brake}} = m_{\text{eff}}a_{\text{brake}}$, the work-energy theorem balances mechanical work against total kinetic energy:

$$m_{\text{eff}}a_{\text{brake}}d_{\text{brake}} = \frac{1}{2}m_{\text{eff}}v^2$$

Dividing both sides by effective mass yields the kinematic braking travel:

$$d_{\text{brake}} = \frac{v^2}{2a_{\text{brake}}}$$

If an engineer evaluates braking capacity using bare chassis mass alone ($a_{\text{nominal}} = F_{\text{brake}}/m$), they omit the kinetic energy stored in the spinning motor rotors. The result overestimates deceleration by the factor m_{eff}/m and underestimates stopping travel by $\frac{m_{\text{eff}}-m}{m} = \sum_i \frac{{N_{\text{gear}_i}}^2 J_{\text{rotor}_i}}{mr^2}$. On the running machine, this correction remains modest. Its two driven wheels use direct-drive hub motors ($N_{\text{gear}_i} = 1$), and because no portion of a hub motor lies outside its tire circumference, each rotor term J_{rotor_i}/r^2 cannot exceed the motor's 9.5 kg total mass. The rotating parts add at most 5.2 percent to the 368 kg loaded mass. However, because the inertia reflection scales with ${N_{\text{gear}_i}}^2$, this rotational overhead becomes substantial on lightweight robot platforms driven through high-ratio planetary or harmonic gearboxes.

The parameter a_{brake} is the credible sustained deceleration the physical plant can reliably exert against the environment, not an idealized rating copied from an actuator datasheet. The retarding force $F_{\text{brake}} = m_{\text{eff}}a_{\text{brake}}$ must fit beneath three independent physical ceilings. First, tire-floor traction imposes a strict friction ceiling. Only the braked wheels transmit retarding shear to the ground,

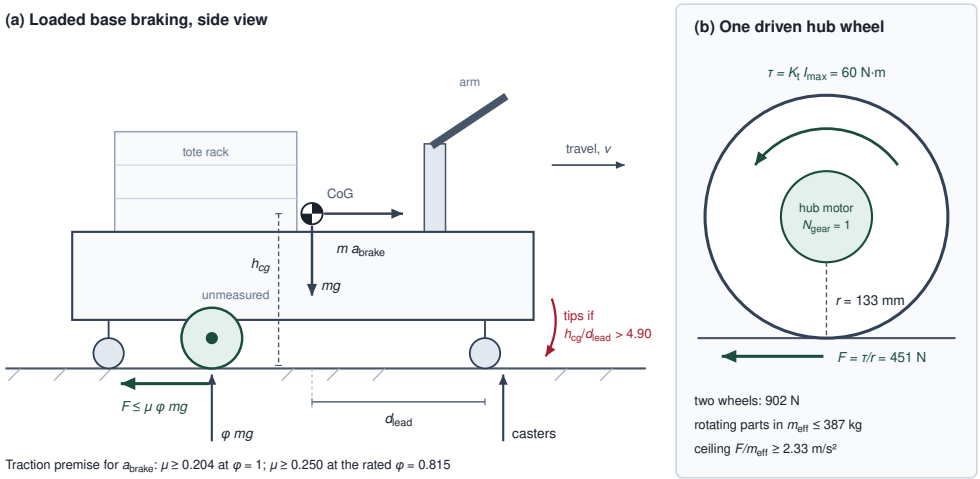


Figure 2.1: Three ceilings on the braking base: (a) Only the driven wheels brake against the floor, so friction there caps the retarding force at $\mu\phi_{\text{drive}}mg$; the credible 2 m/s² needs $\mu \geq 0.204$ with all the weight on those wheels and 0.250 at their rated load share. The inertial load ma_{brake} acts at the center of gravity, a height h_{cg} above the floor, and pitches the body about its leading support unless $h_{\text{cg}}/d_{\text{lead}} \leq 4.90$; neither length has been measured. (b) Each direct-drive hub wheel turns its 60 N·m current-limited torque into a floor force τ/r, 902.3 N for the pair, and the spinning parts are already counted in m_{eff}. The layout is schematic, not to scale.

and friction there can reach at most μ times the normal force they support, $\phi_{\text{drive}}mg$. This caps deceleration at $a_{\text{brake}} \leq \mu g\phi_{\text{drive}}$, where μ is the tire-floor friction coefficient and ϕ_{drive} is the fraction of total vehicle weight carried by the driven wheels. Second, vehicle pitch stability limits deceleration through dynamic load transfer. While braking force acts at the floor contact patch, inertial force acts forward through the center of gravity at height h_{cg} above it. Taking moments about the leading ground support, a horizontal distance d_{lead} ahead of the center of gravity, the overturning inertial moment $ma_{\text{brake}}h_{\text{cg}}$ opposes the restoring gravitational moment mgd_{lead}. The platform stays on all wheels only so long as $a_{\text{brake}} \leq g\, d_{\text{lead}}/h_{\text{cg}}$. Raising or extending a robotic arm alters both h_{cg} and d_{lead} in real time, making this pitch-stability boundary state-dependent. Third, the electromechanical actuators limit retarding force through the maximum torque their inverter current limit allows, a ceiling that section 2.4.2 derives from the motor torque constant. If an inverter restricts phase current, or if the back-EMF of the spinning rotor leaves the inverter too little headroom to control current, the drive cannot deliver the required braking torque. Deceleration a_{brake} degrades silently, expanding braking travel without software notification. The rotor's rotational inertia is already counted in the effective mass m_{eff} and must not be charged a second time. These three ceilings act simultaneously on the loaded chassis (figure 2.1), and notebook 2.3 checks them against the running machine's numbers once the next section derives the drive's torque ceiling.

The constant-deceleration model requires a level surface and a qualified braking response. A conservative implementation charges the transient interval required to develop full retarding force into τ_{delay}, then applies a certified lower bound a_{brake}. The actuator brake-onset allowance (T_{act}) enters that delay once. Any subsequent calculation that models a finite torque ramp must reconcile its ramp travel with this allowance rather than add the same interval twice. Furthermore, empirical stopping trials across declared operating conditions establish the credible deceleration, its distribution, and its safety margin. A sample percentile alone does not constitute a certified lower bound.

In unstructured environments, an autonomous machine cannot allocate its entire clearance to nominal stopping dynamics. Obstacle tracking carries state estimation uncertainty, sensor calibration drifts over time, and localization algorithms introduce position error. The stopping distance d_{stop} that the system defends must therefore include a spatial localization uncertainty bound δ_{loc} and a minimum physical clearance margin δ_{margin}:[6]

6 **Protective Separation Distance**: For speed and separation monitoring of robot arms, the collaborative-application requirements that ISO 10218-2:2025 incorporates from ISO/TS 15066 (which itself remains published and under revision) write the protective separation distance as $S_p = S_h + S_r + S_s + C + Z_d + Z_r$: the person's travel, the robot's travel during its reaction time and while stopping, an intrusion distance set by the sensing, and the position uncertainties of person and robot (International Organization for Standardization 2016, 2025b; Marvel and Norcross 2017). The robot's terms map onto equation 2.2, with $v\,\tau_{\text{delay}}$ as S_r, $v^2/2a_{\text{brake}}$ as S_s, and δ_{loc} as Z_r, although ISO 10218-2:2025 excludes the hazards specific to a manipulator riding a mobile platform, the running machine's case. For a learned policy, an unbounded compute tail lengthens the reaction time, which enlarges both S_h and S_r and forces the protective field outward.

$$d_{\text{stop}} = v\,\tau_{\text{delay}} + \frac{v^2}{2a_{\text{brake}}} + \delta_{\text{loc}} + \delta_{\text{margin}} \tag{2.2}$$

The sum $\delta_{\text{loc}} + \delta_{\text{margin}}$ is fixed spatial overhead that must remain unoccupied when the body comes to a complete rest.

↪ The localization bound δ_{loc} and its dependence on map corrections are developed in section 9.5.1.

Definition 2.2: Dynamic stopping distance

Dynamic stopping distance (d_{stop}) is the minimum physical clearance required to bring a moving mass to a complete halt from its speed v when the hazard is first imaged. It sums three parts. The first is the travel during the pre-brake delay τ_{delay}, which spans the observation age of the frame that shows the hazard and the lease, tick, bus, and brake-onset intervals that follow until retarding force begins (the decomposition of section 1.4.3), and which excludes the separately charged dispatch-to-admission interval. The second is the braking travel under the credible deceleration a_{brake}. The last is the localization bound δ_{loc} and protective clearance δ_{margin}, as equation 2.2 states.

1. **Significance**: Quantifies the non-negotiable physical spatial margin that software proposals must clear before motion permission can be granted.
2. **Distinction**: Unlike static geometric obstacle clearance in classical kinematics, dynamic stopping distance depends on the machine's own speed and on every delay before braking, so each velocity setpoint and each delay term changes it.
3. **Common pitfall**: Assuming an emergency stop command halts the machine instantaneously, ignoring that moving mass carries kinetic energy ($E_k = \frac{1}{2}mv^2$) that requires finite mechanical work and braking distance to dissipate.

Three cases on the running machine show how the terms trade against one another (figure 2.2). With only the terms the body owns, the stop needs 742.5 mm. Charging the full 133.6 ms pre-brake delay of the elementary stopping budget (section 1.4.3), whose terms later chapters measure one by one, gives that elementary stop plus the 150 mm fixed overhead, or 912.9 mm. That stop still fits the 1.10 m clear distance. Raising speed above the drive limit with that same delay pushes the stop to 1,417.2 mm, past the rack end, because speed enters the blind travel linearly and the braking travel quadratically. Notebook 2.2 works the first case term by term.

2.3.2 Dynamic velocity ceilings and clearance budgeting

Because braking travel grows quadratically with speed while blind travel scales linearly with delay (figure 2.2), autonomous systems cannot rely on static, scene-independent speed limits. They require a dynamic velocity ceiling parameterized by instantaneous obstacle clearance. For a stationary obstacle detected at distance D_{clear}, such as a person standing at an aisle intersection or a dropped storage tote, safe operation demands that defended stopping distance remain strictly within the available clear path: $d_{\text{stop}} \leq D_{\text{clear}}$. This constraint is how the first law, irreversibility (principle 1), binds every motion cycle, with each parameter in d_{stop} grounded in the machine's verified physical limits. Using conservative bounds for actuation delay and retarding acceleration, the permission path solves this inequality to determine the maximum permissible command velocity v_{max}. The symbol is the one that equation 2.1 used for the speed of a tracked target, but here it bounds the machine's own speed. Taking the positive physical root of the resulting quadratic relation[7] yields:

$$v_{\text{max}} = -a_{\text{brake}}\tau_{\text{delay}} + \sqrt{(a_{\text{brake}}\tau_{\text{delay}})^2 + 2a_{\text{brake}}(D_{\text{clear}} - \delta_{\text{loc}} - \delta_{\text{margin}})} \tag{2.3}$$

Whenever perceptual range degrades or an obstacle obstructs the trajectory, D_{clear} contracts, continuously lowering the velocity ceiling. When available distance collapses to zero, the allowable forward velocity becomes zero. If the machine is already in motion, however, issuing a zero-velocity setpoint cannot instantaneously eliminate its accumulated kinetic energy. A negative available distance signals that the platform has already breached safe stopping margins, demanding immediate, full-authority emergency braking.

[7] **Kinematic Velocity Root**: Grouping the fixed distance terms into the available braking distance $D_{\text{avail}} = D_{\text{clear}} - \delta_{\text{loc}} - \delta_{\text{margin}}$ gives the quadratic inequality $\frac{1}{2a_{\text{brake}}}v^2 + \tau_{\text{delay}}v - D_{\text{avail}} \leq 0$. Multiplying by $2a_{\text{brake}}$ gives $v^2 + 2a_{\text{brake}}\tau_{\text{delay}}v - 2a_{\text{brake}}D_{\text{avail}} \leq 0$. Applying the quadratic formula and taking the positive root sets the speed ceiling.

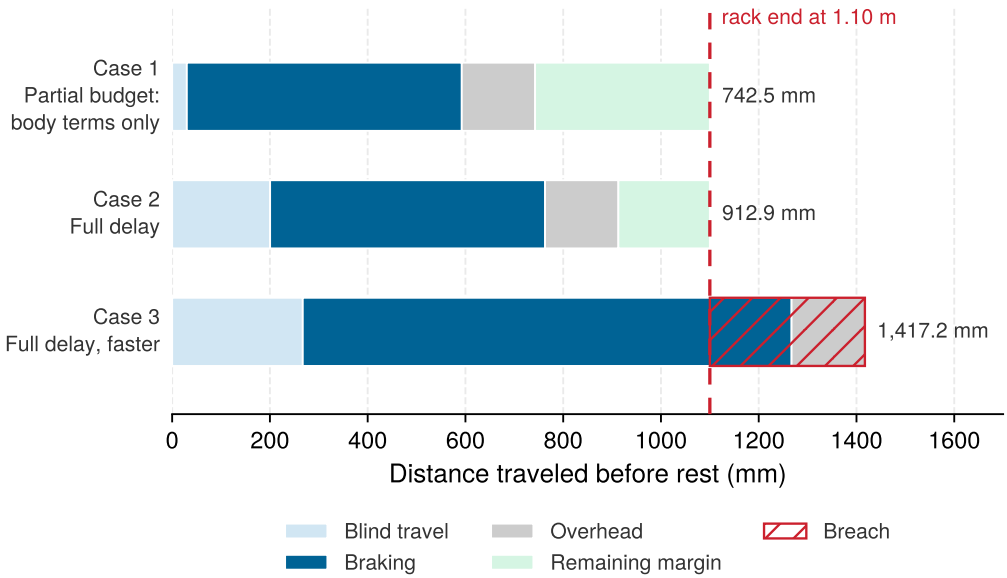

Figure 2.2: Stopping distance of the warehouse mobile manipulator: Each bar splits the stop into blind travel during the pre-brake delay, braking travel under the credible deceleration, and the fixed overhead of the localization bound and protective clearance, against the 1.10 m rack-end clear distance. Case 1 counts only the terms the body owns at the 1.5 m/s drive limit and stops within 742.5 mm. Case 2 charges the full 133.6 ms pre-brake delay of the elementary stopping budget (the kinematic roofline); at 912.9 mm it still fits, although later chapters add a stop profile and a tracking bound. Case 3 raises speed to a hypothetical 2 m/s, above the drive limit, with the same delay; braking travel grows by 77.8 percent and the stop, at 1,417.2 mm, breaches the clear distance.

DRAFT

Napkin Math 2.2: The body's stopping distance

Problem: The loaded warehouse mobile manipulator drives toward a rack end at its drive limit, and a person stands in the aisle at the clear distance. The body owns three terms of equation 2.2: braking travel, the fixed overhead, and the brake onset that enters τ_{delay}. How much of the clear distance do these terms use, what speed would they alone permit, and how do speed and added delay change the answer?

Variables:

- Loaded mass at most 368 kg (derived upper bound, full tote rack) and drive limit $v = 1.5$ m/s (illustrative)
- Clear distance $D_{\text{clear}} = 1.10$ m (illustrative)
- Credible deceleration $a_{\text{brake}} = 2$ m/s² (illustrative; loaded, dry floor)
- Localization bound $\delta_{\text{loc}} = 50$ mm (illustrative) and protective clearance $\delta_{\text{margin}} = 100$ mm (chosen)
- Brake onset $T_{\text{act}} = 20$ ms (illustrative)

Math:

1. Braking travel: For the same credible deceleration, mass cancels from the work-energy balance. The loaded machine's 414 J sets the energy the stopping system must absorb or dissipate, while the specified deceleration sets the braking distance. A different payload can change that deceleration and requires a new bound:

$$d_{\text{brake}} = \frac{v^2}{2a_{\text{brake}}} = \frac{(1.5m/s)^2}{2 \times 2m/s^2} = 562.5mm$$

The stopping distance so far is 562.5 mm.

2. Fixed overhead:

$$\delta_{\text{loc}} + \delta_{\text{margin}} = 50mm + 100mm = 150mm$$

The running total rises to 712.5 mm.

3. Brake onset: Between the brake command and the first retarding force, the base still moves at full speed:

$$vT_{\text{act}} = (1.5m/s) \times (20ms) = 30mm$$

$$d_{\text{stop}}\big|_{\text{body}} = 562.5mm + 150mm + 30mm = 742.5mm$$

The body's own terms leave 357.5 mm of the 1.10 m clear distance for every delay the body does not own.

4. The body-only ceiling: Solving equation 2.2 for speed with $\tau_{\text{delay}} = T_{\text{act}}$:

$$v_{\text{max}} = -a_{\text{brake}}T_{\text{act}} + \sqrt{(a_{\text{brake}}T_{\text{act}})^2 + 2a_{\text{brake}}(D_{\text{clear}} - \delta_{\text{loc}} - \delta_{\text{margin}})} \approx 1.91m/s$$

The body alone would permit 1.91 m/s, above the drive limit. The remaining delay terms, added in later chapters, spend part of this headroom.

5. Speed vs. delay: At a hypothetical 2 m/s, above the drive limit, the braking term alone grows to 1,000 mm, 77.8 percent more than at the drive limit. At the drive limit, each additional 100 ms of pre-brake delay adds 150 mm.

Systems insight: Platform velocity is the most sensitive variable in the stopping budget. Accelerating from 1.5 m/s to 2 m/s adds 437.5 mm in braking travel, as much distance as 291.7 ms of additional pre-brake delay at the drive limit. A velocity setpoint may therefore rise only after re-evaluating the clearance quadratic. Because physical braking distance scales with v^2, granting an aggressive velocity setpoint expands the defended stopping envelope and rapidly exhausts the clear distance margin defended by $d_{\text{stop}} \leq D_{\text{clear}}$.

2.3.3 Applying the velocity ceiling

A dynamic speed ceiling protects the machine only when an independent check on the permission path tests each new velocity request against it before execution. The learned policy proposes an action. The safety check evaluates clearance, delay, and available deceleration to determine whether that request fits the stopping budget. Requesting a lower speed alters future trajectory points but cannot erase the distance required to stop from the current speed. Consequently, the check must evaluate the platform's instantaneous state alongside candidate commands, keeping the machine inside the region from which it can still stop between control ticks under strict bounds on timing jitter, obstacle motion, and actuator response. That per-tick validation belongs to the permission path; section 12.3.2 formalizes it around the jerk-limited deceleration profiles executed on the physical platform. What the physical body contributes is the ceiling itself: a clearance-dependent boundary grounded in physical constraints that drops whenever traction degrades, actuator response slows, or localization uncertainty expands.

Enforcing this speed limit assumes the permission path can demand the deceleration a_{brake} whenever safety requires it. Commanding rapid deceleration, however, requires sudden, large mechanical torque from the drive motors and gearboxes. If the permission path requests a torque step that exceeds what the actuator bandwidth budget allows, the mechanical body cannot deliver the required deceleration, invalidating the model-based stopping ceiling and risking collision. The same drives also shape what happens if the stop falls short. The reflected rotor energy counted in m_{eff} then reaches the obstacle and the gear teeth through the transmission's compliance, so the stopping calculation cannot substitute for a contact-load assessment.

2.4 Actuator Transmission Limits

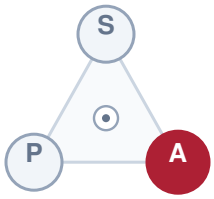
When a policy writes a 50 N·m torque setpoint to a joint register or dispatches an emergency brake command over a Controller Area Network (CAN) bus or EtherCAT, the drive electronics may clamp

↪ The chunk lease, the time an admitted trajectory segment may keep executing without a replacement, is one of the delay terms that spend this headroom. Its sizing from this stopping distance is developed in section 4.4.

the current at half that request while returning a clean acknowledgement packet in sub-millisecond time. In digital software, an execution target either accepts an instruction or raises a fault; in physical hardware, stator winding inductance, DC bus voltage headroom, magnetic saturation, and transmission elasticity bound what the joint actually delivers. The systems engineering challenge is to specify an actuator contract at the physical plant interface, written in delivered force, torque, slew-rate limits, response latency, and tracking error rather than digital setpoints, and to expose those limits directly to the runtime permission path before an unachievable command causes a collision.

2.4.1 Actuation mechanisms and the actuator contract

What that actuator contract must bound depends on how the joint converts stored energy into mechanical force. Electric drives dominate mobile manipulation and power the running machine of this book, where current in copper windings pulls on rotor magnets through a gear train. Other robots rely on pressurized fluid or calibrated mechanical springs, and each mechanism trades peak force density against bandwidth, compliance, and maintenance overhead.



On the sense-plan-act (S·P·A) triad (Appendix D), the actuator contract sits at the Act node, where a command must become delivered force.

Across the broader field, three non-rigid or fluid alternatives illustrate how the physical medium reshapes the contract:

- **Hydraulic servovalves**: For heavy machinery, construction robots, and high-load dynamic platforms, fluid power trades magnetic force for pressure. A cylinder's force is supply pressure times piston area, $F_{\text{cyl}} = pA$, so raising the pressure lets a compact actuator deliver a large force. An electric motor's force, by contrast, is bounded by the magnetic field its magnets and copper can sustain. The miniature servovalves on hydraulic legged robots respond fast, with bandwidths of hundreds of hertz (Scully 2015), so the valve is rarely the slow element. Hydraulic control is bounded instead by fluid compressibility (oil bulk modulus β), nonlinear orifice flow, and the plumbing, pumps, and cooling needed to keep the fluid within its operating range. That maintenance burden is one reason Boston Dynamics retired its hydraulic Atlas humanoid in 2024 in favor of an all-electric successor (Boston Dynamics 2024).
- **Pneumatics and soft actuation**: Pneumatic artificial muscles and elastomeric chambers provide physical compliance that naturally cushions impacts. However, gas compressibility, valve flow restrictions, and acoustic transport delays limit closed-loop bandwidth to tens of hertz. Stored pneumatic energy can also discharge violently during rapid venting or line rupture. Safety validation requires qualifying the envelope of peak chamber pressure, flow rates, and measured contact dynamics.
- **Series elastic actuators (SEAs)**: By placing a calibrated spring directly between the gearbox and the output link (as in the ANYbotics ANYdrive), an SEA incorporates mechanical compliance into the drivetrain itself. The spring acts as a low-pass mechanical filter: it isolates delicate gear teeth from shock loads and decouples the large reflected rotor inertia ($N_{\text{gear}}^2 J_{\text{rotor}}$) from the environment during impact. Its measured deflection also serves as a direct force sensor, since spring stiffness times deflection yields output torque (Pratt and Williamson 1995). Rather than dissipating energy, the spring stores elastic potential ($E = \frac{1}{2} k \Delta\theta_{\text{joint}}^2$) at the joint and can return that energy into an obstacle. The engineering trade-off is reduced closed-loop position bandwidth and low-frequency structural resonance. The safety system and permission path must therefore monitor physical spring deflection directly instead of assuming rigid load tracking.

2.4.2 Electrical time constants, back-EMF, and current clamping

The running machine's wheels and arm joints are electric, so the electric drive is the plant whose limits the stopping budget depends on. To a policy, a torque command is a number written to a register; to the motor, it is a current that must be built up in a coil. Three results from introductory physics describe that conversion (Lynch and Park 2017). First, a wire carrying current across a magnetic field feels a force proportional to the current. Wound around a rotor, those forces produce a torque proportional to current, $\tau_{\text{motor}} = K_t I$, where the **torque constant** K_t (in $\text{N} \cdot \text{m/A}$) collects the magnet strength and the winding geometry. Second, the same wires, swept through the same field by the spinning rotor, have a voltage induced in them. A spinning motor is therefore also a

generator, and its **back-EMF** (back electromotive force) $e_{\text{bemf}} = K_e\omega_m$ opposes the supply. Energy conservation ties the two constants together. The electrical power the motor converts, $e_{\text{bemf}}\,I$, equals the mechanical power it delivers, $\tau_{\text{motor}}\omega_m$, so K_e and K_t are the same number in SI units. A three-phase drive's current and voltage conventions scale them by constant factors, which is why both must be identified under one convention. Third, the winding is a coil, and a coil opposes any change in its current, $v = L_{\text{phase}}\,dI/dt$ for inductance L_{phase}. Current, and therefore torque, cannot jump.

The budget needs two results from the motor controller: the torque delivered for a given current and the delay before that current appears. In a three-phase motor, field-oriented control (FOC) measures the winding currents and adjusts the inverter voltages so that the torque-producing current i_q stays at right angles to the rotor's magnetic field as the rotor turns. Torque is then $\tau_{\text{motor}} = K_t i_q$.[8] The controller splits the stator current into two components that turn with the rotor. The quadrature, or q-axis, current i_q lies at right angles to the rotor field and produces torque. The direct, or d-axis, current i_d lies along the field, produces none, and is normally held at zero. The coordinate transformations inside the drive appear in section 2.4.6.

The delay between commanding a torque and delivering it begins in the stator windings. Adding the three effects around one winding circuit, the supply voltage must cover the resistive drop, the inductive voltage, and the back-EMF, which is Kirchhoff's voltage law for the torque-producing current:

$$L_{\text{phase}}\frac{di_q(t)}{dt} + R_{\text{phase}}i_q(t) = v_q(t) - e_{\text{bemf}}(t)$$

where L_{phase} is phase inductance, R_{phase} is phase resistance, $v_q(t)$ is the applied quadrature voltage from the inverter bridge, $i_q(t)$ is the quadrature-axis (torque-producing) current, and $e_{\text{bemf}}(t) = K_e\omega_m(t)$ is the back-EMF. The stator electrical time constant is:

$$\tau_e = \frac{L_{\text{phase}}}{R_{\text{phase}}}$$

DRAFT

If the inverter applied an uncontrolled voltage step, the current would approach its steady state exponentially along $i_q(t) = I_{\text{final}}(1 - e^{-t/\tau_e})$, taking an entire time constant τ_e to reach 63 percent of the target. A closed-loop current controller drives the winding much faster. It applies full bus voltage until current reaches the setpoint, forcing a ramp rate of nearly $(V_{\text{bus}} - e_{\text{bemf}})/L_{\text{phase}}$. At that point the current loop throttles the voltage to maintain regulation. On the running machine, this electrical rise is rapid. The hub motor windings (line inductance 1.885 mH, line resistance 0.7 Ω) yield $\tau_e = 2.7$ ms. Starting from rest on a depleted 42 V pack, the initial current slope gives a resistance-free rise estimate of 1.1 ms, only 5.6 percent of the 20 ms brake onset budgeted for the platform. The resistive drop slows the ramp as current builds, so this estimate is optimistic and the full winding response must be measured. When braking from forward speed, the rotor continues spinning in the positive direction while the controller reverses the sign of the torque-producing current to oppose motion, so the positive back-EMF reinforces the inverter's negative current drive, accelerates the current ramp further, and reduces the terminal voltage required to sustain peak braking current from $e_{\text{bemf}} + I_{\text{max}}R$ to $e_{\text{bemf}} - I_{\text{max}}R$. In this architecture, electrical rise time does not bottleneck emergency braking. Tire traction, maximum inverter current, and voltage headroom at high speed govern the stopping distance, as detailed in notebook 2.3.

Torque tracks current directly, which means available voltage headroom also dictates the maximum torque slew rate:

$$\frac{d\tau_{\text{motor}}}{dt} = K_t\frac{di_q}{dt} \le \frac{K_t(V_{\text{bus}} - K_e\omega_m)}{L_{\text{phase}}}$$

Inductance and voltage conventions must align consistently: line-to-line values reported on manufacturer datasheets pair with the full DC bus voltage. Per-phase values modeled under space-vector modulation scale by an amplitude of approximately $V_{\text{bus}}/\sqrt{3}$, the modulation voltage limit stated in section C.9. At low wheel speeds, ample voltage headroom enables steep torque ramps. As rotational velocity climbs, back-EMF consumes that headroom, throttling the rate at which the inverter can inject current. An unconstrained policy setpoint requesting an instantaneous torque step is transformed by the motor hardware into a finite physical ramp; any demand exceeding this

8 **Field-Oriented Control (FOC)**: Holding the stator current at right angles to the rotor field is the arrangement that a brushed DC motor's commutator enforces mechanically. An AC machine controlled this way behaves like a DC motor whose torque is set by a single current, i_q. That is what lets a policy command torque at all, because its request becomes a current target whose arrival the winding inductance and the voltage headroom then pace.

maximum slew rate produces severe tracking error. The safety stopping budget must account for this rate-limited response.

Voltage headroom bounds the rate of current rise; power electronics define the maximum current that can safely flow. Inverter bridges enforce a strict current ceiling I_{max} to protect the switching power transistors from thermal failure and prevent magnetic core saturation in the stator. For a motor coupled to a mechanical transmission with gear ratio N_{gear} and mechanical efficiency η_{gear}, this ceiling caps joint output torque at:

$$\tau_{\text{out,max}} = \eta_{\text{gear}} N_{\text{gear}} K_t I_{\text{max}} \tag{2.4}$$

This current limit settles a central safety requirement: whether the drives can sustain the deceleration demanded by the supervisory permission path. A motor drive may silently clamp current setpoints while continuing to acknowledge network commands; the safety path must interrogate measured output currents and status flags rather than inferring torque delivery from successful packet transmission. If emergency braking demands more torque than this ceiling allows, the assumed deceleration model breaks down. Any change to inverter current limits therefore invalidates the robot's qualified stopping envelope and requires recomputing the stopping limit record (section 2.7).

DRAFT

Napkin Math 2.3: Can the drives deliver the credible deceleration?

The running machine brakes through two driven wheels, each a direct-drive 10-inch hub motor (the ZLTECH ZLLG10ASM800, with no gearbox, so $N_{\text{gear}} = 1$ and $\eta_{\text{gear}} \approx 1$) (Shenzhen Zhongling Technology 2022) with rolling radius $r = 133$ mm. Its torque constant $K_t = 2.4$ N·m/A is the datasheet's peak torque divided by its peak current, and the drive's current limit is set at that peak, $I_{\max} = 25$ A. Casters carry the rest of the weight.

Problem: Does the loaded machine's credible deceleration $a_{\text{brake}} = 2$ m/s² fit under the traction, tip-over, and drive-torque ceilings, and does the drive keep control of its current at the 1.5 m/s drive limit?

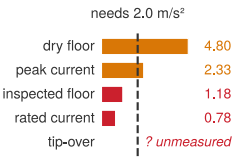
Math:

1. **Traction**: Only the driven wheels brake, so $a_{\text{brake}} \le \mu g \phi_{\text{drive}}$. With all the weight on them ($\phi_{\text{drive}} = 1$), the floor must supply $\mu \ge a_{\text{brake}}/g = 0.204$. The hub motors are rated to carry 300 kg per pair, so on the 368 kg machine $\phi_{\text{drive}} \le 0.815$ and the floor must supply at least $\mu = 0.250$. The dry floor ($\mu = 0.60$) meets that whenever the driven wheels carry at least a fraction 0.34 of the weight, and at the rated load share it supports $\mu g \phi_{\text{drive}} = 4.80$ m/s². The inspected floor, a sealed low-traction surface whose friction a facility inspection certifies only down to $\mu = 0.12$, supports only 1.18 m/s² even with every kilogram on the driven wheels.
2. **Tip-over**: The machine stays on its wheels while $a_{\text{brake}} \le g\, d_{\text{lead}}/h_{\text{cg}}$, so the credible deceleration requires $h_{\text{cg}}/d_{\text{lead}} \le g/a_{\text{brake}} = 4.90$. The machine's specification gives neither the loaded center-of-gravity height nor its distance to the leading support, and extending the arm forward shortens d_{lead}. This ceiling cannot yet be checked.
3. **Drive torque**: Each wheel delivers $K_t I_{\max} = 60$ N·m, so the floor sees $F = 2K_t I_{\max}/r = 902.3$ N. With the rotating-mass bound of section 2.3.1, $m_{\text{eff}} \le 387$ kg, and the torque ceiling is $F/m_{\text{eff}} \ge 2.33$ m/s², at least 16.6 percent above the credible deceleration. With the current limit set at the rated 8.5 A instead, each wheel gives its rated 20 N·m and the ceiling falls to 0.78 m/s².
4. **Voltage at the drive limit**: At 1.5 m/s the wheel turns at $\omega_m = v_{\max}/r = 107.7$ rpm, and the line-to-line back-EMF is $e_{\text{bemf}} = K_e \omega_m = 28.2$ V. Braking current flows with the back-EMF, so holding $I_{\max}$ through the 0.7 Ω line resistance requires only $e_{\text{bemf}} - I_{\max} R = 10.7$ V at the terminals. Even a depleted 42 V pack sits 13.8 V above e_{bemf}. Driving at the same current would need $e_{\text{bemf}} + I_{\max} R = 45.7$ V, more than the depleted pack supplies.

Result: The drives clear 2 m/s² by at least 16.6 percent, but only with the current limit at the motor's peak. Traction holds on the dry floor if the driven wheels carry at least a fraction 0.34

of the weight, and it fails on the inspected floor. The tip-over ceiling remains unverified until the loaded center of gravity is measured, by weighing each wheel on corner scales or by a tilt test, with the arm stowed and extended.

Systems insight: The credible deceleration is a conjunction of three ceilings owned by different parts of the machine: the floor, the mass distribution that the arm changes, and the drive configuration. A current limit lowered to protect the windings cuts the torque ceiling below the stopping premise without any software change, so the configured current limit belongs in the limit record's conditions.



A 2 m/s² stop must clear every ceiling; two fall short and one is unmeasured.

Current regulation also incurs electrical and switching losses. Any stator current vector misaligned with the quadrature axis produces resistive heating without contributing shaft torque. Inverter pulse-width modulation and required protective dead times introduce further nonlinear voltage distortion.[9] Consequently, dynamic torque tracking must be verified through physical dynamometer measurements on the assembled actuator rather than inferred from current setpoints alone.

2.4.3 Reflected rotor inertia and optimal inertia matching

Once electromagnetic torque leaves the motor shaft, mechanical gearing introduces a dynamic asymmetry between torque and inertia. High-reduction joints employ gear ratios between $50{:}1$ and $160{:}1$ to multiply the output torque of compact, lightweight motors. While this reduces the motor torque required by a factor of N_{gear}, the motor rotor must spin N_{gear} times faster than the actuated joint. When an external contact backdrives the joint, it must accelerate that rotor at N_{gear} times the joint's angular acceleration. Because rotational kinetic energy scales with the square of velocity ($\frac{1}{2} J_{\text{rotor}} \omega_m^2$), the rotor's physical inertia J_{rotor} resists load-side acceleration multiplied by the square of the gear ratio (definition 2.3).

Through a 100:1 transmission, a small 50 g rotor imposes the apparent inertia of a heavy 11.2 kg flywheel with a 10 cm radius at the output shaft (Lynch and Park 2017). When the end-effector collides with a rigid surface, the contact force must instantly decelerate this equivalent flywheel through the drivetrain, generating extreme peak stresses that can fracture gear teeth at their roots, as documented in figure 2.4.

Definition 2.3: Reflected rotor inertia

Reflected rotor inertia (J_{ref}) is the apparent rotational inertia of an actuator rotor at the load-side joint output, scaling with the square of the transmission gear ratio:

$$J_{\text{ref}} = N_{\text{gear}}^2 J_{\text{rotor}}$$

1. **Significance**: In high-reduction transmissions ($N_{\text{gear}} \geq 100$) it dominates the apparent load, capping joint acceleration $\ddot{q}$ and setting impact shock loads.
2. **Distinction**: Unlike rotor inertia J_{rotor} or link inertia J_{load}, it acts through transmission stiffness and backlash, so backdriving from the environment meets an N_{gear}^2 barrier.
3. **Common pitfall**: Ignoring reflected rotor inertia during collision and contact modeling. Under sudden obstacle impact, the reflected kinetic energy of the spinning rotor concentrates stress directly on gear teeth before drive current can be interrupted.

The combined equation of motion for a geared joint driving load inertia J_{load} with motor torque τ_{motor} is:

$$\ddot{q} = \frac{N_{\text{gear}} \tau_{\text{motor}}}{J_{\text{load}} + N_{\text{gear}}^2 J_{\text{rotor}}}$$

Maximizing delivered load acceleration $\ddot{q}$ with respect to transmission ratio N_{gear}, by setting $d\ddot{q}/dN_{\text{gear}} = 0$, gives $J_{\text{load}} = N_{\text{gear}}^2 J_{\text{rotor}}$: acceleration peaks when the reflected rotor inertia equals the load inertia. Solving for N_{gear} establishes the classical **inertia matching ratio**:[10]

[9] **Inverter Dead Time**: A short hardware-inserted interval in which both switches of an inverter half-bridge are off, so that the high-side and low-side switches of one leg never conduct together and short the DC bus, a failure called shoot-through. The interval distorts the applied voltage most at low speed and near each current zero crossing, so delivered torque departs from the request exactly where slow, fine contact force is commanded.

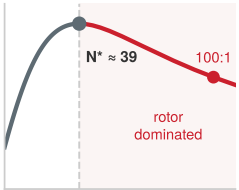
[10] **Inertia Matching**: At N^* the reflected rotor inertia equals the load inertia, the mechanical twin of impedance matching in a circuit, where a source delivers the most power to a load whose impedance equals its own. The analogy carries the same caveat: the matched ratio maximizes acceleration, not efficiency or safety, so practical arms choose lower ratios to protect gear teeth from shock, keep the joint backdrivable, and raise top speed.

$$N^* = \sqrt{\frac{J_{\text{load}}}{J_{\text{rotor}}}} \tag{2.5}$$

Below N^*, joint acceleration is torque-limited: increasing N_{gear} multiplies motor torque to accelerate the heavy load faster. Above N^*, more gearing *decreases* delivered joint acceleration, because the motor expends most of its electromagnetic torque accelerating its own spinning rotor ($N_{\text{gear}}^2 J_{\text{rotor}}$) rather than the external link. For the 50 g rotor above driving an illustrative link of $J_{\text{load}} = 8.5 \times 10^{-3}$ kg·m², the matched ratio is $N^* \approx 39$. At 100:1 the same motor torque delivers only 67.7 percent of the matched-ratio acceleration, because $\ddot{q}(N_{\text{gear}})/\ddot{q}(N^*) = 2\tilde{N}/(1+\tilde{N}^2)$ with $\tilde{N} = N_{\text{gear}}/N^*$. The extra gearing has cost 32.3 percent of the joint's acceleration.

The gear ratio also magnifies the mechanical resistance an external contact meets when attempting to move the link. This resistance to imposed motion constitutes the joint's mechanical impedance. Because link inertia, joint damping, torsional compliance, and seal friction all shape this response, the gear ratio alone does not establish contact forces or structural fracture limits. Transmission selection must balance delivered joint acceleration against the impedance presented to accidental impacts.

Abrupt changes in commanded torque excite the torsional elasticity of geared joints before the physical link responds. Bounding joint acceleration and jerk moderates this excitation, but software trajectory smoothing cannot override mechanical resonance. Trajectory generators formulate control profiles that respect these physical boundaries (Lynch and Park 2017). The hardware platform must provide the empirical response rates and contact stiffness limits required to tune them.



Past $N^* \approx 39$, gearing chokes acceleration; 100:1 keeps 67.7 percent.

↪ Trajectory timing under joint torque and jerk bounds is developed in section 11.4.5.

2.4.4 Transmission compliance, contact impedance, and tooth fracture

Mechanical gearboxes introduce backlash and elasticity that decouple the motor from the driven link. Upon direction reversal, the motor shaft traverses mechanical clearance before the gear teeth engage the opposing flank. Concurrently, as illustrated by the disassembled strain wave gear set in figure 2.3, torsional compliance in gear teeth and flexible elements[11] transforms the rigid link into an elastic system (Spong 1987). Its dynamics follow the flexible-joint formulation given in section B.5.4. Step changes in torque excite this structural spring, driving the drivetrain into limit-cycle[12] chatter. Motor-side encoders conceal this deadband completely. The motor rotates smoothly while the output shaft remains pinned, causing link position q_{out} to diverge from $q_{\text{motor}}/N_{\text{gear}}$ by a load-dependent deflection δ_{lost}. The motor controller observes flawless setpoint tracking while the end-effector stalls, eventually experiencing an impulsive impact when the gear teeth make contact. Repeated shock cycles culminate in the root fatigue failure shown in figure 2.4.

The strain wave gear of figure 2.3 packs a high reduction into a compact joint by deforming its flexspline continuously, and that elasticity has a cost. This intentional compliance decouples rotor position from link position under dynamic loading: while the motor encoder registers smooth rotation, the flexspline winds up like a torsion spring, introducing unmeasured end-effector deflection.

A tooth broken off at its root (figure 2.4) is the end state of that loading. Such failures show why dynamic impact loads, rather than static payload ratings alone, must govern actuator and transmission selection: repeated torque spikes and unmodeled contact shocks concentrate destructive stresses directly at the tooth root fillet. While smooth motion plans mitigate drivetrain vibration, safe physical interaction depends on measuring output torque and enforcing strict mechanical load boundaries.

[11] **Strain Wave Gearing**: Musser (1959) patented the mechanism, now sold as the Harmonic Drive: an elliptical wave generator flexes a thin toothed cup inside a rigid ring that carries two more teeth, so a single stage yields a high ratio with near-zero backlash. The flexing that makes the ratio possible is also the joint's torsional compliance, which makes the link elastic.

[12] **Limit Cycle**: A self-sustained oscillation of fixed amplitude that a nonlinear feedback loop settles into, here excited by the backlash deadband as the motor crosses the gap, the teeth strike, and the controller corrects back across it. Unlike an instability, it does not grow, so it can run unnoticed through a shift while every cycle adds a tooth impact to the fatigue count.

> **Systems Perspective 2.3: Impedance control for contact safety**
>
> When a position-controlled robot encounters a rigid surface (contact stiffness $k_{\text{contact}} \geq 10^5$ N/m), a minor setpoint tracking error of $\Delta x = 1$ mm escalates the contact force to $F_{\text{contact}} = k_{\text{contact}} \Delta x = 100$ N within milliseconds as the inverter commands maximum current against the obstacle. On the mobile manipulator, the gripper contacting the spring-latched door strikes a steel plate with stiffness 4.0×10^5 N/m. Once impact occurs, contact force ramps at $F_{\text{contact}} = k_{\text{contact}} v_{\text{approach}} t$: 12 N/ms under a guarded approach velocity of 0.03 m/s, and 40 N/ms at an unconstrained 0.10 m/s, rapidly exceeding the latch's 100 N structural limit.

Figure 2.3: Strain wave gear set: The three parts of a Harmonic Drive strain wave gear, disassembled: the elliptical wave generator with its thin-race ball bearing (top left), the flexspline cup with external teeth on its open rim (top right), and the rigid circular spline ring with internal teeth (bottom). The wave generator bends the flexspline so that its teeth mesh with the circular spline at two opposite zones; because the flexspline carries slightly fewer teeth, each turn of the wave generator advances it by only that difference, which gives a high reduction with little backlash. (Credit: Pieceofmetalwork, Wikimedia Commons, CC BY-SA 4.0.)

Impedance control (Hogan 1985) reformulates contact interactions away from pure position or force control. An impedance takes motion in and returns force; an admittance takes force in and returns motion. Because a rigid environment behaves as an admittance, yielding motion only when pushed, the manipulator is made to behave as an impedance, which answers a deviation in position and velocity with a restoring force ($F_{\text{contact}} = Z(\dot{x})$, force as a function of the imposed motion). The joint drive controller realizes this relationship by emulating a **virtual spring-damper system**:

$$F_{\text{contact}} = K_p(x_{\text{des}} - x) + K_d(\dot{x}_{\text{des}} - \dot{x})$$

The stiffness K_p multiplies the position error and the damping K_d the velocity error, the roles a proportional and a derivative gain play in a feedback controller. Tuning them in software causes the arm to yield compliantly under tracking errors, shedding peak impact loads. However, closed-loop impedance behavior is physically bounded by current-loop update rates, inverter voltage headroom, and unmodeled joint elasticity. Algebraic control laws cannot alter the unyielding inertia of the rotor during the first milliseconds of an impact. The runtime permission path must therefore enforce approach speed limits derived from physical contact qualification rather than relying on software compliance alone. The impedance command interface, through which a learned policy proposes these gains and the permission path validates them before admission, is defined in section 4.6.1.

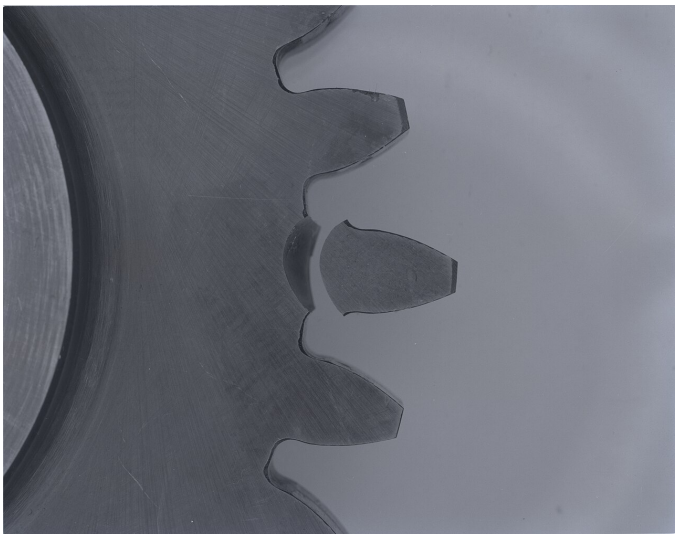


Figure 2.4: Broken gear tooth: A spur gear from gear research at the NASA Lewis (now Glenn) Research Center, photographed in 1974, with one tooth broken away at its root and the fragment lying in the gap. The root is where a tooth's bending stress concentrates, so repeated or impulsive loading that the transmission passes to the teeth ends here. (Credit: Martin Brown, NASA Glenn Research Center, via the U.S. National Archives, NARA 17417956, public domain.)

2.4.5 Actuation regimes and gear reduction trade-offs

The scaling disparity underlying inertia matching, in which output torque scales linearly with ratio ($\tau_{\text{out}} = \eta_{\text{gear}} N_{\text{gear}} \tau_{\text{motor}}$) while reflected inertia scales quadratically (N^2_{gear}), divides robotic actuation into three primary regimes. These regimes trade continuous torque density against mechanical backdrivability, distinguished by gear design, stage count, and reduction ratio (table 2.2): at the lowest ratios, **quasi-direct drive (QDD)** pairs a high-torque motor with a single compact planetary stage; at intermediate ratios, multistage planetary gearboxes reduce motor size at the cost of moderate reflected inertia and backlash; and at the highest ratios, strain-wave gears pack large torque multiplication into a compact joint at the cost of extreme reflected inertia and torsional compliance.

Table 2.2: Actuator transmission trade-off: Reduction ratio (N_{gear}), reflected rotor inertia scaling (N^2_{gear}), and the consequence for learned control policies across quasi-direct-drive (a single low-ratio planetary stage), multistage planetary, and strain wave transmissions. The strain wave range is that of one catalog series (Harmonic Drive AG 2014).

Transmission	Gear Ratio (N_{gear})	Reflected Inertia (N^2_{gear})	Implication for Learned Policies
Quasi-Direct Drive (single-stage planetary)	$3:1$–$10:1$ ($N_{\text{gear}} \leq 10$)	$N^2_{\text{gear}} \leq 100$ (Low)	Lower reflected inertia supports backdriving and current-based torque estimation; contact response still requires qualification.
Multistage Planetary	$15:1$–$50:1$ ($N_{\text{gear}} \approx 30$)	$N^2_{\text{gear}} \approx 225$–$2{,}500$ (Moderate)	Semi-backdrivable; a smaller motor than QDD for the same output torque; gear backlash requires load-side joint sensing.
Strain Wave (Harmonic Drive)	$50:1$–$160:1$ ($N_{\text{gear}} \geq 50$)	$N^2_{\text{gear}} \geq 2{,}500$–$25{,}600$ (Extreme)	High reflected inertia; zero initial backlash; torsional compliance and impact loading require qualification.

Actuator selection must satisfy continuous torque targets and permissible contact dynamics simultaneously. Direct-drive configurations eliminate gear backlash entirely, but require large, heavy motors to produce holding torque (Asada and Kanade 1983). Increasing the gear ratio permits a much smaller motor to produce equivalent output torque, but introduces reflected inertia, friction, and transmission compliance.

Motor thermal limits and torque requirements intersect in an electromagnetic figure of merit. Stator resistive losses follow $P_{\text{loss}} = i_q^2 R_{\text{eff}}$, where R_{eff} is the winding's effective loss resistance, while electromagnetic torque follows $\tau_{\text{motor}} = K_t i_q$. Combining these expressions reveals that resistive dissipation scales with the square of motor torque: $P_{\text{loss}} = (\tau_{\text{motor}}/K_m)^2$. Here the **motor constant** $K_m = K_t/\sqrt{R_{\text{eff}}}$ (in $\text{N}\cdot\text{m}/\sqrt{\text{W}}$) captures the motor's torque-producing capacity per square root of dissipated heat. Motor datasheets specify this parameter directly (TQ-Systems 2014). Section 2.5.1 relates R_{eff} to the phase and line-to-line resistances of section 2.4.2. When driving a mechanical transmission of ratio N_{gear} and efficiency η_{gear}, the motor must supply an internal torque of $\tau_{\text{out}}/(\eta_{\text{gear}} N_{\text{gear}})$, resulting in:

$$P_{\text{loss}} = \left(\frac{\tau_{\text{out}}}{\eta_{\text{gear}} N_{\text{gear}} K_m} \right)^2, \qquad J_{\text{ref,in}} = N_{\text{gear}}^2 J_{\text{in}}$$

where J_{in} represents total input inertia (the rotor plus the transmission input stage), and $J_{\text{ref,in}}$ is that combined inertia reflected to the joint output. Increasing the reduction ratio N_{gear} reduces winding heat by N_{gear}^2 while multiplying reflected inertia by N_{gear}^2. Consequently, for a selected motor and gearbox geometry, their product is invariant to the gear ratio:

$$P_{\text{loss}}\, J_{\text{ref,in}} = \frac{\tau_{\text{out}}^2\, J_{\text{in}}}{\eta_{\text{gear}}^2 K_m^2} \tag{2.6}$$

Adjusting N_{gear} relocates the actuator along a fixed trade-off curve between thermal dissipation and reflected inertia. Improving both characteristics concurrently requires selecting a motor with a superior ratio of K_m^2/J_{in}. Notebook 2.4 evaluates this trade-off for the mobile manipulator's arm joints.

Napkin Math 2.4: What does the gear ratio cost?

The running machine's arm is a seven-joint, torque-sensing manipulator in the class of the Franka Emika Panda (Franka Emika GmbH 2018), whose joints use strain-wave gears (section C.14.1). Franka does not publish the motors in those joints, so this example, like the thermal examples of section 2.5, uses a sourced stand-in. The stand-in is a TQ-RoboDrive ILM 70x18 frameless motor (TQ-Systems 2014) with $K_t = 0.187$ N·m/A and effective loss resistance $R_{\text{eff}} = 0.495\ \Omega$, driving a CSG-25 strain-wave gear (Harmonic Drive AG 2014), whose catalog lists one input inertia for all of that size's ratios. Rotor plus gear input give $J_{\text{in}} = 7.34 \times 10^{-5}$ kg·m². The joint must hold the arm's maximum joint torque $\tau_{\text{out}} = 87$ N·m through a gear of efficiency $\eta_{\text{gear}} = 0.85$ (illustrative).

Problem: How do the copper loss and the reflected inertia change if the same motor drives the joint through 50:1, 100:1, or a quasi-direct-drive ratio of 10:1?

Math:

1. **Motor constant**: $K_m = K_t/\sqrt{R_{\text{eff}}} = 0.266$ N·m/√W, the value the motor's data sheet publishes.
2. **At 50:1**: The motor supplies $\tau_{\text{out}}/(\eta_{\text{gear}} N_{\text{gear}}) = 2.05$ N·m, dissipating $(\tau_{\text{motor}}/K_m)^2 = 59.3$ W, and the joint reflects $N_{\text{gear}}^2 J_{\text{in}} = 0.183$ kg·m².
3. **At 100:1**: The motor supplies 1.02 N·m, the loss falls fourfold to 14.8 W, and the reflected inertia rises fourfold to 0.734 kg·m². The product $P_{\text{loss}} J_{\text{ref,in}}$ is unchanged.
4. **At 10:1**: The motor would have to supply 10.2 N·m, 2.5× its 4.05 N·m peak torque. No current can make this motor hold the load.

Result: Doubling the ratio buys a fourfold cut in holding heat with a fourfold rise in the inertia that an impact must accelerate, and lowering the ratio toward quasi-direct drive fails outright with this motor. The gear ratio moves the joint along a fixed trade; only the motor sets the trade itself.

Systems insight: A low-ratio, backdrivable joint requires a motor with a much larger torque per square root of watt, the route quasi-direct drive takes. A high-ratio arm joint instead accepts the reflected inertia and recovers contact sensitivity by measuring torque at its output.

Mechanical backdrivability measures the ease with which an external load applied at the joint output rotates the motor shaft backward through the transmission. The external torque required to backdrive a geared joint is:

$$\tau_{\text{ext}} = N_{\text{gear}}^2 J_{\text{rotor}} \ddot{q} + \tau_{\text{fric}}$$

where τ_{fric} denotes total joint friction referred to the output link. This friction varies dynamically with operating state (Lynch and Park 2017): breakaway static friction dominates at rest, Coulomb friction opposes motion at constant levels, and viscous damping grows with velocity. The Stribeck effect, a dip in friction just after sliding begins, shapes the response at near-zero speeds. Furthermore, gear tooth mesh friction scales with transmitted load, ambient temperature, and lubrication aging. At low velocities, friction dominates the resistance of high-reduction gearboxes; during sudden impacts, reflected rotor inertia dominates. As a result, backdrivability must be verified through empirical load testing on the assembled joint rather than inferred from the reduction ratio alone.

Quasi-direct drive actuation takes the low-ratio route of notebook 2.4, using large-diameter, high-torque motors so a single modest reduction stage suffices (Seok et al. 2015; Wensing et al. 2017; Katz et al. 2019). Minimizing reflected inertia and internal friction maximizes mechanical transparency, the fidelity with which external interaction forces translate into measurable motor motion and winding currents. The penalty is a substantially heavier motor demand for any given output torque.

Mechanical transparency also dictates what motor currents reveal about contact states. In high-friction gearboxes, motor current primarily overcomes internal transmission losses rather than external loads. Conversely, when transmission friction and inertial resistance remain small, output torque simplifies to:

$$\tau_{\text{out}} \approx \eta_{\text{gear}} N_{\text{gear}} K_t i_q$$

This relationship enables **proprioceptive sensing**, allowing the controller to estimate interaction forces directly from motor current without specialized external sensors. However, accurate estimation requires rigorous calibration across operating temperatures and speeds; current setpoints measure motor electromagnetic effort, portions of which are absorbed by acceleration and drivetrain losses. While backdrivability allows external collisions to displace the joint without shearing gear teeth, low gearing and motor current sensing do not guarantee safe contact forces. High link velocities can still impart severe impulsive shock before the current controller can respond. Safe interaction mandates qualifying the total closed-loop contact response.

High-reduction joints overcome transmission friction by sensing torque directly at the joint output. Strain gauge torque sensors mounted on the output side of strain wave gearboxes measure delivered torque directly, allowing closed-loop current controllers to cancel gearbox friction and cogging torque (Lynch and Park 2017). The running machine's arm adopts this approach, integrating torque sensors within each of its seven joints (Franka Emika GmbH 2018) to achieve transparency through measurement rather than low mechanical reduction. The engineering cost includes increased joint complexity, elevated mass, and the torsional compliance of the strain wave flexsplines, which complicates high-bandwidth motion tracking.

Whether mechanical transparency originates by construction (quasi-direct drive) or by active measurement (output torque sensing), contact operations require qualifying joint compliance, closed-loop torque response, and dynamic sensing fidelity against the operating environment. Dual-encoder architectures and load-side torque sensors expose internal transmission windup and mechanical backlash that motor-side encoders conceal. When load-side deflection departs from the qualified dynamic envelope, the runtime safety system can immediately intercede and reject subsequent motion commands.

2.4.6 Supporting drive and impedance models

Deliverable motor torque and contact shock isolation rest on two compact models of how the drive and transmission transform effort and motion: the rotating-frame torque law behind $\tau_{\text{motor}} = K_t i_q$ (section 2.4.2), and the series-spring impedance that isolates reflected rotor inertia during a fast

impact (section 2.4.4). Inside the physical drive, FOC holds the d-axis current i_d of section 2.4.2 at zero, which minimizes stator losses and makes output torque proportional to the q-axis current alone (section C.9 states the voltage equations that govern both currents in the rotating frame):

$$\tau_{\text{motor}} = \frac{3}{2} N_{\text{poles}} \lambda_{\text{pm}} i_q = K_t i_q$$

where N_{poles} is the number of magnetic pole pairs on the rotor and λ_{pm} is the permanent-magnet flux linkage, the magnetic flux from the rotor magnets that threads each winding. The $\frac{3}{2}$ scaling factor arises from the amplitude-invariant transformation convention adopted in this chapter. Motor drive firmware must enforce a transformation convention consistent with the identified torque constant K_t.

For frequency-domain dynamic analysis, mechanical impedance quantifies the joint's physical resistance to imposed environmental motion. The Laplace variable s stands for differentiation in time, so that for a sinusoidal motion of angular frequency ω it can be read as $s = j\omega$. An impedance term sJ grows with frequency like an inertia, and a term K/s falls with frequency like a spring. The apparent mechanical impedance $Z_{\text{out}}(s) = \tau_{\text{ext}}(s)/\dot{q}(s)$ evaluated at the joint output flange couples the load dynamics directly to the reflected rotor dynamics through the drivetrain's torsional stiffness K_{joint}. An external torque applied at the joint flange splits between two paths that share the same output velocity $\dot{q}(s)$, one accelerating the output link inertia J_{load} directly and the other twisting the transmission spring against the reflected rotor. Along that second path, the transmission spring and the reflected rotor act in series so both stages bear equal transmitted torque while their relative angular velocities sum, causing the spring impedance K_{joint}/s and reflected rotor impedance to combine through their reciprocal sum before adding to the output link impedance (Spong 1987):

$$Z_{\text{out}}(s) = sJ_{\text{load}} + D_{\text{joint}} + \left[\frac{1}{sN_{\text{gear}}^2 J_{\text{rotor}} + N_{\text{gear}}^2 D_{\text{motor}}} + \frac{s}{K_{\text{joint}}} \right]^{-1}$$

DRAFT

The coefficients D_{joint} and D_{motor} account for viscous damping in the output bearings and motor shaft. At low interaction frequencies, the series spring behaves rigidly relative to the rotor, and the environment experiences the aggregate inertia $J_{\text{load}} + N_{\text{gear}}^2 J_{\text{rotor}}$ assumed in rigid-body kinematic models. Above the transmission's natural resonance frequency, the bracketed impedance term simplifies toward K_{joint}/s: external collision forces compress the joint compliance against the link inertia J_{load}, temporarily isolating the rotor's reflected inertia. This series compliance cushions sudden impacts in flexible drivetrains and series elastic actuators, reinforcing why the flexible-joint dynamic model is necessary to calculate contact loads during manipulation.

Checkpoint 2.1: Actuator limits

The drives decide whether the stopping premise can be delivered, and the transmission decides what that delivery costs in heat and inertia.

- ☐ **Torque ceiling**: Can you compute the deceleration ceiling of the two hub drives when their current limit is set at the motor's rated current rather than its peak, and explain why a current limit lowered to protect the windings breaks the stopping premise without any software change?
- ☐ **Current rise**: Can you estimate how long the hub-motor current takes to reach its limit from rest on a depleted pack, and explain why back-EMF at speed helps a braking current but can starve a driving one?
- ☐ **Inertia matching**: Can you explain why the gear ratio that maximizes link acceleration makes reflected rotor inertia equal load inertia ($N_{\text{gear}}^2 J_{\text{rotor}} = J_{\text{load}}$), and why oversizing the gearbox for static torque lowers dynamic joint acceleration?
- ☐ **Heat vs. reflected inertia**: Can you explain why, for a given motor and gear, the ratio cannot reduce holding heat and reflected inertia together, and what must change to improve both?

Operating near these electrical and mechanical ceilings exacts an inevitable thermodynamic toll. Every ampere driving the motor against reflected rotor inertia or sustaining peak clamping torque dissipates resistive heat ($P_{\text{loss}} = i_q^2 R_{\text{eff}}$) in the stator windings. That thermal energy accumulates directly in the motor's thermal mass, bounding the operational duration of peak torque before winding insulation suffers accelerated thermal degradation.

2.5 Thermal Duty Cycles

Holding a load motionless at full reach places deceptive demands on an articulated arm such as the mobile manipulator's. Maintaining a static load against gravity demands continuous phase current through the stator coils, actively converting electrical energy into accumulating heat. Heat arrives in seconds and leaves in minutes, making duty cycle a primary design variable.

2.5.1 Thermal capacity and insulation breakdown thresholds

Although a stationary joint performs zero mechanical work ($W = \int F \cdot dx = 0$), sustaining its holding torque against gravity requires continuous phase current to produce magnetic Lorentz force ($\tau_{\text{motor}} = K_t i_q$). The lumped thermal model uses i_q in the same convention as its torque constant K_t. Here R_{eff} denotes the effective aggregate loss resistance for that current, so total winding copper loss is:

$$P_{\text{loss}} = i_q^2 R_{\text{eff}} = \frac{\tau_{\text{motor}}^2}{K_t^2} R_{\text{eff}}$$

For the amplitude-invariant drive convention above, with balanced phase currents and $i_d = 0$, this effective resistance is $R_{\text{eff}} = \frac{3}{2} R_{\text{phase}}$, where R_{phase} is resistance per phase. Three resistances of one winding therefore appear in this chapter. The phase resistance R_{phase} belongs in the Kirchhoff equation of section 2.4.2. Datasheets quote the line-to-line value measured between two terminals, which for a star-connected winding spans two phases, $2R_{\text{phase}}$. The hub-motor current-rise example used that line value with the line inductance, whose ratio gives the same time constant. The thermal calculations use $R_{\text{eff}} = \frac{3}{2} R_{\text{phase}}$, three quarters of the line-to-line value, and every winding resistance in them, including $R(T_{\text{winding}})$, is this effective resistance. The following illustrative thermal examples stipulate it and the matching current convention.

The copper-loss equation ties torque to current and current to heat. Commanded torque scales linearly with current ($\tau_{\text{motor}} = K_t i_q$), but stator copper loss scales quadratically with torque (τ_{motor}^2). Demanding twice the torque requires four times the thermal dissipation. Because heat has no fast exit, thermal accumulation limits how long an arm can maintain static poses or execute dynamic bursts without mechanical brakes.

Reducing motor current to shed heat also reduces holding torque. A loaded arm therefore needs a response that preserves support, such as transferring the load to a mechanical brake, rather than assuming that thermal derating leaves the task unchanged. Excess winding temperature can damage electrical insulation, while excess rotor temperature can permanently reduce magnet strength. Those material limits bound the allowable temperature trajectory.

The winding and housing respond on different timescales. Copper heats rapidly under current, while the larger core and housing absorb and reject heat more slowly. A case temperature measurement can therefore lag the winding hotspot during a torque burst. The stator in figure 2.5 failed from overheating, and its damage sits where this model puts the heat: in the copper windings and the insulation between them.

A thermal model follows the same energy accounting as the stopping calculation: energy accumulates where the rate entering exceeds the rate leaving. Here the winding receives electrical losses and transfers heat to the core; the core transfers heat to the surroundings. Thermal capacitance measures how much energy raises a component's temperature, while thermal resistance measures how strongly the heat-flow path resists that transfer. Representing the winding and core separately gives the two-node lumped-parameter thermal ordinary differential equation (ODE) system:

$$C_{\text{wind}} \frac{dT_{\text{winding}}(t)}{dt} = P_{\text{loss}}(t) - \frac{T_{\text{winding}}(t) - T_{\text{core}}(t)}{R_{\text{th,wc}}}$$

$$C_{\text{core}} \frac{dT_{\text{core}}(t)}{dt} = \frac{T_{\text{winding}}(t) - T_{\text{core}}(t)}{R_{\text{th,wc}}} - \frac{T_{\text{core}}(t) - T_{\text{amb}}}{R_{\text{th,ca}}}$$

Figure 2.5: Motor stator damaged by overheating: The opened stator of an electric motor that failed from overheating, showing the copper phase windings bound with tape at left, the insulating slot liners where the windings leave the laminated iron core, and the end bell with its bearing seat at right. The windings are where resistive heat ($P_{\text{loss}} = i_q^2 R_{\text{eff}}$) is generated, and the insulation between them is what accumulated heat ages. (Credit: K. Kudelina, Wikimedia Commons, CC BY 4.0.)

where $P_{\text{loss}}(t) = i_q^2(t) R(T_{\text{winding}}) = \frac{\tau_{\text{motor}}^2(t)}{K_t^2} R(T_{\text{winding}})$ is the Joule dissipation source deposited directly into the copper coils, C_{wind} is the small thermal capacitance of the winding, C_{core} is the large thermal capacitance of the laminated stator core and housing, $R_{\text{th,wc}}$ is the conductive thermal resistance from winding to core, and $R_{\text{th,ca}}$ is the convective thermal resistance from core to ambient air.

This separation of timescales creates a dangerous observability gap. Because $C_{\text{wind}} \ll C_{\text{core}}$, under a sudden peak torque burst or sustained stall against gravity, the stator core temperature T_{core} remains virtually clamped over the initial seconds by its large thermal inertia. The internal copper winding temperature surges at the initial adiabatic rate:

$$\left.\frac{dT_{\text{winding}}}{dt}\right|_{t=0} \approx \frac{P_{\text{loss}}}{C_{\text{wind}}}$$

Under sustained peak torque, the internal copper hotspot T_{winding} can climb past the 155 °C Class F rating within tens of seconds (notebook 2.5) while an external thermistor bonded to the motor casing still reads far below the hotspot. The class temperature is not a cliff at which the insulation fails. IEC 60085 assigns it as the hot-spot temperature at which an insulation system reaches its rated life (International Electrotechnical Commission 2007), and insulation aging[13] proceeds as a chemical reaction whose rate grows exponentially with temperature (Dakin 1948). Every excursion above the rating therefore spends insulation life faster than the rating assumes, and the accumulated aging culminates in the insulation charring and turn-to-turn electrical failures documented in figure 2.5. A thermal budget must count accumulated exposure as well as the instantaneous peak.

A first-order approximation can summarize heating over a characterized operating range, with an effective winding temperature T_{winding} and fitted thermal parameters:

$$C_{\text{th}} \frac{dT_{\text{winding}}(t)}{dt} = P_{\text{loss}}(t) - \frac{T_{\text{winding}}(t) - T_{\text{amb}}}{R_{\text{th}}}$$

where $R_{\text{th}} = R_{\text{th,wc}} + R_{\text{th,ca}}$ represents the winding-to-ambient steady-state thermal resistance. The effective capacitance C_{th} sets the fitted time constant $\tau_{\text{th}} = R_{\text{th}} C_{\text{th}}$. This approximation does not re-

[13] **Thermal Aging as an Exchange Rate**: The engineering practice predates the chemistry. Montsinger (1930) proposed loading transformers by the temperature their insulation reaches rather than by current alone, and Dakin (1948) later explained the exponential dependence as Arrhenius reaction kinetics. The consequence is an exchange rate rather than a threshold. Time spent above the rating costs life at a rate that grows exponentially with the excess, so the limit record must count time at temperature rather than merely the peak.

solve a fast winding hotspot separately from the housing. Its transient predictions require validation before they can bound a burst.

At thermal steady state ($dT_{\text{winding}}/dt = 0$), heat generation balances heat dissipation to ambient:

$$P_{\text{loss,ss}} = \frac{T_{\text{limit}} - T_{\text{amb}}}{R_{\text{th}}}$$

Substituting the copper loss identity $P_{\text{loss}} = \frac{\tau_{\text{motor}}^2}{K_t^2} R(T_{\text{limit}})$ reveals the **continuous thermal torque ceiling**:

$$\tau_{\text{cont}} = K_t \sqrt{\frac{T_{\text{limit}} - T_{\text{amb}}}{R(T_{\text{limit}}) R_{\text{th}}}} \tag{2.7}$$

Continuous torque is limited by thermal dissipation, not by the peak current ratings of the drive electronics or the battery. The arm's stand-in motor, for example, is rated for 4.05 N·m peak but only 1.25 N·m continuous, a ratio of 3.2 (TQ-Systems 2014). A brief torque burst of several seconds causes a rapid transient temperature rise that stays within the insulation rating ($T_{\text{limit}} = 155$ °C) if its peak does. However, sustained holding torque or high-frequency cycling drives the winding toward an asymptotic thermal equilibrium $T_\infty = T_{\text{amb}} + \bar{P}_{\text{loss}} R_{\text{th}}$. If that equilibrium exceeds the rating, continuous operation ages the winding insulation far faster than its rated life allows and ends in phase-to-phase short circuits.

The loss term must also change with temperature. Copper's positive temperature coefficient ($\alpha_{\text{Cu}} \approx 0.00393$ K^{-1}) increases the effective winding resistance by 47.2 percent from 20 °C to 140 °C, according to $R(T_{\text{winding}}) = R_0[1 + \alpha_{\text{Cu}}(T_{\text{winding}} - T_0)]$. That upper temperature is the **engineering ceiling** T_{ceil}, a working limit chosen below the 155 °C insulation rating T_{limit} to leave room for the error of the thermal model. The burst horizons and the stall derating below are checked against the rating itself. A schedule of repeated bursts is held to the ceiling, as is the installed continuous rating that the datasheet pitfall of section 2.9 obtains by evaluating equation 2.7 at T_{ceil} in place of T_{limit}. Holding the same torque at the ceiling therefore dissipates 47.2 percent more winding power than at the reference. A fixed-resistance calculation omits this feedback. The burst example below uses that approximation explicitly, and the subsequent stall calculation restores it.

Datasheet thermal ratings are optimistic because they are measured on an unconstrained motor mounted to a large heat sink in free air at 20°C or 25°C. Installed in a sealed chassis beside power electronics, battery packs, and other joints, the motor loses convective airflow, which raises R_{th}. Neighboring loads raise its local ambient above the test ambient before its own coils carry current. Thermal margins must therefore be budgeted from heating and cooling time constants measured with the enclosure sealed and adjacent loads at their p99 power draw.

2.5.2 Transient thermal bursts and periodic duty cycles

Because thermal capacity integrates power over time, a peak torque[14] or peak current rating is meaningless without four parameters: the initial winding temperature $T_{\text{winding}}(0)$, the allowed duration t_{on}, the ambient T_{amb}, and the recovery time t_{off}. An actuator that can produce three times its continuous torque sustains it only while the integral of copper loss ($P_{\text{loss}} = i_q^2 R_{\text{eff}}$) stays within the margin below the insulation limit. From a cold winding, that can last tens of seconds, and from a heat-soaked one a fraction of that (notebook 2.5).

> Napkin Math 2.5: Thermal accumulation across duty cycles
>
> This example uses the arm's sourced stand-in joint of notebook 2.4: a CSG-25-50 strain-wave gear (Harmonic Drive AG 2014) driven by a TQ-RoboDrive ILM 70x18 frameless motor (TQ-Systems 2014), whose rated current is $I_{\text{cont}} = 6.7$ A. The motor has effective aggregate loss resistance $R_{\text{eff}} = 0.495\ \Omega$, lumped thermal capacitance $C_{\text{th}} = 120$ J/K, and installed thermal resistance $R_{\text{th}} = 2.5$ K/W (both thermal values illustrative, because the motor's data sheet leaves them to the installation). It runs in an enclosed ambient $T_{\text{amb}} = 40$ °C with Class F insulation rated to 155 °C. The thermal time constant is $\tau_{\text{th}} = R_{\text{th}} C_{\text{th}} = 300$ s.

[14] **Duty Type and RMS Torque**: IEC 60034-1 rates a motor for a duty type: S1 is continuous running at constant load long enough to reach thermal equilibrium, and S3 is an intermittent periodic duty of identical load-and-rest cycles too short to reach it (International Electrotechnical Commission 2022). Because copper loss grows with τ_{motor}^2, the torque that heats the winding over a cycle short compared with the thermal time constant is the root-mean-square value $\tau_{\text{rms}} = \sqrt{\frac{1}{T}\int_0^T \tau_{\text{motor}}^2\, dt}$, and it is the RMS, not the peak, that must stay under the continuous rating. A peak rating means nothing without its duty type, which is why figure 2.6 draws the S1 and S3 regions separately.

Problem: How does the initial winding temperature change how long a threefold rated-current burst can last before the insulation limit?

Math:

1. **Continuous equilibrium**: At $I_{\text{cont}} = 6.7$ A the winding settles at $T_{\text{eq}} = T_{\text{amb}} + I_{\text{cont}}^2 R_{\text{eff}} R_{\text{th}} = 95.6$ °C, below the limit.
2. **Peak burst**: At $I_{\text{peak}} = 20.1$ A the dissipation rises ninefold to $P_{\text{peak}} = 200.0$ W, whose asymptote $T_\infty = T_{\text{amb}} + P_{\text{peak}} R_{\text{th}} = 540.0$ °C lies far above the limit.
3. **Survival horizons**: With $T_{\text{winding}}(t) = T_\infty - (T_\infty - T_{\text{winding}}(0))\, e^{-t/\tau_{\text{th}}}$, the time to reach the limit is
$$t_{\text{limit}} = \tau_{\text{th}} \ln \frac{T_\infty - T_{\text{winding}}(0)}{T_\infty - T_{\text{limit}}}$$
which gives 78.4 s from a cold start at ambient and 43.1 s from a heat-soaked start at T_{eq}.

Result: The heat-soaked joint holds the burst 45.1 percent less time than the cold one, so peak torque cannot be budgeted without tracking thermal history.

Systems insight: Peak torque is a stock of heat margin that thermal history spends, not a fixed rating. The admission check $\hat{T}_{\text{wind}} \le T_{\text{limit}}$ must use the current estimate of the winding temperature, and these first-order horizons are optimistic, because the winding hotspot of the two-node model runs ahead of the lumped temperature.

For repeated cycles of period $t_{\text{cycle}} = t_{\text{on}} + t_{\text{off}}$, the engineering ceiling $T_{\text{ceil}} = 140$ °C sets a cycle-average power ceiling $\bar{P}_{\max} = (T_{\text{ceil}} - T_{\text{amb}})/R_{\text{th}} = 40$ W. With peak dissipation during t_{on} and none during t_{off}, this average-power screen bounds the duty cycle $D_{\text{cycle}} = t_{\text{on}}/t_{\text{cycle}}$ by

$$D_{\text{cycle}} \le \frac{T_{\text{ceil}} - T_{\text{amb}}}{P_{\text{peak}} R_{\text{th}}} \tag{2.8}$$

which here is 20.0 percent, so a 3 s burst calls for a recovery of $t_{\text{off}} = t_{\text{on}}(1 - D_{\text{cycle}})/D_{\text{cycle}} \approx 12$ s. The average does not bound the hottest instant. Because heat arrives in seconds during bursts but dissipates over minutes during recovery, the peak transient hotspot temperature during periodic pulsing strictly exceeds the time-averaged calculation,[15] reaching 142.0 °C (above the ceiling) before the rise of $R(T_{\text{winding}})$ adds more. Average-power screening is optimistic, and a burst schedule is certified only against the transient hotspot trajectory.

[15] **Periodic steady-state thermal peak**: Over a repeating cycle of period $t_{\text{cycle}} = t_{\text{on}} + t_{\text{off}}$, summing the heating and cooling exponentials gives the periodic peak temperature rise: $\Delta T_{\text{peak}} = P_{\text{peak}} R_{\text{th}} \frac{1 - e^{-t_{\text{on}}/\tau_{\text{th}}}}{1 - e^{-t_{\text{cycle}}/\tau_{\text{th}}}}$. As the cycle period $t_{\text{cycle}} \to 0$, this peak approaches the average-power screen ($D_{\text{cycle}} P_{\text{peak}} R_{\text{th}}$); for any finite burst length, the peak winding temperature exceeds the average.

2.5.3 Torque-speed operating envelopes and back-EMF roll-off

The burst calculation limits duration, while the back-EMF relation in section 2.4.2 limits torque at speed. A feasible maneuver must satisfy both. At low speed, the drive can supply the current needed for a burst, but the winding temperature limits how long it may do so. At higher speed, back-EMF consumes voltage headroom and can prevent that current from appearing at all. On the arm's stand-in joint motor, voltage headroom and thermal history bound the usable torque-speed region simultaneously (figure 2.6). Because steady-state operation at full supply voltage splits the bus voltage between the resistive drop $i_q R_{\text{phase}}$ and the back-EMF $K_e \omega_m$, rising torque demands more current, consumes a larger resistive voltage drop, and pulls the motor's voltage-limited speed linearly down from 2,110 rpm at no load to 1,570 rpm at peak torque, while the burst that a cold winding sustains for 78.4 s reaches the insulation class in only 43.1 s from continuous-duty equilibrium.

The continuous-duty region (S_1) permits sustained operation under the declared cooling conditions. The larger intermittent region (S_3) permits periodic bursts only with the starting temperature, duration, and recovery interval established above. Both regions narrow when speed consumes the drive's voltage headroom. Their intersection with the current thermal state, rather than the catalog peak, gives the available torque for the next maneuver.

A simulator that uses only a fixed torque clamp can therefore teach a policy an unavailable action: maximum torque while the rotor is already near its voltage-limited speed, or a repeated burst without recovery. The actuator model and permission limits must include speed and thermal history.

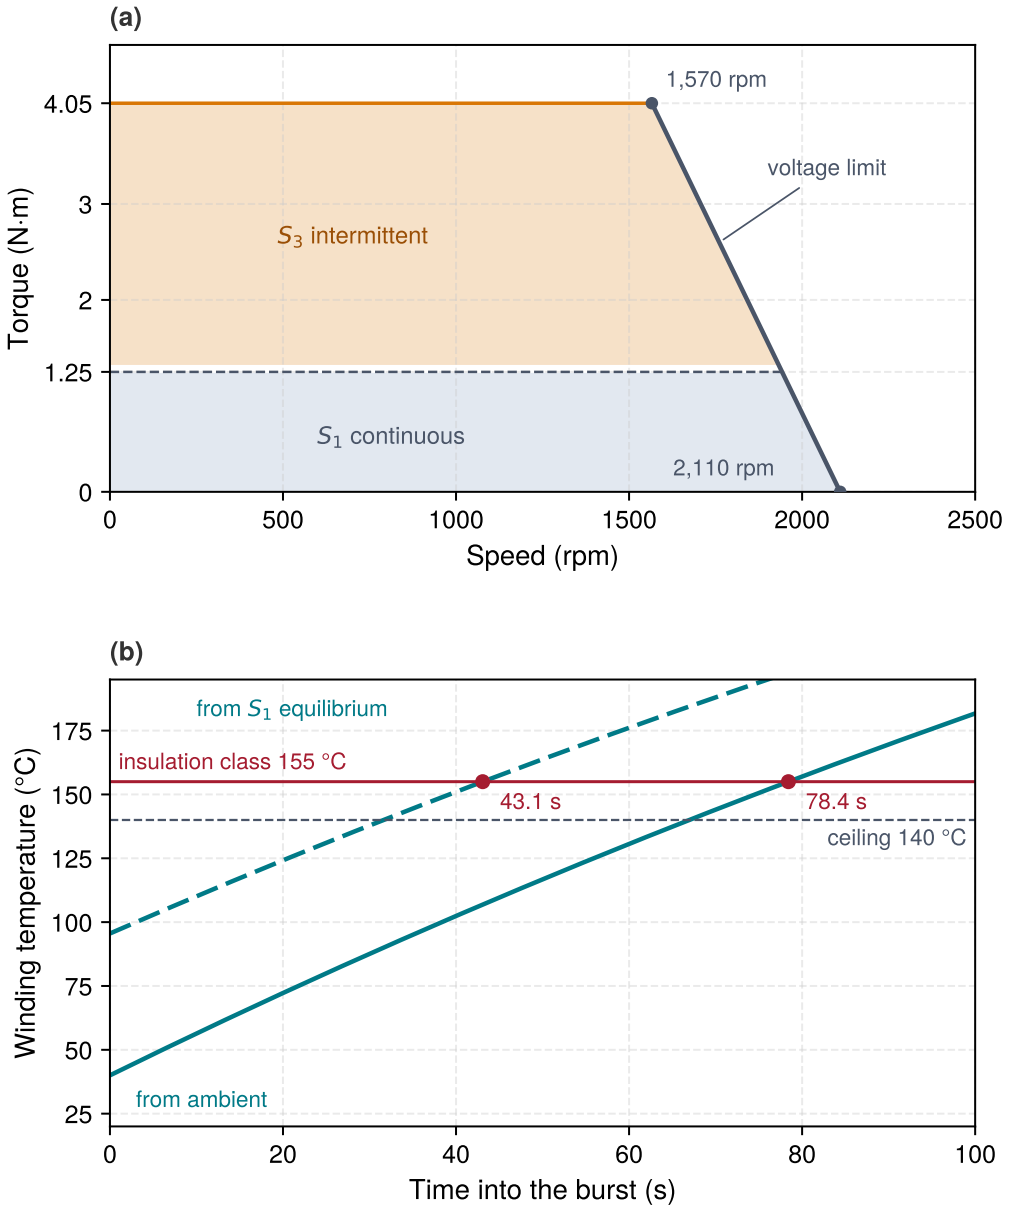

Figure 2.6: Torque, speed, and time on one joint motor: (a) The TQ-RoboDrive ILM 70x18 of the arm's stand-in joint on its 48 V supply. Continuous duty S_1 extends up to the 1.25 N·m rated torque; intermittent duty S_3 extends to the 4.05 N·m peak. Both end where back-EMF plus the resistive drop uses up the supply, from the 2,110 rpm no-load speed down to 1,570 rpm at peak torque; winding inductance, neglected here, pulls that boundary lower. (b) The winding temperature of the threefold-current burst of notebook 2.5, a first-order rise toward 540.0 °C with $\tau_{\text{th}} = 300$ s. From ambient the burst reaches the 155 °C insulation class after 78.4 s; from the continuous-duty equilibrium it gets there after 43.1 s. The thermal values are illustrative, because the data sheet leaves them to the installation.

Temperature-dependent winding resistance further shrinks the available region during a sustained hold.

The standard remedy in legged-robot sim-to-real transfer replaces the clamp with an actuator model identified on the hardware. For the series elastic actuators of the ANYmal quadruped, Hwangbo et al. (2019) trained a small network on a few minutes of logged joint data to map a short

history of position errors and velocities to the torque the actuator actually delivered. The network then ran inside the simulator in place of an ideal actuator. The ideal model, which assumes any commanded torque appears instantly, failed to predict the measured torque. The same structure carries the envelope of this section into training: an actuator model that also takes speed, bus voltage, and winding temperature as inputs lets the simulator deny the torque the hardware cannot deliver.

↪ How actuator dynamics mismatch is measured and closed in the training simulator is developed in section 6.5.

2.5.4 Copper resistance feedback and stall thermal runaway

The copper-resistance rise calculated in section 2.5.1 must enter the runtime estimate as well as the design calculation. An external thermistor can lag the winding hotspot, so a thermal observer combines measured current with the characterized heating and cooling model. A discrete update of the lumped energy balance is:

$$\hat{T}_{\text{wind}_{k+1}} = \hat{T}_{\text{wind}_k} + \frac{\Delta t}{C_{\text{th}}} \left[{i_q}_k^2 R(\hat{T}_{\text{wind}_k}) - \frac{\hat{T}_{\text{wind}_k} - T_{\text{amb}}}{R_{\text{th}}} \right]$$

where $R(\hat{T}_{\text{wind}_k}) = R_0[1 + \alpha_{\text{Cu}}(\hat{T}_{\text{wind}_k} - T_0)]$. The update interval, model error, and temperature uncertainty must fit the thermal margin. As the estimate approaches its ceiling, the permission path reduces admissible effort or transfers the load to a qualified support mechanism. Removing holding current without securing a gravity-loaded arm would exchange a thermal fault for uncontrolled motion. A static hold shows how copper's feedback changes the sustainable torque (notebook 2.6).

Napkin Math 2.6: Static holding torque and stall derating

The arm's elbow, the same Panda-class stand-in joint as notebook 2.5, is asked to hold the arm's maximum joint torque $\tau_{\text{hold}} = 87$ N·m at stall ($\omega_m = 0$) through its $N_{\text{gear}} = 50{:}1$ strain-wave gear ($\eta_{\text{gear}} = 0.85$, illustrative). Its motor has $K_t = 0.187$ N·m/A and cold effective aggregate loss resistance $R_0 = 0.495\ \Omega$ at $T_0 = 20$ °C. The illustrative installed thermal resistance is $R_{\text{th}} = 1.80$ K/W, lower than the 2.5 K/W of the burst example and so a better-cooled installation. The Class F limit is 155 °C, and the limb ambient is $T_{\text{amb}} = 40$ °C.

Problem: With copper's resistance rising with temperature, where does the stalled winding settle, and what holding torque is thermally sustainable?

Math:

1. **Stall current**: $\tau_{\text{motor}} = \tau_{\text{hold}}/(\eta_{\text{gear}} N_{\text{gear}}) = 2.05$ N·m, so $i_q = \tau_{\text{motor}}/K_t = 10.9$ A and the cold dissipation is $P_0 = i_q^2 R_0 = 59.3$ W.
2. **Runaway**: With $R(T_{\text{winding}}) = R_0[1 + \alpha_{\text{Cu}}(T_{\text{winding}} - T_0)]$, the steady rise satisfies

   $$\Delta T = i_q^2 R_0 \left[1 + \alpha_{\text{Cu}}(T_{\text{amb}} - T_0 + \Delta T)\right] R_{\text{th}}$$

   Rearranging terms yields $\Delta T = \frac{i_q^2 R_0 [1 + \alpha_{\text{Cu}}(T_{\text{amb}} - T_0)] R_{\text{th}}}{1 - i_q^2 R_0 R_{\text{th}} \alpha_{\text{Cu}}}$. The denominator establishes the **thermal runaway criterion**: if the positive feedback loop gain satisfies $i_q^2 R_0 R_{\text{th}} \alpha_{\text{Cu}} \geq 1$, this fixed-current, linear-resistance model cannot settle to a stable thermal equilibrium. Above one, heat generation increases with temperature faster than heat removal, producing exponential growth. At exactly one, the temperature-dependent terms cancel and the remaining positive heating causes linear growth. In this stall scenario, the feedback factor is $0.4196 < 1$, so temperature settles at a finite (yet fatal) equilibrium given by $\Delta T = 115.16 + 0.4196\ \Delta T$. This yields $\Delta T = 198.4$ K and drives the winding to 238.4 °C, far above its rating.
3. **Derating**: At the limit the allowable rise is 115 K, so the sustainable dissipation is $P_{\text{loss,ss}} = \Delta T_{\text{limit}}/R_{\text{th}} = 63.89$ W. At the hot resistance $R(T_{\text{limit}}) \approx 0.758\ \Omega$, that allows $I_{\text{cont}} = \sqrt{P_{\text{loss,ss}}/R(T_{\text{limit}})} \approx 9.18$ A and a hold of $\tau_{\text{hold,max}} = \eta_{\text{gear}} N_{\text{gear}} K_t I_{\text{cont}} \approx 73.0$ N·m.

Result: Held without control, the stall drives the winding toward 238.4 °C, and staying within the insulation rating requires a 16.1 percent derating, from 87 N·m to 73.0 N·m.

Systems insight: At stall the motor does no mechanical work, so every watt it draws becomes heat, and copper's rising resistance makes that heat grow with temperature. Continuous gravity holding above the thermally sustainable torque therefore needs another support mechanism, such as a friction brake or counterweight, in the premise the permission path admits; holding within that torque can remain electrically sustained under the stated thermal conditions.

Thermal capacity governs how long an actuator can sustain torque before winding insulation degrades or thermal runaway occurs, bounding continuous holds and transient bursts by the plant's ability to reject heat. Motor windings, however, do not generate those thermal loads in isolation. Delivering the current pulses that drive these torque trajectories simultaneously stresses the upstream power distribution network, shifting the engineering constraint from heat dissipation in copper to transient voltage stability on the shared direct-current bus.

2.6 Electrical Power Integrity

When the mobile manipulator swerves hard to avoid a collision, every drive motor, joint inverter, and accelerator demands peak current at once from one direct-current distribution bus. In simulation, current flows from an idealized source. On hardware, delivery is bounded by finite capacity, source impedance, and transient voltage stability. A machine that browns out mid-motion fails physically; the electrical supply is a shared resource.

Rail sag, regenerative overvoltage, and thermal accumulation are manifestations of one bounded energy network on different time scales. Of the three, voltage moves fastest, within microseconds to milliseconds whenever current demand exceeds what the source can deliver at that instant. Compute, sensing, and motor inverters draw from a common bus, so when a policy commands coordinated accelerations across several joints, the sum of their currents changes the voltage delivered to every node on the machine.

2.6.1 Power distribution impedance, transient droop, and brownout resets

The mobile machine's battery, harnesses, connectors, and protection switches all contribute source impedance.[16] Local capacitors supply part of a sudden load increase, so current drawn by the loads need not equal current arriving through the harness. For a source feeding one bus node through resistance and inductance,

$$V_{\text{source}}(t) - V_{\text{bus}}(t) = R_{\text{bus}} I_{\text{source}}(t) + L_{\text{bus}} \frac{dI_{\text{source}}}{dt} \tag{2.9}$$

where R_{bus} is the lumped source resistance, L_{bus} is the loop inductance, and I_{source} is the current through that source path. The local capacitor bank C_{bus} supplies the difference between load current I_{load} and source current. In the ideal-capacitor model, charge removed from that bank lowers the same bus voltage:

$$V_{\text{bus}}(0) - V_{\text{bus}}(t) = \frac{1}{C_{\text{bus}}} \int_0^t [I_{\text{load}}(s) - I_{\text{source}}(s)]\, ds.$$

These equations jointly determine the voltage response; the capacitor's voltage change is not an additional drop to add to equation 2.9.

Compute and motion must be budgeted together because they share this path. An obstacle response can require fresh inference at the same time as a large drive-current change, so testing each load separately misses the combined step that the supply must support. Harness inductance limits how quickly source current can rise. Local capacitors supply the initial current deficit, while harness resistance continues to lower the rail after source current catches up with a sustained load. Once the currents settle, the inductive voltage is zero and the sustained drop is $I_{\text{source}} R_{\text{bus}}$. The worked example below screens that sustained condition. It does not establish the minimum voltage during the transient. If the actual voltage crosses a regulator's undervoltage threshold, computation or communication may stop or reset. Power qualification must establish the voltage at the supplied devices during coincident load and the physical response if those devices lose power.

[16] **Source Resistance**: The lumped source resistance is $R_{\text{bus}} = R_{\text{cell}} + R_{\text{harness}} + R_{\text{switch}}$, the sum of battery cell, harness and connector, and protection-switch on-state resistances. The cell term is the one that moves. It rises as the pack ages and as it cools, so a sustained screen passed at commissioning can fail on a cold morning years later. That drift belongs in the rail's limit record as a condition, with a detector that measures the drop under load.

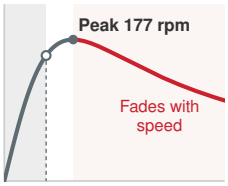
↪ Sizing the bus capacitance against that droop, and the undervoltage lockout it must avoid, is developed in section C.10.

2.6.2 Unpowered states and unmanaged fallback dynamics

A brownout reset turns the electrical fault into a mechanical one. Voltage supervisors pull the reset line on microcontrollers and gate drivers, clocks halt, register configurations vanish, and communication buses float. An acceleration command issued just before the reset stays physically active until the gate-driver stage collapses. If the driver then floats, phase current ceases, torque falls to zero, and the body coasts under gravity and inertia into workpieces or hardstops. If it instead shorts the low-side switches for dynamic braking, back-EMF ($e_{\text{bemf}} = K_e\omega_m$) produces an immediate, abrupt counter-torque that jerks the mechanics at the joint limits.

Power removal is an unmanaged state transition, not an automatic return to safety. Cutting power leaves an actuator in one of three unpowered states, namely free coasting, phase-short dynamic braking, or spring-engaged mechanical braking, and each enforces a distinct mechanical behavior. Free coasting simply allows gravity to accelerate unconstrained joints without any resistance. An electromechanical friction brake requires 30 ms to 80 ms for its mechanical spring to overcome magnetic coil decay and engage its friction pads, during which gravity accelerates an overhead arm downward.

Phase-short dynamic braking generates a counter-torque that at low speed grows in proportion to angular velocity ($\tau_{\text{motor}} \approx \frac{K_t K_e}{R_{\text{phase}}}\omega_m$) and gives zero holding torque at zero velocity. The proportionality does not last. As speed rises, the winding inductance limits the short-circuit current. The shorted winding is a resistance and an inductance driven by the back-EMF $K_e\omega_m$, which alternates at the electrical speed $N_{\text{poles}}\omega_m$. An inductance opposes an alternating current in proportion to its frequency, with reactance $N_{\text{poles}}\omega_m L_{\text{phase}}$, and that opposition adds to the resistance in quadrature. The current is therefore $K_e\omega_m / \sqrt{R_{\text{phase}}^2 + (N_{\text{poles}}\omega_m L_{\text{phase}})^2}$. The braking torque, the power dissipated in R_{phase} divided by ω_m, is $K_t K_e \omega_m R_{\text{phase}} / (R_{\text{phase}}^2 + (N_{\text{poles}}\omega_m L_{\text{phase}})^2)$. That torque peaks where the electrical speed $N_{\text{poles}}\omega_m$ equals $R_{\text{phase}}/L_{\text{phase}}$ and falls beyond it, so above that speed a phase short brakes less the faster the joint turns. For the base's hub motors that peak lies at 177.3 rpm of the wheel, above the 107.7 rpm of the drive limit, so braking torque still rises across the base's speed range, though not strictly in proportion to speed. A fast, high-ratio joint motor has no such guarantee.



Phase-short braking peaks at 177.3 rpm, above the base's 107.7 rpm limit.

Industrial machine stop categories and drive safety functions sequence these states. The machinery standard defines three stop categories (International Electrotechnical Commission 2016a): remove power at once, stop under control and then remove power, or stop under control and keep power applied. Each category still requires specific physical evidence before a safety case can credit it (table 12.3). Beneath every category lies one physical fact. Once torque is removed, a joint enters one of the three unpowered states above. A drive's Safe Torque Off (STO) therefore leaves a moving joint in free coast until a brake engages. The trajectory a machine follows after an electrical cutoff must be measured under full mechanical payload, not deduced from circuit diagrams. The choice of which safe fallback state the machine should enter belongs to system safety architecture, but the physical dynamics of an unpowered joint are unalterable mechanical constraints of the body.

↪ The placement of Safe Torque Off in the machine's hardwired interlock is developed in section 4.6.

2.6.3 Regenerative overvoltage surges and dynamic brake choppers

Regenerative deceleration drives the bus toward its opposite boundary, overvoltage, as part of the machine's kinetic energy returns electrically. Returned braking energy needs an absorption or dissipation path, and a battery cannot be assumed to accept it under every state of charge, temperature, or protection state. If the battery management system disconnects charge input, the remaining bus components must handle the regenerated energy without exceeding their voltage ratings.

Under the conservative assumption that the battery management system has disconnected and the local bus capacitance C_{bus} must absorb the entire returned kinetic energy E_{regen} without dissipation, the terminal DC bus voltage rises to:

$$V_{\text{final}} = \sqrt{V_{\text{initial}}^2 + \frac{2E_{\text{regen}}}{C_{\text{bus}}}} \tag{2.10}$$

where V_{initial} is the bus voltage when deceleration begins (section C.10 derives this energy balance). The worst case is a full pack, the state in which the battery management system refuses further charge.

The capacitor-only endpoint is a screening calculation: if it exceeds a component rating, the stop requires another energy path. A dynamic brake chopper switches an absorption resistor across the bus when voltage reaches a chosen clamp threshold. Its resistor must handle both the peak regenerated power and the pulse energy, with enough recovery between stops. The worked bus calculation below sizes the peak-power requirement for the warehouse machine.

Power integrity is an architectural constraint. The design sets coordinated power budgets and current slew-rate limits across accelerators and drives. The permission path arbitrates simultaneous multi-axis accelerations so that their dI/dt transients do not compound. Brake choppers protect the inverters from regenerative feedback during emergency stops. Notebook 2.7 works both halves of that budget, the bus's sag and the stop's regenerative surge, on the mobile manipulator's 48 V drive bus.

Napkin Math 2.7: DC bus voltage sag and regenerative surge

The mobile manipulator's lithium-ion pack feeds a 47.7 V nominal drive bus, with the voltage envelope of a commercial 48 V-class mobile robot's pack (Mobile Industrial Robots 2025). The bus carries the wheel drives, the arm's joint drives, and a 48-to-24 V converter that supplies the application processor and control electronics. The converter shuts off when its input falls to 33 V (MEAN WELL 2026).

Problem: Under the coincident current step of an inference burst and the drive motors, and then a stop from the drive limit, does the bus remain within the operating limits of the converter and the motor inverters?

Math:

1. **Parameters**:
   - Machine mass, travel speed, and credible deceleration: $m = 368$ kg (upper bound, full tote rack), $v = 1.5$ m/s, $a_{\text{brake}} = 2$ m/s²
   - Bus characteristics: pack voltage from 54 V at full charge to 42 V depleted, source resistance $R_{\text{bus}} = 60$ mΩ (illustrative), bulk link capacitance $C_{\text{bus}} = 22{,}000$ µF
   - Operating limits: converter lockout $V_{\text{uvlo}} = 33$ V, converter continuous input maximum 67.2 V, inverter switch rating $V_{\text{breakdown}} = 100$ V
2. **Sustained-load screen**:
   - As an illustrative coincident load, the two drive motors and the arm's joint drives add 68.6 A while the application processor, drawing its 60 W thermal design power (TDP) through the converter at 91 percent efficiency, adds 1.4 A. Their aggregate increase is $\Delta I = 70$ A. Assume the stated pack voltage is the unloaded source voltage and this coincident demand is the total load in the screen.
   - After source current settles to the increased load, the additional resistive drop is:

$$\Delta V_{\text{sustained}} = \Delta I R_{\text{bus}} = 4.2V$$

   - The resulting sustained bus voltage at full charge and when depleted is:

$$V_{\text{bus, sustained}} = 54V - 4.2V = 49.8V \text{ (full)}, \quad 42V - 4.2V = 37.8V \text{ (depleted)}$$

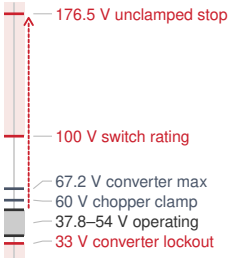
   - Even from the depleted pack, the bus stays 4.8 V above the converter's lockout; it would take a 150 A step to spend the 9 V between the depleted pack and the lockout. This screen does not establish the transient minimum, which inductance and capacitor depletion push lower.
3. **Regenerative surge**:

- During a stop from the drive limit, the loaded machine's kinetic energy must be dissipated:
$$E_k = \tfrac{1}{2}mv^2 = \tfrac{1}{2}\,(368kg)(1.5m/s)^2 = 414J$$
- A full pack is the worst case, because that is when the battery management system refuses charge. If it disconnects charge input and an illustrative 75 percent of kinetic energy returns to the bus ($E_{\text{regen}} = 310.5$ J), an unprotected, lossless capacitor-only energy balance would end at:
$$V_{\text{final}} = \sqrt{V_{\text{full}}^2 + \frac{2E_{\text{regen}}}{C_{\text{bus}}}} \approx 176.5V$$
- *Failure mechanism*: Raising the capacitor from full charge to the 60 V clamp absorbs only 7.5 J of the 310.5 J, so long before the bus reached that endpoint it would cross the converter's input maximum and then the 100 V switch rating.

4. **Dynamic braking clamp**:
   - Under constant deceleration over $T_{\text{stop}} = 750$ ms, speed falls linearly, so the regenerated power, force times speed, falls linearly from its peak to zero. The peak is twice the average $E_{\text{regen}}/T_{\text{stop}}$:
$$P_{\text{regen, peak}} \approx \frac{2E_{\text{regen}}}{t_{\text{stop}}} = 828W$$
   - The clamp $V_{\text{clamp}} = 60$ V sits above the full-charge voltage, so it never fires while charging, and within the converter's input range. To hold it there, the brake chopper must divert this peak power through an absorption resistor. A resistor across the bus at the clamp voltage dissipates $V_{\text{clamp}}^2/R_{\text{brake}}$, which must be at least the peak power:
$$R_{\text{brake}} \le \frac{V_{\text{clamp}}^2}{P_{\text{regen, peak}}} \approx 4.35\Omega$$

Result: The sustained-load screen leaves the bus at 49.8 V from a full pack and 37.8 V from a depleted one, 4.8 V above the converter lockout. Unbuffered regenerative braking would drive the bus past the converter's input maximum and the 100 V switch rating, which calls for a dynamic brake chopper whose resistor is no larger than 4.35 Ω and absorbs an 828 W peak (satisfied by an illustrative 3.9 Ω, 1 kW component).

Systems insight: Mechanical motion and electrical power are bidirectionally coupled. Acceleration requires a supply that sustains the coincident current demand; deceleration requires an adequate absorption or dissipation path. On this 48 V bus the depleted pack still sits 9 V above the converter lockout, more than twice this step's resistive drop, so the sustained screen passes. The transient minimum, pulse energy, repetition, cooling, and component tolerances still require qualification.



The bus must stay between the 33 V lockout and the clamp; an unclamped stop reaches 176.5 V.

Checkpoint 2.2: Freshness, stopping, heat, and supply

The actuator budget was checked in checkpoint 2.1. Before measuring these limits on an assembled machine, verify your understanding of the other four:

- ☐ **Freshness deadline**: Can you calculate the maximum allowable measurement age for the mug riding the pick-station conveyor at 0.20 m/s, with a 15 mm grasp tolerance of which the initial estimate already spends 3 mm? Can you explain why that age is counted from

exposure on the sensor rather than from the start of inference, and why the base's stop for a standing person instead charges age as blind travel?

- ☐ **Velocity ceiling**: Can you solve $d_{\text{stop}} \leq D_{\text{clear}}$ for the admissible speed on the running machine's numbers, and explain why doubling the pre-brake delay expands the stopping distance linearly while doubling travel speed expands the braking term quadratically?
- ☐ **Thermal horizons and runaway**: Can you explain why an actuator can produce three times its rated torque for seconds but overheats its winding insulation if held there for minutes, and distinguish a sustained stall that reaches an excessive finite equilibrium from one in which copper's resistance feedback causes thermal runaway?
- ☐ **Rail sag and regeneration**: Can you explain how a coincident compute and drive current step sags a shared rail through resistance, inductance, and capacitor depletion, and why a stop from speed pumps energy back into the bus that a brake chopper must divert?

Preserving power integrity ensures that transient acceleration spikes do not trigger brownout resets and that regenerative braking does not overvoltage the bus, completing the analytical formulation of the five physical budgets. Calculating these envelopes from datasheets and circuit models, however, cannot guarantee operational safety on a physical robot. In deployment, source impedances rise as batteries age, contact friction varies across facility floors, and enclosed packaging degrades thermal dissipation. Defending these budgets in production requires measuring what the integrated hardware actually delivers under live operational stress.

2.7 Measuring a Machine's Own Limits

A brake that stops an unloaded base on a cool laboratory floor has not established how the loaded mobile manipulator stops after repeated maneuvers. Characterization must connect each calculation to measurements under the conditions in which the machine will use it. A dynamometer, a test stand that applies a controlled mechanical load, isolates actuator behavior, just as the instrumented propulsion test stand in figure 2.7 evaluates an assembled electromechanical powertrain under live aerodynamic and structural loads. Integrated trials then establish what changes when the actuator shares a chassis, cooling path, and power supply with the rest of the machine. A defensible limit states what was measured, how uncertain the result is, and which conditions must remain true for a later decision to rely on it.

2.7.1 Dynamometer testing and instrument intrusion

On a dynamometer, a controlled load machine resists the actuator while torque, speed, current, and voltage are measured on a shared timebase. Four tests connect the earlier models to measurable parameters:

- **Torque and back-EMF transduction (K_t and K_e)**: By commanding the inverter's Field-Oriented Control (FOC) current loop across a sweep of quadrature phase currents i_q while the dynamometer absorbs torque at constant speed, engineers measure electromechanical torque transduction:

  $$\tau_{\text{motor}} = K_t i_q$$

  Driving the unpowered motor at known speed and measuring open-circuit voltage supplies the corresponding back-EMF constant $K_e = e_{\text{bemf}}/\omega_m$. These tests establish the conversion factors used in section 2.4.2.
- **Electrical rise time and inductive bandwidth ($\tau_e = L_{\text{phase}}/R_{\text{phase}}$)**: With the rotor held so that the test current produces no torque, the inverter applies a small voltage step V_{step} across the winding. The current response:

  $$i_{\text{phase}}(t) = \frac{V_{\text{step}}}{R_{\text{phase}}}\left(1 - e^{-t/\tau_e}\right)$$

  reveals the electrical time constant. The step must stay small, because its steady current $V_{\text{step}}/R_{\text{phase}}$ flows through a winding of low resistance: the full 42 V of a depleted pack across

Figure 2.7: An instrumented propulsion test stand: An electric motor with its propeller, speed controller, and wiring secured at the top of the Airvolt test stand at the NASA Armstrong Flight Research Center in 2016, instrumented to collect data on the propulsion system under load. A stand like this measures what a data sheet only asserts, on the assembled drive under stated conditions. (Credit: Lauren Hughes, NASA Armstrong Flight Research Center, AFRC2016-0100-05, public domain.)

a hub motor's 0.7 Ω would drive 60 A, 2.4× the motor's peak current. The current probe and acquisition path must resolve the rise; otherwise the instrument smooths the response being measured and hides the actuator limit.

- **Enclosed thermal resistance (R_{th}) and continuous torque ceilings**: A heating trial under the installed cooling conditions measures the winding temperature rise and loss power, establishing $R_{\text{th}} = \Delta T / P_{\text{loss}}$. The continuous torque ceiling from section 2.5.1 is then:

$$\tau_{\text{cont}} = K_t \sqrt{\frac{T_{\text{limit}} - T_{\text{amb}}}{R(T_{\text{limit}}) R_{\text{th}}}}$$

  The test must reproduce the enclosure and neighboring heat loads under which that ceiling will be used. An open-bench rating overstates continuous capacity whenever the installed shroud restricts airflow or adjacent actuators warm the mounting frame.

- **Backdrive friction and impact dynamics**: By driving the actuator output shaft with the dynamometer load motor, the testbed measures the torque needed to backdrive the joint across speed, load, and temperature:

$$\tau_{\text{ext}} = N_{\text{gear}}^2 J_{\text{rotor}} \ddot{q} + \tau_{\text{fric}}$$

  The measured response establishes whether the transmission can yield under the intended external load and maps the friction term that section 2.4.5 shows is not a constant. Contact qualification must additionally exercise the relevant compliance and impact conditions. The backdrive model alone does not predict tooth failure.

Measurement can change the plant. A series current shunt lowers the supplied voltage, and an embedded temperature probe changes a local heat-flow path. These effects belong in the uncertainty budget along with sensor resolution, bandwidth, and clock alignment.

The sensor mechanisms in section 2.2.1 also affect characterization. Velocity estimated from encoder samples by backward differencing trades resolution against latency, and that trade-off must enter the reported uncertainty and response time. Vibration above the sensor's sampled bandwidth can likewise appear as slower motion:

$$f_{\text{alias}} = |f_{\text{vib}} - k f_s|$$

The integer k identifies the sampling-frequency multiple that folds the vibration into the observed band. Qualification must distinguish that measurement artifact from the motion used to establish the limit.

A limit means nothing without the context of its test. Every recorded limit states the payload, ambient temperature, supply voltage, enclosure state, firmware version, and concurrent computational workload of the run. A thermal time constant measured on an open bench does not transfer to the same actuator in a sealed fairing in sunlight, because enclosing the motor raises R_{th} and with it $\tau_{\text{th}} = R_{\text{th}}C_{\text{th}}$. The hotter ambient also shrinks the margin below the insulation rating. A rail characterization that omits whether vision-language model inference (Brohan, Brown, Carbajal, Chebotar, Dabis, et al. 2023; Brohan, Brown, Carbajal, Chebotar, Chen, et al. 2023) was running during motor stalls describes an idle board rather than the combined draw of full compute and peak torque.

2.7.2 Zero-failure bounds and wear over life

The absence of a failure during testing bounds the failure rate statistically; it does not establish safety. If the mobile manipulator completes $n = 3{,}000$ loaded stops without a brownout or an overrun, the data support only a per-stop failure rate below roughly $3/n$, the rule of three, which is about one stop in 1,000 at 95 percent confidence. The bound holds only if the trials are independent and stationary, so that one trial does not influence another and the failure probability stays the same from trial to trial.

↪ The rule of three, and the trial campaigns it sizes, is developed in section 7.6.

Thermal history and wear can change the conditions between trials:

- **Heating across consecutive trials**: Repeated stops heat the windings, changing resistance and the available torque response. Trials taken at different starting temperatures do not characterize the same operating condition.
- **Rising battery resistance over life**: Battery aging increases source resistance, reducing the voltage margin under a current step.
- **Growing gearbox backlash**: Transmission wear changes reversal response and tracking error, invalidating a limit measured on a less worn assembly.

These changes make characterization a standing obligation. **Lifecycle degradation** changes the conditions behind a limit, so its record must identify when recalibration or a reduced operating envelope is required.

2.7.3 The six elements of a limit record

The stopping and power calculations become usable by other layers only when their assumptions travel with their values. A **limit record** carries those assumptions together with the evidence that supports the limit. The learned proposer uses the limits to constrain candidate actions, while the independent permission path checks them before actuation. Recording a value does not certify it: the illustrative entries below still require measurements and uncertainty estimates before they can support operation. The six elements in table 2.3 make that missing evidence visible for the mobile manipulator's credible deceleration, the drive torque ceiling that must support it, and the drive bus's undervoltage lockout.

↪ The handoff record that carries each limit record to the permission path is developed in section 4.9.

Two of the elements are easily conflated. Uncertainty describes what is not known about the measurement (observation noise, instrument tolerance, sensor bandwidth, and calibration drift). Margin is the physical clearance the machine defends against what is not known. The provenance element then says how far the value itself can be trusted, by naming its evidence category. Every number that governs a machine falls in one of five categories: a direct measurement, a value derived from measurements through a stated model, a datasheet rating, an illustrative example, or a budget the designer chose. Only the first two can support a safety margin or a timeout. A value computed from datasheet inputs, such as the drive torque ceiling below, keeps the datasheet's weaker standing until measurements replace its inputs. A chosen budget, such as the protective clearance δ_{margin}, binds only once it is checked against the measured number it must fit.

Table 2.3: The limit record on the mobile manipulator: The six elements of a limit record, filled in for the credible deceleration that sets the stopping distance, for the drive torque ceiling that must support it, and for the converter lockout that bounds the shared drive bus. None of the three yet has samples or an established uncertainty, and the provenance element names the measurement that would replace each.

Element	What the record states	Credible deceleration a_{brake}	Drive torque ceiling	Drive-bus converter lockout
Value	The value or empirical distribution, with its sample count and the tail percentiles it reports	2 m/s², taken as the credible low tail of loaded stops; no samples yet	At least 2.33 m/s² from 60 N·m per wheel; computed from datasheet values, no samples yet	33 V at the 48-to-24 V converter input; no samples on the assembled bus
Conditions	The context listed earlier under which it was established, plus the surface for any limit that depends on traction	Loaded to at most 368 kg; $\mu\,\phi_{\text{drive}} \geq 0.204$, so $\mu \geq 0.250$ at the hub motors' rated load share and never on the inspected floor ($\mu = 0.12$); tip-over geometry not yet measured; usable powered braking and energy absorption; tires at commissioning wear	Drive current limit at 25 A; both driven wheels in traction; rotating mass within the 9.5 kg per-wheel bound; windings and bus within their rated ranges	Sustained coincident load on the 48 V bus; the permission path isolated on its held-up rail; drive power and physical stopping behavior require separate qualification
Uncertainty	The measurement uncertainty of each instrument, with its observation point and bandwidth	Not established	Datasheet tolerances only; the torque constant's tolerance is not published	Not established
Margin	The engineering margin separating the operating target from the breakdown threshold	No justified deceleration margin yet; the chosen 100 mm protective clearance must be checked against the eventual uncertainty bound	At least 16.6% above a_{brake}; none if the current limit falls to the rated 8.5 A	4.8 V from a depleted pack under sustained coincident load; transient minimum not established
Detector	The runtime check that catches an excursion while the machine runs, such as a phase-current sensor, an optical interrupter, or a supply-rail monitor	Deceleration monitor comparing commanded with measured deceleration from the wheel encoders and the Bosch BMI088 inertial unit, on every stop	Drive saturation flag and measured phase current against the configured limit, read on every stop	Bus-voltage monitor flags undervoltage; the permission path selects a response whose power and mechanical premises still hold
Provenance	The evidence category and the instrument or model that produced the value	Illustrative, from the base's class profile; to be replaced by loaded stopping trials	Datasheet standing: computed from the hub motor's datasheet values; to be replaced by wheel-torque measurements at the current limit on a loaded braking trial	Converter datasheet; source resistance illustrative; to be replaced by a bus characterization under coincident load

The detector element matters most once the machine leaves the test stand, because operation can carry a limit outside the conditions under which it was established. The saturation duration against which the Schiaparelli lander's inertial unit had been accepted was such a limit. The lander's loss in 2016 shows what follows when a limit's conditions are exceeded in operation and nothing downstream checks the result.

War Story 2.1: ExoMars Schiaparelli IMU saturation (2016)

Context: On October 19, 2016, the European Space Agency's ExoMars Schiaparelli lander executed its atmospheric entry and descent toward the Martian surface, relying on an onboard Guidance, Navigation, and Control (GNC) computer to fuse Inertial Measurement Unit (IMU) gyroscopes with a Doppler radar altimeter (ESA Investigation Board 2017).

Mechanism: About three minutes after atmospheric entry, the parachute inflated and set the lander oscillating. The IMU measured a pitch rate larger than expected and raised a saturation flag, which persisted longer than the 15 ms assumed when the unit was accepted. While the flag was set, the GNC software integrated the saturation threshold rate as though it were the true rate, although the lander was in reality oscillating, and its attitude estimate drifted by about 165°, nearly upside down. When the radar altimeter later returned valid slant ranges, the software projected them onto that attitude and computed a negative altitude. No onboard check tested that altitude for plausibility.

Impact: Taking the negative altitude as a valid estimate, the guidance logic released the parachute and backshell, fired the braking thrusters for 3 seconds instead of the planned 30 seconds, and activated its on-ground systems as if it had landed. The lander was still about 3.7 km above the surface. It fell freely for about half a minute and struck the ground at about 150 m/s (540 km/h).

Response: The ESA inquiry board recommended robust sanity checks in the onboard software, among them that altitude cannot be negative and cannot change from 3.7 km to a negative value in one second, and a design that handles IMU saturation explicitly, for example by inhibiting IMU inputs during parachute deployment.

Systems lesson: A physical body cannot transcend the saturation ranges of its sensory transducers. When a sensor's physical limit (a gyroscope's rate ceiling or an accelerometer's dynamic range) is exceeded, a state estimator that integrates the saturated measurement as if it were valid drifts away from the physical state. The saturation duration against which the IMU had been accepted was a limit with conditions, and once descent exceeded them, no detector checked the estimate before it commanded an irreversible action.

Checkpoint 2.3: Limit records

A limit governs a decision only together with the conditions, evidence, and detector that travel with it.

- ☐ **Uncertainty vs. margin**: Can you distinguish the uncertainty of a measured deceleration from the margin the machine defends, and explain why only a measured value, or one derived from measurements, can support that margin?
- ☐ **Zero-failure bound**: Can you estimate how many failure-free loaded stops would bound the per-stop failure rate below one in 10,000 at 95 percent confidence, and state the two assumptions about the trials that the bound requires?
- ☐ **Record conditions**: Can you name the condition of the credible-deceleration record that a lowered drive current limit, the inspected floor, and an arm extended forward would each violate?
- ☐ **Detector**: Can you explain why the Schiaparelli lander's accepted saturation duration failed as a limit in flight, and which detector in table 2.3 plays the missing role for the credible deceleration?

Measured and recorded one at a time, the five limits describe the body budget by budget, each under its own conditions. In operation, however, a single maneuver draws on all five budgets at once, and a change in one budget's state can erode the margin of another. Which limit binds first therefore depends on both the machine's physical class and the specific command under evaluation.

2.8 Which Physical Budget Binds First

A single command from an action-chunking policy to accelerate a loaded mobile manipulator draws concurrently against all five physical budgets, which is why the simultaneous admission invariant of section 2.1 admits it only when every margin is non-negative at once. The command executes against a camera frame that has already aged during neural inference, so that age enters the pre-brake delay.

At the same time, the acceleration injects kinetic energy into the chassis, which friction brakes or regenerative drives must eventually dissipate. Generating that motion forces the arm's geared joints to accelerate reflected rotor inertia, while the base's direct-drive hubs add their rotating inertia to the stopping load. The phase currents that produce those torques dump resistive Joule heat into stator windings, which shed thermal energy only over minutes. The same currents pull transient current from the shared DC rail that powers the onboard compute host. Each of the five budgets pairs a governing physical law against the software assumption it invalidates, exposing a characteristic vulnerability by machine class and demanding a hardware-enforced runtime invariant (table 2.4).

2.8.1 Which budget binds in each machine class

A mobile manipulator integrates two of the machine classes from section 1.5 onto a single chassis: a Class 1 wheeled base governed primarily by chassis momentum and stopping distance, and a Class 2 articulated arm constrained by reflected rotor inertia, contact compliance, and static holding heat. While the classes identify the primary vulnerabilities, the instantaneous maneuver determines which budget binds first. For instance, holding a heavy payload in a cantilevered pose can drive joint windings toward their thermal dissipation limit over tens of seconds. Conversely, a sudden multi-axis acceleration burst coupled with full neural network execution can deplete electrical bus margins within milliseconds. The coupled calculations below compare the evidence behind the running machine's limits and identify a stopping qualification priority. They do not establish an ordering of all five physical margins for an unspecified maneuver.

Table 2.4: Cross-class physical constraint matrix: The five budgets, the law that governs each, the assumption a software-trained policy makes about it, the class characteristically vulnerable, and the runtime invariant that answers it.

Physical Budget / Factor	Governing First Principle & Scaling Law	Software Illusion vs. Hardware Ground Truth	Characteristic Vulnerability by Class	Systems Architect Takeaway & Runtime Invariant
1. Measurement Freshness & Age	$\Delta t_{\text{fresh}} \leq \frac{e_{\max}}{v_{\max}}$; $\delta\theta_{\text{enc}} = \frac{2\pi}{2^n}$; end-to-end age measured from exposure	*Illusion:* High inference rate (50 Hz) guarantees real-time control. *Truth:* Age begins at exposure; encoder differentiation amplifies quantization noise; vibration harmonics alias into IMU attitude drift.	**Class 1 & 2:** Erodes clearance margins and destabilizes high-gain contact loops.	Tag frames with hardware timestamps; enforce $t_{\text{age}} \leq$ the budgeted age at motor registers; drop stale commands.
2. Momentum & Stopping Distance	$d_{\text{stop}} = v\,\tau_{\text{delay}} + \frac{v^2}{2a_{\text{brake}}} + \delta_{\text{loc}} + \delta_{\text{margin}} \leq D_{\text{clear}}$; $m_{\text{eff}} = m + \sum_i \frac{N_{\text{gear}_i}^2 J_{\text{rotor}\,i}}{r^2}$	*Illusion:* Deceleration can be commanded instantaneously. *Truth:* Braking distance scales quadratically (v^2); retarding torque must decelerate reflected rotor inertia; the stopping system must absorb or dissipate energy.	**Class 1 (Mobility):** Primary constraint. Doubling speed quadruples the braking term.	Solve clearance quadratic $v_{\max}(D_{\text{clear}}, \tau_{\text{delay}})$ on the safety microcontroller at the rate the stopping budget sets; clamp policy velocity.
3. Actuator & Reflected Inertia	$J_{\text{ref}} = N_{\text{gear}}^2 J_{\text{rotor}}$; $\tau_{\text{motor}} = K_t i_q$; $\tau_e = \frac{L_{\text{phase}}}{R_{\text{phase}}}$; $\frac{d\tau_{\text{motor}}}{dt} \leq \frac{K_t(V_{\text{bus}} - e_{\text{bemf}})}{L_{\text{phase}}}$	*Illusion:* Motor torque tracks policy tensors instantaneously. *Truth:* Current rise limits response; gearboxes square rotor inertia (N_{gear}^2); high ratios increase resistance to rapid contact motion.	**Class 2 (Manipulation):** Contact stiffness and reflected inertia constrain interaction.	Limit acceleration and torque slew; measure load-side response; select gearing and compliance for the qualified contact envelope.

Physical Budget / Factor	Governing First Principle & Scaling Law	Software Illusion vs. Hardware Ground Truth	Characteristic Vulnerability by Class	Systems Architect Takeaway & Runtime Invariant
4. Thermal Limits & Duty Cycle	$C_{\text{th}}\frac{dT_{\text{winding}}}{dt} = \frac{\tau_{\text{motor}}^2}{K_t^2}R(T_{\text{winding}}) - \frac{\Delta T}{R_{\text{th}}}$; $\tau_{\text{cont}} = K_t\sqrt{\frac{T_{\text{limit}}-T_{\text{amb}}}{R(T_{\text{limit}})R_{\text{th}}}}$	*Illusion:* Motors deliver catalog peak torque continuously. *Truth:* Torque is current, current is heat ($P_{\text{loss}} \propto \tau_{\text{motor}}^2$); continuous torque is limited by heat rejection at the characterized winding-temperature limit T_{limit}.	**Class 3 (Thermal) & Class 2:** Holding above the qualified continuous torque can overheat the windings.	Run discrete I^2t thermal observers on the safety microcontroller; dynamically derate speed and torque when hotspot models approach limits.
5. Electrical Power Integrity	$V_{\text{source}} - V_{\text{bus}} = R_{\text{bus}}I_{\text{source}} + L_{\text{bus}}\frac{dI_{\text{source}}}{dt}$; $C_{\text{bus}}\frac{dV_{\text{bus}}}{dt} = I_{\text{source}} - I_{\text{load}}$; $V_{\text{final}} = \sqrt{V_{\text{initial}}^2 + \frac{2E_{\text{regen}}}{C_{\text{bus}}}}$	*Illusion:* Power rails act as infinite, ideal voltage sources. *Truth:* Bus impedance collapses rail voltage under combined compute+motor bursts; braking surges overvoltage.	**Class 1 & 3:** Peak multi-axis acceleration trips microcontroller brownout resets; regen surges destroy inverter FETs.	Enforce coordinated compute-actuation power budgets and dI_{source}/dt limits; install dynamic brake choppers; characterize unpowered fallbacks.

2.8.2 Cross-budget coupling and permission rail isolation

When an autonomous agent commands an aggressive multi-axis acceleration, the physical margins do not degrade in isolation. They deplete together. Drive inverters draw substantial current to overcome both chassis inertia and reflected rotor inertia. This transient current surge causes the shared DC bus voltage to sag, even as resistive losses ($P_{\text{loss}} = i_q^2 R_{\text{eff}}$) steadily deposit thermal energy into motor windings. Because motor phase currents are pulse-width modulated by inverters and do not map directly to battery draw, systems architects must evaluate input current at the primary DC bus. This coincident load step establishes the true operating baseline across all subsystems.

On the 48 V drive bus, the sustained electrical screen passes under its stated assumptions. As shown in the coincident power step of notebook 2.7, a depleted battery pack at 42 V sags to 37.8 V under the coincident load step. Even under that sustained step, the rail keeps a 4.8 V buffer above the 33 V undervoltage lockout (UVLO) threshold of the 48-to-24 V converter, although the sustained screen does not establish the transient minimum.

The stopping dynamics expose a concrete qualification priority. Under emergency braking, the drive motors clear the required deceleration by only 16.6 percent, and only with phase current at the motor's catalog peak. The chassis tip-over boundary has not been measured at all. For the arm, the optimistic stand-in thermal model gives a heat-soaked joint a threefold current burst of 43.1 s before its winding reaches the insulation rating. Additionally, the chassis stopping distance at the full 1.5 m/s travel limit leaves 357.5 mm of clearance to accommodate perception latency, communication jitter, and tracking variance. The whole stopping budget inherits the credible-deceleration premise, which rests on the peak current limit and the unmeasured center of gravity, so that premise requires qualification before relying on the stop. The transient rail minimum and installed arm thermal response remain unresolved too. Ranking the budgets requires a specified maneuver and duration, with comparably qualified limits for each.

Modern SoC architectures deploy dynamic voltage and frequency scaling (DVFS) algorithms to regulate die temperature and energy consumption. While DVFS protects silicon from thermal degradation, its timing penalties propagate directly into physical workspace clearance:

SoC thermal dissipation $\longrightarrow$ DVFS clock throttling $\longrightarrow$ vision latency stretch $\longrightarrow$ observation age inflation $\longrightarrow$ pre-brake travel expa

When sustained motor currents and high-throughput perception pipelines elevate temperatures across the shared enclosure, the host kernel throttles the clock frequencies of onboard CPU and GPU accelerators. On the running machine, this thermal intervention stretches the navigation backbone that the stopping budget charges, not the grasp path of table 2.1, from 22 ms to 33 ms. This delay adds 11 ms directly to the end-to-end observation age t_{age}, inflating the pre-braking reaction time τ_{delay}. When traveling at the maximum base velocity of 1.5 m/s, this algorithmic latency injects 16.5 mm of unmonitored chassis travel before emergency brakes can even begin mechanical engagement.

In this manner, a standard operating-system power policy designed for digital silicon silently shrinks the robot's stopping margin.

↪ Thermal clock throttling on the shared die, and the placement decisions that bound its effect on the safety path, are developed in section 13.4.

Surviving a sustained bus voltage drop does not qualify the shared power rail to support safety-critical control channels. Transient dips during motor reversals remain difficult to bound completely, and electrical faults such as an open circuit breaker, a battery management system (BMS) overcurrent disconnect, or a blown DC-DC stage drop bus voltage to zero instantly. The running machine addresses these common supply faults with a **dual-rail architecture** that decouples motor dynamics from safety enforcement. In this design, the primary shared bus powers high-current traction inverters and steps down voltage for the primary application processor. An isolated, reverse-blocked permission rail separately powers the safety microcontroller, deterministic fieldbus transceivers, and holding-brake release coils. Under the drive-rail faults covered by its isolation and hold-up qualification, this separate supply preserves the permission loads. It does not make the detector, controller, or communication path infallible.

The permission rail incorporates local capacitive energy storage to preserve control availability during a loss of its upstream supply. For the stated constant 70 W permission load, ideal energy sizing gives an onboard 2.025 F supercapacitor bank 140 J of usable energy between its minimum nominal charge voltage (21.5 V) and regulator dropout (18 V), targeting 2 s of hold-up. Establishing a minimum available duration requires qualification of initial charge, capacitance tolerance and aging, conversion losses, equivalent series resistance, current demand, and regulator behavior. The 750 ms stop from the drive limit plus the 80 ms slow end of spring-brake engagement is a comparison for the powered stopping model only. Total main-battery failure does not establish that this model remains available. The qualified control interval must cover detection and decision, the duration of the response available under the fault, and brake engagement when those stages are sequential, or their actual sequence when they overlap. Section 12.9 checks the hold-up against the longest stop its fallback ladder commands.

Under the qualified rail and intact detector and controller assumptions, maintaining permission-rail power preserves the opportunity to detect power loss and initiate a response, but it does not supply the mechanical energy or high-current paths necessary for controlled regenerative braking. A controlled, powered stop requires intact inverter switching, sufficient bus voltage, and an operational energy dump, such as a dynamic brake chopper or a regenerative battery sink, to absorb kinetic deceleration energy. When a catastrophic power fault removes the supply or absorption path needed for a powered stop, that stopping model no longer applies. Under such conditions, stopping distances must be governed by the unpowered physical fallbacks analyzed in section 2.6.2. A held-up permission rail does not change what the mechanical brakes deliver. Powering their release coils from that rail lets the permission logic choose when the spring brakes engage, but it does not give them the deceleration of a powered drive stop. Systems architects must treat stopping performance as conditional: isolate the safety supervisory rail, and then characterize the exact deceleration capabilities that remain active across every distinct electrical fault state. Downstream runtime enforcement and hardware qualification must preserve these underlying electrical premises.

2.9 Fallacies and Pitfalls

Physical limits rarely respect subsystem boundaries. In embodied machine learning systems, an architecture whose individual component budgets balance cleanly on paper can fail catastrophically when thermal rise, bus latency, power supply sag, and mechanical dynamics interact under compound operational load.

Fallacy: *Model inference time defines the measurement freshness latency.*

Consider an engineering team that compresses its vision backbone, cutting neural network inference time from 30 ms to 10 ms. While this optimization provides a threefold compute speedup, the physical robot still executes actions based on visual state that traversed camera exposure, sensor readout, DMA transfers, and kernel queuing delays. Once the model outputs an action, that command must traverse a real-time network fieldbus before motor drive inverters can slew coil currents and produce physical force. A 45 ms scheduling or transport jitter spike elsewhere along this pipeline eclipses the 20 ms compute gain, consuming safety margins before the robot can react. Real-time control requires budgeting and bounding the worst-case tail of the entire capture-to-onset

pipeline across synchronized hardware clocks, rather than certifying loop safety from isolated model benchmarks.

Architect's countermeasure: Measure the true capture-to-onset latency tail on synchronized hardware clocks; never certify real-time safety from neural network inference benchmarks alone.

Fallacy: *Software step commands deliver instantaneous physical torque.*

Reinforcement learning policies trained in simulation routinely issue piecewise-constant torque or position setpoints at 50 Hz, implicitly assuming the physical actuator behaves as an ideal, memoryless force source. In physical reality, an electric drive is an electromechanical dynamic system governed by electromagnetic and inertial limits. Developing torque requires inner Field-Oriented Control (FOC) loops whose current rise rate is strictly bounded by stator winding electrical time constants ($\tau_e = L_{\text{phase}}/R_{\text{phase}}$) and DC bus voltage headroom ($\frac{d\tau_{\text{motor}}}{dt} \leq \frac{K_t(V_{\text{bus}} - e_{\text{bemf}})}{L_{\text{phase}}}$). Mechanically, a high-ratio gearhead amplifies rotor inertia quadratically ($J_{\text{ref}} = N_{\text{gear}}^2 J_{\text{rotor}}$), imposing a steep low-pass filter on achievable link acceleration.

When a discrete tensor update demands an abrupt torque step, substantial electromagnetic effort is diverted into accelerating the spinning rotor rather than moving the external link. Transmission compliance and joint elasticity convert these high-frequency torque transients into structural vibration and limit-cycle oscillations. Simultaneously, repeated high-current corrections waste energy as resistive heat dissipation ($P_{\text{loss}} = \frac{\tau_{\text{motor}}^2}{K_t^2} R_{\text{eff}}$), rapidly burning through the actuator's thermal margin. Systems architects must filter and shape setpoints against actual plant dynamics, validating commanded trajectories against delivered physical response rather than assuming numerical smoothness in software guarantees smooth physical execution.

Architect's countermeasure: Bound acceleration and torque slew using measured actuator response, include electrical current rise and reflected inertia in the model, and qualify the chosen transmission and controller for the intended contact task.

Pitfall: *Treating isolated component datasheets as operational system guarantees.*

Hardware component datasheets report performance envelopes measured under idealized bench conditions. When a motion planner adopts a motor vendor's continuous torque rating or an IMU vendor's nominal noise floor as operational bounds, it ignores the harsh realities of system packaging. A motor catalog rating reflects vendor test benches (section 2.5), typically an open motor bolted to an enormous aluminum heatsink in still air at $25\ ^\circ$C, not a sealed robotic joint housing tucked inside an unventilated composite limb on a chassis dissipating heat from a 60 W application processor.

In physical deployment, an actuator's continuous torque is strictly constrained by steady-state heat dissipation up to the winding's engineering ceiling T_{ceil}, so the installed rating is equation 2.7 evaluated at the ceiling rather than the insulation rating:

$$\tau_{\text{cont}} = K_t \sqrt{\frac{T_{\text{ceil}} - T_{\text{amb}}}{R(T_{\text{ceil}}) R_{\text{th}}}}$$

Given a 140 °C engineering ceiling, shifting the motor from the vendor's 25 °C bench into the 40 °C interior of an enclosed chassis strips away 6.7 percent of continuous torque. Because thermal dissipation scales inversely with the square root of thermal resistance ($1/\sqrt{R_{\text{th}}}$), eliminating forced convection and heatsink mass degrades capacity even further: doubling R_{th} inside the arm housing cuts total usable continuous torque by 34.1 percent relative to the catalog rating. If trajectory planners treat catalog continuous torque as achievable duty, persistent copper losses ($P_{\text{loss}} = \frac{\tau_{\text{motor}}^2}{K_t^2} R_{\text{eff}}$) will exceed heat dissipation rates, triggering thermal cutouts or permanently degrading winding insulation.

Sensors suffer the same systemic degradation: inertial measurement units and optical encoders calibrated on quiet granite surface plates suffer severe vibration rectification, thermal drift, and mechanical aliasing once bolted near high-frequency switching inverters and planetary gearsets. System limits must reflect empirical measurements collected on the fully assembled machine under peak operational stress rather than pristine standalone datasheets.

Architect's countermeasure: Calibrate actuator continuous torque ceilings and sensor noise profiles on fully assembled, enclosed hardware across the entire operational temperature envelope rather than copying open-bench catalog numbers into planner configuration files.

Pitfall: *Treating dynamic voltage and frequency scaling (DVFS) as a transparent software optimization.*

In server computing, DVFS operates as an invisible operating-system service that reduces clock frequency and core voltages to prevent silicon junction overtemperature. In an embodied system, however, DVFS directly degrades the real-time control contract. Consider a mobile manipulator whose high-current drive motors heat a shared structural chassis during intense maneuvering. As heat conducts into the compute bay, the application processor throttles its clock frequency to avoid thermal shutdown.

The system kernel treats clock throttling as an isolated power-management decision. However, a downclocked vision backbone adds observation age, and observation age at speed is unmodeled blind travel before the safety monitor can command braking. Section 2.8.2 prices that travel on the running machine. Although thermal throttling successfully shields the processor silicon, the vehicle's dynamic stopping envelope silently expands beyond calibrated safety margins.

Architect's countermeasure: Feed SoC thermal and clock-frequency telemetry directly into the motion safety monitor, dynamically derating maximum travel speed whenever compute throttling inflates perception age.

Pitfall: *Scaling operational velocity without recalculating quadratic braking distances and thermal dissipation.*

Facility operators frequently seek to increase robot throughput by raising maximum cruise velocity in software configurations. This operational change couples two punishing physical nonlinearities. First, the braking term grows with the square of speed, which is why Case 3 of figure 2.2 breaches the clear distance at 2 m/s.

Second, absorbing the kinetic energy of the faster machine demands large dynamic braking currents that dump heat directly into motor stator windings and drive electronics via Joule heating ($P_{\text{loss}} = i_q^2 R_{\text{eff}}$). An isolated emergency stop performed during commissioning may pass thermal checks when the machine starts cold. However, when an autonomous vehicle repeats that higher-speed duty cycle across an eight-hour shift, winding temperatures compound across successive maneuvers, rapidly outstripping the chassis thermal dissipation budget. System planners must treat operating velocity as a gated admission parameter: any commanded speed increase requires re-evaluating both the expanded quadratic stopping envelope and the cumulative multi-cycle thermal duty budget.

Architect's countermeasure: Treat operating speed as an admission parameter that re-evaluates both quadratic stopping envelopes and multi-cycle thermal accumulation before granting velocity increases.

Fallacy: *Compute accelerators and motor inverters operate on independent, ideal power rails.*

Software architectures typically treat accelerator power consumption and motor drive power as decoupled subsystems, verifying each against isolated power supply ratings. In physical mobile machines, however, both systems draw from a shared, unregulated DC battery bus.

Consider a scenario where a heavy neural network vision burst coincides precisely with the drive motors accelerating to push the mobile base over an uneven threshold. On the shared 47.7 V electrical bus, this coincident current surge demands a combined 70 A step. Drawn through the 60 mΩ source resistance of cell, harness, and switch, this sudden draw induces a sustained 4.2 V voltage sag. That sag consumes nearly half of the 9 V voltage margin separating a depleted battery pack from the 33 V UVLO threshold of the application processor's DC-DC converter, even before harness inductance and bulk capacitor discharge deepen the dynamic transient. A step of 150 A, or the identical current demand drawn from an aging or cold battery with sufficiently elevated internal impedance, reaches the UVLO threshold and can interrupt the primary processor's supply.

If safety microcontrollers and brake solenoids share that unbuffered power rail, the resulting brownout crashes the safety supervisor simultaneously. The machine is plunged into the uncontrolled, unpowered fail states described in section 2.6 while carrying significant physical momentum, rather than executing an orderly, controlled deceleration. Software power budgets must acknowledge electrical coupling at the physical bus. System qualification demands testing coincident worst-case

compute and motor loads at minimum battery state of charge, while ensuring safety permission logic and electro-mechanical brakes operate on an isolated, held-up power rail (section 2.8).

Architect's countermeasure: Isolate the permission logic and brake releases, then qualify both their hold-up and the physical stopping response under coincident motor and compute load at minimum battery state of charge. A powered stop also requires the drive rail and energy-absorption path to remain usable.

Fallacy: *Passing isolated single-variable bench tests guarantees physical survival under compound operational stress.*

Development teams often qualify physical AI systems through single-variable stress testing: a robotic manipulator verifies maximum payload capacity inside a 20°C air-conditioned laboratory, then undergoes thermal validation inside a 45°C environmental chamber with an unloaded gripper. Neither benchmark, however, validates whether the manipulator can lift maximum payload in high ambient heat while operating from a depleted battery pack.

Physical failure modes couple nonlinearly across subsystem domains. Under simultaneous operational stress, manipulating maximum payload demands sustained high motor currents that dramatically increase resistive winding losses ($P_{\text{loss}} = i_q^2 R_{\text{eff}}$). An ambient temperature of 45°C severely compresses the thermal gradient required to reject that heat to the environment, accelerating stator insulation degradation. Concurrently, a low battery state of charge depresses DC bus voltage, stripping away the voltage headroom required to overcome motor back-EMF (e_{bemf}) and severely degrading current slew rates ($\frac{di_q}{dt}$). An arm that moves smoothly in isolated tests may experience joint stall, severe tracking errors, or premature thermal shutdown under their compound interaction. Hardware and software qualification cannot rely on orthogonal single-variable test sweeps. Engineering teams must validate boundary envelopes on fully integrated machines subjected to simultaneous peak stresses across payload, thermal ambient, battery state of charge, and control frequency.

Architect's countermeasure: Test boundary envelopes under worst-case simultaneous physical stress (maximum payload, elevated ambient temperature, depleted battery, and high-frequency actuation) to catch multi-budget coupling failures.

2.10 Summary

Every motion plan in physical AI must ultimately satisfy hardware invariants. Five coupled budgets translate a high-level trajectory request into concrete engineering constraints: observation age, stopping distance, delivered torque, winding temperature, and supply voltage. Because these budgets are tightly coupled, no single limit can be evaluated in isolation. Consider the warehouse robot operating on a 48 V drive bus: while the sustained electrical draw clears the converter lockout even from a depleted battery pack, the stopping budget rests on fragile assumptions. The machine's credible deceleration margin is narrow and holds only while the drive current limit stays at the motor's peak. Furthermore, its traction model depends on dynamic wheel loading, and its anti-tip threshold lacks empirical center-of-mass validation. Isolating and sustaining the safety permission path on a dedicated capacitor-backed supply protects digital control availability during bus transients. Certifying the physical safety envelope, however, still requires verifying the actual drive power or passive braking dynamics available during an electrical fault.

To make these boundaries enforceable, a physical limit cannot be treated as a bare scalar. Instead, systems engineers structure each boundary as a limit record that documents valid operating conditions, measurement uncertainty, safety margins, runtime detection mechanisms, and calibration provenance. On the reference mobile manipulator traveling at its 1.5 m/s drive limit, mechanical stopping dynamics consume 742.5 mm of the 1.10 m clearance distance. That figure already includes the localization bound and protective clearance, so the remaining 357.5 mm is a design budget. It covers the delay terms the body does not own (observation age, chunk lease, permission tick, and bus cycle), stopping-profile shaping, and the tracking bound that later chapters add. These are the first three rows of the stopping budget, which table 12.1 completes term by term, with the chapter that prices each one. These analytical values guide initial system architecture, while physical characterization of the fully assembled robot establishes the empirical envelopes that production controllers enforce across the governing relations of all five budgets (table 2.5).

Table 2.5: Key equations of the physical body: Each load-bearing equation of the chapter, the limit it bounds or the decision it settles, and the equation where it is derived; $D_{\text{avail}} = D_{\text{clear}} - \delta_{\text{loc}} - \delta_{\text{margin}}$.

Equation	What it bounds or decides	Derived in
$\Delta t_{\text{fresh}} \leq e_{\max} / v_{\max}$	The largest observation age before a moving target's own motion spends the position tolerance	equation 2.1
$d_{\text{stop}} = v\,\tau_{\text{delay}} + \frac{v^2}{2a_{\text{brake}}} + \delta_{\text{loc}} + \delta_{\text{margin}}$	Whether the body stops within the clear distance, $d_{\text{stop}} \leq D_{\text{clear}}$	equation 2.2
$v_{\max} = -a_{\text{brake}}\tau_{\text{delay}} + \sqrt{(a_{\text{brake}}\tau_{\text{delay}})^2 + 2a_{\text{brake}}D_{\text{avail}}}$	The admissible speed for a given clearance, pre-brake delay, and credible deceleration	equation 2.3
$\tau_{\text{out,max}} = \eta_{\text{gear}} N_{\text{gear}} K_t I_{\max}$	The largest torque the configured current limit allows, and so whether a_{brake} is deliverable	equation 2.4
$N^* = \sqrt{J_{\text{load}} / J_{\text{rotor}}}$	The gear ratio that maximizes joint acceleration for a given motor torque	equation 2.5
$P_{\text{loss}} J_{\text{ref,in}} = \tau_{\text{out}}^2 J_{\text{in}} / (\eta_{\text{gear}}^2 K_m^2)$	The fixed trade between holding heat and reflected inertia that the gear ratio cannot escape	equation 2.6
$\tau_{\text{cont}} = K_t \sqrt{(T_{\text{limit}} - T_{\text{amb}}) / (R(T_{\text{limit}})\, R_{\text{th}})}$	The torque a winding sustains indefinitely under the declared cooling	equation 2.7
$D_{\text{cycle}} \leq (T_{\text{ceil}} - T_{\text{amb}}) / (P_{\text{peak}}\, R_{\text{th}})$	An average-power screen on a burst schedule, optimistic against the transient peak	equation 2.8
$V_{\text{source}} - V_{\text{bus}} = R_{\text{bus}} I_{\text{source}} + L_{\text{bus}}\, dI_{\text{source}}/dt$	Rail droop under a coincident current step, against the undervoltage lockout	equation 2.9
$V_{\text{final}} = \sqrt{V_{\text{initial}}^2 + 2E_{\text{regen}}/C_{\text{bus}}}$	The capacitor-only bus voltage after a regenerative stop, and so whether a brake chopper is needed	equation 2.10

Key Takeaways: The physical body and invariant budgets

- **Age begins at physical transduction**: The data freshness budget spans the entire timeline from physical photon or contact arrival to mechanical force delivery. Because stage latencies vary dynamically, an end-to-end tail percentile is never the simple sum of individual stage percentiles. Robust software must preserve hardware capture timestamps, account for downstream actuation lag, and reject any action proposal whose underlying sensory evidence will be stale when the actuator responds.
- **Speed sets the stopping envelope**: The clearance quadratic in speed determines an admissible velocity ceiling only while runtime state, stopping mechanics, and credible deceleration satisfy its mathematical premises. In turn, credible deceleration cannot exceed the strictest bound among tire traction, vehicle tip-over thresholds, and available motor braking torque.
- **Gearing trades torque for reflected inertia**: A transmission multiplies actuator torque linearly by the gear ratio N_{gear}, but reflects rotor inertia back to the joint by N_{gear}^2. Because physical motion also depends on current rise times, inverter voltage headroom, mechanical compliance, and joint friction, software acceptance of a setpoint command never guarantees physical trajectory tracking.
- **Thermal history limits available torque**: Resistive copper loss ($P_{\text{loss}} = i_q^2 R_{\text{eff}}$) scales quadratically with current, and winding resistance increases as internal temperatures climb. Actuator burst schedules must therefore respect transient thermal peaks rather than relying on average power limits. Furthermore, reducing holding current to alleviate thermal strain requires mechanical brakes or counterbalancing mechanisms capable of supporting static gravity loads.
- **The supply rail is shared**: Motor inverters and digital compute share a common DC bus. Coincident acceleration demands induce inductive rail droop, rapidly depleting voltage headroom above converter undervoltage lockouts, while unclamped regenerative braking can elevate bus voltage and damage inverter stages. An isolated, capacitor-

backed power domain preserves safety permission logic through transient brownouts. However, completing a controlled emergency stop still requires sufficient braking torque, energy absorption, and stopping clearance; otherwise, the machine must rely entirely on a qualified unpowered response.

- **A limit is a record, not a number**: An engineering threshold safely governs an execution decision only when coupled with its valid operating regime, measurement uncertainty, safety margin, fault detector, and calibration provenance. Moreover, these limits lapse as hardware degrades (rising thermal resistance, increasing battery internal impedance, transmission backlash wear), so they require continuous lifecycle monitoring and recalibration.

Every budget in this chapter ends the same way, as a number the permission path can compare against a proposal before that proposal becomes current in a winding. That comparison is how the first law, irreversibility (principle 1), enters the machine as engineering rather than as a warning. Work delivered across the causal boundary cannot be recalled, so each command must remain subject to refusal before it produces physical work. Refusing it takes a limit that states its value, the conditions under which it holds, how uncertain it is, and what detects its violation. In operation, each relevant limit record must support the proposed maneuver under its actual conditions. On the running machine, the electrical budget passes only its sustained screen, and the arm's illustrative thermal model gives a burst lasting tens of seconds. The credible deceleration rests on peak drive current, a dry floor, and an unmeasured center of gravity, and every stopping calculation inherits those conditions. When a budget looks comfortable, the first question is which condition of its record the next maneuver could violate, and the second is whether a detector would notice before the stop is needed.

2.11 Historical Perspective and Further Reading

The freshness budget rests on foundations established well before the advent of digital control. Nyquist (1928) quantified the transmission capacity of telegraph channels relative to available bandwidth. Shannon (1949) formalized the sampling theorem in the form used throughout this chapter: a continuous signal band-limited below half the sampling frequency is completely determined by discrete samples, whereas unattenuated higher-frequency dynamics fold back into the passband as aliasing distortion. Clock synchronization subsequently migrated from software operating systems directly into physical networking silicon. The Precision Time Protocol (IEEE 2020a) and its profile for time-sensitive Ethernet (IEEE 2020b) capture packet timestamps at the physical layer interface. They allow an embodied system to preserve each sensor measurement's capture timestamp under bounded capture and clock-synchronization uncertainty as it travels through the compute fabric.

Modern actuator architectures trace back to two distinct engineering lineages. The first lineage eliminated mechanical transmissions entirely to maximize backdrivability. Asada and Kanade (1983) developed early direct-drive robot arms to bypass the nonlinear friction, backlash, and torque ripple inherent in high-ratio gearboxes. Three decades later, the MIT Cheetah quadruped revisited this architecture with the quasi-direct drive of section 2.4.5, coupling high-torque-density motors with low-ratio single-stage planetary gearsets to keep most of that transparency while adding impact resilience (Seok et al. 2015; Wensing et al. 2017). The second lineage treated transmission compliance not as an unwanted defect, but as an explicit design variable. Musser (1959) patented the strain wave gear (harmonic drive), whose compact form factor and high reduction ratio trade off torsional stiffness for torque density. To analyze these mechanics, Spong (1987) introduced the flexible-joint model, demonstrating how elastic coupling dynamically decouples motor inertia from the load link. Moving beyond rigid position tracking, Hogan (1985) reframed physical contact as an exchange of energy governed by a programmed mechanical impedance. Building directly on this concept, Pratt and Williamson (1995) introduced series elastic actuators, deliberately placing an elastic element between the gearbox and the output link so that spring deflection provides reliable force sensing while shielding gear teeth from shock impacts. Learned policies successfully mastered these compliant systems once Hwangbo et al. (2019) replaced idealized torque sources in simulation with compact neural networks identified directly from physical hardware.

Thermal and electrical budgets descend from classical electrical machine design and power systems engineering. Montsinger (1930) demonstrated that operational limits for electrical machines should be governed by winding insulation temperature rather than instantaneous current thresholds alone. Dakin (1948) modeled this insulation degradation as a chemical reaction obeying Arrhenius kinetics, proving that thermal aging accelerates exponentially with operating temperature. Modern international standards such as IEC 60085 (International Electrotechnical Commission 2007) still formalize this trade-off between operating temperature and motor operational lifespan. Similarly, standardized stop categories and drive safety functions (International Electrotechnical Commission 2016a, 2016b) codify decades of industrial safety practice for removing power from moving physical mass under fault conditions. Physical AI introduces a new challenge: learned policy proposers operate without built-in guarantees regarding these physical budgets. Deterministic safety monitors must therefore enforce these boundaries directly, translating thermal, electrical, and kinematic constraints into explicit limit records checked along the permission path.

- **Mechanics and actuation from first principles** (Lynch and Park 2017). A comprehensive derivation of rigid-body dynamics, kinematic chains, gearing, and contact mechanics.
- **Impedance control** (Hogan 1985). The seminal paper establishing contact manipulation as dynamic interaction rather than pure position or force control, introducing the virtual spring-damper formulations used to regulate interaction forces.
- **Flexible-joint dynamics** (Spong 1987). The analytical foundation modeling elastic transmission compliance as a torsional spring, demonstrating why motor-side encoders cannot certify link motion or guarantee end-effector trajectory tracking.
- **Series elastic actuators** (Pratt and Williamson 1995). The deliberate introduction of mechanical compliance to trade control bandwidth for impact tolerance, energy storage, and accurate force sensing.
- **Proprioceptive actuator design** (Wensing et al. 2017). Details how low-ratio transmissions paired with high-torque electric motors allow motor current to serve as a reliable contact-force signal, highlighting the associated thermal limits and torque-density trade-offs.
- **Learned actuator models** (Hwangbo et al. 2019). Demonstrates that compact neural networks trained on minutes of empirical hardware data close the reality gap between idealized simulator torques and nonlinear physical actuators.

What's Next: From body limits to brain proposals

Every budget in this chapter now ends as a limit record, and all five can hold while the machine still does nothing useful. At the pick station the observation can be fresh, the stop inside its clearance, the windings cool, and the bus above lockout, yet nothing in the body says which object on the conveyor is the mug or where its handle is. That judgment comes from a learned proposer, and chapter 3 opens with the cost of supplying it in time. A model large enough to recognize unfamiliar objects streams its weights through the same onboard processor that sensing and control depend on, so it renews its proposal far more slowly than the servo loops run. The chapter derives the two-speed brain that the machine card commits to, a slow intent model above a fast chunk policy, and shows why an action chunk keeps the arm supplied without keeping its evidence fresh. The freshness deadline and stopping budget derived here are the windows those proposals must arrive within, and chapter 4 joins the two, admitting each chunk only under a bounded lease that the body's limit records define.

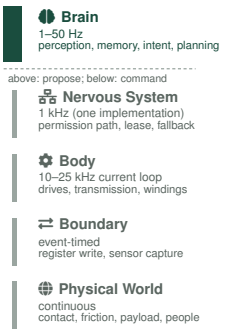
Purpose

Why can a robot recognize what to do yet still be too late to act?

Learned models are what let a physical machine handle objects and scenes that no engineer enumerated, and they are also the largest and least predictable computation the machine carries. A model that recognizes the right object still has to move its weights through an onboard processor that sensing and control also depend on, and a larger model that recognizes more takes longer to answer. While it computes, the world keeps moving, so a correct answer can arrive after the conditions that justified it have changed. Predicting a sequence of future motions keeps the actuators supplied between model updates, but it cannot make those motions respond to observations the model has not yet received, and a proposal that arrives on time can still be wrong in ways the model's own confidence does not reveal. An engineer who treats the learned model as a function that returns actions cannot size the processor, set the rates at which proposals are renewed, or say how long the machine may keep moving on an answer that has gone stale. Because motion beyond the causal boundary cannot be recalled, every learned proposal must remain a request that an independent permission path can refuse in time.



Learning Objectives

- Compare classical analytical pipelines and learned representations on coverage, sensory robustness, and formal verifiability
- Calculate the memory wall bound on a model's fresh-evaluation rate ($f \leq \text{BW}_{\text{mem}}/M_{\text{weights}}$) under the embodied batch size 1 constraint, and explain why weight-only quantization shortens the bandwidth-bound decode but not the compute-bound prefill
- Estimate key-value cache expansion from multi-camera tokenization, hidden dimensions, and retained history windows
- Explain how action chunking (H) amortizes off-chip weight transfers without improving closed-loop reaction latency, and why that gap requires a second, smaller proposer
- Compare autoregressive, one-pass, and iterative action decoders by the sequential evaluations and off-chip transfers one chunk costs
- Apply replanning period, inference latency, and target drift to size an action chunk for a dynamic target
- Evaluate the interface between a slow and a fast proposer by what the permission path can check against its own evidence
- Diagnose cognitive failure modes: semantic hallucinations, uncalibrated softmax overconfidence, perceptual chattering, and expired intent leases
- Identify the trajectory, timestamps, and validity information a proposer must hand to independent real-time verification

3.1 The Embodied Brain

DRAFT

The body's limit records tell the permission path what it must refuse, but they cannot say what the machine should do next. That choice belongs to the Brain, the deliberative layer that interprets incoming sensor telemetry and proposes what the physical body should execute next. Over the past decade, physical AI architectures have transitioned from hand-authored geometric pipelines and finite-state machines to learned models, notably vision-language-action (VLA) architectures that map natural language instructions and camera pixels directly to candidate end-effector motions for objects no engineer explicitly modeled. This shift places the machine's most computationally intensive workloads on its least predictable path. A deep neural proposer requires billions of operations, contends for shared memory bus bandwidth with low-latency sensing and control tasks, and predicts future actions for an environment that continues to evolve during inference. A physical constraint governs this interaction: a learned proposal remains useful only if it arrives, and remains physically valid, within the time window permitted by environmental dynamics. Furthermore, every candidate trajectory remains strictly a proposal. The hard-real-time permission path beneath the proposal boundary holds exclusive authority to validate and admit candidate motions before they actuate physical hardware.

The warehouse mobile manipulator illustrates this boundary concretely. The robot can operate within every torque, thermal, voltage, and braking limit of its body and meet the freshness deadline that the body's budgets set for this same pick-station grasp. It can still fail to grasp an unfamiliar ceramic mug traveling along an active conveyor. Low-level limits safeguard physical actuators against structural and electrical damage, but they cannot interpret natural language instructions, recognize a target handle amid visual clutter, or plan an obstacle-free trajectory around a coworker's arm. A learned vision-action model supplies this missing semantic interpretation, which must then be projected into metric Cartesian space using calibrated depth sensing and forward kinematics despite specular reflections, dynamic shadows, and transient occlusions. Because this proposer's training coverage does not establish a closed-loop safety guarantee, and its execution demands must fit within the throughput, memory bandwidth, and thermal envelope of the onboard processor, every generated action sequence remains an unverified candidate until the permission path checks it against fresh telemetry and established safety envelopes.

↩ The mobile manipulator's torque, thermal, voltage, and braking limits are established in section 2.1.

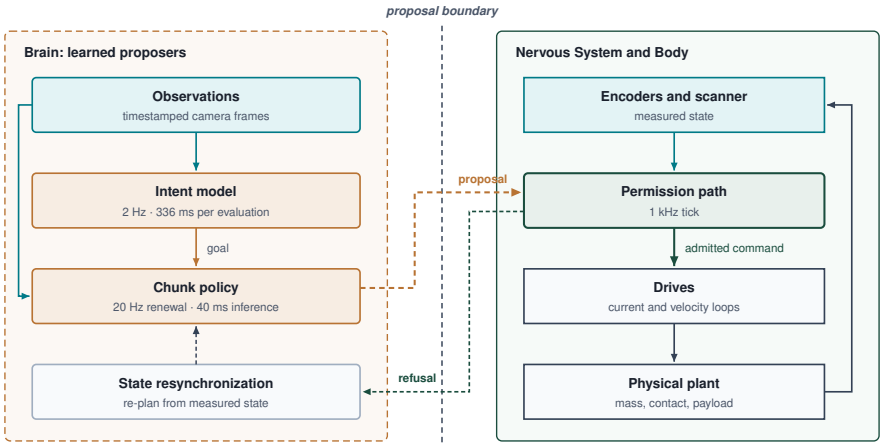


Figure 3.1: Two-speed brain architecture: Above the proposal boundary, two learned proposers run at their own rates, an intent model at 2 Hz and a chunk policy renewing at 20 Hz. Below it, the permission path checks each proposal against measured state on a 1 kHz tick, and the drives close their own current and velocity loops. A proposal carries no authority until it is admitted; a refusal returns the proposers to a plan from measured state.

This division exposes a timing dilemma, because physical dynamics do not pause while inference runs. As the vision model evaluates sensory frames, the conveyor belt advances, and the manipulator must continue tracking previously admitted waypoints without stalling or jerking. Deploying a larger foundation model can enhance open-world object recognition, but the resulting inference latency delays subsequent updates. Systems architects must therefore decouple three distinct temporal quantities: the observation frequency at which the proposer ingests fresh sensor frames, the trajectory horizon spanning the future waypoints contained within each proposal, and the validity window over which those predictions remain physically accurate. Synthesizing longer action horizons can bridge execution between inference cycles, but generating additional waypoints does not refresh the perceptual evidence that produced them.

The machine card of section 1.4.2 already commits the running machine to one answer, the **two-speed brain architecture**: a slow intent model revised at 2 Hz above a fast chunk policy renewed at 20 Hz. Both propose to a permission path that checks measured state on a 1 kHz tick (figure 3.1). The card states these rates; this chapter prices and checks that design. The slow intent model names a target. The fast chunk policy emits an action chunk, the short sequence of future setpoints from one inference that section 1.2 introduced, so the drives below have motion to track between evaluations (Zhao et al. 2023; Chi et al. 2025). Three claims govern this split. Because no single large model can renew its proposal fast enough to supply the arm, the fast policy must emit multi-step chunks, yet a chunk keeps the arm supplied without keeping the evidence behind it fresh. Consequently, the permission path can evaluate and refuse the slow model's intent alongside the fast model's candidate motion only when that intent arrives as a target checkable against independent depth measurements and time: a metric pose stamped with the capture time of the frame that generated it (section 3.5.3).

A first estimate shows why one model cannot do both jobs. If every fresh evaluation must stream all of a model's weights from off-chip memory, its renewal rate can be no higher than the sustained bandwidth divided by the bytes of weights, a ceiling that falls in proportion to parameter count (figure 3.2). The intent model stores its weights as 4-bit integers (INT4, priced in section 3.4.2) rather than 16-bit floating point (FP16), which raises its ceiling fourfold. Both of the machine's proposers still sit below their ceilings, because reading the input tokens in one pass through the model (the *prefill*) and then decoding the output add work that weight streaming alone ignores. Neither approaches the kilohertz rate at which the permission path and the servo loops run. The design problem is therefore deciding which computation can finish before the observation it started from goes stale. Section 3.4.1 derives the ceiling and the work above it; the figure is a preview of where the derivation lands.

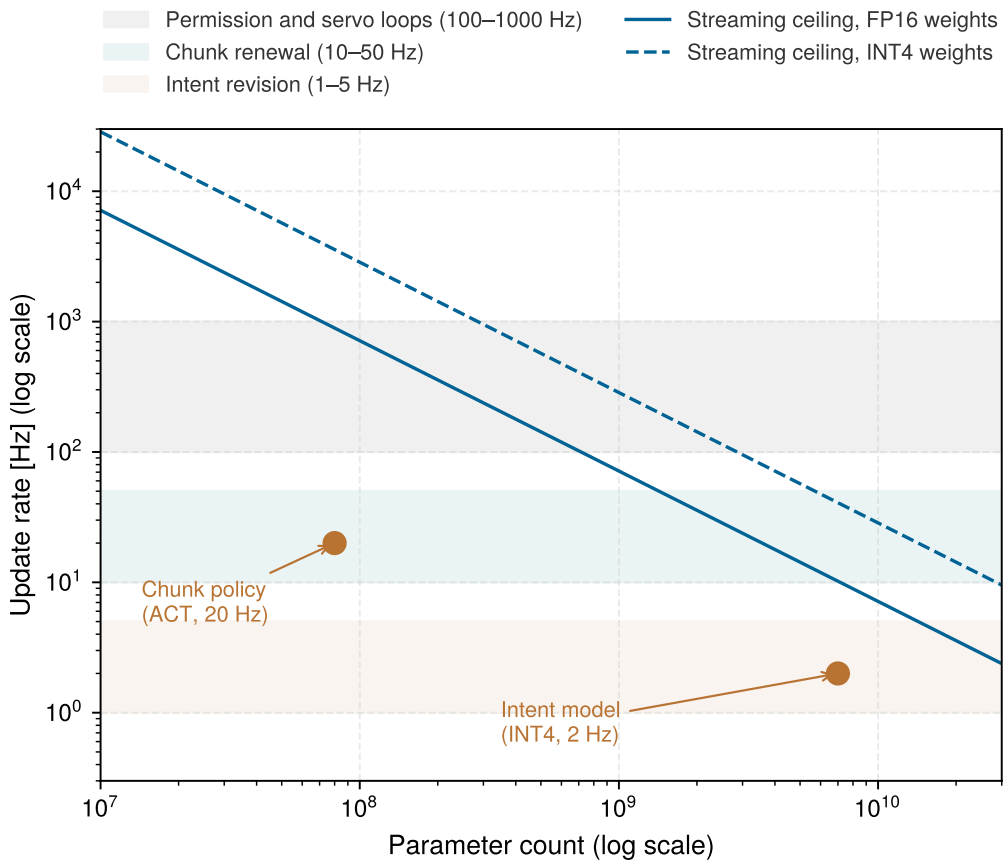

Figure 3.2: Cadence regimes on the machine's processor: The weight-streaming ceiling $f \leq \mathrm{BW}_{\mathrm{mem}}/M_{\mathrm{weights}}$ on the mobile manipulator's application processor for FP16 and INT4 weights (16-bit floating-point and 4-bit integer representations, section 3.4.2) plotted against model parameter counts, alongside the operating points for the machine's intent model and chunk policy. This ceiling establishes an upper bound on throughput rather than an achieved operating frequency, because input token prefill, vision encoding, and autoregressive generation consume execution cycles beyond raw DRAM weight traffic (section 3.4.1).

Testing the two-speed design takes five steps. Classical pipelines built on hand-authored geometry and rigid state machines show why a learned proposer is needed at all, because open-world variability exhausts manual rule sets (section 3.2). Learned representations restore semantic breadth but pay for it in tokens, cache, and bus traffic (section 3.3). Pricing one fresh evaluation of the intent model on the application processor then exposes the memory wall and what quantization can and cannot do about it (section 3.4). Sizing the chunks that keep the arm supplied next separates the motion a chunk supplies from the time its evidence stays true (section 3.5). Because a proposal can arrive on schedule and still be wrong, the last step examines the failures that leave the permission path to refuse an on-time proposal (section 3.6).

3.2 The Classical Wall

In a fixed industrial workcell, a robotic gripper can approach the exact same fixture along an identical trajectory on every production cycle. Engineers can specify such repetitive motions through analytical geometry, rigid-body equations of motion, and deterministic state transitions. Classical control theory and traditional robotics flourish within this analytical formulation (Wiener 1948; Rudolph Emil Kalman 1960; Craig 2005). The engineering challenge sharpens, however, when the work moves from a rigid fixture to an unconstrained scenario, such as retrieving a randomly oriented mug from

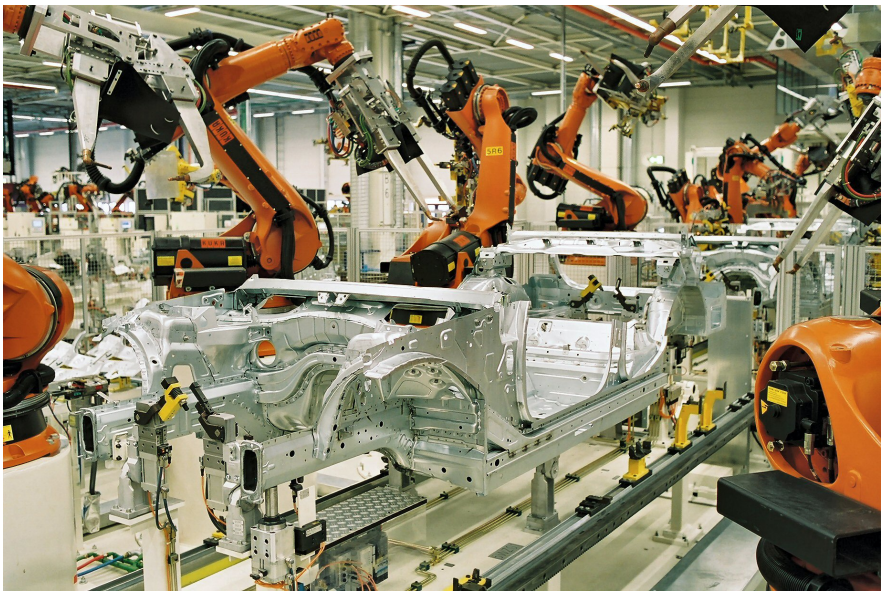

Figure 3.3: Industrial spot-welding workcell: Multiple six-degree-of-freedom articulated robots execute preprogrammed spot welding paths on stamped automotive chassis at the BMW Leipzig plant. The calibrated setting uses repeatable fixtures and safety interlock cages to constrain the conditions for those preprogrammed motions. (Credit: BMW Werk Leipzig, Wikimedia Commons, CC BY-SA 2.0 DE.)

a moving conveyor belt. There the engineer cannot enumerate every combination of object geometry, pose, and physical contact in advance.

Analytical kinematics and dynamics map target end-effector[1] trajectories into joint angles, velocities, and actuator torques.[2] Classical perception routines register incoming sensor point clouds against reference computer-aided design (CAD) models, while a synchronous finite-state machine steps the manipulator through sequential phases: approaching, aligning, grasping, and retracting. In a calibrated workcell, these analytical components reliably solve bounded manipulation tasks under explicit operational assumptions. Their computational latency and real-time execution bounds depend strictly on the chosen numerical solver, processor throughput, and contact dynamics model.

Where the operational environment remains structured and bounded, classical methods provide dependable behavior within their modeled operating envelopes. In a body shop (figure 3.3), the chassis sits in submillimeter tooling fixtures, and controlled lighting and interlock fencing constrain variation under stated fixture, access, and model assumptions. This controlled regime permits explicit physical modeling, servo timing analysis, and formal Lyapunov stability analysis.[3] Establishing selected trajectory tracking error bounds ($\|\mathbf{e}(t)\| \leq \epsilon_{\text{track}}$), stability properties, or software execution guarantees requires justified model, implementation, and execution evidence; the absence of training data does not establish those properties.

When an embodied machine steps outside the structured factory cage into unstructured, open-world environments, however, this analytical paradigm hits the **classical wall** (Brooks 1991; Levine et al. 2018). Physical reality defies closed-form geometric modeling: real objects deform under contact, ambient illumination shifts unpredictably, and scenes present near-infinite visual and mechanical variety. A rescue test arena of tilted ramps and a victim dummy on a high shelf (figure 3.4) has none of the fixtures that made the welding cell analyzable: no part arrives at a known pose, and no template describes the terrain. In such unmapped, irregular settings, preauthored geometric templates and rigid state machines lose state coverage and fail to generalize.

Outside structured fixtures, the analytical perception-and-control pipeline breaks down whenever scenes vary beyond its hand-coded rules. A rigid CAD template fails on deformable cloth or irregular food items; glare or cast shadows can wipe out the depth edges needed to separate adjacent parcels; and an unexpected obstacle invalidates the guard conditions of a preauthored grasping state machine.

1 | **End-Effector**: The tool, gripper, or hand at the distal tip of a manipulator, the only part of the arm meant to touch the workpiece. Workspace and keep-out checks are written against its pose rather than against joint angles, which is why the proposal payload later in this chapter carries end-effector poses alongside joint targets.

2 | **Manipulator Equation**: Classical control computes joint torques from $\mathbf{M}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{g}(\mathbf{q}) = \tau$, with a configuration-dependent inertia matrix $\mathbf{M}$, Coriolis and centripetal terms $\mathbf{C}$, and gravity $\mathbf{g}$. Torque is linear in inertia, and a link's inertia grows with the square of its distance from the joint, so an outstretched arm needs more torque for the same angular acceleration. Unmodeled contact, friction, or deformable objects break this rigid-body model, which is the gap learned proposers enter; section B.2.4 shows how classical control inverts this model to compute torque.

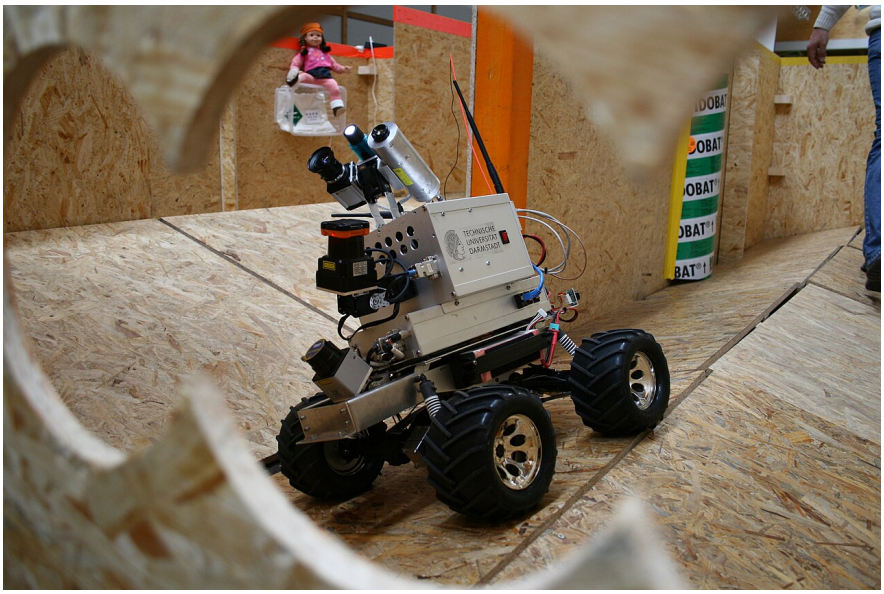

Figure 3.4: Unstructured search-and-rescue robot: A four-wheeled rescue robot carrying cameras and a laser scanner on a pan-tilt mast works through a test arena of tilted ramps and narrow openings, with a victim dummy placed on a high shelf. In such unmapped environments, preauthored geometric models and rigid state machines can lose coverage; learned policies may help infer spatial affordances and traversability from sensory streams. (Credit: Hector, Technische Universität Darmstadt, at the 2010 RoboCup German Open; photo by Mike1024, Wikimedia Commons, public domain.)

Engineers can add templates, heuristic thresholds, and recovery branches to patch each failure, but the cases multiply faster than they can be tuned and tested.

Machine learning exits this trap by learning from diverse physical interactions and demonstrations rather than enumerating geometric rules by hand. Neural models extract graspable features and motion policies directly from high-dimensional sensor streams without a bespoke CAD model for every object. Those learned models do not replace the downstream analytical controller: deterministic feedback loops still enforce kinematic bounds and track trajectories at high rates. Instead, learning inserts a compute-heavy proposal stage whose memory traffic, arithmetic cost, and latency must fit inside the timing contract of the real-time controller.

3.3 Learned Representations

When commanded to pick an unfamiliar ceramic mug from a conveyor, a learned model relates the text prompt to visual features of the handle and proposes a plausible grasp region without an exact CAD model. VLA models combine multi-camera imagery, natural-language instructions, and proprioceptive robot state to produce candidate actions (Brohan, Brown, Carbajal, Chebotar, Dabis, et al. 2023; Brohan, Brown, Carbajal, Chebotar, Chen, et al. 2023; Kim et al. 2024). These systems descend from early embodied language models such as SayCan and PaLM-E, which emitted high-level semantic plans rather than low-level motor commands (Ahn et al. 2022; Driess et al. 2023). The operational value of a VLA stems from broad generalization across diverse objects and ambient environments acquired during large-scale pretraining, rather than formal guarantees of correct scene interpretation.

Teleoperated demonstrations can likewise teach coordinated sensorimotor policies for tasks whose contacts and structural deformations resist analytic kinematic modeling. In a bimanual teleoperation workcell (figure 3.5), an operator moves low-cost leader arms while follower arms with parallel grippers reproduce the motion, and overhead and wrist cameras record what the followers saw. Those recordings become the training data for policies that later act alone (Zhao et al. 2023; Chi et al. 2025). The running machine's chunk policy takes its size from ACT, which was trained on exactly such recordings. What such a policy learns from them is the action chunk itself, a short stretch of the operator's motion predicted from one view. How demonstrations become a policy

[3] **Lyapunov Stability**: Aleksandr Lyapunov's 1892 method establishes stability near an equilibrium using a positive-definite, energy-like function whose derivative along the modeled dynamics is nonpositive; asymptotic convergence requires stronger decrease or invariance conditions (Slotine and Li 1991). Applying the method requires a justified closed-loop dynamics model and verified certificate conditions; a learned proposer does not acquire such a certificate merely from training. The barrier certificates of section 12.5 reuse the idea to keep the machine inside a safe set rather than at a point.

↩ The causal boundary, where an admitted command becomes physical work, is established in section 1.4.

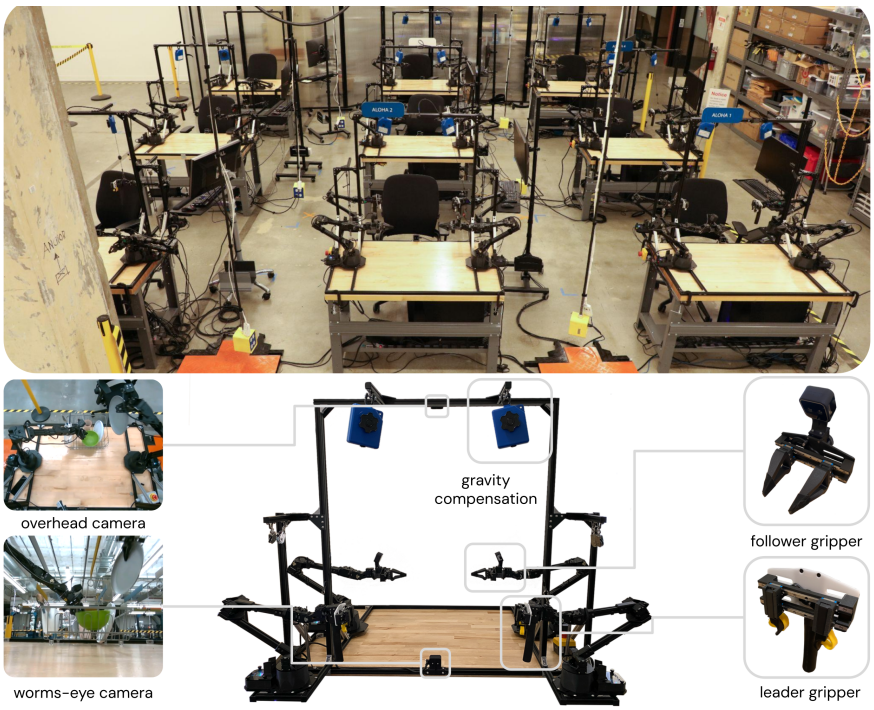

Figure 3.5: Bimanual teleoperation workcell: Dual-arm teleoperation setup featuring two six-degree-of-freedom follower arms, two leader arms for kinesthetic teleoperation, multi-view cameras (overhead and wrist-mounted), and parallel grippers mounted to an extruded aluminum frame. The physical AI policy ingests synchronized multi-camera streams to predict continuous end-effector trajectories, and the permission path must refuse any proposal that would cause self-collision or motor over-torquing during closed-loop execution. (Credit: ALOHA 2 Team, ALOHA 2: An Enhanced Low-Cost Hardware for Bimanual Teleoperation, arXiv:2405.02292, CC BY 4.0.)

belongs to chapter 6; this chapter prices what the trained policy costs to run. Although learned representations tolerate sensory variations captured across training distributions, executing any proposed motion safely still demands calibrated spatial geometry and strict physical boundary enforcement. Empirical task success demonstrates capability over tested operating envelopes, but out-of-distribution shifts in illumination, surface friction, or payload dynamics can quickly induce behavioral drift or outright failure.

The computational cost of this capability depends directly on the model's underlying representation. A transformer does not read pixels or words directly; it reads *tokens*, embedding vectors that each represent one slice of input, such as an image patch, a word fragment, or a joint angle. Across a VLA model, that token sequence flows from camera patches and prompt embeddings through self-attention to candidate action chunks (figure 3.6). Multi-view camera frames consume significant memory bandwidth during ingestion, historical context expands key-value (KV) cache footprints in memory, and the inference engine must produce subsequent actions before the physical state diverges from the initial observation. Evaluating an embodied learned model alongside a classical perception-planning pipeline requires assessing both task generalization and the end-to-end latency required to refresh action proposals.

To grasp the mug, the model turns camera images and a language instruction into candidate trajectories in three learned stages: tokenization, attention across the tokens in a backbone, and an action decoder that projects the backbone's output into proposed motion. A proposal boundary separates all three from actuation, so every candidate action passes independent permission checks before it reaches the motor drives. Evaluating this pipeline from a systems perspective means tracing what each stage stores in memory, transfers across the memory bus, and delivers to the controllers below it:

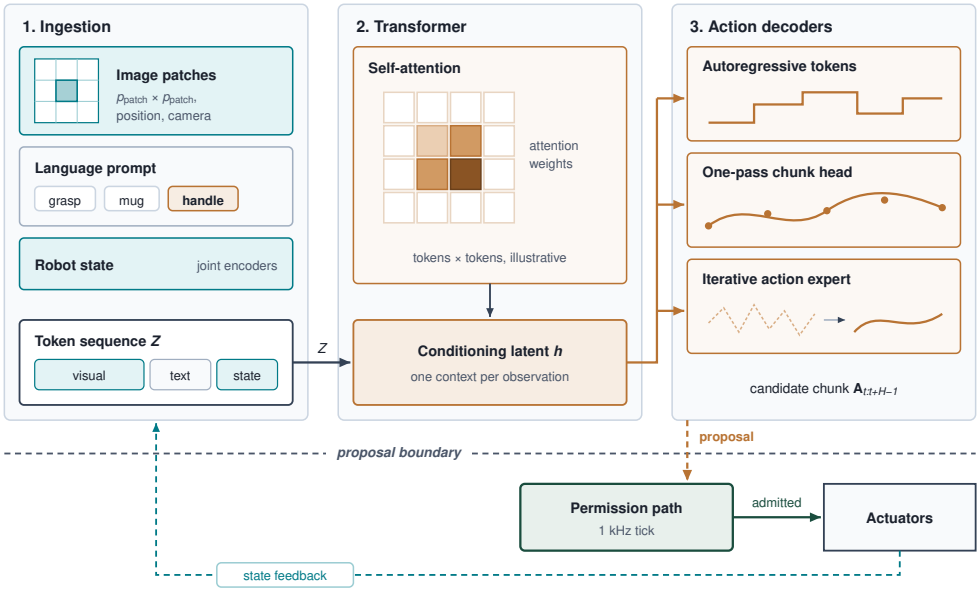

Figure 3.6: Embodied Vision-Language-Action (VLA) architecture: A representative dataflow. (1) Camera patches receive 2D image-position and camera identifiers alongside language and robot-state tokens; metric depth still requires calibrated evidence. (2) Self-attention mixes the combined token sequence; the colored grid illustrates internal attention weights, not a verified affordance or grasp pose. (3) Autoregressive token decoders emit tokens sequentially, whereas one-pass chunk heads and iterative action experts generate candidate multi-step chunks ($\mathbf{A}_{t:t+H-1}$) in one pass or over several refinement steps. (4) An independent permission path checks candidate motion against sensed state and modeled limits before actuation. (Synthesized from Brohan et al. (Brohan, Brown, Carbajal, Chebotar, Dabis, et al. 2023; Brohan, Brown, Carbajal, Chebotar, Chen, et al. 2023), Kim et al. (Kim et al. 2024), and Octo Model Team (Octo Model Team et al. 2024)).

1. *Sensory ingestion and spatial tokenization (the inputs).* A vision transformer (ViT) frontend (Dosovitskiy et al. 2021) slices each incoming camera frame into a grid of non-overlapping pixel patches of size $p_{\text{patch}} \times p_{\text{patch}}$ (typically 14×14 or 16×16 pixels). Each patch is linearly projected into a vector of width d, augmented with a position embedding (learned in the SigLIP and DINOv2 encoders that OpenVLA uses (Kim et al. 2024), sinusoidal in some other designs), and tagged with a learned camera identifier.
   In an illustrative three-camera configuration (left wrist, right wrist, and an overhead torso mount) capturing 224×224 images, the image frontend prepares a buffer for each view. Each frame yields $(224/14)^2 = 256$ spatial patches. Across 3 cameras, ingestion injects 768 visual tokens into the model's sequence on every perceptual step. When concatenated with tokenized natural language commands (about 32 tokens) and proprioceptive joint state embeddings (about 16 tokens), the initial context runs slightly past 800 tokens, which the estimates below round to $S \approx 800$. In 16-bit floating-point (FP16) precision (2 bytes per element) with hidden dimension $d = 4096$, the token embeddings for one such step occupy
   $$M_{\text{embed}} = S \times d \times 2\,\text{bytes} = 800 \times 4096 \times 2 \approx 6.55\,\text{MB}$$
   a few megabytes, negligible beside the multi-gigabyte weights that section 3.4.1 prices. Tokens therefore cost the machine through the arithmetic every weight performs on each of them and through the cache they leave behind, not through the storage of the embeddings themselves. Neither 2D image coordinates nor internal attention patterns constitute metric depth. Projecting an end-effector into physical 3D space requires calibrated extrinsic camera matrices and depth telemetry.
2. *Multimodal alignment and attention (the backbone).* For the illustrative backbone, the token sequence passes through $N_L = 32$ transformer layers where standard multi-head self-attention computes pairwise token interactions (Vaswani et al. 2017). To relate each new token to the earlier ones, every layer keeps a *key* and a *value* vector for every token it has already

processed, the **KV cache**. The arithmetic of attention grows with the square of the sequence length ($\mathcal{O}(S^2 d)$ FLOPs), but the memory the cache occupies grows only linearly with it, as equation 3.1 gives:

$$M_{\text{KV}} = 2 \times N_L \times d \times S \times s_{\text{elem}} \tag{3.1}$$

The estimate assumes full-width keys and values, meaning every attention head in every layer stores its own. For a 32-layer model with $d = 4096$ using FP16 storage, each context token then claims 524,288 bytes, about 0.524 MB, of KV cache, so an observation step of several hundred tokens holds hundreds of megabytes.

Whether the machine pays that charge more than once depends on what the model keeps between evaluations. Single-observation VLAs such as OpenVLA rebuild their context from each new frame and carry no cache across control steps, and the running machine's intent model is one of them. Only a design that conditions on retained history rereads the cache on every step, and section 3.5.2 prices what retaining several seconds of history would cost. Such rereading is not free, because the processor uses a unified memory architecture (UMA), in which the CPU, the GPU, and the camera interfaces share one DRAM. Every byte of cache read is bus time taken from weight streaming and from the direct memory access (DMA) transfers that deliver sensor frames. Grouped-query attention (GQA) narrows the cache by letting several query heads share one key and value; cross-attention can instead limit which retained representations the decoder reads. Either saving depends on the architecture, and action chunking does not provide it.

Attention weights are also not geometry. A strong weight between the language tokens "mug handle" and a visual patch does not establish a graspable affordance[4] or collision-free clearance, and the KV cache does not keep track of an object while it is occluded. The formal patch-embedding, position-encoding, and attention formulations appear in section A.3.2.

3. *Specialized action decoders (the outputs).* Instead of generating open-ended conversational text, the final hidden representation $\mathbf{h}_{\text{context}} \in \mathbb{R}^d$ is routed to specialized action decoders. The running machine's chunk policy proposes base velocity and arm targets together in one whole-body stream (section 3.5.2), so its decoder is a manipulation decoder whose outputs include the base. Separate navigation models that decode waypoints over a topological map of the building (figure 3.7) follow the same proposal rules but are not part of this machine. Manipulation (VLA) models diverge sharply in how they bridge semantic representations to physical motion: Discrete action decoders map each action dimension to a categorical token by dividing its continuous range into bins (Brohan, Brown, Carbajal, Chebotar, Dabis, et al. 2023; Brohan, Brown, Carbajal, Chebotar, Chen, et al. 2023; Kim et al. 2024). Autoregressive decoders such as RT-2 and OpenVLA then generate those tokens sequentially, requiring one complete model evaluation per action dimension (Brohan, Brown, Carbajal, Chebotar, Chen, et al. 2023; Kim et al. 2024). However, discretization does not require sequential decoding. RT-1 predicts all action tokens simultaneously in a single forward pass, and its authors demonstrated that autoregressively conditioning each action dimension on preceding dimensions yielded no accuracy gains while more than doubling inference latency (Brohan, Brown, Carbajal, Chebotar, Dabis, et al. 2023).

   What separates modern decoders in systems practice is the computational cost of generating a trajectory chunk and the volume of model weights reread during inference. Three architectural families dominate implementations as of 2026:

   - *Autoregressive tokens.* Each token requires a separate sequential evaluation. With one token per action dimension per control step, predicting a chunk of H timesteps across d_a dimensions demands Hd_a sequential evaluations, causing inference latency to scale with both horizon and degree of freedom. Per-step binning also breaks down at high control frequencies: consecutive continuous setpoints differ negligibly, producing runs of identical token targets from which next-token training learns almost nothing. Frequency-space action sequence tokenization (FAST) resolves this scaling bottleneck by applying a discrete cosine transform across each action dimension over the chunk horizon, representing the trajectory as a linear combination of cosine basis functions (Pertsch et al. 2025). Smooth physical motions concentrate energy in low-frequency coefficients, allowing aggressive

[4] **Affordance**: Gibson's term for the action possibilities an environment offers an agent, defined jointly by object properties and agent physical capabilities (Gibson 1979). A handle affords a grasp only when its physical dimensions and clearance accommodate the robot's gripper geometry and kinematics. While self-attention weights across image patches highlight semantically relevant features such as a handle, they do not certify mechanical grasp stability or kinematic reachability, the failure mode section 3.6.1 analyzes.

truncation. FAST quantizes these coefficients and compresses them with byte-pair encoding, which repeatedly merges the most frequent adjacent pair of symbols into a new token, tying token counts directly to trajectory information complexity rather than Hd_a. On a 50 Hz bimanual task, FAST compressed 700 raw binned tokens to 53, achieving a 13.2× reduction (Pertsch et al. 2025). Token generation nevertheless remains sequential. The authors report an inference latency of approximately 750 ms per chunk for FAST-π_0, compared to 100 ms for the flow-matching variant on an identical desktop GPU.

- *One-pass chunk heads.* Action Chunking with Transformers (ACT) regresses an entire trajectory chunk in a single feedforward decoder pass (Zhao et al. 2023). OpenVLA-OFT adapts an autoregressive VLA into a one-pass generator by passing placeholder action tokens through bidirectional self-attention and directly regressing continuous values for all action steps in parallel, increasing throughput by 26× on 8-step chunks (Kim et al. 2025). However, deterministic regression heads trained with mean squared error struggle with multimodal demonstration data: when presented with two equally valid paths around an obstacle, a naive regression loss averages them into an infeasible trajectory directly through the obstacle (Chi et al. 2025). Section 6.2.3 develops this *mode averaging* from the training side. ACT mitigates it by conditioning its decoder on a latent style variable, a code that records which of several demonstrated ways of doing the task a trajectory follows, learned with a conditional variational autoencoder (CVAE, section A.5.1).
- *Iterative action experts.* Diffusion Policy formulates action generation as iterative denoising, starting a candidate chunk from random noise and repeatedly removing the noise a network predicts, adapting continuous diffusion processes originally developed for generative vision models (Ho et al. 2020; Chi et al. 2025). The π_0 architecture pairs a 300M-parameter flow-matching[5] **action expert** with a pretrained vision-language model, yielding 3.3B total parameters (Black et al. 2024). The large vision-language backbone processes perceptual observations once and caches its key-value activations; the action expert then generates the continuous trajectory chunk across 10 numerical integration steps while attending to that static cache. Each integration step is a forward Euler step. The expert starts the candidate from Gaussian noise, evaluates a learned velocity field that says which direction moves it toward a plausible action chunk, and moves the candidate a small distance that way; after 10 steps the candidate is the chunk. Each step requires a forward pass only through the lightweight action expert and its cross-attention reads into the cached backbone KV activations, avoiding any re-evaluation of the multi-billion-parameter vision-language backbone. Subsequent designs such as $\pi_{0.5}$ and GR00T N1 employ this exact decoupling (Black, Brown, et al. 2025; Bjorck et al. 2025), with $\pi_{0.5}$ combining FAST-token pretraining on the backbone with flow-expert execution at runtime.

[5] **Flow Matching**: A method that trains a neural network to predict a continuous velocity field carrying samples from Gaussian noise to the target data distribution along nearly straight paths (Lipman et al. 2022). Because those paths are straight, numerical solvers can generate samples in a handful of Euler steps, whereas older denoising diffusion models needed hundreds of sequential steps (Ho et al. 2020). On an embedded robot processor, the step count directly sets latency because each solver step reread the action expert's weights and cached visual context from off-chip memory.

Across all three families, the continuous output forms a multi-step trajectory chunk:

$$\mathbf{A}_{t:t+H-1} = [\mathbf{a}_t, \mathbf{a}_{t+1}, \dots, \mathbf{a}_{t+H-1}] \in \mathbb{R}^{H \times d_a}$$

Here H specifies the future prediction horizon in discrete setpoints and d_a denotes the degrees of freedom per action; section 3.5.1 states the formal definition (3.2) once the memory wall has shown why chunks are needed. Published horizons span from tens to hundreds of setpoints: Diffusion Policy predicts 16 steps and executes the initial 8 (Chi et al. 2025), π_0 predicts 50 steps (Black et al. 2024), and ACT predicts 100 steps at 50 Hz (Zhao et al. 2023). The structural gap between prediction and execution horizons resurfaces in section 3.5.2 as the interface between asynchronous trajectory generation and real-time permission filtering. A trajectory chunk provides an open-loop sequence of future setpoints derived from a single sensory context, amortizing inference latency without incorporating intervening sensor observations. Section 3.5.1 evaluates the computational efficiency of these three decoder families on target silicon, while section A.5.1 gives the discrete tokenization rule and details how generative decoders capture multimodal demonstration distributions without averaging conflicting trajectories.

4. *The proposal boundary (isolation from actuators).* Whether the model plans navigation or manipulation, its output is an unprivileged candidate proposal strictly outside the proposal boundary

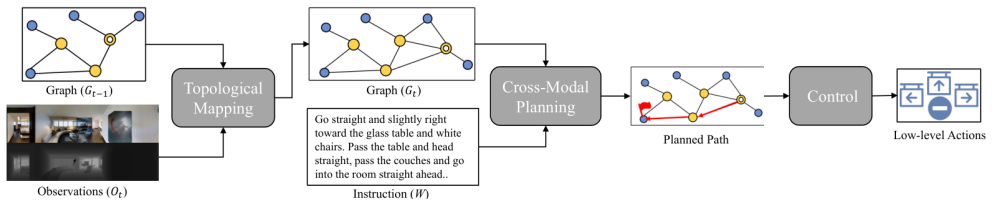

Figure 3.7: Topological vision-language navigation: Embodied navigation architecture executing natural-language spatial instructions. Panoramic visual observations are encoded into perceptual tokens, matched against prompt embeddings, and cross-referenced with a dynamically updated topological navigation graph. The action decoder prunes unreachable nodes and emits metric waypoint offsets $(\Delta x, \Delta y)$ and heading setpoints to guide the chassis along traversable semantic frontiers without requiring an exact geometric prior map. (Adapted from An et al. (2023), arXiv:2304.03047, CC BY 4.0.)

(definition 1.3). Under the concrete machine model established in section 1.7, the foundation model runs in unprivileged user space on the host application processor and has no direct memory-mapped access to pulse-width modulation (PWM) registers or motor coil current drivers. Instead, the Brain hands candidate motion, stamped with the capture times of the sensory frames that generated it, to a permission path whose kilohertz loops a slow inference cannot preempt or bypass. That path refuses proposals that would collide, violate joint limits, or drive the arm into a kinematic singularity (an arm configuration in which the joints lose the ability to move the end effector in some direction). Section 4.6 isolates this gating logic on a dedicated real-time safety microcontroller, completely segregated from the application processor hosting the learned model.

The choice of sensory representation and action decoder dictates the memory traffic and latency profile of every control cycle. Maintaining historical token context accumulates KV cache overhead that consumes memory bus bandwidth, while running multi-billion-parameter backbones on resource-constrained embedded systems demands heavy weight streaming from off-chip DRAM. An embodied agent needs both semantic breadth and rapid trajectory renewal, and these costs suggest that one monolithic model on an embedded processor cannot deliver both. Whether it can is a question of numbers, and the place to get them is one fresh evaluation of the machine's intent model on its own application processor.

3.4 The Cost of a Fresh Evaluation

At the pick station the mobile manipulator's arm consumes a new setpoint every few tens of milliseconds, while the mug keeps moving along the conveyor. Whether one large model could supply those setpoints depends on how long one fresh evaluation of it takes on the application processor, and that time depends on which resource the evaluation exhausts first, the memory bus or the arithmetic units. The intent model's evaluation is priced first, together with what quantization can buy back; section 3.5 then checks the motion buffer that the selected split relies on against the target's drift. The single large-model cases below are alternatives used to expose the trade-off, not changes to the selected machine.

After ingestion (the tokenization of section 3.3), four learned stages turn those tokens into action proposals, and each hands the next a record that ages (figure 3.8). Across the proposal boundary, an isolated safety microcontroller (MCU) running the permission path on a 1 kHz tick decides whether candidate setpoints become admitted drive commands. These stages describe what the machine must compute, not how its networks are divided; the three learned stages of section 3.3 describe the inside of one transformer. On the running machine, the intent model recognizes the mug and names the target (perception and intent), a tracker carries the mug's estimate from frame to frame (memory), and the chunk policy, reading its own camera frames, turns the target into setpoints (planning). *Memory* here means the belief the machine keeps about the world, not DRAM. The chapters of Part III, beginning with chapter 8, develop each stage in depth; here they matter only for what each hands downstream and how quickly that record goes stale.

Perception grounds what it recognizes in metric coordinates relative to the base, so that the mug has a 3D position and orientation (an $SE(3)$ pose)[6] and a graspable handle rather than an abstract semantic label; its output ages from the moment of capture. Memory carries those estimates through

6 **SE(3) Pose**: SE(3), the special Euclidean group in three dimensions, is the set of rigid-body poses, a rotation plus a translation with six degrees of freedom; "special" excludes mirror reflections, which no rigid object can undergo. A pose can be compared with measured depth and aged from its capture time, while a semantic label such as "mug handle" can be neither, which is why the handoff to planning is a pose and not a label.

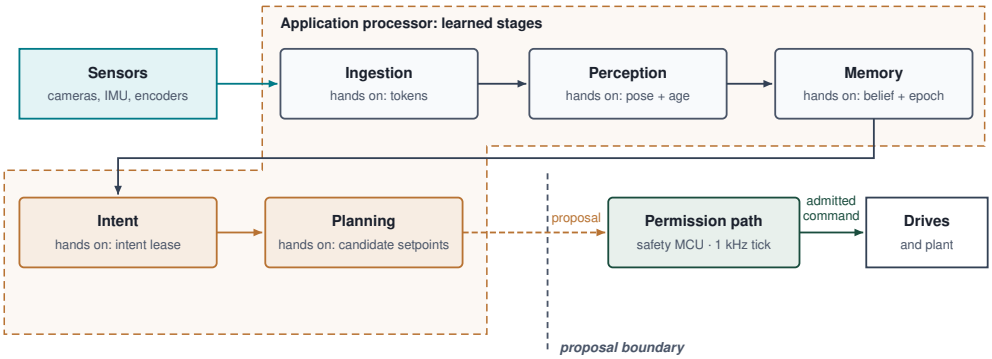

Figure 3.8: The physical AI cognitive flow: The learned stages run on the application processor and each hands the next a record that ages: ingestion produces tokens, perception a metric pose with its age, memory a belief with its evidence epoch, intent an intent lease, and planning candidate setpoints. Everything up to planning is proposal. Only the permission path, on its own 1 kHz tick across the proposal boundary, can turn a proposal into an admitted command for the drives.

occlusion and must let each one expire when the evidence behind it does. Intent decomposes a task such as "take the ceramic mug off the conveyor and hand it to the coworker at the packing station" into subgoals, and because the mug moves while the intent model deliberates, it hands the planner a target that expires, an intent lease in the vocabulary of Part III. Planning converts that target into candidate setpoints for the base and the arm, the proposals the permission path will judge.

↪ The observation contract that dates each perception output from its capture epoch is developed in section 8.8.

↪ The intent lease and the deadlines that end it are developed in section 10.8.

These stages, and the ingestion before them, all run on the application processor and draw on the same unified memory bus, which is where the machine's cadence is decided. On an edge robotics system-on-chip (SoC), memory bandwidth, arithmetic rate, and power envelope are fixed allocations, and model weights, sensor transfers, and host computation share that bandwidth. A policy cannot budget the full bus for itself while assuming that new camera frames arrive without interference, and scaling the model up only draws harder against the same ceiling. The transfer bound below is therefore a lower bound on evaluation time. The worked comparison later uses an assumed sustained fraction of peak bandwidth. Section 13.3 models how weight fetches, camera transfers, and telemetry writes queue for the shared memory controller.

↩ That every added layer of onboard compute draws against fixed memory bandwidth, electrical power, and thermal dissipation is established in section 1.10.

Published measurements on the machine's own module show how far apart those costs sit before any of that arithmetic. The MLPerf Inference edge suite times one query at a time, its single-stream scenario, for a fixed set of reference models (Reddi et al. 2019). Vendor submissions for the 64 GB Jetson AGX Orin place those reference latencies directly against the three cadences of the running machine (figure 3.9).

Only three of the seven reference models answer inside the 50 ms chunk period: classification in 0.64 ms, question answering, and detection in 11.7 ms. A six-billion-parameter language model takes 4.2 s to produce one summary, 8× the 500 ms intent period, and the span from fastest to slowest is about 16,000×. The figure is a measured version of the two-speed argument. A language-model proposer on this module can revise intent only at a fraction of the rate the arm consumes setpoints. The same submission also shows that the cost is not fixed by the silicon alone. The language model's latency was 10.2 s one round earlier on identical hardware, so the software stack sets the cost as much as the silicon does. Which bytes that software moves per evaluation is what the memory-wall analysis below quantifies.

3.4.1 The memory wall

A multi-billion-parameter model takes hundreds of milliseconds on a processor rated at tens of tera-operations per second. Its weights do not fit in on-chip static RAM (SRAM) or cache, so every fresh evaluation must stream them from off-chip low-power DRAM (LPDDR5) across a narrower shared bus. On-chip SRAM and caches can reuse weights and intermediate state without another external transfer only while the working set fits the memory allocated to that workload. Nominal chip-wide capacity does not guarantee that even a small action head stays resident when competing

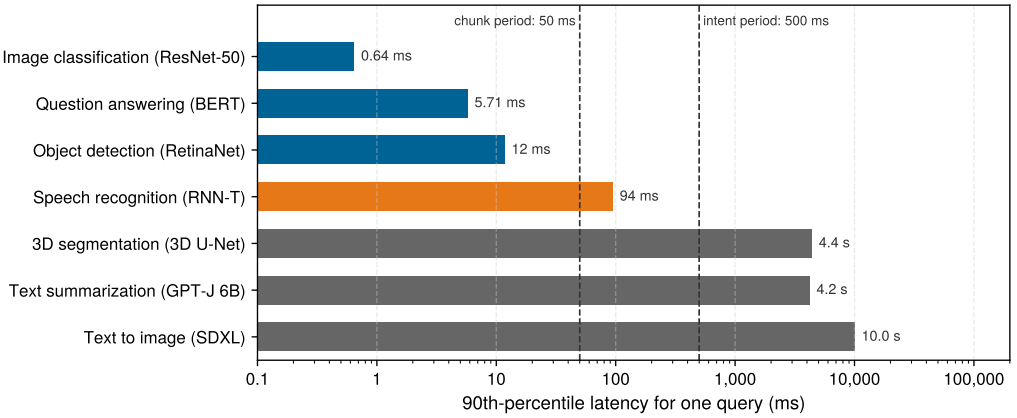

Figure 3.9: Measured single-query latency on the application processor: The 90th-percentile time to answer one query, on a logarithmic axis, for each MLPerf Inference edge reference model on the 64 GB Jetson AGX Orin, the module in the running machine. Dashed lines mark the machine's chunk renewal period and intent revision period; blue bars finish within one chunk period, the orange bar within the intent period, and gray bars within neither. The reference models span four orders of magnitude on the same silicon, so which proposer a design can afford is fixed by the model class before any tuning. Vendor submissions, latest round per model (v3.1, or v4.1 for the two generative models); data from the MLCommons inference results repositories (Reddi et al. 2019).

tasks share the processor. When operands cannot reach the arithmetic units as fast as those units can multiply them, memory bandwidth, not arithmetic speed, limits the update rate. That ceiling is the memory wall, and on a moving robot its cost is a delayed proposal while the body keeps traveling.

Consider a robot that generates continuous motor actions one discrete step at a time through an autoregressive foundation model, such as a multi-billion-parameter VLA. Its weights are *nonresident*, too large to stay in on-chip memory, so each token step streams them across the external DRAM bus. In single-token decoding with FP16 weights and request batch size $B = 1$, the dense weight projections become matrix-vector operations ($\mathbf{y} = \mathbf{W}\mathbf{x}$), in which each fetched weight takes part in a single multiply-add before it is discarded. The bus, not the arithmetic, then sets the pace. The sustained memory bandwidth $\mathrm{BW}_{\mathrm{mem}}$ and model weight footprint M_{weights} bound the maximum fresh-evaluation frequency, as equation 3.2 states:

$$f \leq \frac{\mathrm{BW}_{\mathrm{mem}}}{M_{\mathrm{weights}}} \tag{3.2}$$

This bound must use the bandwidth actually available to the policy and the weights it transfers at the selected precision. It prices only the weight transfer. A fresh evaluation first reads its input tokens (image patches and the instruction) through the backbone in one pass, the **prefill**. That pass reuses every fetched weight across all of those tokens, so arithmetic rather than bandwidth can bind it. Notebook 3.1 prices both terms for the mobile manipulator's intent model. When a decoder emits one token per action dimension, each action dimension requires another token; if each token revisits off-chip parameters, that decode latency scales linearly with degrees of freedom.

Single-token decoding at batch size 1 Servers can combine independent requests so that a weight matrix multiplies several input vectors at once, reusing fetched weights. A robot waiting for its next action token often has only one such request. Waiting for future observations to form a batch would add delay, and sequentially dependent action tokens cannot all be evaluated at once by an autoregressive decoder. This limits reuse in those projections. It does not make every operation in an embodied model a matrix-vector product. Image patches, multiple camera views, prompt tokens, and parallel action decoders can expose matrix-matrix work within one robot's request. The one-use-per-fetch estimate therefore describes the single-token weight sweep, not the complete perception-and-action workload.

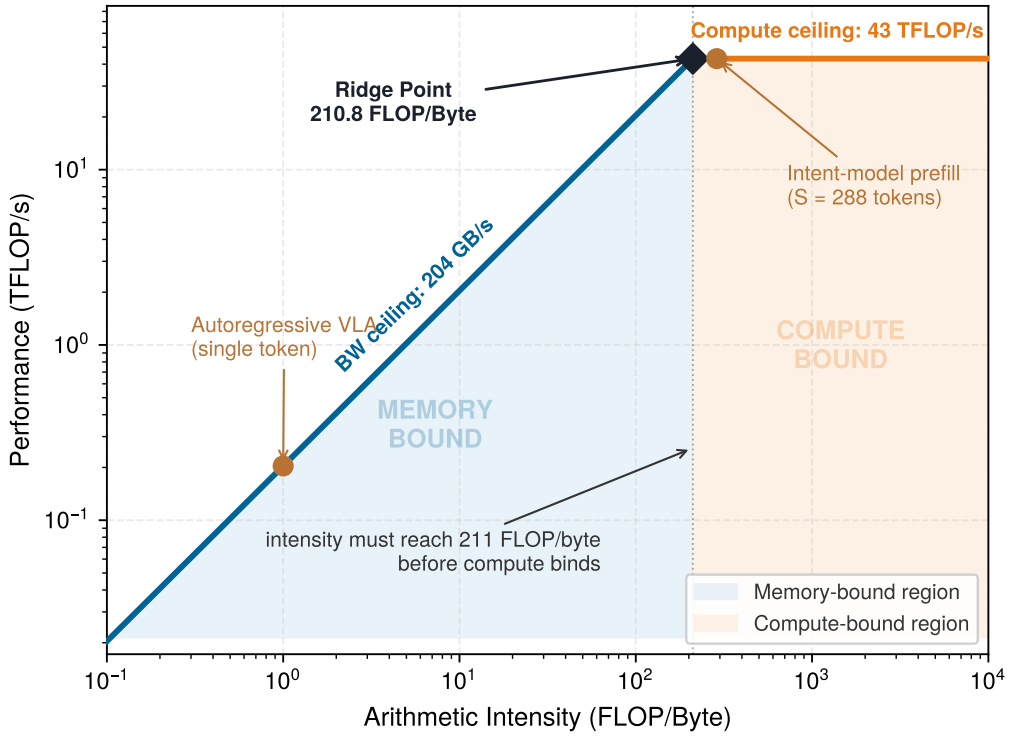

Figure 3.10: Illustrative embodied roofline: Arithmetic intensity (operations per byte moved from off-chip memory, equation 3.3) against attainable throughput using the application processor's dense FP16 GPU ceiling and rounded peak memory bandwidth. Single-token weight streaming sits deep in the memory-bound region, while the intent model's prefill, which reuses each fetched weight across all of its input tokens, lies past the ridge, the intensity at which the bandwidth roof meets the compute roof, where compute binds. Chunk length alone does not determine arithmetic intensity; chunked workloads require measured operations and memory traffic. A separate real-time loop executes accepted waypoints between fresh model updates.

Whether a phase of the evaluation meets the memory wall or the arithmetic limit is decided by how much work it does per byte it moves, its **arithmetic intensity** (I), defined in equation 3.3 as:

$$I = \frac{\text{FLOPs}}{\text{Bytes transferred from off-chip memory}} \tag{3.3}$$

For the dense weight projections of single-token decoding at batch size 1, each a matrix-vector product $\mathbf{y} = \mathbf{W}\mathbf{x}$, counting weight traffic alone gives an optimistic estimate, because activation and context traffic add further bytes. In FP16 each weight occupies 2 bytes and participates in exactly one multiply-accumulate operation (2 FLOPs), so

$$I_{\text{GEMV, 16-bit}} = \frac{2\,\text{FLOPs}}{2\,\text{Bytes}} = 1.0\,\text{FLOP/byte}$$

The roofline model (Williams et al. 2009) turns that ratio into a bound (figure 3.10). It plots attainable throughput against arithmetic intensity as two roofs. Below a crossover, the ridge point, throughput is capped by a sloped roof equal to bandwidth times the intensity; above it, by a flat roof equal to the processor's peak arithmetic rate. It is read the same way as the stopping-budget plot of section 1.4.3, where delay travel and braking travel trade dominance at a crossover speed. Both plots show two regimes and the point at which one gives way to the other.

The mobile manipulator's application processor is a Jetson AGX Orin module (section C.14.1). In its 60 W maximum-performance power mode, its dense FP16 GPU Tensor Core ceiling is 43

TFLOP/s; the aggregate sparse INT8 rating cannot be used for this FP16 workload. Using the registry's rounded peak memory bandwidth of 204 GB/s, the hardware ridge point occurs at:

$$I_{\text{ridge}} = \frac{R_{\text{peak}}}{\text{BW}} = \frac{43TFLOP/s}{204GB/s} \approx 210.8FLOP/byte$$

For this weight-streaming example, $I_{\text{GEMV, 16-bit}} = 1.0\,\text{FLOP/byte}$ is far below 210.8 FLOP/byte, so memory bandwidth sets the roofline ceiling. Attainable throughput is bounded by the peak bandwidth times $I_{\text{GEMV, 16-bit}}$, or 0.204 TFLOP/s, about 0.47 percent of the dense FP16 peak; the sustained bandwidth that the notebook below uses lowers it further. That ratio is a workload throughput bound, not a measurement of how many cores are idle. Both roofs also assume the maximum-performance mode. A battery-powered base often runs a lower power mode, down to 15 W on this module, where lower clocks drop both the compute and the bandwidth roof; the chassis thermal budget sets the mode the machine can sustain.

Definition 3.1: Memory wall

Memory wall is the limit on a workload's rate that arises when its operands cannot reach the arithmetic units as fast as those units could consume them, so that the bytes moved from off-chip memory, not the operations performed, set the time per evaluation.

1. **Significance**: A proposer whose weights do not stay on chip must stream them at least once per fresh evaluation, which gives equation 3.2. On the machine's application processor, the intent model's 14 GB of FP16 weights at 142.8 GB/s sustained allow at most 10.2 Hz before any vision or decoding work, two orders of magnitude below the 1 kHz permission tick.
2. **Distinction**: A compute bound yields to faster arithmetic; the memory wall yields only to fewer bytes per evaluation (fewer or narrower weights, or weights that stay resident on chip) or to more bandwidth. It is also distinct from memory capacity: a model can fit in DRAM and still be too slow to stream.
3. **Common pitfall**: A frequent misconception is that a processor's peak arithmetic rating predicts its batch-1 inference rate. Single-token weight streaming on this processor reaches only about 0.47 percent of its dense FP16 peak, so the rating overstates the attainable rate by orders of magnitude.

On the mobile manipulator's application processor, then, the memory wall[7] caps the intent model's fresh-evaluation rate, before any vision or decoding work, far below the 100–1000 Hz at which stabilization, joint impedance control, and reflex-level collision avoidance run (notebook 3.1). Each of those loop rates is set by the physical time constant of the motion its loop must stabilize, a derivation carried out in section 4.3. A model renewed that slowly can say where the arm should go, but it cannot close the loop on moving mass, so it proposes waypoints and a faster loop below it tracks them. That conclusion is about timing only. The separate requirement that learned outputs remain proposals, even when they arrive in time, comes from the failures of section 3.6.

Repeated off-chip transfers also consume memory-system energy. Their power cost depends on the DRAM, controller, access pattern, and transfer rate, so a bandwidth calculation alone does not establish battery drain or actuator heating. Whatever the processor dissipates is heat released inside the same sealed chassis as the joint motors, and it raises the ambient temperature against which section 2.5.1 rates each motor's continuous torque.

A fresh evaluation is not a single point on the roofline. Its prefill reuses each fetched weight across all of its input tokens and lands past the ridge, while its decode returns to the memory-bound point, one full weight sweep per token. For a decoder that emits S_{out} tokens one after another, equation 3.4 adds the two phases:

$$t_{\text{infer}} \approx \max\left(\frac{O_{\text{prefill}}}{\eta_{\text{hw}} R_{\text{peak}}}, \frac{M_{\text{weights}}}{\text{BW}_{\text{mem}}}\right) + (S_{\text{out}} - 1)\,\frac{M_{\text{weights}}}{\text{BW}_{\text{mem}}} \tag{3.4}$$

[7] **Wulf and McKee**: Their short paper named the memory wall (Wulf and McKee 1995), observing that processor speed was improving far faster than DRAM latency, so that memory access would eventually dominate run time whatever the processor did. Caches postponed the wall for workloads that reuse their data, but a batch-1 model on a robot meets it directly. When each weight is used once per fetch, the bus, not the arithmetic, sets how often a fresh proposal can arrive.

Here O_{prefill} counts the prefill's operations, R_{peak} is the processor's peak arithmetic rate at the activation precision, and η_{hw} is the fraction of that rate the prefill achieves. The prefill cannot finish before its own weight sweep, hence the maximum; the prefill emits the first token, and each of the other $S_{\text{out}} - 1$ tokens costs one more sweep. Notebook 3.1 prices both phases for the machine's intent model.

Prefill creates KV state that decode extends within one evaluation. Figure 3.11 follows a single observation through prefill, first-token sampling, and subsequent decode passes, then marks the boundary at which the running machine rebuilds its context.

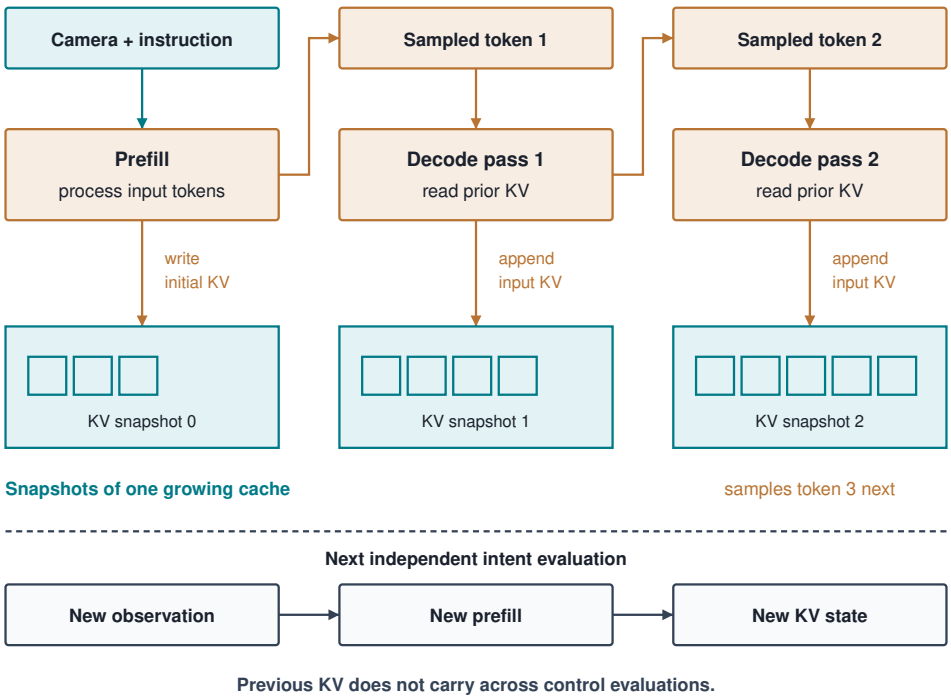

Figure 3.11: KV State Within One Intent Evaluation: Prefill processes camera and instruction tokens and supplies the output from which the first token is sampled. Each subsequent decode pass takes the previously sampled token, reads prior keys and values, and appends the input token's keys and values before sampling the next output. The cache panels are successive snapshots of one growing cache, with schematic token counts. The running machine's single-observation intent model begins the next independent evaluation with new context rather than retaining this cache across control evaluations.

Cache reuse avoids recomputing the prefix projections during that evaluation. It neither refreshes the captured observation nor turns token state into a spatial memory of the room. A model that deliberately retains observation history has a different memory and bandwidth obligation.

Napkin Math 3.1: Pricing one intent-model evaluation

Problem: The mobile manipulator's intent model is a 7B-parameter vision-language model sized after OpenVLA (Kim et al. 2024), running on the application processor. Where OpenVLA decodes a step of end-effector motion, the machine's model decodes the same number of tokens to name a target pose (section 3.5.3). How long does one fresh evaluation take, which resource binds each part of it, and what renewal rate can the machine therefore state?

Variables:

- Parameters $P = 7$B in $N_L = 32$ layers of width $d = 4096$ (Datasheet). The decoder emits $S_{\text{out}} = 7$ tokens, one per output dimension, one after another (Datasheet).
- Input tokens $S = 288$: 256 patches from one 224×224 view (Derived) plus 32 instruction tokens (Illustrative).
- Dense FP16 peak $R_{\text{peak}} = 43$ TFLOP/s (Datasheet), of which the prefill achieves $\eta_{\text{hw}} = 50$ percent (Illustrative).
- Peak bandwidth 204 GB/s (Datasheet), of which 70 percent is sustained (Illustrative), so $\text{BW}_{\text{mem}} = 142.8$ GB/s.
- Stored weights: FP16 (2 bytes per parameter) or INT4 (half a byte), with activations kept in 16 bits (Chosen).

Math:

The memory wall. FP16 weights occupy 14 GB. If every evaluation streams them once, the bound above gives

$$t_{\text{sweep}} = \frac{M_{\text{weights}}}{\text{BW}_{\text{mem}}} = \frac{14GB}{142.8GB/s} \approx 98.0ms, \qquad f \leq \frac{1}{t_{\text{sweep}}} \approx 10.2Hz$$

The prefill binds on arithmetic. All S input tokens pass through the backbone together, costing two FLOPs per parameter per token (each weight multiplies one input value and adds the product to a running sum) plus a small attention term:

$$O_{\text{prefill}} \approx 2NS + 2N_L dS^2 = 4.03 \times 10^{12} + 2.17 \times 10^{10} \approx 4.05 \times 10^{12} \text{ FLOP}$$

Each fetched weight now serves S tokens, so the intensity is about $S \approx 288$ FLOP/byte, beyond the 210.8 FLOP/byte ridge of figure 3.10. Arithmetic binds, and the weight sweep runs underneath it:

$$t_{\text{prefill}} = \frac{O_{\text{prefill}}}{\eta_{\text{hw}} R_{\text{peak}}} = \frac{4.05 \times 10^{12} \text{ FLOP}}{0.5 \times 43TFLOP/s} \approx 188.5ms$$

The decode binds on bandwidth. The prefill emits the first action token. Each of the remaining $S_{\text{out}} - 1 = 6$ tokens is a matrix-vector pass that rereads every weight:

$$t_{\text{FP16}} = t_{\text{prefill}} + (S_{\text{out}} - 1)\, t_{\text{sweep}} \approx 189ms + 6 \times 98.0ms \approx 189ms + 588ms = 777ms$$

That is about 1.3 Hz.

INT4 weights shrink only the bandwidth term. Storing the weights in four bits cuts them to 3.5 GB and each sweep to 24.5 ms, but the prefill still multiplies 16-bit activations at the FP16 rate:

$$t_{\text{INT4}} \approx 189ms + 6 \times 24.5ms \approx 189ms + 147ms = 336ms, \qquad f \leq 2.98Hz$$

Sensitivity. Parallel decoding (Kim et al. 2025) moves the action tokens into the prefill ($S + S_{\text{out}} = 295$) and removes the decode sweeps, giving 194 ms, only 2.9 percent inside a 200 ms period with the processor busy for all of it. Three camera views ($S \approx 800$) raise the INT4 total to 676 ms.

Result: At INT4 one evaluation takes about 336 ms. A published measurement of the same model and quantization on this processor reports 336 ms per frame (Franklin 2024), a gap of 0.1 percent. That agreement is closer than two illustrative factors deserve. It shows that the model has the right terms, not that η_{hw} and the sustained fraction are exactly right. A 3 Hz rate would need a 333 ms period, so the machine runs its intent model at 2 Hz, one evaluation per 500 ms.

Systems insight: The binding resource depends on the phase. Prefill reuses weights across tokens and is compute-bound; decode rereads them per token and is bandwidth-bound (Pope et al. 2023). Weight-only quantization attacks only the second, so after INT4 the compute-bound prefill is most of the latency, and the next gain must come from fewer input tokens, lower-precision arithmetic that the processor's kernels support, or a faster compute roof. Section 3.4.2 develops that choice and its accuracy cost.

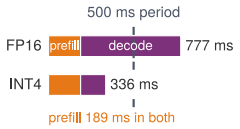
3.4.2 Quantizing the intent model

The memory wall leaves two levers on the weight term, fewer weights or fewer bytes per weight. A smaller model may lose task recognition capability, which requires task evidence, so the selected design keeps the 7B-parameter model and pulls the second lever. **Quantization** stores each weight as a low-precision integer plus a shared scale, and reconstructs an approximate weight when the kernel needs it. In the common symmetric form, the weights are divided into groups of b_{block}, each group keeps one 16-bit scale s, and each weight w_i becomes a b-bit integer q_i (Jacob et al. 2018; Lin et al. 2024):

$$s = \frac{\max_{i \in \text{group}} |w_i|}{2^{b-1} - 1}, \qquad q_i = \text{clamp}\left(\text{round}\left(\frac{w_i}{s}\right), -2^{b-1}, 2^{b-1} - 1\right), \qquad \hat{w}_i = s\, q_i$$

Rounding moves each reconstructed weight $\hat{w}_i$ at most $s/2$ from w_i, so one large weight in a group coarsens the step for all the others; choosing which weights to protect from that error is where quantization methods differ. The stored size is $b/8$ bytes per weight plus the scales' share. At $b = 4$ with the 128-weight groups that activation-aware weight quantization (AWQ) uses (Lin et al. 2024), the scales add 3.1 percent to the four-bit payload, which the half-byte-per-parameter figure used here leaves out.

Two families of quantization act on different terms of the latency. *Weight-only* quantization, the machine's choice, restores each weight to 16 bits inside the kernel just before the multiply. It shrinks the bytes every decode sweep rereads, but the arithmetic still runs at the 16-bit rate, so the compute-bound prefill does not move. *Weight-and-activation* quantization makes both operands integers, so the multiplications themselves run on integer units and can shorten the prefill as well. It pays off only when three conditions hold: the processor has fast integer units for that precision, the runtime has kernels for the model's layer shapes, and the activations tolerate the coarser grid. A format without a kernel is only a smaller file. Evaluating the intent model at three weight precisions with the prefill-plus-decode model of notebook 3.1 shows how closely the two-term estimate tracks measurements of the same model on the same module (table 3.1) (Franklin 2024).



INT4 shrinks the decode; the 189 ms prefill it cannot touch now dominates.

Table 3.1: Weight-only quantization of the intent model: Computed latency uses the sustained bandwidth and the illustrative prefill utilization of section 3.4.1; measured latency and action scores are the Jetson AI Lab means over BridgeData V2 episodes on the 64 GB Jetson AGX Orin module (Franklin 2024). The episodes were included in training; the reported score is one minus the mean range-normalized root-mean-square error against their recorded actions, not agreement with FP16 or a closed-loop task-success rate. The source labels its 8-bit build FP8, but runs it in a mode that stores 8-bit weights and computes in 16 bits, the same weight-only form the computed row assumes. The FP16 measurement used a general-purpose runtime (Hugging Face) rather than the optimized one (MLC) used for the other two.

Weight format	Bytes per parameter	Weights	Weight sweep	Computed latency	Measured latency	Action score (1 – mean NRMSE)
FP16	2	14 GB	98.0 ms	777 ms	840 ms	95.3%
8-bit	1	7 GB	49.0 ms	483 ms	471 ms	95.2%
INT4 (deployed)	0.5	3.5 GB	24.5 ms	336 ms	336 ms	90.1%

The computed and measured columns agree within 2.5 percent for the 8-bit format and 0.1 percent for INT4. The model underestimates the FP16 run by 7.5 percent, consistent with that run's slower runtime, so the comparison supports the model's two terms rather than its exact constants. The table also shows where weight-only quantization stops paying. Each halving of the bytes halves the sweep, but the 188.5 ms prefill is untouched, and at INT4 it is already 56 percent of the latency. Even weights that cost no bytes at all would leave the prefill, so no weight-only format can lift the intent model above 5.3 Hz. Beyond that ceiling, the gain must come from integer arithmetic in the prefill, fewer input tokens, or a processor with a higher compute roof.

The last column carries the cost. On this module the INT4 build's action score fell from 95.3 percent to 90.1 percent (Franklin 2024). OpenVLA's authors, measuring task success on a real robot with a desktop GPU, found a different pattern. INT4 weights kept 71.9 percent success against 71.3 percent for bfloat16, while INT8 weights through a general-purpose quantization library fell to 58.1 percent. The cause was time, not rounding. The library's added quantization operations cost more than the saved bytes, so the INT8 policy ran at 1.2 Hz on the evaluation GPU, against

the 5 Hz control rate of its training data. The robot therefore met each observation later than the demonstrations had (Kim et al. 2024). On the module an 8-bit format was nearly free and INT4 reduced the offline action score; on the desktop GPU the 8-bit build lost success through its slower loop and INT4 was nearly free. The two 8-bit results used different software and kernels, and the two studies scored different tasks, so the pair shows that a bit width alone does not predict the outcome; the quantization method, the kernels, the control rate they allow, and the task together do.

A quantized checkpoint is therefore a different model. It must be evaluated on the machine's own contact tasks at the deployed precision, carry its own calibration, and be named as such by the `model_id` of the proposal payload (section 3.5.4). The footprint saving also has a systems value. Dropping from 14 GB to 3.5 GB of weights returns memory that retained context and perception also need, though how much of the computed latency saving survives when the cameras and the chunk policy share the bus must be measured under load. Even with that saving, quantization leaves the machine's intent model at 2 Hz, one fresh proposal every 500 ms, while the arm below it consumes setpoints tens of times faster. No lever on the weight term closes a gap that large, and the gap raises two questions the weights cannot answer: how the arm stays supplied between evaluations, and how long whatever supplies it stays true.

Checkpoint 3.1: The memory wall and its levers

One fresh evaluation of a large proposer pays a compute-bound prefill and a bandwidth-bound decode, and each lever moves only one of them.

- ☐ **Weight-streaming ceiling**: Given a model's parameter count, its bytes per parameter, and a sustained bandwidth, can you compute the ceiling of equation 3.2 and say what it leaves out?
- ☐ **Prefill vs. decode**: Can you explain, from arithmetic intensity, why the intent model's prefill lands past the ridge of figure 3.10 while each decode token sits on the sloped roof?
- ☐ **Weight-only quantization**: Which term of equation 3.4 does INT4 shrink, and why does that leave a rate ceiling that no weight-only format can pass?
- ☐ **Shorter-input estimate**: The INT4 evaluation is a 189 ms prefill of $S = 288$ tokens plus 6 sweeps of 24.5 ms. Treating the prefill as proportional to S, estimate whether halving the input tokens would fit one evaluation inside the 200 ms period of a 5 Hz rate.

3.5 Chunk Supply and Evidence Validity

One INT4 evaluation of the intent model takes 336 ms. Over that interval the mug keeps riding the conveyor, and an arm tracking a new setpoint every few tens of milliseconds would have nothing to track if each proposal named a single setpoint. Predicting a sequence of setpoints per evaluation solves the supply problem but raises a second one that the memory wall never touched. Every setpoint in such a sequence descends from one observation, so the sequence can outlast the evidence behind it. Sizing those sequences for the machine's two proposers leads to three further questions: how long the supply stays true, what the slow proposer should hand the fast one, and what a proposal must carry for the permission path to refuse it.

3.5.1 Action chunking

If a proposer emits only one future setpoint per evaluation and takes longer than one setpoint step to finish the next inference pass, the controller runs out of planned motion while the processor is still computing. To keep dense waypoints flowing despite slow full-model inference, modern physical AI policies employ **action chunking** (definition 3.2), predicting a multi-step trajectory segment in a single pass (Zhao et al. 2023; Chi et al. 2025). Each chunk crosses the proposal boundary as one packet, reusing one evaluation across several outputs, though it does not make the next fresh camera observation arrive any sooner.

Definition 3.2: Temporal action chunking

Temporal action chunking is the policy formulation that predicts an entire horizon of H future continuous actions $\mathbf{A}_{t:t+H-1} = [\mathbf{a}_t, \dots, \mathbf{a}_{t+H-1}]$ in a single neural evaluation or diffusion rollout, amortizing parameter memory transfers across extended physical execution windows.

1. **Significance**: Chunking divides the weight traffic per supplied setpoint by H, 16 on the mobile manipulator, but leaves the delay before a new observation can change the motion at one renewal period plus one inference, 90 ms for its chunk policy. It does not make fresh observations or policy decisions arrive at the waypoint rate; a downstream controller tracks the accepted trajectory between model updates.
2. **Distinction**: Unlike single-step policies $\mathbf{a}_t \sim \pi(\cdot \mid \mathbf{o}_t)$, which condition only on the current observation and re-evaluate the full neural network at every control step, action chunking deliberately generates multi-step feedforward trajectories. It executes only the start of each before the next replaces it (receding-horizon execution), and it blends across overlapping chunks to reconcile slow neural deliberation with fast closed-loop control.
3. **Common pitfall**: Executing action chunks open-loop, without smoothing across chunk boundaries or a check by the permission path. Without smooth blending across overlapping chunk boundaries, switching between independently generated horizons injects acceleration jumps and torque shocks that excite mechanical gearbox resonances.

Predicting a horizon[8] of H actions per forward pass spreads the multi-gigabyte DRAM weight streaming cost over $H \times \Delta t_{\text{step}}$ seconds of physical execution. On the mobile manipulator's application processor, a 7B FP16 model (14 GB) generating single-step actions at the 40 Hz setpoint rate would demand 40×14 GB $= 560$ GB/s of memory bandwidth, 3.9 times the 142.8 GB/s it can sustain. A chunk of $H = 16$ waypoints cuts that demand to 35 GB/s, 24.5 percent of the sustained bandwidth, if one sweep supplies each full chunk. More frequent replanning, decoder work, and competing memory traffic consume additional bandwidth. The saving is in weight traffic per supplied waypoint, not an equal gain in arithmetic intensity: predicting a chunk adds decoder work, and its position on the roofline depends on the operations performed and the bytes actually transferred. Predicting a sequence also changes how a learned policy uses recent actions, so this supply calculation establishes only the weight traffic for the stated schedule, not that the policy attends to the right evidence or recovers from an unfamiliar contact.

8 | **Receding Horizon**: Model predictive control optimizes over a fixed horizon, executes only the first part of the plan, and then replans from the newly measured state, so the horizon recedes as time advances (Mayne et al. 2000). A chunked policy is the learned analog and inherits the same rule: the unexecuted tail of a chunk is a buffer that the next evaluation may overwrite, never a commitment the machine owes to finish.

Supply rate vs. closed-loop reaction latency On the running machine, the smaller chunk policy follows its own illustrative schedule, in which three quantities separate the rate at which setpoints reach the servos from the delay before a new observation changes a proposal:

- *Setpoint supply cadence* ($f_{\text{exec}} = 1/\Delta t_{\text{step}} = 40$ Hz, $\Delta t_{\text{step}} = 25$ ms): The rate at which the trajectory queue delivers discrete waypoints to the joint servo loop.
- *Policy replanning rate* ($f_{\text{replan}} = 20$ Hz, period $T_{\text{chunk}} = 50$ ms): The cadence at which the smaller chunk policy begins an evaluation from fresh sensory frames. The period is chosen as a whole number of setpoint steps, here 2, so that every renewal begins on a setpoint boundary.
- *Closed-loop reaction latency* ($T_{\text{reaction}} = T_{\text{chunk}} + t_{\text{infer}} = 50$ ms $+ 40$ ms $= 90$ ms): The worst sampling-phase wait plus the assumed inference time until a revised proposal is available, excluding further admission and physical response delay.

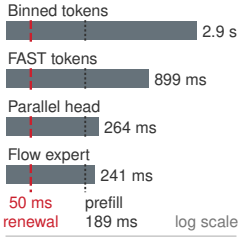
In this illustrative schedule, a disturbance immediately after capture can wait up to 90 ms for a revised learned proposal, before any additional admission and actuation delay. The independent permission path need not wait for that revision. Current qualified evidence, meaning measurements whose error bound and age have been established for this use (section 8.6 develops how), can trigger a protective response while the policy computes. Its ability to detect the relevant obstacle and complete a feasible response needs its own timing and sensing evidence. Chunking keeps candidate waypoints available; it establishes neither that response nor its deadline.

Pricing the decoder families The three decoder families of section 3.3 differ in how they turn one observation into a chunk, and the machine's processor prices that difference. Suppose the intent-sized backbone, with its deployed INT4 weights, produced one fresh chunk of $H = 16$ setpoints of 7

values each. Every family first pays the same compute-bound prefill of the observation, about 189 ms, and then the families part ways:

- Binned autoregressive tokens need 112 sequential decode steps, each rereading the backbone weights, for about 2.9 s.
- FAST tokens cut the sequence to about 30 tokens, the count its authors report per arm for a one-second chunk and therefore generous for this shorter chunk, about 899 ms, still sequential.
- A parallel head folds every action into one longer prefill, about 264 ms.
- A π_0-sized action expert of 600 MB in 16-bit weights integrates 10 steps. Each step rereads the expert and the backbone's 151 MB of cached keys and values rather than the backbone weights, about 5.3 ms per step on bandwidth, for about 241 ms in all. Section A.5.2 derives the noise-prediction and flow-matching objectives these experts train on.

The decoder choice spans 12× in latency on the same backbone, the cost that parallel decoding and action experts were introduced to remove (Kim et al. 2025; Black et al. 2024). In the expert design, weights of hundreds of megabytes far exceed the processor's on-chip caches, so each refinement step pays another off-chip transfer. A head small enough to stay resident would change that term. Reducing the number of refinement steps shortens the decoder provided the proposals keep the required task quality. Neither change touches the prefill of a fresh observation. None of the four therefore renews within the chunk policy's 50 ms period, because the prefill alone exceeds it. A large backbone that reads each observation fresh cannot also be the fast renewer on this processor, whatever its decoder. Deployed dual systems reach the same conclusion by assigning renewal to a separate, smaller model, as table 3.2 records, and the machine does the same with its ACT chunk policy.



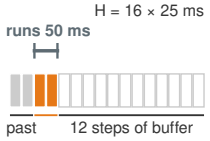
No decoder renews within 50 ms; the prefill alone is too slow.

Whatever the decoder, chunking creates one more problem, **chunk seam continuity**. Because each action chunk is generated independently from rolling sensory observations, the tail of chunk k and the head of chunk $k+1$ may show slight positional and velocity discrepancies. If a controller concatenated these chunks directly, the resulting step-discontinuities in acceleration would inject large jerk ($\dddot{\mathbf{q}}$) into the physical linkages, inducing mechanical shock, acoustic vibration, gear-tooth wear, and motor overcurrent faults. To reduce discontinuities between overlapping chunks, systems can implement **temporal ensembling**, blending overlapping trajectory predictions via exponentially weighted averaging:

$$\mathbf{a}_t = \frac{\sum_{k=0}^{K-1} w_k \, \mathbf{a}_t^{(k)}}{\sum_{k=0}^{K-1} w_k}, \quad w_k = \exp(-m \cdot k)$$

where $\mathbf{a}_t^{(k)}$ is the action for step t predicted by the k-th oldest of the K chunks that cover step t ($k=0$ is the oldest), and $m > 0$ is a tunable weighting rate. Following ACT, the oldest prediction receives the largest weight, which favors smoothness over responsiveness; a smaller m lets new observations enter the blend faster (Zhao et al. 2023). The formula assumes that the policy is queried at every control step, as ACT does, so that $K = \min(t+1, H)$. The mobile manipulator's chunk policy renews every 2 setpoints instead, and because its 50 ms renewal period is a whole number of 25 ms steps, each new chunk starts on a setpoint boundary. Because imitation-learned policies are trained on recorded demonstrations to predict motion starting from the instant the camera frame was captured, the waypoints use capture-relative times rather than starting when inference finishes, so elapsed entries are not newly executed when a chunk arrives. The first setpoint is dated at capture, and each following interval advances by 25 ms, so the last interval reaches the capture-relative horizon. By the time the 40 ms evaluation completes and the chunk arrives, the first 2 entries are already past; the next 2 setpoints precede replacement. The same formula then applies with k counting renewals rather than steps. A 16-setpoint chunk renewed every 2 setpoints gives at most $K = 8$ overlapping predictions at any step. A renewal period that fell between setpoints would leave each chunk's first action off the grid, and the blend would first have to interpolate every chunk onto common setpoint times. Below the proposal boundary, the permission path interpolates the admitted waypoints into a setpoint for every bus cycle, and the drives close their own velocity and current loops on those setpoints.

↪ The interpolation that turns admitted waypoints into per-cycle setpoints, and the fallback it executes when waypoints stop arriving, is developed in section 4.4.2.



Each chunk runs 2 of its 16 steps; later chunks overlap the rest.

Ensembling has two limits. It averages, and the average of two valid predictions need not be valid, the same mode averaging that defeats a regression head. If an older chunk passes left of an obstacle and a newer one passes right, the blend steers between them (Black, Galliker, et al. 2025). It also ignores what executes while the policy computes. With the assumed 40 ms inference and 25 ms setpoints, the arm consumes 2 setpoints of the previous chunk before the new one exists, so no new prediction can change them. *Real-time chunking* treats those setpoints as committed. It freezes the part of the previous chunk that will execute during inference and has a flow or diffusion policy fill in the rest of the new chunk so that it agrees with that frozen prefix, rather than blending afterward (Black, Galliker, et al. 2025). The method arrives from the learning side at this chapter's distinction, in which the committed prefix is motion already admitted and the tail is a buffer that the next evaluation may still rewrite.

↪ The chunk-prediction objective and the modal commitment it buys in training are developed in section 6.2.5.

Systems Perspective 3.1: The temporal ensembling jerk trap

Exponentially weighted temporal ensembling averages overlapping predictions, but averaging sampled setpoints alone guarantees neither continuous position nor continuous velocity between samples or at chunk boundaries. The interpolator on the permission path determines those properties. If successive chunks disagree in slope, a controller can receive a step in commanded velocity even when position remains continuous. In joint proportional-derivative (PD) tracking ($\tau = \mathbf{K}_p\mathbf{e} + \mathbf{K}_d\dot{\mathbf{e}}$), that velocity jump produces a finite torque step. With an illustrative derivative gain for one joint, the diagonal entry $K_d = 40\,\mathrm{N\cdot m\cdot s/rad}$ of $\mathbf{K}_d$, and an illustrative velocity discontinuity $\Delta\dot{q} = 0.5\,\mathrm{rad/s}$, the derivative term changes by $\Delta\tau = K_d\Delta\dot{q} = 20\,\mathrm{N\cdot m}$. Dividing by the servo period would instead describe a torque slew rate, not a torque. Abrupt torque changes can excite mechanical resonances or exceed drive limits. Interpolation must match position, velocity, and acceleration at adjoining segments, the property called C^2 continuity, while enforcing the machine's velocity, acceleration, and torque limits. Smoothness alone does not establish that the requested motion is feasible.

↪ The quintic spline that matches position, velocity, and acceleration across a chunk seam is developed in section 11.4.4.

A chunked policy therefore has two rates that a single "action rate" conflates: the spacing of the waypoints it supplies and the interval between the fresh observations that change them. Supplying more waypoints from one sensory context does not refresh the observation on which they depend. A downstream controller can use current state measurements while tracking admitted waypoints between renewals, and its feedback corrects tracking errors within its capabilities, but a newly perceived obstacle still requires a timely checking or replanning response. The mobile manipulator's own budget makes this distinction quantitative, first for supply and then for the time the evidence behind a chunk stays true.

3.5.2 Two proposers and the evidence horizon

Chunking reduces the weight traffic per waypoint, but the decoder pricing showed that each fresh context still waits for the large backbone's prefill, whatever the decoder. That prefill floor and the weight-streaming ceiling of figure 3.2 explain why embodied models in the published literature split into two parameter regimes rather than converging on a single model size (figure 3.12). Across 1,526 language and robotics models with disclosed parameter counts in the Epoch AI catalog between 2018 and 2026 (1,484 language and 42 robotics models) (Epoch AI 2026), language models climbed continuously past hundreds of billions of parameters. Embodied vision-language-action backbones followed that curve upward, from RT-1 (35M) to GR00T N1 (2.2B), π_0 (3.3B), OpenVLA (7B), Helix System 2 (7B), RT-2 (55B), and PaLM-E (562B), to inherit web-scale semantic and visual breadth (Brohan, Brown, Carbajal, Chebotar, Dabis, et al. 2023; Bjorck et al. 2025; Black et al. 2024; Kim et al. 2024; Figure AI 2025; Brohan, Brown, Carbajal, Chebotar, Chen, et al. 2023; Driess et al. 2023). Alongside those backbones, a compact tier of visuomotor chunk policies and action experts, including ACT (80M), Octo-Base (93M), Helix System 1 (80M), and the π_0 action expert (300M), stayed near 10^8 parameters (88× smaller than the machine's 7B intent model) so that onboard processors can renew trajectories at tens of hertz (Zhao et al. 2023; Octo Model Team et al. 2024).

This two-tier split, a slow intent model above a fast chunk policy, can now be budgeted on the warehouse mobile manipulator, and the chunks the fast policy supplies can be checked against how

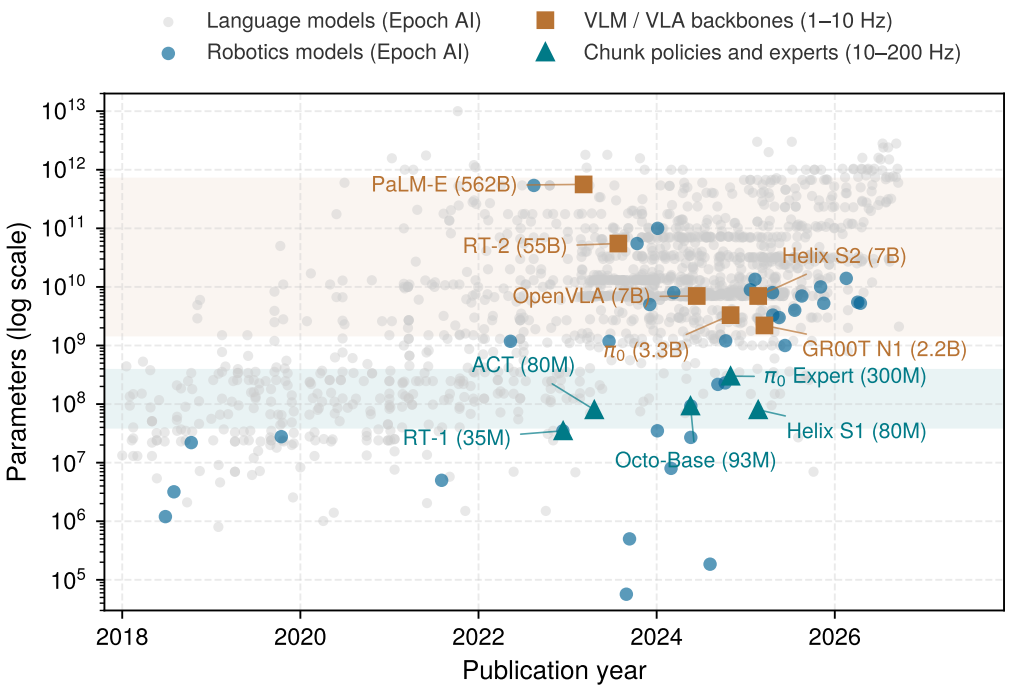


Figure 3.12: Parameter scaling of language and robotics models, 2018 to 2026: Each point plots one model with a disclosed parameter count on a logarithmic axis against its publication date. Language models scale continuously past 10^{11} parameters, while robotics models after 2022 bifurcate into multi-billion-parameter vision-language-action backbones that supply open-world semantic grounding and compact 80M–300M visuomotor chunk policies and action experts that fit real-time renewal budgets on embedded processors. Catalog series from Epoch AI (2026); component sizes for ACT, Helix System 1, and the π_0 action expert from Zhao et al. (2023), Figure AI (2025), and Black et al. (2024).

long they stay true. Budgeting that split also uses a term that the stopping budget of section 1.4.3 already charged, a lease, authority that lapses unless it is renewed. The motion the chunk policy proposes runs under a chunk lease, the longest an admitted chunk may keep driving the actuators without an admitted successor. Section 4.4 sizes that lease against the stopping budget, so that a late renewal is contained by that lease rather than by the length of the chunk. Notebook 3.2 applies the memory bound to the split and checks whether chunking alone could give the larger model the required renewal cadence.

Napkin Math 3.2: The renewal gap

Problem: Chunking spreads one weight sweep across many setpoints. Can it let the intent model renew proposals within the chunk policy's 50 ms period, or does the machine need a second, smaller proposer, and how much of the shared bus do the two proposers then take?

Variables:

- Intent model: 14 GB of FP16 or 3.5 GB of INT4 weights (Derived), an INT4 evaluation of 336 ms that decodes $S_{\text{out}} = 7$ tokens (Derived, notebook 3.1), run at 2 Hz (Chosen).
- Chunk policy: 80M parameters, ACT's size (Datasheet), 0.16 GB in FP16 (Derived), renewed at 20 Hz (Chosen).
- Chunk of $H = 16$ setpoints at $\Delta t_{\text{step}} = 25$ ms (Chosen); sustained bandwidth $\text{BW}_{\text{mem}} = 142.8$ GB/s (Derived).

Math:

Amortization. Counting weight traffic only, as section 3.5.1 did, and setting aside the prefill's arithmetic and the other decode sweeps, one FP16 sweep that emitted a whole chunk would be shared by H setpoints:

$$t_{\text{amort}} = \frac{t_{\text{stream}}}{H} = \frac{98.0ms}{16 \text{ setpoints}} \approx 6.1ms \text{ per setpoint}$$

Renewal. A fresh chunk still waits for a whole INT4 evaluation, prefill and decode together, while the chunk policy streams its own weights in about a millisecond; the rest of its inference target goes to vision encoding and the decoder's arithmetic:

$$\frac{t_{\text{INT4}}}{T_{\text{chunk}}} = \frac{336ms}{50ms} \approx 6.7 \text{ renewal periods}, \qquad \frac{0.16GB}{142.8GB/s} \approx 1.12ms$$

Bus share. The INT4 intent model streams its weights S_{out} times per evaluation, once under the prefill and once per remaining token (equation 3.4); the chunk policy streams its weights once per renewal:

$$S_{\text{out}}\, M_{\text{INT4}}\, f_{\text{intent}} + M_{\text{chunk}}\, f_{\text{chunk}} = 7 \times 3.5GB \times 2Hz + 0.16GB \times 20Hz = 49GB/s + 3.2GB/s = 52.2GB/s$$

Result: Amortization cuts the weight time per setpoint to 6.1 ms, but each fresh intent-model chunk arrives 6.7 renewal periods after its capture. The chunk policy's sweep takes 2.2 percent of its period. Together the two proposers average 52.2 GB/s of weight traffic, 37 percent of the sustained bandwidth.

Systems insight: Amortization is a supply lever, not a renewal lever, so the machine renews with a second, smaller proposer. The average hides the timing. For 147 ms of every 500 ms, the intent model's decode sweeps are modeled at the full sustained bandwidth, so a chunk-policy evaluation that overlaps them competes for the same bus, and its latency target holds only if it is measured under that contention. A late renewal is not free: the arm keeps moving on the previous chunk, and the chunk lease bounds how far.

The selected design follows. The 80M-parameter chunk policy uses ACT as its size reference and is assumed to be adapted to the mobile manipulator. It proposes base velocity and arm joint targets together at 20 Hz (a 50 ms replanning period), emitting waypoints spaced at $\Delta t_{\text{step}} = 25$ ms (a 40 Hz supply rate), within a 40 ms p99 inference target that includes vision. The permission path interpolates admitted waypoints into per-cycle setpoints and the drives close their velocity and current loops at their own faster rates. The intent model revises its target at 2 Hz. That is a candidate architecture, not a measured timing result. Loaded execution must establish the inference target, and a percentile target still permits overruns; the chunk lease contains a missed renewal.

What retained history would cost The intent model as deployed reads one frame and keeps nothing between evaluations, so the budget above is complete for it. A variant that conditioned on several seconds of history would add memory pressure that the weights alone do not show, and the cost is worth knowing before anyone proposes one. The per-token charge from section 3.3, 0.52 MB of full-width FP16 keys and values across all 32 layers through equation 3.1, now scales with history. One synchronized set of 3 224×224 frames ($3 \times 256 = 768$ patch tokens) adds 402.7 MB. This is a standard multi-head attention estimate for a hypothetical multi-camera extension, not a measured cache footprint for the published OpenVLA checkpoint. Counting language and proprioception tokens along with the visual patches raises each step to $S \approx 800$ tokens, so each observation step adds 419.4 MB of KV cache. Retaining an unpruned 5 s historical context window at 10 Hz would yield 21.0 GB of KV cache. This hypothetical history exceeds the published OpenVLA checkpoint's configured context window; the calculation exposes the storage cost of such an extension, rather than claiming that the checkpoint supports it. Combined with the intent model's 14 GB of weights, this example claims 35.0 GB, about half of the application processor's 68.7 GB (the module sold as 64 GB counts in binary gigabytes, 64×2^{30} bytes) before runtime overhead. Perception, mapping, and the chunk policy also need that memory. Even where memory capacity permits, reading a large

cache is further traffic on that same bus. Bounding retained history therefore serves both capacity and timely renewal. Spatial pooling or cross-attention can reduce context traffic; fixed-horizon action output does not by itself bound the observation history retained by the backbone.

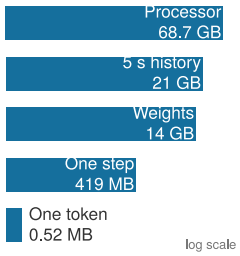
The split fixes how often each proposer renews. The moving target fixes how long each renewal stays true. At the pick station the arm takes the mug from a moving conveyor, and a chunk is useful only while the mug stays within the grasp tolerance r_{tol} of where the chunk's evidence placed it, starting from the handle estimate's initial error e_0. Untracked, the belt's steady speed v_{conv} uses up the margin $r_{\text{tol}} - e_0$ within the freshness deadline $e_{\max}/v_{\max}$ of section 2.2, here with $e_{\max} = r_{\text{tol}} - e_0$ and $v_{\max} = v_{\text{conv}}$. A tracker removes that steady motion. It is the memory stage of the pipeline, re-estimating the mug's position and velocity from each new frame, and a chunk computed from its estimate aims at where the mug will be if the belt keeps its speed. What that extrapolation cannot foresee is a change of speed after capture, the mug slipping on the belt at a residual acceleration a_{slip}. The chunk's setpoints were fixed at its capture, so later frames do not correct them, and extrapolation over an evidence age T drifts by $\frac{1}{2} a_{\text{slip}} T^2$. Setting that drift equal to the margin gives the **evidence horizon** of the tracked mug, the longest time the evidence behind a chunk keeps the mug within tolerance, in equation 3.5:

$$\tau_{\text{ev}} = \sqrt{\frac{2\,(r_{\text{tol}} - e_0)}{a_{\text{slip}}}} \tag{3.5}$$

When inference meets the stated target and no further admission delay is charged, a chunk is replaced one renewal period plus one inference after the capture it was computed from, the reaction latency $T_{\text{chunk}} + t_{\text{infer}}$ of section 3.5.1. That span must fit inside τ_{ev}, and the chunk must carry enough setpoints to bridge it, as equation 3.6 requires:

$$h_{\min} = \left\lceil \frac{T_{\text{chunk}} + t_{\text{infer}}}{\Delta t_{\text{step}}} \right\rceil \tag{3.6}$$

Together, equation 3.5 and equation 3.6 distinguish the setpoint buffer a chunk carries from the duration its evidence remains valid. Notebook 3.3 applies both bounds to the machine's schedule.



5 s of retained context outweighs the 14 GB of weights.

Napkin Math 3.3: Buffer, not permission

Problem: The chunk policy renews every 50 ms, is assumed to need 40 ms per evaluation, and emits 16 setpoints 25 ms apart. Does the schedule depend on tracking the mug, how many setpoints must a chunk carry, and how much of each chunk may the arm execute on the evidence behind it?

Variables:

- Conveyor speed $v_{\text{conv}} = 0.20$ m/s and residual slip acceleration $a_{\text{slip}} = 0.50$ m/s² (Illustrative).
- Grasp tolerance $r_{\text{tol}} = 15$ mm (Chosen) and initial handle error $e_0 = 3$ mm (Illustrative), a margin of 12 mm.
- Renewal period $T_{\text{chunk}} = 50$ ms, setpoint step $\Delta t_{\text{step}} = 25$ ms, and $H = 16$ (Chosen); inference $t_{\text{infer}} = 40$ ms, a p99 target that includes vision (Illustrative).

Math:

Untracked deadline. The belt alone uses up the margin in

$$\frac{r_{\text{tol}} - e_0}{v_{\text{conv}}} = \frac{12\ \text{mm}}{0.20\ \text{m/s}} = 60\ \text{ms}$$

Tracked horizon. With the steady motion removed, equation 3.5 gives

$$\tau_{\text{ev}} = \sqrt{\frac{2 \times 12\ \text{mm}}{0.50\ \text{m/s}^2}} \approx 219\ \text{ms}$$

Age at replacement and supply. equation 3.6 and the drift over the evidence age since capture give

$$T_{\text{chunk}} + t_{\text{infer}} = 50 + 40 = 90\,\text{ms}, \quad \tfrac{1}{2} a_{\text{slip}} T^2 = \tfrac{1}{2} \times 0.50 \times (0.09\,\text{s})^2 \approx 2.0\,\text{mm}, \quad h_{\text{min}} = \lceil \tfrac{90}{25} \rceil = 4$$

The whole chunk. Executed open-loop to its end, one chunk would carry the mug to

$$H\,\Delta t_{\text{step}} = 16 \times 25\,\text{ms} = 400\,\text{ms}, \quad e_0 + \tfrac{1}{2} \times 0.50 \times (0.40\,\text{s})^2 = 3 + 40 = 43\,\text{mm} > 15\,\text{mm}$$

Sensitivity. Renewing at 10 Hz instead raises the age at replacement to 140 ms, still inside τ_{ev}, and h_{min} to 6.

Result: Untracked, the mug leaves tolerance after 60 ms, before the first replacement at 90 ms, so this schedule depends on the tracker. Tracked, the evidence holds for about 219 ms: 4 setpoints bridge each renewal, and the 90 ms evidence age at replacement permits drift of only 2.0 mm. The 400 ms chunk outlasts its evidence by 181 ms.

Systems insight: The chunk is sized for supply, not for execution. Its tail beyond τ_{ev} keeps setpoints flowing if a renewal slips, but it is not permission to finish the motion, because the drift it would carry the arm through cannot be taken back once the gripper closes on the wrong place. The permission path therefore ages each chunk's evidence against τ_{ev}, and when renewal stops, the chunk lease, not the chunk length, bounds how far the arm may keep going.

On one clock, the schedule looks like figure 3.13. With direct replacement, each chunk is in force for only 50 ms before its successor replaces it, so motion computed from that capture ends when the capture is 90 ms old, inside the 219 ms evidence horizon. Temporal ensembling instead retains contributions from older chunks. A blend must exclude contributions whose evidence has expired and carry the oldest capture time among the contributions it retains; the direct-replacement timing strip does not bound the age of that blend. If the chunk policy overruns its inference target, the notebook's assumption no longer holds, and if renewal stops altogether, a further setpoint remains eligible only while both its evidence and the active chunk lease remain valid. If the implementation uses temporal ensembling, it must filter expired contributions before blending and date the result from the oldest retained evidence; seam continuity and feasibility still require independent checks.

Under the stated assumptions, the conveyor calculation supplies the quantities needed to connect cognition to physical permission. One chunk covers 400 ms of motion, a new chunk is assumed to meet its 40 ms inference target, and the evidence stays within the stated grasp tolerance for about 219 ms. The Nervous System must combine these proposer limits with the body's measured limits to establish its handoff record. That requires more information than a trajectory tensor alone. Timely delivery and usable evidence bound how long a proposal can remain eligible; they do not establish that the proposed grasp was correct.

3.5.3 Handing intent to the chunk policy

Whether the permission path can audit the slow intent model's goal alongside the fast chunk policy's trajectory depends on what crosses the interface between the two tiers. That two-tier split is not peculiar to this machine. Helix runs a 7B-parameter vision-language model at 7 to 9 Hz above an 80M-parameter policy at 200 Hz (Figure AI 2025), and GR00T N1 runs its vision-language model at 10 Hz above a flow-matching transformer at 120 Hz (Bjorck et al. 2025). Across these and other published designs (table 3.2), the reported rates bracket the machine's own 2 Hz and 20 Hz. What separates them is less their rates than what the slow model hands the fast one, and that choice decides what the permission path can check.

Deployed systems use three kinds of interface between the two tiers. With a *latent vector*, Helix's slow model passes a single continuous latent that conditions the fast policy (Figure AI 2025), and GR00T N1's policy attends to token embeddings taken from an intermediate layer of its vision-language model (Bjorck et al. 2025). Because a latent is trained end to end, it carries whatever the fast policy finds useful and costs no decoding. Other architectures pass a *language subtask*: $\pi_{0.5}$ first predicts the next subtask as text and then generates actions conditioned on it (Black, Brown, et al. 2025), while the orchestrating model of Gemini Robotics 1.5 sends its action model natural-language step instructions (Gemini Robotics Team 2025a). Still others emit an explicit *geometric target*, as in

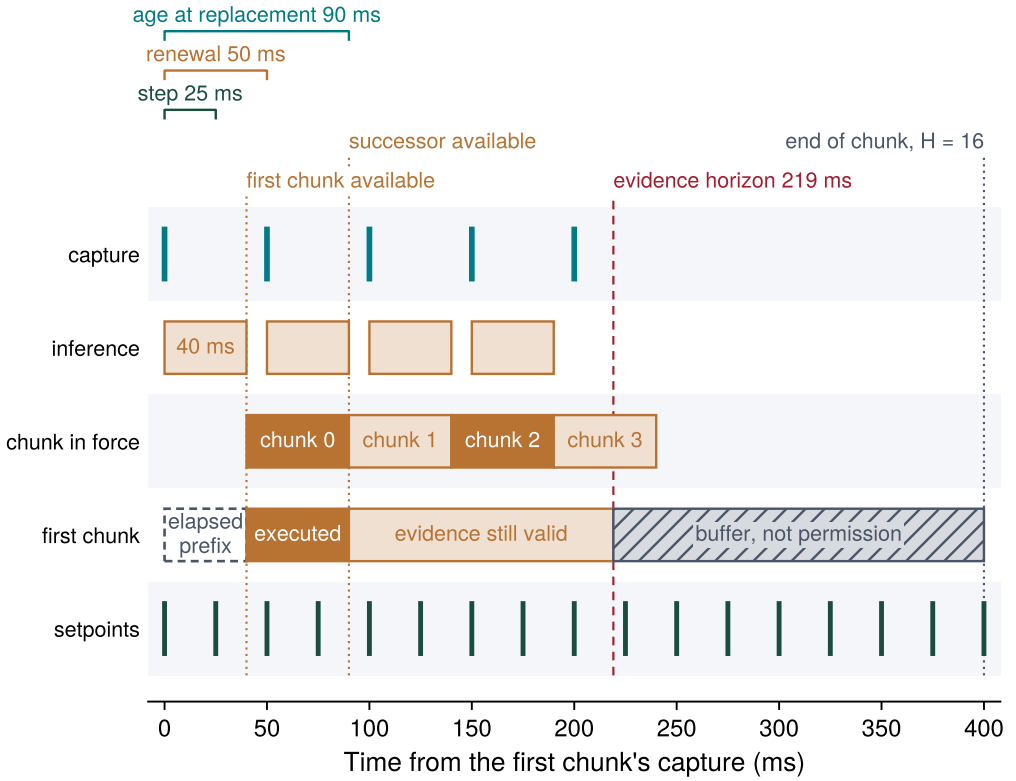


Figure 3.13: Chunk supply against the evidence horizon: With direct replacement, time runs from the capture that the first chunk is computed from. The chunk policy renews every 50 ms and needs 40 ms per evaluation, so each chunk is in force for one renewal period and is replaced when its evidence is 90 ms old. The first chunk predicts a capture-relative horizon of 400 ms, including the prefix already elapsed before arrival, but the tracked mug stays within the grasp tolerance only for the 219 ms evidence horizon; the hatched tail is supply that keeps the setpoint stream full if renewal slips, not permission to execute it.

Gemini Robotics-ER, which predicts points, two- and three-dimensional boxes, trajectories, and grasps with coordinates in the scene (Gemini Robotics Team 2025b).

The permission path can check only a claim it can compare with its own evidence, and the three interfaces differ exactly there. A latent vector means something only to the network that reads it. No independent checker can tell whether it refers to the mug or to the photograph of a mug on a carton (section 3.6.1), and it carries no position that could age against the evidence horizon τ_{ev}. A text subtask can be checked against the task predicates the permission path has admitted, but "pick up the mug" names no location, so it can be neither compared with measured depth nor aged against drift. A geometric target allows both checks. It can be compared with calibrated depth and keep-out geometry, and aged from the capture time of the frame it came from. This geometric interface lets the machine's intent lease be enforced, because that lease names a grounded target, never a path, and expires at the earliest of the time its evidence stays valid and the deadlines the permission path sets. With a latent or a text interface, the permission path can still check each chunk's motion under the chunk lease, but the target behind that motion lacks this independent grounded-position check.

The mobile manipulator therefore has its intent model emit a target: a position, an orientation, and a gripper command, the same seven values OpenVLA decodes as a step of motion, together with the capture time of the frame it read. The timing shows why that target cannot stand alone. One evaluation takes 336 ms, longer than the 219 ms evidence horizon of the tracked mug, so the pose the intent model read is stale before its target arrives. The intent model therefore contributes which object to take and approximately where, and the tracker of section 3.5.2 supplies where that object is now. The tracker binds the target to its own latest estimate of the mug, and the 80M-parameter

chunk policy aims at that fresh pose. The two leases then age against different clocks. The intent lease ages from the capture time of the tracker's latest estimate and is renewed each time the tracker confirms the same mug, so it lapses when tracking is lost or a permission-path deadline passes. Each chunk carries the capture time of the oldest observation behind it, normally the frame the chunk policy itself read, and its evidence ages from that time against τ_{ev}.

The geometric bottleneck costs capability. A target pose cannot say how to fold a shirt or where to regrasp a cable, information a latent carries without a schema, so a checkable interface limits the tasks a single target can express. The machine accepts that limit in exchange for an intent the permission path can refuse. The same reasoning applies one level down to the chunk policy's action space. Joint targets can be checked directly against joint limits and end-effector poses against workspace keep-out regions, which is why the proposal payload of section 3.5.4 carries both.

Table 3.2: State of practice in learned proposers, as of 2026: Published decoder mechanisms, sizes, and rates, with the interface each dual system passes from its slow model to its fast one. Rates and latencies are as the authors report them on different hardware, so they compare designs, not processors; none was measured on the machine's application processor.

System (year)	Decoder mechanism	Reported sizes and rates	Slow-to-fast interface
OpenVLA (2024) (Kim et al. 2024)	Autoregressive binned tokens, one per action dimension	7B; about 6 Hz on a desktop GPU	None (single model)
OpenVLA-OFT (2025) (Kim et al. 2025)	Parallel decoding, continuous regression head	109.7 Hz against 4.2 Hz throughput for OpenVLA, 8-step chunks	None (single model)
π_0 (2024) (Black et al. 2024)	Vision-language backbone with a flow-matching action expert	3.3B including a 300M expert; $H = 50$, 10 integration steps; 73 ms per chunk on a desktop GPU; control up to 50 Hz	None (single model)
π_0-FAST (2025) (Pertsch et al. 2025)	Autoregressive compressed (DCT and byte-pair) tokens	About 30 tokens per arm per one-second chunk (60 for two arms); about 750 ms per chunk against about 100 ms for π_0	None (single model)
$\pi_{0.5}$ (2025) (Black, Brown, et al. 2025)	One model: text subtask, then flow-matching action expert	10 integration steps; control at 50 Hz; one text subtask decoded before each action chunk	Language subtask
Helix (2025) (Figure AI 2025)	Vision-language model above a cross-attention visuomotor transformer	7B at 7–9 Hz; 80M at 200 Hz over 35 degrees of freedom; onboard embedded GPUs	Latent vector
GR00T N1 (2025) (Bjorck et al. 2025)	Vision-language model above a flow-matching transformer	2.2B total, 1.34B in the language model; 10 Hz and 120 Hz; $H = 16$, 4 steps; 63.9 ms per chunk on a data center GPU	Intermediate-layer token embeddings (latent)
Gemini Robotics (2025) (Gemini Robotics Team 2025b, 2025a)	Cloud-hosted backbone with an on-robot action decoder; embodied-reasoning model as orchestrator	Backbone under 160 ms; about 250 ms end to end; 50 Hz control with chunks	Points, boxes, and grasps (ER); language step instructions (1.5)
This machine	INT4 intent model above an ACT chunk policy	7B at 2 Hz (336 ms computed); 80M at 20 Hz, $H = 16$ at 25 ms	Target pose with capture time

3.5.4 Information the proposer must supply

The conveyor budget gives each payload field a physical purpose. The receiver needs the candidate motion, the capture time from which its evidence ages, and the conditions limiting its validity. Bundling that information with delivery metadata defines the proposal payload rather than a new evidence record in the book's record chain. Section 4.4.1 wraps this payload in the proposal header the permission path validates, and the Nervous System's handoff record combines this supply with the body's limits.

The **proposal payload** $\mathcal{P}$ is the typed candidate motion that the unprivileged Brain sends to the real-time Nervous System, packaged with the capture time of its evidence, the time after which it lapses, and the provenance the receiver needs to check it:

$$\mathcal{P} = \langle t_{\text{capture}}, t_{\text{valid}}, H, \Delta t_{\text{step}}, \mathbf{Q}_{1:H}, \dot{\mathbf{Q}}_{1:H}, \mathbf{X}_{1:H}, \mathbf{g}_{1:H}, \text{model_id}, \text{lease_id}, \hat{p}, \text{crc} \rangle$$

The capture and validity times let the receiver compare the motion with freshness and calibration requirements it establishes independently; for the conveyor pick, t_{valid} can lie no later than $t_{\text{capture}} + \tau_{\text{ev}}$.

The payload requests motion. It is neither execution permission nor the handoff evidence record, and a payload that omits its observation time or validity horizon invites the receiver to execute a proposal computed from a scene that no longer exists.

The fields in table 3.3 illustrate the information needed to interpret a candidate trajectory, rather than prescribing a second wire format. The proposer supplies trajectory and observation information. Validity claims require supporting evidence, while the receiver applies the separately established chunk lease. A `lease_id` associates the request with that permission process; it does not let the proposer grant itself authority. The header and handoff record specify delivery, admission, and expiration.

Table 3.3: Illustrative proposal payload fields: Candidate-motion information and associated metadata. The proposal header and handoff record belong to the Nervous System; this illustration adds no separate qualification record.

Field	Type	Unit	Systems Semantics and Verification Rule
`t_capture`	`uint64_t`	ns	Hardware timestamp of oldest sensory observation conditioning the proposal.
`t_valid`	`uint64_t`	ns	Monotonic time after which proposal expires ($\leq t_{\text{capture}} + \tau_{\text{ev}}$).
`horizon_H`	`uint16_t`	count	Number of prospective trajectory setpoints ($H = 16$ on this machine).
`delta_t`	`uint32_t`	µs	Temporal interval between consecutive waypoints ($\Delta t_{\text{step}} =$ 25,000 µs, a 40 Hz supply rate).
`q_traj`	`float32[H][n]`	rad	Candidate joint trajectory array across n degrees of freedom.
`q_dot_traj`	`float32[H][n]`	rad/s	Velocity setpoints; checked for continuity when adjoining chunks meet.
`x_cartesian`	`position + orientation[H]`	m, quat	End-effector target poses; verified against workspace keep-out boundaries.
`gripper_cmd`	`float32[H]`	$[0, 1]$	Gripper closure target; evaluated against grasp force and slip limits.
`model_id`	`uint32_t`	identifier	Identifier resolving to the model architecture, weights checkpoint, and calibration profile.
`confidence`	`float32`	$[0, 1]$	Score $\hat{p}$ from the method named in the calibration profile (softmax margin for token decoders; sample dispersion, ensemble disagreement, or a conformal set for continuous decoders); absent when no method is qualified.
`lease_id`	`uint64_t`	identifier	Identifier linking the proposal to a time-limited permission record.
`crc32`	`uint32_t`	checksum	Integrity checksum protecting shared-memory ring buffer payload.

↪ **Byte layout:** The wire format that carries a chunk's evidence time, expiry, horizon, and joint setpoints, with offsets, types, and checks, is given in section C.15.1.

Checkpoint 3.2: Chunk supply and evidence horizons

Before analyzing runtime failure modes, check that you can separate what a chunk supplies from how long the evidence behind it holds.

- ☐ **Amortization vs. renewal**: Can you explain why a chunk cuts the intent model's weight time per setpoint to 6.1 ms yet leaves each fresh intent-model chunk several renewal periods late, and why that forces a second proposer?
- ☐ **KV cache growth**: Can you use equation 3.1 to size the cache for a retained history, and explain why reading that cache competes with current sensor transfers on the same bus?
- ☐ **Supply vs. validity**: Can you explain why a chunk must carry at least $h_{\min}$ setpoints to bridge one renewal, why the evidence age of motion from one observation must stay inside τ_{ev}, and why the remaining setpoints are a buffer rather than a plan?
- ☐ **Slip estimate**: If residual slip on the conveyor quadrupled, by what factor would equation 3.5 shrink τ_{ev}, and would the 90 ms age at replacement still fit inside it?

3.6 Cognitive Vulnerabilities

A chunk proposed by a mobile manipulator's policy can arrive within its 40 ms execution budget, with every joint setpoint smooth and within kinematic limits, and yet still collide the gripper into the rim of the mug. The trajectory meets its real-time deadline, but its physical content is wrong, and the most consequential failures of learned physical AI systems sit in that gap. Learned foundation models expand task coverage across open-world environments, but no general proof of their integrated, closed-loop behavior across unconstrained state spaces is available. Engineering practice must instead analyze verified components within explicitly bounded operating regions.

Without a verified input domain and sensitivity bound, small sensing changes to a learned proposer can yield unexpectedly large changes in proposed motion, a sensitivity demonstrated early by imperceptible image perturbations that flipped image classification outputs (Szegedy et al. 2013). Benchmark success does not establish closed-loop stability, timing bounds, or physical safety under unseen operating conditions; those guarantees require independent evidence across the model, the software runtime, and the physical plant.[9] Even when a valid sensitivity bound exists, it characterizes only the relationship between input perturbations and output deviations over a specified domain. It provides no proof that the nominal proposed action is collision-free or physically admissible, meaning analytical bounds can inform, but never replace, an independent permission decision.

A numerical interface easily traps malformed tensors, NaN values, and out-of-range floating-point setpoints, but it cannot detect a wrong grasp plan. Both classical pipelines and learned models can emit well-formed yet wrong commands; learning, however, adds failures rooted in high-dimensional latent features, out-of-distribution hallucinations, and uncalibrated confidence scores. Independent safety monitors can reject proposals that contradict measured geometry or joint limits, but they cannot infer true task intent. Safe operation in the physical world requires examining each of these failure modes and stating the evidence checks needed beyond packet formatting.

[9] **Lipschitz Continuity in Neural Policies**: Although neural networks with smooth activations are continuous on compact domains, a sensitivity bound $L_{\text{lip}} = \sup_{\mathbf{x}_1 \neq \mathbf{x}_2} \frac{\|\pi(\mathbf{x}_1) - \pi(\mathbf{x}_2)\|}{\|\mathbf{x}_1 - \mathbf{x}_2\|}$ must be established over a stated operating region. Where that bound holds, sensor error $\|\Delta\mathbf{x}\| \leq \epsilon$ bounds the action change by $\|\Delta\mathbf{a}\| \leq L_{\text{lip}}\epsilon$; an unverified L_{lip} gives no usable action-error guarantee. Full derivations appear in section A.4.2.

3.6.1 Semantic hallucinations

Consider a mobile manipulator clearing items near a conveyor. A discarded shipping carton carries a high-resolution printed photograph of a ceramic mug. The robot's vision backbone attends to the visual texture, and the policy proposes an end-effector trajectory that closes the parallel jaws around the printed handle. The trajectory tensor is numerically flawless: smooth, within joint velocity and acceleration bounds, and clear of modeled obstacles. The handle it targets, however, is flat ink on cardboard. In web-scale vision models, attention maps track statistical correlations across 2D pixel arrays rather than measured 3D geometry.

Independent geometric evidence exposes this hallucination directly. A runtime validator compares the proposed grasp pose against calibrated depth returns to check whether physical relief supports the handle. If the depth sensor shows a flat cardboard surface within measurement resolution, the runtime rejects the proposal; if sensor dropouts or occlusion leave the region uncertain, the grasp remains unverified and must not be admitted. In neither case can a 2D attention map stand in for a 3D depth measurement. The proposer must therefore supply both its target coordinate frame and the supporting observation timestamps so that downstream checks can separate a physically grounded motion plan from an unverified visual guess.

↪ How depth error is bounded and qualified before a spatial claim can be trusted is developed in section 8.6.

3.6.2 The softmax illusion and out-of-distribution overconfidence

A natural temptation is to filter out hallucinations like the cardboard mug, or frames degraded by intense specular glare, dynamic shadows, and water droplets on camera lenses, by rejecting proposals whose reported confidence falls below a threshold. That defense fails when deployment interfaces conflate mathematical normalization with the physical probability of task success. In discrete classification, classification-based tokenization, or categorical action heads, raw output logits are transformed via the softmax operator:[10]

$$\sigma(\mathbf{z})_i = \frac{e^{z_i}}{\sum_{j=1}^{K} e^{z_j}}$$

whose outputs sum to one purely by algebraic construction. When an embodied machine encounters those out-of-distribution (OOD) observations or novel visual textures, the network can still emit

[10] **Softmax** (soft arg max): Bridle (1990) named the normalized exponential "softmax" because it is a differentiable version of the winner-take-all operation that picks the largest input. A function built to pick a winner keeps doing so far from its training data, pushing its top output toward one whenever one logit separates from the rest, whether or not the input resembles anything the model has seen.

confidence scores near one for physically disastrous actions. Modern deep networks are often overconfident even on in-distribution inputs (Guo et al. 2017), and networks constructed from rectified linear units provably approach maximum confidence on inputs far from their training distribution (Hein et al. 2019).

Calibration evaluates how closely a model's predicted confidence aligns with observed empirical success rates under specified conditions. A confidence score is useful for selecting or abstaining from a proposal only to the extent that this relationship holds for the deployed task. Section A.2.3 formalizes binned expected calibration error and post-hoc temperature scaling. From a systems perspective, the execution runtime must bind calibration metadata directly to the model identity (`model_id`), preventing supervisory layers from mistaking uncalibrated algebraic certainty for physical permission.

In modern physical AI systems, populating the action payload's `confidence` field is rarely as straightforward as extracting a softmax probability, because contemporary chunking policies do not operate as discrete classifiers. Action Chunking with Transformers (ACT), for example, decodes each multi-step chunk deterministically at inference time by clamping its latent style variable to the prior mean (Zhao et al. 2023). Similarly, diffusion and flow-matching policies iteratively denoise trajectories from Gaussian noise vectors. Neither architecture natively emits a normalized score. For these continuous decoders, confidence must be derived through an explicit, qualified estimation technique. Three primary architectures are used in practice:

- *Sample dispersion.* The system draws multiple trajectory chunks for the identical sensory observation by varying random diffusion noise seeds or sampling latent vectors. Measuring geometric dispersion across these trajectories describes the policy's sampled output variability. Wide dispersion can reflect several valid motions as well as uncertainty; it does not by itself isolate uncertainty caused by missing knowledge.
- *Ensemble disagreement.* Multiple independently trained policy heads evaluate the same sensory input simultaneously. Downstream monitors measure the variance among their trajectory proposals, treating significant disagreement as an indicator of model uncertainty.
- *Conformal thresholds.* To convert heuristic dispersion or disagreement metrics into actionable statistical guarantees, the runtime applies inductive conformal prediction. Using a held-out calibration dataset, the system establishes an empirical threshold such that, under the assumption of exchangeability,[11] the predicted set covers the calibrated target with a chosen marginal coverage probability. Specifically, each candidate trajectory receives a nonconformity score measuring its residual error or disagreement, and the conformal set collects all candidates whose scores fall within the quantile threshold measured on the calibration trials, so high sensory ambiguity widens the set to include distinct trajectories while pairing the threshold with an admissibility filter can leave no candidate in the set at all. Physical validity still requires independent checks against current geometry and plant limits. If the conformal set is empty or contains mutually conflicting actions, the runtime refuses the candidate or abstains; if active motion is no longer admissible, it requires a physically qualified response or operator intervention (Ren et al. 2023; Angelopoulos and Bates 2023).

[11] **Exchangeability**: The conformal guarantee assumes only that the calibration trials and the new trial are exchangeable, a weaker condition than independent and identically distributed data (Vovk et al. 2005). A deployed robot can break even that weaker assumption because its actions change the scenes it meets next, the endogenous data of the second law (section 1.10). A threshold calibrated under one policy therefore has to be re-established after every policy or deployment change, and its stated coverage lapses in between.

Each uncertainty estimation strategy incurs distinct hardware and memory-bandwidth costs. Generating multiple samples from a single observation can reuse visual backbone features and batch each decoding iteration through the policy head, sharing a weight read across samples. Iterative decoders still revisit their weights across refinement steps, and the balance between arithmetic and memory traffic depends on the batch and kernels. In contrast, an ensemble of disparate models requires reading separate sets of weights across the memory bus for every head, multiplying memory bandwidth traffic by the number of heads. The action payload must therefore treat the confidence scalar $\hat{p}$ as meaningful only when accompanied by the identifier of the method that produced it and the corresponding calibration record, both resolved through `model_id`. A model lacking a qualified estimation pipeline must omit the confidence score entirely rather than emit an ungrounded default value.

The stipulated values in table 3.4 illustrate how environmental and hardware shifts can open a gap between confidence and success; they describe nominal illustrative regimes rather than a single deployed benchmark. The near-OOD row is a *covariate shift*, a change in the inputs the

deployed model meets while the task stays the same. Across all shifted regimes, reported confidence significantly outstrips actual task success. A supervisory filter relying solely on an uncalibrated score threshold would mistakenly admit hazardous trajectories. Choosing an appropriate supervisory response depends on the integrity of the remaining sensor streams and the physical capabilities of the machine; a confidence discrepancy alone cannot dictate whether the robot should slow down, collect additional sensor frames, or execute an emergency stop.

Table 3.4: Illustrative Confidence–Success gaps under distribution shift: Stipulated confidence and task-success rates for four operating regimes, with candidate responses requiring separate physical justification. These values are illustrative, not test results.

Distribution Shift Regime	Physical & Environmental Trigger	Conf. vs. Success (conf vs. success)	Confidence–Success Gap (conf − acc)	Downstream Supervisory Action
In-Distribution (Nominal Baseline)	Clean optics, structured laboratory lighting, nominal workpiece textures	conf $= 0.91$, acc $= 0.89$	$+0.02$	Apply independent limits before nominal execution
Near-OOD Shift (Covariate Shift)	Specular reflections, lens water droplets, dynamic shadow transitions	conf $= 0.89$, acc $= 0.52$	$+0.37$	Abstain or seek new evidence; permit probing only with a qualified contact policy
Far-OOD Shift (Semantic Shift)	Uncataloged deformable obstacles, human limb intrusion into workspace	conf $= 0.78$, acc $= 0.08$	$+0.70$	Reject proposal; use feasible controlled response
Sensor Degradation (Hardware Drift)	Photodetector thermal noise (> 75°C), focal blur from vibration	conf $= 0.84$, acc $= 0.31$	$+0.53$	Restrict operation to modes supported despite the sensor degradation

DRAFT

3.6.3 Perceptual chattering and covariate shift

When sensory observations hover near a boundary between competing object classes or grasp modes, small frame-to-frame noise flips the winning label back and forth, a failure known as *perceptual chattering*. If a motion planner treats each label flip as an abrupt change in the physical world, it discards and resets its trajectory on every frame. In the fatal 2018 Tempe autonomous vehicle collision, the National Transportation Safety Board record documents this failure in the automated driving system: the perception module alternated between classifying a pedestrian pushing a bicycle as a vehicle, a bicycle, and "other." After each reclassification the path predictor dropped the object's earlier locations, preventing the motion planner from seeing that the obstacle was crossing the vehicle's path (National Transportation Safety Board 2019). Covariate shift, the near-OOD regime of table 3.4 in which the inputs change while the task stays the same, pushes more frames toward those boundaries; section 5.2 develops it.

In robotic manipulation, perceptual chattering injects rapid direction reversals into joint trajectory setpoints. Over a discrete control interval Δt, a sharp step in commanded velocity demands an instantaneous acceleration $\Delta\dot{\mathbf{q}}/\Delta t$ beyond what the actuators can deliver. PD joint controllers react to the resulting velocity errors by commanding large opposing motor torques, the same derivative-gain torque step that the temporal-ensembling jerk trap of section 3.5.1 priced at a single chunk seam, now repeated at every flip. The resulting current spikes, tracking errors, and heat strain the power stage and gearbox, risking protective drive faults or structural vibration. Physical AI runtimes suppress perceptual chattering with three defenses:

1. *Temporal hysteresis and debouncing.* Requiring a newly observed class or spatial mode to persist across N consecutive perception frames before committing a state change, just like switch debouncing[12] in embedded firmware.
2. *Recursive state filtering.* Fusing successive observations into a running estimate so that a single noisy frame cannot overwrite an established world state.

↩ The tracking-history loss under classification changes in the 2018 Tempe collision is established in section 1.8.1.

12 **Debouncing**: The contacts of a mechanical switch bounce for milliseconds when pressed, so embedded firmware accepts a new switch state only after it has persisted for a set interval. The same N-frame rule applied to class labels suppresses chattering, but it delays every genuine change by N frames, time charged to the observation-age budget before any proposal is renewed.

3. *Rate and jerk limiting.* Enforcing joint acceleration and jerk bounds in the real-time controller so that high-level label flicker cannot reach the motor shafts as torque shocks.

3.6.4 When intent expires

↪ Recursive state estimation, which accumulates evidence across frames instead of trusting the latest one, is developed in section 9.2.

Even when perception neither hallucinates nor chatters, the physical scene continues to move after a valid goal is issued. Notebook 3.3 already showed a chunk outliving its evidence, and the same failure applies one level up, to intent. Renewing a high-level goal identifier, or retransmitting a previous trajectory, does not refresh the observation that placed the mug. High-capacity intent models, which deliberate over long time horizons at low update rates, must therefore provide goals whose validity can be continuously audited against fresh, real-time telemetry while high-frequency reactive policies stream immediate motion.

The execution receiver must distinguish between rejecting a stale proposal and terminating an active, executing trajectory. Dropping an incoming proposal that failed its arrival deadline or validity check does not automatically invalidate the chunk currently running on the motors. The active chunk continues executing so long as its own chunk lease, the intent lease governing its target, the evidence behind it, its state bounds, and its safety margins all remain valid. If the active chunk lease or the governing intent lease expires, or the evidence behind the active chunk lapses, the supervisory permission path must end nominal tracking and engage the qualified fallback unless a valid successor restores the required authority. Because holding position, decelerating to a controlled stop, and removing torque require distinct physical preconditions, section 12.9 develops the formal fallback ladder across these operational regimes.

Each of the four vulnerabilities ends the same way. Hallucination, overconfidence, chattering, and expiry cannot be reliably ruled out by the proposer's own output and require checks against independently qualified evidence, which is why the opening comparison of classical and learned methods resolves into a partition rather than a choice. Physical AI architectures assign semantic interpretation to the learned proposer and execution authority to the permission path (table 3.5). Learned foundation models supply flexible task coverage across unstructured environments, but their lack of closed-loop formal guarantees requires treating their outputs as unprivileged proposals. Conversely, classical analytical checks enforce strict physical invariances and real-time bounds, yet their guarantees remain conditional on accurate kinematic models and fresh sensor data. Safety therefore rests on the interface, which must never let an unverified proposal bypass the checks of the permission path.

Table 3.5: Classical analytical methods vs. learned foundation models: Trade-offs across generalizability, verifiability, pacing, and fallback, with the synthesis that partitions proposal capability from execution authority.

Systems Dimension	Classical Analytical Methods	Learned Foundation Models	Physical AI Architectural Synthesis
Foundational Principle	Analytical differential equations, geometry, CAD models, Lyapunov stability	High-capacity neural representations fitted to empirical multimodal data	**Hybrid Hierarchy:** Learned intent proposals gated by the permission path
Generalizability & Perception	**Model-dependent:** Explicit geometry and features may lose coverage under shift	**Data-dependent:** Open-vocabulary grounding can improve coverage but may fail under shift	**Unprivileged Deliberation:** Foundation models synthesize continuous semantic goals
Mathematical Verifiability	**Conditional:** Selected properties can be proved within model assumptions	**Limited:** Empirical behavior needs separate bounds and runtime evidence	**Proposal Boundary:** Gate checks modeled limits using independent evidence
Temporal Pacing	**Boundable:** Selected controllers support real-time deadlines under stated execution assumptions	**Multi-Rate:** Full inference, chunk refresh, and waypoint execution have distinct rates	**Split Proposers:** A small chunk policy renews while the intent model revises goals
Failure Modes & Fallback	Implementation defects; model mismatch; failure on uncataloged objects	Semantic hallucinations; out-of-distribution overconfidence; expired intent	**Conditional Fallback:** Reject detected violations and execute a feasible response

Checkpoint 3.3: Proposals that arrive on time and are wrong

A proposal can meet every deadline and still target the wrong thing, so the receiver needs evidence the proposer cannot supply about itself.

- ☐ **Classical vs. learned**: For the welding cell and the conveyor mug pick, which approach would you use to propose motion in each, and which properties could you still prove or measure for each?
- ☐ **Interface checkability**: Can you explain why the permission path can enforce this geometric intent lease on a target pose with a capture time but not on an ungrounded latent vector alone?
- ☐ **Hallucination vs. staleness**: For the grasp on the carton photograph and for a smooth chunk that arrives after τ_{ev}, which payload field or independent measurement lets the receiver refuse each?
- ☐ **Threshold estimate**: Assuming every attempt in a regime receives its tabulated confidence score, if the receiver admitted every proposal scoring above the far-OOD confidence in table 3.4, which regimes would pass, and what stipulated fraction of near-OOD attempts would fail?

3.7 Fallacies and Pitfalls

Learned models expand the behavioral repertoire of robotic systems, but their predictions remain ungrounded hypotheses until verified against physical dynamics and environmental constraints. In deployed systems, critical failures emerge when software architectures treat statistical confidence, numerical formatting, or kinematic smoothness as an unconditional license to command hardware. Avoiding these hazards requires separating candidate generation from deterministic safety enforcement.

DRAFT

Fallacy: *An engineering team must choose entirely between formal classical safety proofs and learned empirical capability.*

Engineers often frame robot control as a mutual exclusion: either adopt a classical controller with provable stability guarantees, or deploy an expressive neural policy that achieves broad task coverage through empirical learning. Consider an assembly plant routing flexible wiring harnesses. A classical model-based controller enforces rigid kinematic constraints and workspace boundaries, yet it struggles to model the nonlinear dynamics of deformable cables. Conversely, a learned diffusion policy navigates cable deformation successfully, but occasionally proposes motions that exceed physical clearance limits.

The proposal boundary dissolves this dilemma. The diffusion policy proposes, and an independent minimal-intervention filter corrects any command that would cross a clearance limit before it reaches the actuators. The correction preserves the modeled safety constraint without guaranteeing completion of the harness insertion, so systems architects must track task completion, proposer error distribution, and protective intervention frequency as independent performance metrics.

↪ The minimal-intervention filter, which replaces an inadmissible command with the smallest correction that satisfies the physical constraints, is developed in section 12.7.

Pitfall: *Allowing a neural model's high confidence to bypass deterministic geometric boundaries.*

A cleanroom manipulator handling reagent vials mistakes specular glare on a transparent glass partition for open workspace and plans a reach directly through the barrier. The resulting action packet satisfies standard transport validation: joint coordinates are finite and in range, the command arrives on schedule, and the neural proposer reports an output confidence of $\hat{p} = 0.98$. However, a high score indicates only that one output dominated the alternatives. Section 3.6.2 showed that a network can be most confident on inputs far from anything it was trained on. The same specular reflection that deceived the perceptual front-end also corrupts the confidence head, producing an assertive proposal for an impossible motion.

Actuation permission must always derive from deterministic geometric validation rather than statistical self-assessment. Before energizing motor drives, the real-time execution monitor must validate candidate trajectories against qualified local geometric boundaries derived from independent

sensors, such as acoustic rangefinders, time-of-flight sensors, or calibrated structural keep-out zones. Because an isolated microcontroller or real-time checker lacks the memory and compute budget to evaluate a full host-resident 3D occupancy grid, the boundary handoff contract must deliver explicit spatial bounds along with verified validity intervals before motors receive current.

Fallacy: *Raw softmax probabilities or predicted confidence scores reflect true physical success rates.*

An industrial bin-picking policy can assign near-unity scores to grasp candidates that fail immediately under altered lighting or surface conditions. The softmax function merely transforms unbounded real-valued logits into an artificial probability distribution that sums to one across the discrete candidate set. This mathematical normalization quantifies relative preference across the model's training distribution rather than mechanical stability in physical contact.

Post-hoc calibration methods, such as temperature scaling, align predicted probabilities with empirical accuracy only while operating under conditions identical to the calibration distribution. As the illustrative gaps in table 3.4 depict, calibration can degrade sharply when lighting, surface friction, or geometry shifts out of distribution. Relying on an abstention threshold applied to raw model scores will silently allow unstable grasps or collisions during operational shifts. Production systems must backstop model proposals with independent physical verification, including tactile slip sensing, force-torque thresholds, and deterministic geometric checks.

Pitfall: *Coupling high-frequency semantic classifications directly to motor setpoints without continuous filtering.*

A delivery robot navigates past reflective tarps flapping over traffic cones. At every perception update (20 Hz), the vision pipeline alternates its discrete classification between an open corridor, a rigid obstacle, and a compliant drape. If the motion planner maps these discrete classification switches directly into motor setpoints, perceptual noise commands instantaneous velocity reversals. Each reversal is a step in velocity reference, which a PD servo loop turns into the derivative-gain torque step that the temporal ensembling jerk trap computed for a single chunk seam, repeated at every flip. Chattering commands of this kind saturate motor drive currents, cause mechanical backlash wear, and excite dangerous structural resonances throughout the chassis.

Physical architectures must decouple discrete semantic classification from continuous motor control. Engineers introduce temporal debouncing, Bayesian belief filters, or hysteresis thresholds to suppress semantic switching noise. Furthermore, the permission path's interpolator must hold setpoints within explicit acceleration and jerk limits before dispatching them to the drives. Even when the resulting trajectory appears smooth, the real-time execution engine must verify dynamic feasibility against hardware torque and thermal limits.

Fallacy: *A numerically valid and smooth action chunk can safely be executed whenever it arrives.*

Modern action-chunking architectures generate sequences of future setpoints to bridge the rate mismatch between slow neural inference on an application processor and fast motor control loops. Consider a mobile manipulator grasping an item from a moving conveyor. A host policy computes a smooth, multi-step arm trajectory toward the target, but operating system scheduling jitter, memory paging, or bus stalls delay packet delivery beyond the sensor evidence horizon. When the action chunk finally reaches the motor controller, its waypoints remain mathematically continuous and within joint kinematic limits. Meanwhile, conveyor motion has shifted the actual object outside the grasp envelope.

Executing an outdated chunk causes the arm to track a phantom path. A motor controller must reject stale packets regardless of their internal smoothness. Action chunks must carry explicit timestamps and temporal validity leases tied to the freshness of their underlying sensor observations. The real-time receiver may execute an active trajectory only while its lease remains valid. If an expected chunk fails to arrive before the lease expires, the controller must execute a qualified deceleration or compliant hold to keep the hardware within safe operational limits. Kinematic smoothness cannot compensate for expired temporal validity.

3.8 Summary

Learned representations give the mobile manipulator what hand-authored geometry could not, the ability to recognize and act on objects no engineer enumerated, and the machine pays for that breadth in memory traffic, arithmetic, and time. A fresh evaluation splits into a compute-bound prefill and a bandwidth-bound decode, so weight-only quantization shortens one term and leaves the other, and a large intent model on an embedded processor renews only a few times per second. Supply and validity are therefore separate budgets. A chunk keeps the arm supplied between renewals, but every setpoint in it descends from one observation, so the time the target stays within tolerance, not the length of the chunk, bounds how much of it may run. What the slow proposer hands the fast one decides what the permission path can check, and because a proposal can arrive on time and still be wrong, every proposal must carry its capture time, validity limit, and provenance so that it remains refusable. Six core quantitative relations govern these trade-offs across the chapter, each bounding a distinct stage of proposal generation and expiration (table 3.6).

Table 3.6: Key equations of the cognitive brain: The bounds that price a learned proposer on the machine's processor and size its chunks against a moving target, with the place each is derived.

Equation	What it bounds or decides	Derived
$f \leq \mathrm{BW}_{\mathrm{mem}} / M_{\mathrm{weights}}$	The memory wall: the peak renewal frequency when every evaluation cycle streams nonresident weights from memory before performing additional work	equation 3.2
$I = \mathrm{FLOPs/bytes\ transferred}$	Arithmetic intensity vs. the processor ridge point, determining whether a workload phase is bandwidth-bound or compute-bound (batch-1 decode sits near one FLOP per byte; prefill approaches S FLOPs per byte)	equation 3.3
$t_{\mathrm{infer}} \approx \max\left(\frac{O_{\mathrm{prefill}}}{\eta_{\mathrm{hw}} R_{\mathrm{peak}}}, \frac{M_{\mathrm{weights}}}{\mathrm{BW}_{\mathrm{mem}}}\right) + (S_{\mathrm{out}} - 1)\frac{M_{\mathrm{weights}}}{\mathrm{BW}_{\mathrm{mem}}}$	The latency of a complete evaluation, combining compute-bound prefill with bandwidth-bound decode sweeps; weight-only quantization reduces only the second term	equation 3.4
$M_{\mathrm{KV}} = 2 \times N_L \times d \times S \times s_{\mathrm{elem}}$	The memory capacity occupied and reread by retained context, scaling linearly with the preserved token sequence length	equation 3.1
$h_{\mathrm{min}} = \left\lceil (T_{\mathrm{chunk}} + t_{\mathrm{infer}}) / \Delta t_{\mathrm{step}} \right\rceil$	The minimum setpoint count an action chunk must deliver to keep actuators supplied across a complete replanning and inference cycle	equation 3.6
$\tau_{\mathrm{ev}} = \sqrt{2(r_{\mathrm{tol}} - e_0)/a_{\mathrm{slip}}}$	The evidence horizon during which target tracking remains within physical tolerance; the total latency span $T_{\mathrm{chunk}} + t_{\mathrm{infer}}$ must fit inside this limit	equation 3.5

Key Takeaways: Learned proposers and deliberation limits

- **Memory traffic and arithmetic both bound fresh inference**: When an evaluation cycle streams nonresident weights from memory, the total weight footprint and sustained memory bandwidth establish a hard latency floor. Fetching the intent model's 14 GB of FP16 weights requires 98.0 ms. Input token prefill operates in the compute-bound regime, whereas per-token autoregressive decoding is bandwidth-bound. Consequently, even with INT4 weights, a single evaluation consumes approximately 336 ms. This supports the selected intent renewal rate of 2 Hz, which is far too slow to drive real-time actuator chunk renewal directly.
- **Chunking supplies motion without refreshing evidence**: Generating a chunk of 16 setpoints amortizes a single backbone evaluation across 400 ms of candidate motion. Although this amortizes memory bus traffic across waypoints, the robot executes that motion without incorporating new visual evidence until the subsequent policy evaluation completes.

- **Supply and validity bound different horizons**: In the conveyor pick task, actuator continuity requires a minimum supply horizon of 4 setpoints to bridge neural renewal intervals, whereas target drift constrains the sensory evidence horizon to approximately 219 ms. A deeper queue of setpoints cannot extend that validity. A setpoint stays eligible only while the evidence behind it holds and the active chunk lease runs, and when renewal stops, the chunk lease bounds how far the arm continues.
- **Retained context competes with current sensing**: Retaining the hypothetical five-second history at the stated sampling rate occupies 21.0 GB of key-value cache memory. Because storing and rereading past attention state directly contends for DRAM bandwidth with incoming sensory observations and proposal generation, temporal context retention must be explicitly managed within the system timing and memory budget.
- **Proposer interfaces dictate runtime verifiability**: An opaque latent embedding passed from a high-level intent model to a low-level policy cannot be cross-referenced with measured workspace geometry or aged against target drift. Conversely, an explicit Cartesian target pose accompanied by an observation timestamp provides a checkable contract. This auditable geometric interface allows the machine's permission path to enforce its intent lease alongside the high-rate chunk lease.
- **Reported confidence requires independent physical validation**: A softmax probability or normalized confidence score emitted by a learned model cannot guarantee physical execution success under real-world distribution shift. While calibration validates score reliability across known operating regimes, runtime safety demands independent geometric constraints, kinematic limits, and physical contact monitoring.
- **Proposals must remain rejectable**: Trajectory proposals must bundle explicit observation timestamps, kinematic assumptions, and validity envelopes alongside their raw setpoints. The Nervous System combines these proposer constraints with real-time body state measurements to validate trajectory headers, manage handoffs between successive chunks, and enforce fail-safe execution windows.

The conveyor pick separates two kinds of inadequacy that call for different fixes. A proposer that cannot renew before its evidence expires has design remedies: fewer input tokens, a smaller or differently quantized model, more bandwidth, or a slower target. A proposer that renews in time and still proposes a wrong grasp is not repaired by any of them, which is why its output stays a proposal however fast it arrives. Both cases end at the first law (principle 1). Motion executed on evidence that has gone stale, or toward an affordance that does not exist, delivers energy that cannot be recalled. The time a proposal may keep driving the machine therefore has to be set below the proposer, from the body's stopping budget, rather than by the proposer's own schedule.

3.9 Historical Perspective and Further Reading

The two-speed architecture developed throughout this chapter, which couples a slow deliberative proposer with a high-frequency execution loop that continuously services the actuators, is robotics' recurring answer to a timing constraint. Physical machines have wrestled with this division since Shakey's deliberative planning (Nilsson 1984), Brooks' reactive subsumption layers (Brooks 1986), and ALVINN's direct learned steering (Pomerleau 1989). The classical industrial pipelines examined in section 3.2 retained explicit geometric representations by restricting robot operation to structured, calibrated workcells where rigid kinematic models hold, while end-to-end learning gained broad behavioral coverage from data at the cost of formal analytical guarantees.

↩ The lineage from Shakey's deliberative planning through Brooks' subsumption layers to ALVINN's learned steering is established in section 1.2.

The hardware bottlenecks that govern modern policy inference stem from a parallel evolution in computer architecture. Wulf and McKee (1995) identified the widening memory wall, observing that processor speed was improving far faster than DRAM access time. Williams et al. (2009) formalized this relationship into the roofline model, establishing operational arithmetic intensity, the ratio of floating-point operations performed to memory bytes transferred, as the metric that reveals whether an execution phase is memory-bandwidth-bound or compute-bound. Modern autoregressive models collide directly with these bandwidth ceilings. The Transformer architecture requires every newly generated token to attend over cached keys and values from all preceding context tokens (Vaswani et

al. 2017). As Pope et al. (2023) demonstrated through analytical modeling of distributed Transformer inference, generating one token at a time splits execution into a compute-bound prompt prefill phase, which processes all input tokens together, and a memory-bandwidth-bound autoregressive decoding phase. In embodied setups, where real-time interactive control requires generating action tokens with a batch size of 1, the memory wall dominates the decode, as notebook 3.1 prices for the machine and checks against a published measurement on its processor. To alleviate this memory traffic, integer-only quantization demonstrated that low-precision arithmetic could run efficiently on mobile processors with small accuracy loss on the vision networks it evaluated (Jacob et al. 2018). As the intent-model measurements of table 3.1 show, however, the cost of a given bit width depends on the method, the kernels, and the task. Modern weight-only formats such as AWQ protect salient weight channels while cutting the bytes transferred across the memory bus on each decoding pass (Lin et al. 2024).

Learned proposers emerged when these sequence architectures were adapted to robot sensorimotor trajectories. The Vision Transformer demonstrated that self-attention could replace convolutional feature extractors on raw image patches without losing spatial coherence (Dosovitskiy et al. 2021). RT-1 and RT-2 extended this foundation to robotics by tokenizing continuous physical actions directly into the vocabulary of large vision-language models (Brohan, Brown, Carbajal, Chebotar, Dabis, et al. 2023; Brohan, Brown, Carbajal, Chebotar, Chen, et al. 2023), while OpenVLA established an open, reproducible seven-billion-parameter architecture that enabled systematic hardware profiling and fine-tuning (Kim et al. 2024). However, evaluating large transformer backbones autoregressively at every single control step proved computationally impractical for low-latency physical loops. Action Chunking with Transformers (ACT) and Diffusion Policy resolved this bottleneck by shifting the unit of prediction from isolated steps to short trajectories (Zhao et al. 2023; Chi et al. 2025), amortizing inference latency over multiple timesteps and reducing the compounding of per-step errors. Advancing this approach, π_0 coupled a high-capacity vision-language backbone with a flow-matching action expert capable of generating high-frequency motor commands (Black et al. 2024). Real-time action chunking hid the inference delay behind execution by freezing the setpoints that run during inference and generating the rest of the next chunk to agree with them (Black, Galliker, et al. 2025), a formulation that recasts classical receding-horizon model predictive control through the lens of deep learning (Mayne et al. 2000). Modern embodied platforms, including Helix (Figure AI 2025) and GR00T N1 (Bjorck et al. 2025), adopt the same two-speed separation. The contract between the two tiers remains an open design question. Deployed systems pass latent vectors, language, or geometry from the slow model to the fast one (table 3.2). This chapter's case for a checkable geometric target, together with the invariants a real-time monitor must enforce on it, is one position in that question rather than a settled standard.

Six works trace this lineage from reactive robotics to modern vision-language-action architectures:

- Brooks (1986) introduces the subsumption architecture, organizing autonomous robots into layered, asynchronous behaviors that each close their own sensorimotor loop. The paper presents the foundational systems argument that fast reactive loops must never block on deliberative planning, establishing the conceptual basis for modern two-speed execution.
- Williams et al. (2009) introduces the roofline model, a visual bound relating arithmetic intensity to processor compute and memory bandwidth ceilings. The paper provides the standard methodology for diagnosing whether an inference kernel is memory-bound or compute-bound before undertaking hardware optimization.
- Pope et al. (2023) models Transformer inference from first principles, demonstrating how batch size, sequence length, and tensor partitioning dictate whether execution binds on memory bandwidth or arithmetic execution units. This analysis underpins the performance characterization of batch-size-1 policy inference explored throughout this chapter.
- Zhao et al. (2023) introduces Action Chunking with Transformers (ACT) and temporal ensembling for precise bimanual manipulation. The authors demonstrate that predicting action sequences rather than individual steps dampens compounding tracking errors and stabilizes learned policies, establishing the trajectory chunking approach that real-time learned policies now rely on.
- Chi et al. (2025) develops Diffusion Policy, demonstrating why multimodal human demonstrations with multiple valid solutions require expressive generative decoders rather than

unimodal regression. The paper explicitly characterizes the systems cost of iterative refinement, quantifying the computational latency required to evaluate multiple diffusion steps per action chunk.

- Kim et al. (2024) provides a complete, open-source seven-billion-parameter vision-language-action model, detailing its training pipeline, data mixture, and deployment trade-offs. The paper includes 4-bit and 8-bit quantization benchmarks, which make it a common reference point for profiling learned embodied policies on edge hardware.

What's Next: From learned proposals to the permission path

A physical machine cannot allow a candidate proposal to continue driving hardware indefinitely when its successor fails to arrive. The mobile manipulator's chunk policy targets a proposal period of 50 ms, whereas the intent model updates at a slower cadence, and either level can stall, miss its deadline, or misjudge the target object. A check that waits on the proposer it checks stalls along with it. Chapter 4 therefore begins with where the permission path must run to stay independent of the learned models. It next derives each tier's rate from a physical time constant and passes proposals between tiers without letting a slow writer block a fast reader. Only then does it price the chunk lease from the body's stopping budget and the proposer's renewal floor, ensuring that an admitted chunk commands the joints for a bounded interval before a deterministic fail-safe response begins.

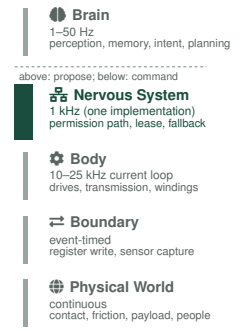
Purpose

Why must a moving machine keep checking its commands when its learned model stops responding?

A learned model can pause for a fraction of a second while it interprets a scene, but the machine carrying it keeps moving, and a loaded base covers tens of centimeters in that pause. Every delay between a decision and the current it becomes is therefore paid in clearance. A general-purpose computer hides such delays behind queues, retries, and priorities. A moving machine cannot, because a command that arrives late acts on a body that has already moved, and a check that waits on the model it checks protects nothing once that model stalls. Treating timing and communication as implementation details produces machines whose safeguards share a processor, a supply rail, or a memory bus with the model they guard, and so fail together with it. A machine that acts on learned decisions therefore needs a timed path between proposal and actuator whose delays are bounded, whose checks never wait on the proposer, and whose grant of authority to each proposal expires on its own. At the causal boundary, time granted to a proposal becomes motion that software cannot recall.



Learning Objectives

- Explain why the permission path's independence from the proposer is a requirement to be demonstrated rather than a property of separate processors
- Derive update rates and loop placement from actuator time constants, the phase lag of sampling and transport delay, and proposal renewal limits
- Evaluate mailbox exchanges for bounded reads, complete payloads, and proposal freshness when the writer stalls
- Size a chunk lease between the renewal floor and the pre-brake ceiling, and explain why a host heartbeat cannot renew it
- Distinguish measured latency percentiles from response-time bounds that include computation, blocking, and interference
- Compare position, velocity, torque, and impedance commands by what each leaves the permission path to check
- Evaluate interface timing violations using handoff records that distinguish allocated budgets, supporting evidence, and unresolved bounds

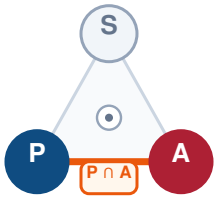
4.1 The Multi-Rate Bridge

The running machine joins two computational regimes that run on clocks roughly three orders of magnitude apart. A deep neural network processes camera frames into action proposals over tens to hundreds of milliseconds, with latency that fluctuates from frame to frame. An electric motor drive, by contrast, regulates winding current every few tens of microseconds, in a loop that can never pause because the mass it moves keeps its momentum whether or not a new command arrives. The architectural layer between them, the machine's **Nervous System**, routes action proposals downward toward the actuators, streams physical telemetry back up, and arbitrates whether any proposal is permitted to move the hardware. Industrial motion control, avionics, and automotive engineering solved similar coordination problems decades ago for classical feedback controllers whose worst-case execution times were statically bounded before deployment (Kopetz 2011). Learned proposers break those classical assumptions. Their inference latencies have long tails, their software runtimes can stall unexpectedly, and their outputs can fail in ways that cannot be exhaustively enumerated at design time.

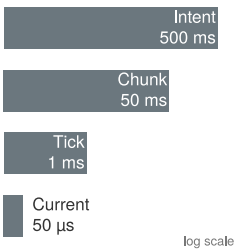
This asymmetry sets the chapter's central design question, which chapter 3 left open with two proposers (a chunk policy and an intent model, either of which can stall, miss its deadline, or misjudge the target). The question is how long the physical plant may keep executing the last valid proposal when an inference step stalls or drops a frame. That duration cannot be an arbitrary software timeout or the proposer's own schedule; it must follow from the machine's stopping distance and mechanical limits.

On the warehouse mobile manipulator, that gap appears every time the vision-language-action (VLA) policies plan a grasp on a conveyor-belt mug while the brushless motor drives regulate winding current thousands of times per second. If motor regulation ever blocks on deliberative reasoning, or contends for shared memory without a bound on its wait, a heavy inference burst can push the control loop past its hard deadline. Moving mass and electromagnetic coils force one conclusion. *The Brain needs time to deliberate, while the Body needs continuous control.*

Coupling these domains across a shared blocking execution path forces the fast loop to inherit the tail latency of the slow one. If the motor control loop stalls waiting for inference or drains an outdated FIFO queue of stale setpoints, the resulting actuation commands arrive at a physical body that has already moved past the target state. Unmanaged transport delay (T_d) also injects phase lag directly into the feedback loop, adding $\Delta\phi = \omega T_d$ radians at angular frequency ω. That lag erodes the loop's phase margin, the extra lag it can absorb before its corrections start to reinforce the motion instead of damping it (made precise in section 4.3.1). The Nervous System must bound these end-to-end transport delays deterministically while ensuring that high-rate local control remains autonomous whenever high-level deliberation stalls.



On the sense-plan-act (S·P·A) triad (Appendix D), proposals cross from Plan to Act only through the permission path.



Each tier runs at least ten times faster than the one above it, and none may wait on a slower one.

To enforce this isolation, the Nervous System splits work across four tiers, separating what each tier controls alongside how often it runs. Each tier runs decoupled from the tiers above it, so fast safety and stabilization loops never wait on slower deliberative tiers:

1. **Actuator current and velocity regulation:** Dedicated motor drives close the inner winding-current and joint-velocity loops locally in hardware. Field-oriented control (FOC)[1] aligns the stator voltage vector with the rotor's magnetic flux in every carrier period (the switching period of the drive's pulse-width modulation, or PWM). The winding then produces the commanded torque within a few current-loop samples.
2. **Permission and position supervision:** The deterministic real-time supervisory controller verifies proposal freshness and kinematic limits, sends admitted position setpoints across the fieldbus, checks tracking error against physical safety envelopes, and commands a fail-safe stopping trajectory if proposal authority expires.
3. **Action-chunk policy:** The learned mid-level policy emits a short sequence of future waypoints (an action chunk), giving local controllers a continuous motion segment to track between discrete inference steps.
4. **Intent planning:** Slower vision-language or task-planning models read camera frames and language instructions to set high-level goals, steering the action-chunk policy without directly touching drive setpoints.

[1] **Field-Oriented Control (FOC)**: The drive rotates the three measured phase currents into a frame that turns with the rotor's magnetic field, where torque and flux become two slowly varying currents that ordinary proportional-integral loops can hold. The rotation needs a fresh rotor angle in every carrier period, so the loop cannot wait on anything slower than its own sensors. That is why the current loop runs inside the drive, beside the encoder and the current shunts, and why no proposer, however fast, ever sits inside it.

Section 4.3.1 gives each tier its rate, while one rule holds all four together and comes first: a stalled or crashed proposer must never block or delay a lower tier's checks. Conventional computing architectures break that rule because they rely on shared processors, unified memory buses, and multi-level caches managed by general-purpose operating systems. In such environments, hardware isolation is weak. When a large deep neural network streams gigabytes of model weights from DRAM across a shared memory fabric, its high-throughput direct memory access (DMA) bursts contend directly with real-time telemetry and control packets. Because hardware bus transactions cannot be preempted by software thread priorities, control packets queue up at the memory controller. A control path that shares an execution environment with machine learning runtimes is also exposed to operating-system jitter, because kernel page faults, garbage collection cycles, driver interrupts, and thermal frequency throttling can each stall execution for tens of milliseconds. Physical stability therefore demands an architecture in which local control loops keep updating the actuators on schedule whatever delays the inference path suffers.

The physical numbers show why the fast tiers cannot wait. An electromagnetic motor winding has an electrical time constant ($\tau_e = L_{\text{phase}}/R_{\text{phase}}$) of a few milliseconds, 2.7 ms for the running machine's direct-drive hub motors (section 2.4.2), while the moving links carry substantial kinetic energy ($E_k = \frac{1}{2}mv^2$). Delaying or dropping an actuation command by a fraction of a second can exhaust the clearance before a new inference cycle finishes. On the warehouse robot the mismatch appears in two mechanical domains:

- The base (Class 1) cruises at up to its 1.5 m/s drive limit (illustrative; see the Reader Guide). At this speed, it travels 60 mm during a single 40 ms action-chunk inference, and 503 mm across one 336 ms intent-model inference cycle. Unless an independent supervisory process monitors plant telemetry and commands braking, the chassis travels half a meter open-loop before deliberative planning produces an updated command, nearly half the rack-end clear distance on the machine card.
- The arm (Class 2) couples motor rotors to joints through high-ratio gearboxes, reflecting rotor inertia back to the joint output as $N^2_{\text{gear}} J_{\text{rotor}}$, the scaling derived in section 2.4.3. The drives keep closing their own joint loops when the proposer stalls, but they keep tracking the last admitted command. If that command was set for a grasp on a conveyor mug or a turn of a door latch the scene no longer matches, the reflected inertia and the drives together keep pressing the mechanism into the contact. Contact forces then escalate rapidly. Whether this interaction breaches structural limits depends on the contact compliance, surface friction, and mechanical response times alongside the reflected inertia.

↩ The intent model's inference latency, priced from its compute-bound prefill and its bandwidth-bound weight sweeps, is established in section 3.4.1.

Software discipline, operating system thread priorities, and runtime exception handlers cannot by themselves keep the plant safe. Safety requires an explicit, physically deterministic computing, memory, and communication fabric. That fabric forms the Nervous System of the five-level machine

model (section 1.7), hosting the dedicated permission path so the physical plant retains a measured, feasible response whenever higher-level inference pauses or fails. Its primary design requirement is an interface whose temporal bounds, command authority, and fault responses can be verified directly against the machine's physical safety budget. Enforcement algorithms later turn these requirements into per-tick admission decisions, while the mechanisms of this layer fix the contracts those decisions must satisfy.

Building and pricing that fabric proceeds from silicon isolation to the system handoff record. Section 4.2 shows why the timed path to the actuators must remain independent of unbounded interference and stalls from deliberative inference, stating the two-processor split that meets this requirement as a hypothesis the machine's silicon must still confirm under load. Section 4.3 derives the rate of each tier from a physical time constant and passes proposals between tiers through a mailbox that never blocks the faster reader. Section 4.4 then answers the chapter's central question with the *chunk lease*, the bounded interval during which an admitted proposal may keep driving the actuators, priced in the stopping budget. Section 4.5 bounds the computation and the drive network (the *fieldbus*) on which that price depends. Because bounded timing still requires exclusive control of the actuators and survival under host faults, section 4.6 and section 4.7 keep the permission path the sole writer of the drives and keep it alive when the proposer fails, while section 4.8 states the execution contract its checks must meet however fast the proposer runs. Finally, the handoff record of section 4.9 locates every limit at one of five interfaces, coupling this layer's lease to the stopping distance of the Body and the renewal rate of the Brain.

↪ The per-tick admission decisions that must satisfy these contracts are developed in section 12.1.

4.2 The Independence Requirement and the Two-Processor Hypothesis

When an inference model suffers a transient stall or drops a frame, the robot can safely reject the stale proposal and fall back to local control. When a permission check stalls, however, the delay burns directly through the machine's stopping budget, regardless of whether the processor eventually catches up. The two workloads therefore optimize for different guarantees. A neural chunk policy needs high compute throughput and memory bandwidth to stream motion proposals at its target renewal rate, whereas the permission path needs a strict, provable upper bound on the time required to validate and dispatch each step.

Standard operating-system schedulers decide which ready task executes next, but software priority alone cannot guarantee deterministic timing. Raising a control task's priority reduces processor contention, yet it cannot prevent microarchitectural delays. A sudden page fault suspends execution while the virtual memory subsystem resolves the missing page. Lock contention on shared kernel primitives leaves a real-time thread waiting behind uncritical background tasks. Memory requests stall at the arbiter while DMA transfers from a GPU or neural accelerator saturate the system interconnect. Long inference latency tails[2] therefore threaten closed-loop stability even when average proposal latency remains well within nominal bounds.

Bounding the permission tick against those microarchitectural stalls requires separating the parts of its cycle using the standard terms of real-time scheduling (Buttazzo 2011; Kopetz 2011). The permission tick runs as a periodic task i released once every **period** T_i, set here to 1 ms. Each release is a single job that must finish before its relative **deadline** D_i, measured from the release instant and set here to 400 µs. The deadline is shorter than the period so that each admitted setpoint is ready within the cycle that computed it rather than one tick later, a delay whose cost section 4.3.1 prices. It also leaves the rest of the period free for lower-priority work. A deadline is *hard* when a single miss can cause a physical hazard, as on the permission tick, where one late check adds one more millisecond of unchecked motion. The total wall-clock time from task release to job completion is its **response time** R_i. The part of that response time spent running the task's own instructions is bounded above by its **worst-case execution time (WCET)**[3] C_i.

> Definition 4.1: Worst-case execution time
>
> ***Worst-case execution time*** is the longest time a task can take to run to completion on a given processor, over every admissible input and every state its caches, pipeline, and buses can be in, with no other task competing for the processor.

[2] **Inference Latency Distribution**: The median and p99 alone do not fix the exceedance probability at a given deadline, which must be measured or modeled separately. Tail-model assumptions and exceedance estimates require representative workload data and an account of dependence and uncertainty; section A.10 develops these conditions.

[3] **Worst-Case Execution Time (WCET)**: A static WCET is a bound proved over every path through the binary and every state the processor's caches and pipeline can be in; analyzers compute it by abstract interpretation of the code against a model of that hardware (Wilhelm et al. 2008). Caches, branch predictors, and shared buses make that model either pessimistic or intractable, so a timed path earns a tight bound by avoiding them. The bounded sources listed in section 4.5.1 therefore favor tightly coupled memory and fixed pipelines, giving up average speed for a bound that analysis can prove.

1. **Significance**: It is the C_i term of every response bound in this chapter, and every margin above it is sized on it. The permission tick declares 250 µs against an unloaded run of 135 µs. The 115 µs between them is a claim that analysis must justify before the 400 µs deadline, and the stopping budget behind it, can rely on the number.
2. **Distinction**: Unlike a mean or a high percentile such as p99, which describe the executions a test happened to reach, the WCET covers every admissible path and processor state. A declared WCET is a third quantity, a number the design commits to, which evidence must show is no smaller than the true one.
3. **Common pitfall**: Recording the largest measured execution time as the WCET. A measured maximum can refute a declared bound but never establish it, because a test campaign reaches only some of the processor states in which the code can run (Wilhelm et al. 2008).

The rest of the response time is spent waiting rather than running. **Blocking** B_i is the time a task spends waiting for a lower-priority task to release a shared hardware or software resource, whereas **interference** I_i is the time taken by higher-priority tasks, kernel interrupts, and exception handlers that preempt the job. Because blocking and interference vary from one release to the next, the exact timing of recurring events shifts from cycle to cycle, a variation called **jitter**. Task releases, sensor samples, and job completions each have their own jitter, so a tick released on schedule can still miss its completion deadline if its internal wait times fluctuate. Later, section 4.5.1 combines C_i, B_i, and I_i into a provable bound on R_i.

Placed on one axis, the terms separate an illustrative unloaded observation from the bound the schedule assumes (figure 4.1). The unloaded run of 135 µs is an illustrative observation, not a reported measurement. The 115 µs above it, up to the declared 250 µs, is a claim that WCET analysis must certify. The slack from there to the 400 µs deadline is all the room left for blocking and interference. Underneath, the base covers 1.5 mm during every tick at its 1.5 m/s drive limit, so each of these microsecond terms is ultimately paid in millimeters.

Blocking introduces an architectural vulnerability that priority schemes alone cannot resolve. In **priority inversion**, a high-priority task waits for a shared resource held by a low-priority task, while medium-priority tasks that need no shared resource preempt the lock holder and so starve the high-priority task for as long as they run. Only a real-time locking protocol, such as priority inheritance or priority ceiling emulation, can bound that wait. The recurring resets of the 1997 Mars Pathfinder spacecraft are the canonical case of an inversion left unbounded; war story 4.1 in section 4.5.1 traces it once the response-time bound it violated is in hand.

POSIX real-time extensions (such as `SCHED_FIFO` priority scheduling and memory locking via `mlockall()`), real-time Linux kernels (`PREEMPT_RT`), and dual-kernel architectures (such as Xenomai) target specific software sources of delay. Locking physical memory via `mlockall()` eliminates demand paging inside the timed control loop. Assigning processor affinity confines threads to specific CPU cores to avoid migration latency and cache thrashing. Priority inheritance elevates a low-priority lock holder's priority whenever a high-priority task requests its mutex. These operating-system mechanisms, however, guarantee determinism only when supported by proper configuration, bounded system calls, and verified timing evidence.

↪ The scheduling, interrupt, and memory mechanisms whose formal contribution enters a response bound are developed in section C.3.

Shared hardware introduces delays that operating-system software priorities cannot control. A control task cannot read an optical encoder buffer while a high-bandwidth peripheral monopolizes a shared PCI Express (PCIe) link or system memory bus. Any physical infrastructure that two processing domains share, whether system memory, power regulation, a thermal path, or a reference oscillator, can delay or silence the permission path without a single software fault. Cataloging those physical couplings and gathering the evidence required to verify their isolation belongs to placement (section 13.2). The requirement that analysis tests can be stated now. Under any workload the proposer can generate, the permission path must meet its response bound and keep its authority to refuse an unsafe motion. This chapter calls that requirement independence.

The running machine meets the independence requirement by putting the two paths on two processors, a hypothesis it must still test (figure 4.2). An application processor runs perception, the 2 Hz intent model, and the 20 Hz chunk policy. A separate safety microcontroller unit (MCU) runs the

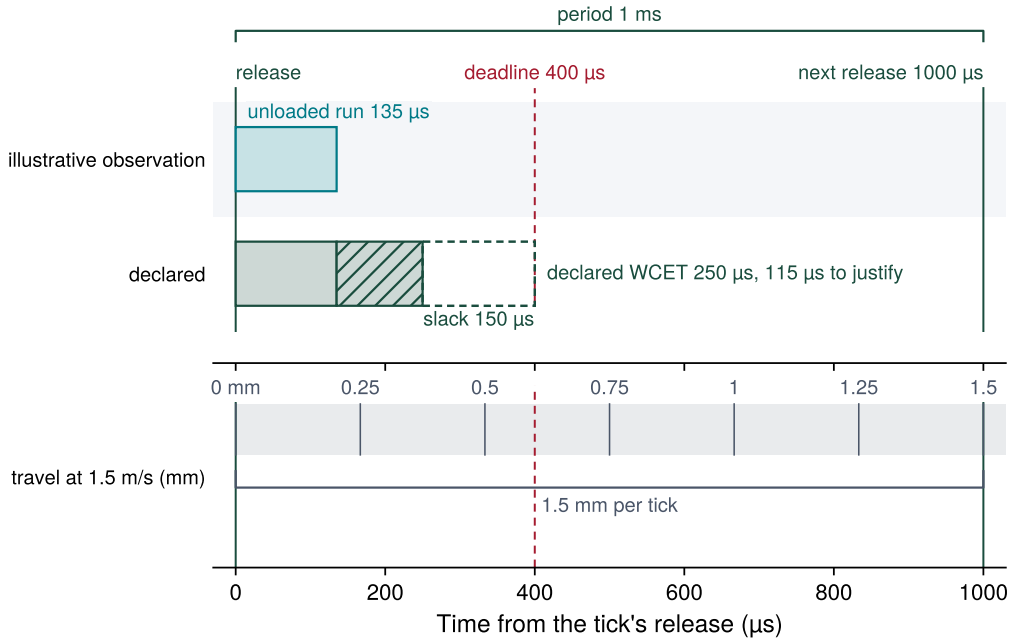


Figure 4.1: One permission tick: A job is released at the start of each 1 ms period and must finish by its 400 µs deadline. The unloaded run of 135 µs is an illustrative observation, not a reported measurement; the declared WCET of 250 µs is the bound the schedule assumes, and the hatched 115 µs between them is what WCET analysis must justify. The slack to the deadline is the budget for blocking and interference. The bottom row counts the base's travel on the same axis, 1.5 mm per tick at the 1.5 m/s drive limit.

permission path and alone drives the motors. Between them runs a board link, a serial peripheral interface (SPI) or Controller Area Network with Flexible Data-rate (CAN FD) bus carrying framed packets with cyclic redundancy checks (CRCs) and sequence numbers. The link is treated as a *black channel*, one the endpoints do not trust, so each frame carries its own integrity and timing checks (section 4.4.1). The two paths share no processor cores, caches, or memory buses, and the learned proposers on the host have no memory-mapped input/output (MMIO) access to the drive registers. Candidate chunks cross the link into the MCU's own SRAM through a double buffer. A receive DMA transfer fills a private receive buffer. The receive interrupt copies each checked frame into a single mailbox slot guarded by a sequence lock, or *seqlock*, whose protocol section 4.3.2 develops. A 1 kHz permission tick reads that slot, checks each proposal's freshness, lease, and kinematic limits against measured encoder feedback, and is the only code that can send an admitted setpoint to the drives. The host is an unprivileged client; the microcontroller, with a short and cycle-counted loop, is the part whose worst-case execution time can be bounded.

Physical separation onto separate chips represents one realization. A single system-on-chip can also host both paths, provided that on-chip interconnects, cache partitioning, and memory controllers demonstrate equivalent response bounds and fault containment under stress. Choosing between discrete silicon and partitioned on-chip cores is the central placement trade-off, and until loaded experiments settle it, physical separation remains a foundational design hypothesis. Scheduling both paths on shared processor cores introduces the problem of *mixed-criticality scheduling*, in which each task carries execution-time bounds of graduated assurance levels. The operating system guarantees each deadline only under the bound its own criticality demands, which allows the proposer to overrun while the permission path executes deterministically (Vestal 2007). Sharing memory on a single die also demands explicit memory-bandwidth regulation to prevent tensor accelerators from starving real-time safety routines.

↪ Mixed-criticality scheduling, memory-bandwidth regulation, and the other remedies for shared-die contention are developed in section 13.6.

Designating an embedded controller as a *safety microcontroller* claims far more than physical separation on a circuit board. It denotes a device developed, qualified, and assessed under the

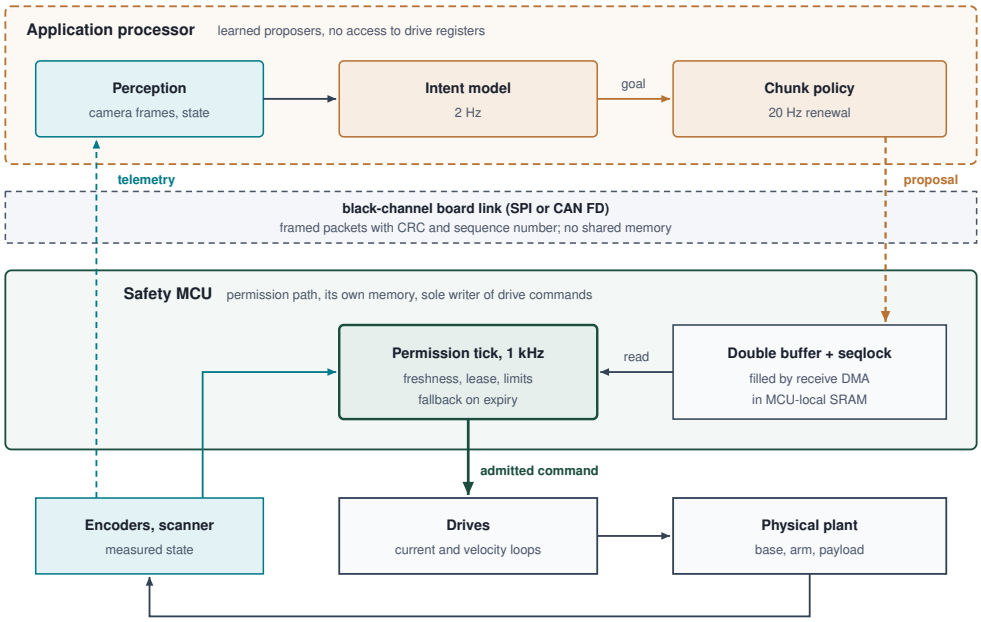

Figure 4.2: The two-processor implementation: The application processor runs the learned proposers and has no access to the drive registers. Proposals cross a black-channel board link as framed packets into a double buffer in the microcontroller's own memory. The receive DMA fills a private receive buffer, and the receive interrupt copies each checked frame into the seqlock-guarded mailbox slot, so the processors share no memory. The permission tick reads the latest proposal, checks it against measured state, freshness, and the lease, and sends only an admitted command to the drives, which close their own current and velocity loops. Measured state returns to the application processor as telemetry over the same link.

IEC 61508 functional-safety standard, accompanied by a safety manual specifying its certified integrity level and the operational conditions that support depends on (International Electrotechnical Commission 2010b). At the silicon level, a safety MCU integrates specialized hardware redundancy to detect internal faults autonomously. Dual processor cores execute in lockstep while a comparator flags divergent execution. Error-correcting codes (ECC) protect internal SRAM and flash memories against single-event upsets. A hardware memory protection unit (MPU) confines each task to its assigned memory range. Analog monitors continuously watch the clock and supply voltages. Built-in self-tests run at power-up and periodically during operation to verify internal logic. An external watchdog timer, clocked by its own oscillator and serviced within a strict time window or through challenge-response messages, monitors the core. Because the watchdog relies on an independent clock source, a physical fault that stops the microcontroller's oscillator cannot stall the watchdog, allowing it to detect that silent processor failure and command a qualified out-of-band response. Successful physical containment still depends on the response path, its surviving power, and the actuator premises.

Two different protections meet at this microcontroller, and keeping them apart explains the standards that follow. The chunk lease protects the stopping budget against a proposer that stalls or misbehaves. The rated claim that the machine will not strike a person rests elsewhere, on the independent protective path of section 1.4.3 (a certified safety scanner wired to the drives, with its own sensing, timing, and power) and on the drives' certified stop functions. Hardware diagnostic features alone do not confer a safety rating on the robot. Under functional safety standards, integrity belongs to a specific safety function, such as revoking actuator authority when a lease expires, rather than to an individual chip. The industrial standard IEC 61508 classifies safety functions by Safety Integrity Level (SIL 1 through SIL 4), where each numerical increment demands approximately an order-of-magnitude reduction in the allowable rate of dangerous failure (International Electrotechnical Commission 2010a). The machinery standard ISO 13849-1 grades safety functions by

Performance Level (PL a through PL e) (International Organization for Standardization 2023a). A Performance Level combines four architectural factors. The structural Category ranges from single-channel architectures using well-tried components (Categories B and 1), through single channels with periodic diagnostic testing (Category 2), to dual-channel redundant designs in which no single hardware fault defeats safety enforcement (Categories 3 and 4). Component reliability is quantified as the mean time to dangerous failure. Diagnostic coverage defines the fraction of dangerous failures detected by internal testing. Physical defenses guard against common-cause failure, where a shared disturbance disables redundant channels simultaneously. The safety microcontroller contributes certified failure rates and diagnostic coverage to this calculation, while the target Performance Level is dictated by the severity and exposure of the physical hazard the safety function must mitigate.

↪ The Performance Level each certified stop and speed function of the running machine must reach is developed in section 12.9.3.

The physical architecture of the robot makes a deliberate engineering trade-off that functional safety certification must evaluate. Its permission path executes real-time performance tasks, validating trajectory proposals and interpolating admitted waypoints into drive setpoints, alongside the safety function intended for qualification: revoking actuator authority and commanding a safe stop when a chunk lease expires or the host heartbeat falls silent. The algorithmic admission checks themselves carry no formal safety rating, which is why the protective claim stays with the scanner and the drive stop circuits (section 12.9.3). Standard functional-safety practice keeps complex control algorithms out of the certified safety channel, relying instead on an independent monitoring channel to satisfy Category 3 and Category 4 redundancy requirements. Modern motor drives supply part of that second channel through integrated hardware safety functions such as Safe Stop 1 (SS1), which brakes the motor under drive control and then removes torque.

↪ How Safe Stop 1 and the other drive safety functions realize the industrial stop categories is developed in section 12.9.2.

Any hardware split must keep the permission path the sole writer of the actuators and bound its check time across all expected hardware and software faults. Putting the two paths on separate chips is the cleanest way to start, though empirical timing evidence under load must still confirm that isolation. Separate processors, however, run on asynchronous clocks at very different rates, so the link between them must pass trajectory updates continuously without ever forcing the fast permission reader to wait on the slower host writer.

4.3 Multi-Rate Cadences

A motor drive cannot wait for the next camera-based proposal before regulating winding current. Conversely, forcing a learned policy to evaluate at current-loop rates wastes compute without generating fresher sensory observations. Decoupling these cadences allows each workload to meet its distinct physical or computational deadline, provided the boundary interface preserves data freshness and never blocks local real-time control.

4.3.1 Physical time constants and sampling phase lag

The mobile manipulator's motor inverters regulate winding current every 50 µs (20 kHz), while its chunk policy requires 40 ms at p99 latency to ingest camera frames and generate an action chunk. No single cadence can serve both the winding's electromagnetic dynamics and the cost of deep visual inference. The four tiers named in section 4.1 therefore each take their rate from a different time constant:

1. **Inner Commutation and Current Loop (20 kHz, 50 µs cycle):** The PWM carrier frequency, selected to balance switching losses, current ripple, and acoustic noise, fixes the sampling instants. Phase currents are sampled once per carrier period at its midpoint, so a 20 kHz carrier yields $T_s = 50$ µs. The stator winding's electrical time constant establishes the plant pole that the current regulator must compensate. For the hub motors, $\tau_e = L_{\text{phase}}/R_{\text{phase}} = 2.7$ ms (section 2.4.2) places that pole near 59 Hz. The closed-loop current bandwidth is tuned well above this pole and at least a factor of ten below the sampling rate, reaching at most about 2 kHz (Franklin et al. 1998). This loop executes directly within drive silicon and commands electromagnetic torque through the motor controller.
2. **Permission and Position-Supervision Tick (1 kHz, 1000 µs $\pm$ 10 µs cycle):** The rate here is set by distance rather than by a plant pole. Each tick of detection delay is base travel the stopping budget must absorb, and each tick must also supply the drives a fresh position setpoint. At one tick per millisecond both demands are met with the margins quantified below, while the drives close the subordinate velocity and current loops.

3. **Action-Chunk Policy Stream (20 Hz, 50 ms cycle):** Bridging observation age and mechanical execution, the local policy emits receding-horizon action chunks ($H = 16$ waypoints spaced 25 ms apart). On this machine, the policy is a compact visuomotor network following the Action Chunking with Transformers (ACT) architecture, which decodes an entire chunk in a single forward pass. Section 3.5.1 priced it against the iterative diffusion and flow-matching heads that trade more passes for expressiveness. Each pass must stream the model's weights from memory on the application processor's accelerator, which caps the pass rate near $f \leq \mathrm{BW}_{\mathrm{mem}}/M_{\mathrm{weights}}$. Because one pass yields all 16 setpoints, that sweep is paid once per chunk rather than once per setpoint, which is what lets the policy renew at this rate.
4. **Multimodal Intent Planner (2 Hz, 500 ms cycle):** A high-capacity VLA model turns camera frames and a natural-language instruction into task goals and navigation targets. Its period is set by the prefill and weight sweeps of section 3.4.1, not by any plant dynamics. It may therefore steer the chunk policy but never hold a chunk lease, the authority to keep driving the actuators that section 4.4 sizes in tens of milliseconds.

The two proposer cadences reflect mainstream action-chunking and VLA architectures as of 2026, and their frequencies will shift as models and accelerators evolve. The method developed below does not depend on them. It anchors the lease's lower limit to what the proposer can supply and its upper limit to the physical stopping budget.

The current-loop rate follows directly from the winding's electrical time constant $L_{\mathrm{phase}}/R_{\mathrm{phase}}$, and the loop closes within the drive's local inverter. The harder timing question arises one level up, at the joint. There, inertia and structural compliance set the required closed-loop bandwidth, and every digital stage between sensor and actuator (sampling, computation, bus transport) exacts a penalty in phase lag. The crossover frequency ω_c marks the point where open-loop gain equals unity. At this frequency, the phase margin[4] defines the maximum additional phase lag the system can absorb before feedback transitions from stabilizing attenuation to self-reinforcing oscillation.

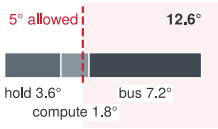
Excess phase lag causes corrective control torques to arrive out of phase with physical joint motion, eventually turning stabilizing negative feedback into unstable positive feedback (Nyquist 1932). Closing a feedback loop across the permission tick accumulates three distinct sources of latency. The discrete sample-and-hold introduces an effective transport delay equal to half the sample period ($T_s/2$). The enforcer requires compute time (T_{comp}) to evaluate constraints. The resulting command then incurs fieldbus transit latency (T_{bus}) before reaching the drive. Because a pure delay T_d removes ωT_d radians of phase across all frequencies, these stages collectively erode the phase margin at crossover according to equation 4.1, the total-delay relation given in section B.5.5:

$$\Delta\phi = \omega_c \left(\frac{T_s}{2} + T_{\mathrm{comp}} + T_{\mathrm{bus}} \right) \tag{4.1}$$

Consider an illustrative joint-loop crossover of 20 Hz and a design phase erosion allowance of 5°. At a 20 Hz crossover, each 1 ms of pure delay along the loop spans that fraction of a full 360° oscillation cycle and costs 7.2° of phase margin. A 1 ms tick's sample-and-hold accounts for 3.6°, which fits comfortably within the budget. However, the 1 ms fieldbus transit cycle contributes 7.2° on its own, and the enforcer's declared worst-case execution time of 250 µs adds another 1.8°. The combined delay of 1.75 ms imposes 12.6° of phase lag, 2.5× the allowance. If the controller delays output release until the subsequent tick boundary, total phase erosion escalates to 18° over 2.5 ms. Because the phase budget tolerates at most 0.69 ms of total delay, less than a single bus cycle, no increase in tick frequency can keep a 20 Hz loop closed across this communication bus within its erosion allowance. The loop might remain stable, but it would spend phase margin the design never allocated to delay. Given 1.75 ms of unavoidable transit and processing latency, a 1 ms tick stays within the chosen phase erosion allowance only at crossover frequencies no greater than 7.9 Hz. Reducing the tick rate to 500 Hz increases the sample-and-hold penalty alone to 7.2°, whereas driving the tick frequency toward infinity still leaves the bus transport penalty untouched. Loop placement, rather than clock scaling, resolves this architectural constraint.

Consequently, the machine closes its high-rate joint velocity and current loops directly within the decentralized motor drives, where co-located encoder sampling bypasses the fieldbus entirely. The centralized 1 ms permission tick operates strictly as a supervisor and trajectory setpoint generator. This decouples the tick from joint-level phase margin constraints, replacing them with two distinct

4 **Phase Margin**: Bode (1945) introduced gain and phase margins to measure how far a feedback amplifier sits from instability, turning the stability criterion of Nyquist (1932) into a practical design margin. In cyber-physical loops, delay erodes the modeled phase reserve and can destabilize the loop under its nominal assumptions. Establishing actual damping and stability requires the complete sampled plant, compensation, and timing response. Because a pure transport or compute delay T_d subtracts $\omega_c T_d$ radians of phase regardless of cause, bus cycles, compute stages, and zero-order holds all draw from the same finite phase budget.



The bus cycle alone spends more phase than the loop can spare.

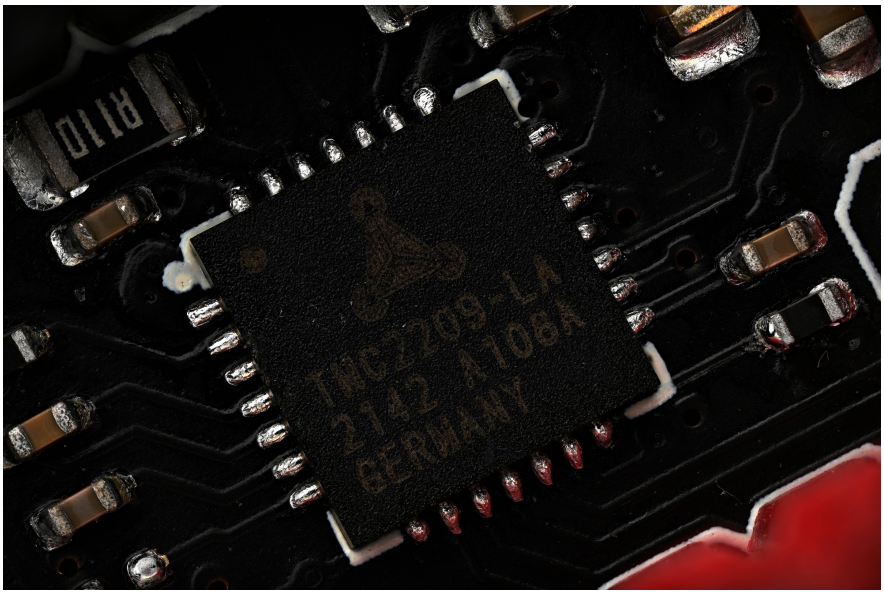


Figure 4.3: Integrated motor-driver silicon: A Trinamic TMC2209 stepper-motor driver in a quad flat no-lead (QFN) package, with a low-value current-sense resistor (marked R110) beside it on the board. The chip carries its own power transistors and current regulation, so the winding current is measured and switched next to the motor it drives rather than by the host processor. A photograph shows the placement; the timing of the current loop is a property of the silicon that the datasheet and measurement must establish. (Credit: Phiarc, Wikimedia Commons, CC BY-SA 4.0.)

systems requirements. First, as a safety supervisor, each millisecond of detection delay incurs 1.5 mm of unbraked base travel at maximum drive velocity, directly consuming clearance from the stopping budget (notebook 4.1). Second, as a setpoint source, the tick must evaluate the admitted trajectory frequently enough to supply smooth kinematic references to the drives. Transport delay along this reference path introduces tracking lag rather than eroding the drive loop's phase margin, because the reference sits outside the feedback loop. Any outer supervisory corrections closed across the bus, such as cartesian compliance trims, must restrict their crossover bandwidth below 7.9 Hz.

Closing those loops in the drive is a hardware arrangement rather than merely a firmware setting. The fastest loop sits beside its sensor and its switch, so phase current is measured and switched next to the winding with no host processor in the loop. Dedicated PWM timers in the same silicon enforce the gap between complementary switch transitions that keeps the power bridge from shorting.[5] The running machine's brushless hub drives follow this arrangement at a larger scale; the small stepper-motor driver of figure 4.3 shows it on one chip.

[5] **Dead-Time Delay**: The interval in which both switches of a half-bridge leg are off, so the leg never shorts the DC bus, is the inverter dead time introduced in section 2.4.2. Dedicated pulse-width modulation timers insert it in hardware (100–500 ns) on every transition, and drive firmware applies online volt-second compensation for the voltage error it introduces.

Perception pipelines feeding the policy stream execute at intermediate cadences constrained by optical physics, sensor exposure durations, and relative scene velocity. In a typical 300 lux warehouse lighting environment requiring a 15 ms exposure, the robot base traveling at its 1.5 m/s drive limit covers $\Delta x = v t_{\text{exp}} = 22.5$ mm while the shutter is open. Resulting image-plane blur interacts with scene depth and optical geometry, setting physical limits on feature tracking. The achievable signal-to-noise ratio, spatial motion blur, and image preprocessing latency jointly establish the feasible sensing cadence for visual control, a trade-off chapter 8 develops. For the permission path the exposure matters as time. An observation is dated at its exposure midpoint, so half the exposure is already part of its age before any processing begins, and that age is the first interval the lease budget must charge (table 4.1).

The chunk-policy generation rate must satisfy the proposal-supply budget set in section 3.5.1. For our mobile manipulator, a 20 Hz renewal cycle paired with an $H = 16$ waypoint horizon (Zhao et al. 2023) bridges visual perception and high-rate actuation. The 50 ms renewal period matches 2 discrete setpoint steps of 25 ms, so every scheduled renewal lands on a setpoint boundary, provided the handoff between the two clocks never makes the faster reader wait.

4.3.2 Lock-free and wait-free mailbox exchanges

If a 1 kHz safety loop blocks on a mutual exclusion lock held by a 20 Hz neural network runtime, one page fault or scheduling hiccup in the runtime becomes an unbounded priority inversion, and the hard real-time controller misses its cycle deadline. Because the tiers run on different processors at different rates, every exchange across a rate boundary must give the faster reader bounded, nonblocking access. Panel (b) of figure 4.4 follows the remedy developed here, the mailbox, through a clean exchange, a write preempted by the tick, and a stalled host, and in none of the three does the reader wait. Panel (a), which shows what the tick does when the proposer stops renewing altogether, returns in section 4.4 once the lease that governs it is defined.

Standard inter-process communication libraries rarely provide deterministic execution bounds out of the box. Message serialization, dynamic memory allocation, intermediate queueing, and thread scheduling can each introduce unpredictable delivery stalls. While shared memory eliminates buffer copying and kernel context switches, it requires concurrency controls to prevent the reader from ingesting partially written, inconsistent command payloads. The communication protocol must strictly bound the consumer's execution time, even when the producer stalls at the most unfavorable point in its write cycle.

While a first-in, first-out (FIFO) queue guarantees sequential message delivery, message ordering is the wrong semantic model for physical motion control. If the control consumer falls behind the rate of production, queued motion plans represent progressively stale physical state estimates. Backpressure, the queue's way of slowing a producer, cannot pause moving mass. The real-time enforcer requires the freshest complete proposal, paired with a strict temporal deadline. This principle does not prevent the controller from buffering the future waypoints of an already admitted trajectory; those waypoints follow an explicit execution schedule governed by a valid lease. Rather, it prevents treating the delayed consumption of historical commands as valid control inputs. Real-time distributed systems distinguish these two communication semantics. An *event message* is queued and consumed exactly once, where dropping a message loses state history. A *state message* represents current environmental state and updates in place, allowing new observations to overwrite older ones without queuing (Kopetz 2011). The proposal mailbox implements state-message semantics via a single-slot seqlock, following the non-blocking write protocol of Kopetz and Reisinger (1993) to ensure mutual independence between writer progress and reader execution.

A baseline nonblocking exchange uses a **single-producer single-consumer (SPSC) seqlock mailbox**[6] in the microcontroller's own static memory. The proposal first crosses the board-level link as a framed packet, which a DMA transfer lands in a private receive buffer. A receive interrupt outside the tick checks the frame's CRC and sequence number and copies the proposal into the mailbox slot. Both participants therefore execute on the microcontroller, the receive interrupt as writer and the permission tick as reader, and the application processor never touches mailbox memory.

The writer increments the sequence counter to an odd value, copies the checked frame into the slot, and increments the counter to an even value using store-release memory ordering. The reader makes exactly one bounded read attempt per control cycle and rejects the snapshot if the counter begins odd or changes before the read finishes. A snapshot that passes becomes the active chunk only after its integrity, freshness, and physical-admissibility checks succeed, and the tick then interpolates it into setpoints (section 4.4.2). A rejected read leaves the previously admitted chunk in force, so the reader never blocks on the writer. Because the timer tick has higher priority than the receive interrupt, a tick that arrives mid-write sees the odd counter and discards the torn read in $\mathcal{O}(1)$ time without spinning. It keeps executing the active chunk for as long as its lease and evidence remain valid. A crashed or stalled application processor cannot leave the counter odd, because it never writes the slot. Its failure appears only as an absence of incoming frames, and the active chunk's lease expires on schedule.

Formally, the reader validates the snapshot using two boundary counter observations:

$$c_{\text{start}} \equiv c_{\text{end}} \equiv 0 \pmod 2 \quad \text{and} \quad c_{\text{start}} = c_{\text{end}},$$

where an odd count signals an active write and a value mismatch signals preemption during the copy. Unlike mutexes or semaphores, this protocol never suspends either participant. Because the reader never retries within a single tick, its computational overhead remains strictly $\mathcal{O}(1)$ regardless of writer activity. Correct execution requires that memory loads occur in strict programmatic

[6] **Versioned Read**: Lamport (1977) showed that a reader can detect a concurrent, overlapping write without acquiring mutual exclusion locks. By incrementing a version counter before and after updating payload data, and having the reader sample the counter in reverse order, any mismatch reliably flags a torn read.

↪ The boundary contract that keeps the application processor out of the microcontroller's mailbox memory is developed in section 13.5.

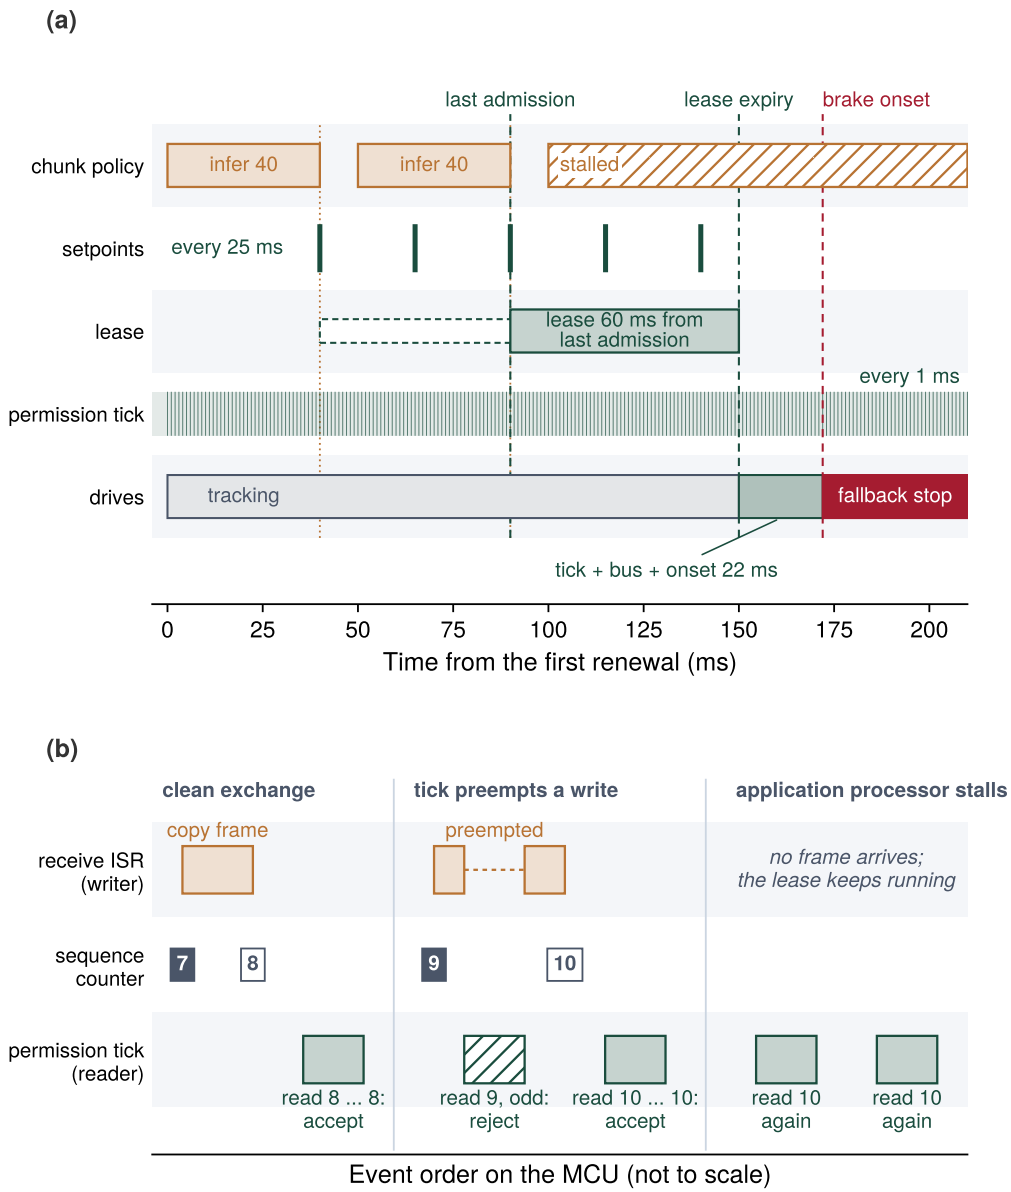

Figure 4.4: Multi-rate cadence and the mailbox exchange: (a) The running machine's clocks during a proposer stall, to scale. The chunk policy renews every 50 ms and needs 40 ms; the admitted chunk supplies a setpoint every 25 ms. When the third renewal never completes, the tick keeps executing the admitted chunk only until the 60 ms lease from the last admission lapses; the tick, bus, and brake onset then put the fallback stop 82 ms after that admission. (b) The single-slot seqlock in the microcontroller's own memory, in event order. The receive interrupt makes the counter odd, copies a checked frame, and makes it even; the tick accepts a copy only when it reads the same even value before and after. A tick that preempts a write reads an odd value and keeps its last validated chunk, and a stalled application processor leaves the slot unchanged while the lease runs.

order. Within a single core arbitrating between an interrupt handler and the periodic tick, compiler optimization barriers prevent instruction reordering. However, when a DMA engine or a second processor core writes the slot directly, hardware memory barriers become mandatory. On Arm Cortex-M profile cores, this requires the full-system data memory barrier instruction (`DMB`) (ARM Limited 2012). Omitting this barrier allows out-of-order execution pipelines to speculatively load

payload fields before validating the sequence counter, silently allowing torn data into the control loop.

A **wait-free three-slot mailbox**[7] can avoid read/write collisions by assigning separate slots to the writer, the published proposal, and the reader. Atomic publication transfers slot ownership; it must never let the writer overwrite the reader's active slot. Unlike the one-attempt seqlock, this design can provide a complete published snapshot without discarding a collided read. Its extra storage and ownership protocol must still be checked on the target hardware. Simpson's four-slot mechanism reaches the same guarantee, a complete snapshot for a reader that never waits, using only single-bit control variables written with ordinary stores and no atomic read-modify-write instruction (Simpson 1990). Neither design makes an old proposal fresh or extends its lease.

Sequential diagnostic telemetry, by contrast, operates under event semantics. A single-producer single-consumer (SPSC) ring buffer preserves an ordered log of events until its bounded capacity fills, whereas the proposal mailbox exposes only the latest complete candidate state. The permission interface relies on these bounded-access guarantees to eliminate wait states; it intentionally discards historical command queues.

No robotics middleware setting can stand in for the chunk lease, because none derives its parameters from the physical stopping budget and none executes on the consumer's own hardware clock at the point of actuation. Middleware can still approximate the mailbox's state-message semantics, and the mapping shows how far configuration goes. In ROS 2, communication relies on the Data Distribution Service (DDS) or equivalent publish-subscribe transports (Macenski et al. 2022), whose Quality-of-Service (QoS) policies reflect real-time contracts only partially (Object Management Group 2015). Configuring a *keep-last* history depth of one provides state-message semantics by retaining only the freshest sample. Selecting *best-effort* reliability drops lost packets rather than triggering retransmissions, avoiding the burst of stale samples that *reliable* delivery releases after network blips. A DDS *deadline* policy raises notification events when sample inter-arrival times exceed a threshold, acting as an alerting heartbeat without enforcing authority revocation. Similarly, a DDS *lifespan* policy purges samples whose age exceeds a configured threshold, but this mechanism relies on synchronized network clocks, defaults to arrival timestamps when synchronization degrades, and controls only message transport rather than granted actuation authority. Callback scheduling within middleware executors also introduces variable dispatch jitter, requiring dedicated response-time analyses across end-to-end processing chains (Casini et al. 2019). At the direct hardware interface, the ros2_control framework implements a nonblocking realtime buffer using a single try-lock attempt. If the writer holds the mutex, the read aborts and the controller retains its prior command (ros2_control Development Team 2025), which mimics the one-attempt semantics of a seqlock. Regardless of middleware abstractions, the physical permission path must independently enforce its own freshness checks and lease bounds.

Because the receive interrupt write routine is brief and resumes immediately after the tick completes, an access collision discards at most one read attempt without delaying the tick. However, if the upstream link halts completely, the mailbox slot remains unchanged across thousands of consecutive ticks. Bounded reader execution time does not guarantee bounded publication latency. The system therefore requires an explicit physical policy governing how long a previously admitted motion chunk may continue commanding actuators. Under the first law, irreversibility (principle 1), every millisecond that a stalled proposal retains actuation authority produces physical displacement that cannot be retracted. That exposure has to be priced against the stopping budget, which makes the length of a proposal's authority the next design decision.

[7] **Wait-Free**: Herlihy (1991) defined an implementation as wait-free when every operation finishes in a bounded number of its own steps, whatever the other processes do. That is stronger than lock-free progress, which guarantees only that some operation completes while a particular one may retry indefinitely. The one-attempt seqlock read is bounded but can come back empty-handed; the slot mailbox is bounded and always returns a complete snapshot, and the extra slot is the price of that second property.

↪ The memory-ordering primitives, cache-line padding, and slot-ownership protocols that implement both exchanges are developed in section C.8.

↪ The inverse failure, middleware that reports healthy delivery while transmitting stale payload data, is developed in section 9.9.

4.4 Chunk Lease Sizing from the Stopping Budget

A learned policy runtime can stall for many reasons: a page fault, thermal throttling on the vision accelerator, memory fragmentation, or an uncaught exception in perception preprocessing. The robot does not stop when its software does. A loaded base keeps its momentum ($p = mv$) and covers 1.5 mm every millisecond at the drive limit, while the downstream controller keeps converting the remaining waypoints of the last admitted chunk into setpoints. To keep an unrenewed chunk from driving the machine into an obstacle, the permission path must end that chunk's authority on its own hardware clock, whether or not the proposer ever reports its failure. How long it should wait before doing so is a question about distance, not software.

Definition 4.2: Chunk lease

Chunk lease is the interval, counted on the permission path's own clock from a chunk's admission, during which that admitted chunk may keep driving the actuators without a successful replacement; when it expires, the permission path ends the chunk's authority and commands the state-matched fallback, a stop profile chosen from the machine's measured speed and pose.

1. **Significance**: The lease enters the pre-brake delay τ_{delay} of the stopping budget, so each millisecond of it costs v of clear distance, 1.5 mm at the running machine's drive limit. The machine's 60 ms lease, with the tick and bus cycle that detect and deliver its expiry, adds 93 mm to the stopping budget (notebook 4.1).
2. **Distinction**: Unlike a heartbeat timeout, which shows only that the host is alive, a lease is renewed only by a freshly admitted proposal. Its length is derived from the plant rather than configured: above the proposer's renewal floor and below the stopping budget's ceiling. Unlike an evidence deadline, it bounds how long one motion segment may execute, not how long the observation behind it stays valid.
3. **Common pitfall**: Lengthening the lease to ride out proposer hiccups. A longer lease buys continuity with clearance, and a lease that reaches the pre-brake ceiling commits the machine to motion it can no longer stop in time.

In classical distributed systems, a lease grants bounded access to a shared digital resource, such as a distributed lock or cache entry, expiring automatically if the leaseholder crashes (Gray and Cheriton 1989). In physical AI, the leased resource is the kinetic authority to move mass through space. Because physical motion cannot be undone, the duration of a lease must be formally derived from the physical stopping budget. The distance covered during the lease, the detection latency, the fieldbus transit, and the brake onset, together with the braking distance itself, must fit within the available clearance D_{clear} after the localization uncertainty and protective margin are subtracted. Rearranging the stopping-distance relation of equation 2.2, $v\,\tau_{\text{delay}} + v^2/2a_{\text{brake}} + \delta_{\text{loc}} + \delta_{\text{margin}} \le D_{\text{clear}}$, and dividing the remaining pre-braking distance by vehicle velocity yields the **pre-brake ceiling**, representing the maximum tolerable delay τ_{delay} before physical braking deceleration must commence:

$$\tau_{\text{delay}} \le \frac{D_{\text{clear}} - \delta_{\text{loc}} - \delta_{\text{margin}} - v^2/2a_{\text{brake}}}{v} \tag{4.2}$$

where v represents operating velocity, a_{brake} denotes verified braking deceleration, and δ_{loc} and δ_{margin} represent the localization uncertainty and safety clearance of that formulation. As operating speed v decreases, the required braking distance shrinks quadratically while the velocity divisor decreases linearly, causing the pre-brake ceiling to expand toward infinity at rest. At maximum operating speed, however, every millisecond allocated to the lease path consumes exactly v units of stopping clearance.

Panel (a) of figure 4.4 draws the lease on the running machine's own clocks. The chunk policy renews twice and then stalls. The tick keeps executing the last admitted chunk only until the lease counted from that admission lapses, and the next tick, one bus cycle, and the brake onset then bring the fallback stop. Notebook 4.1 evaluates equation 4.2 for the mobile manipulator at its drive limit and prices that sequence inside it.

Napkin Math 4.1: The price of a lease

Problem: In the illustrative aisle scenario, the warehouse mobile manipulator cruises at its drive limit toward a person who has stepped out from a rack end and stopped. The permission path admits one last chunk and then receives no admissible replacement. How much time remains before braking must begin, and how much of it, and of the clear distance, does the chunk lease spend?

Variables:

- Speed $v = 1.5$ m/s, the drive limit (illustrative); braking deceleration $a_{\text{brake}} = 2$ m/s², loaded on a dry floor (illustrative).
- Clear distance $D_{\text{clear}} = 1.10$ m (illustrative), less localization error $\delta_{\text{loc}} = 50$ mm (illustrative) and protective clearance $\delta_{\text{margin}} = 100$ mm (chosen).
- Brake onset $T_{\text{act}} = 20$ ms (illustrative); permission tick $T_{\text{tick}} = 1$ ms (chosen); bus cycle $T_{\text{bus}} = 1$ ms (illustrative).
- Chunk lease $T_{\text{lease}} = 60$ ms; renewal period $T_{\text{chunk}} = 50$ ms with a 5 ms variation allowance T_{jitter} (all chosen).

Math: The braking term and the ceiling of equation 4.2:

$$\frac{v^2}{2a_{\text{brake}}} = \frac{(1.5\ \text{m/s})^2}{2 \times 2\ \text{m/s}^2} = 562.5\ \text{mm}$$

$$\tau_{\text{delay}} \leq \frac{1100 - 150 - 562.5\ \text{mm}}{1.5\ \text{m/s}} = 258.3\ \text{ms}$$

The stopping-budget terms that section 2.3 already charged (braking, the localization and clearance overheads, and onset travel $vT_{\text{act}} = 30$ mm) hold 742.5 mm of the clear distance. The lease path, lease plus the tick that notices its expiry plus the bus cycle that delivers the stop, is the next term:

$$v\,(T_{\text{lease}} + T_{\text{tick}} + T_{\text{bus}}) = 1.5\ \text{m/s} \times (60 + 1 + 1)\ \text{ms} = 93\ \text{mm}$$

$$742.5 + 93 = 835.5\ \text{mm}, \quad 1100 - 835.5 = 264.5\ \text{mm}$$

In time, from the last admission to brake onset, and against the ceiling:

$$62 + 20 = 82\ \text{ms}, \quad 258.3 - 82 = 176.3\ \text{ms}$$

Continuous tracking also sets a floor under the lease:

$$T_{\text{chunk}} + T_{\text{jitter}} = 50 + 5 = 55\ \text{ms} < T_{\text{lease}} = 60\ \text{ms}$$

Systems insight: A chunk lease is a term in the stopping budget, not a timeout chosen for convenience. Each millisecond added to it costs 1.5 mm of clear distance at the drive limit, distance that the observation age and the stop profile still need, so the lease sits just above its renewal floor rather than anywhere under the ceiling.

The renewal floor is the lease duration needed to cover the budgeted inter-arrival interval between successful admissions without starving trajectory execution. Because this floor cannot rely solely on the model's 99th-percentile (p99) inference latency, it must accommodate bus transit, validation overhead, and mailbox synchronization jitter. If a renewal fails to arrive before the lease expires, the system terminates trajectory tracking rather than granting an unearned extension. The 176.3 ms remaining under the pre-brake ceiling is not spare margin either. It must still absorb the observation's age at admission, which section 4.9.1 charges against it, and the jerk limits of the braking profile.

Every charge in this budget is an interval between the four boundary events introduced in section 2.2.2. *Capture* dates an observation at its exposure midpoint, *dispatch* hands that evidence to the proposer, *admission* accepts a chunk built on it and starts the chunk's lease, and *brake onset* marks the first physical braking force at the drives. In the worst-case stall scenario, an obstacle enters the path just after *capture* of the camera frame that produces the last healthy chunk, which therefore travels from *capture* through *dispatch* to *admission* without reflecting the hazard. When the subsequent renewal stalls, the robot continues tracking that last admitted chunk from *admission* until its lease expires and *brake onset* engages, chaining all three intervals end to end. Between these four events lie three intervals, each derived in exactly one chapter (table 4.1). Only row 3, the stalled-proposer response, is derived here, from the lease notebook. Rows 1 and 2 enter Part I as allocations: the observation age that section 8.4.1 will build stage by stage, and the dispatch-to-admission interval

that section 13.6.2 will charge to the board link and the validator. Later chapters charge time against these events and this table rather than keeping their own stage lists.

Table 4.1: The capture-to-brake-onset timing budget of the running machine: Four events bound three intervals, and each interval is derived in one chapter. Rows 1 and 3 together form the 133.6 ms pre-brake delay of the stopping budget; row 2 is the allocation that budget must still pay for. Row 2 charges the whole inference after dispatch, although its vision stage already lies in row 1, so the sum is conservative. Every value is an allocation or an illustrative stage time to qualify on the loaded machine, not a measurement.

Interval	Opens at	Closes at	What it contains	Allocation	Derived in
1. Observation age t_{age}	capture	dispatch	Half the exposure, readout, transport, DMA, image signal processing, perception backbone, hand-off to the proposer	51.6 ms	section 8.4.1
2. Dispatch to admission Δ_{da}	dispatch	admission	Proposer inference (charged in full), board link, deserialization, whole-plan validation, activation, wait for the next tick	63.3 ms	section 13.6.2
1 + 2. Replacement latency L_{lat}	capture	admission	Rows 1 and 2; validation is counted once, inside row 2	**114.9 ms**	section 11.3.1
3. Stalled-proposer response	admission	brake onset	Chunk lease, one permission tick, one fieldbus cycle, brake onset	82 ms	section 4.4
1 + 2 + 3. Capture to brake onset	capture	brake onset	All three intervals	**196.9 ms**	section 12.3.1

The table also shows why the stopping budget and the lease rule charge different ages. The stopping budget's pre-brake delay sums rows 1 and 3 and leaves row 2 to be paid from the spare that the elementary budget of section 1.4.3 left. The reason is that row 2's length depends on where the proposer and the permission path run, a decision section 13.6.2 makes. A renewal cannot defer that payment. A replacement chunk spends row 2 before its lease even starts, so the evidence age that the lease rule of section 4.9.1 charges at admission is rows 1 and 2 together.

4.4.1 Supervisory timers and proposal wire contracts

Granting a fresh lease at admission without charging the time the observation already spent in inference and board-link transit lets the drives keep tracking a trajectory whose sensory evidence is already stale. Waiting on a single timeout while a hung policy thread sits inside a live host kernel lets them keep tracking a trajectory whose producer has stopped updating. Evidence keeps aging from capture onward, and admitting a chunk starts its lease on the microcontroller's clock without rolling that age back. Neither the dispatch timestamp nor the newly granted lease accounts for the dispatch-to-admission interval, so the evidence-age check must charge row 2 of table 4.1 explicitly. Authority over an admitted chunk then ends at the earliest of four events: its evidence freshness deadline passes, its lease expires without a successful replacement, the host heartbeat times out, or an independent safety reflex such as the protective scanner path detects an obstacle. None of these waits for the others, and which fires first depends on the scene. At the conveyor, the tracked evidence horizon that section 3.5.2 computed is several times longer than the lease, so there a stalled chunk loses its authority to the lease. The chunk lease bounds how long one admitted motion segment may execute. How long the strategic goal stays meaningful is a separate grant, the intent lease of section 10.8, and neither is the nominal planning horizon.

↩ The freshness deadline that bounds how old evidence may be at actuation is established in section 2.2.

Three independent supervisory timers guard the exchange, and each monitors a distinct failure domain:

1. **The chunk lease ($T_{\text{lease}} = 60$ ms):** Bounds how long an admitted proposal may command actuators. Only a freshly validated, admitted proposal chunk renews the lease. Its duration is derived directly from the physical stopping budget, sitting between the renewal floor and the pre-brake ceiling (notebook 4.1).
2. **The host heartbeat ($f_{\text{heartbeat}} = 100$ Hz, timeout 30 ms):** Asserts that the application processor operating system kernel and user-space runtime remain alive. Expiry of this timeout revokes the active proposal without waiting for the chunk lease. Heartbeat pulses **never renew the**

chunk lease, because a live process can easily suffer algorithmic livelock or produce corrupted, out-of-distribution setpoints.

3. **The microcontroller self-watchdog ($T_{\text{self}} = 5$ ms):** Monitors whether the permission path completes its required checks within the watchdog interval. The permission loop feeds this hardware watchdog only upon successfully completing all verification checks in a tick; a hung enforcer trips the watchdog even if timer interrupts continue firing (section 4.10).

A watchdog refresh confirms only that the specific task servicing the timer is still executing. In *Bookout v. Toyota* (2013), litigation centered on whether a timer-tick interrupt could continue petting a watchdog while application-level control tasks had hung (Barr 2013). Although federal investigations by NASA and NHTSA identified no electronic mechanism capable of causing large unintended accelerations (NASA Engineering and Safety Center 2011), the dispute highlights a real-time principle. Watchdog refresh points must be coupled to the completion of safety-critical algorithmic cycles rather than independent periodic interrupts.

Real-time safety requires wrapping the proposer's payload in a transport and authority envelope. The system enforces chunk leases through the **proposal header**, a structured wire contract that enables the permission path to validate candidate trajectories without placing trust in host application software. The header encapsulates a monotonically increasing sequence number and the evidence timestamp of the source sensory frame (including clock conversion error bounds). It also carries the host dispatch timestamp and the requested lease duration (which the permission path caps at the lease it derives, so a proposer can ask for less authority but never more). A cryptographic parent-record digest supports provenance tracking. The remaining fields are the coordinate frame identifier, the payload type enum, and a 32-bit cyclic redundancy check (CRC-32). For the default payload type the payload consists of H kinematic waypoints specifying joint coordinates and velocities. The payload-type field is where other command forms announce themselves, so an impedance target (section 4.6.1) carries its stiffness and damping gains beside its equilibrium waypoints. In this layered architecture, the learned policy expresses kinematic intent, the permission enforcer converts admitted waypoints into position setpoints, and the drives regulate joint velocity and motor current. The payload deliberately omits raw torque commands; while direct-torque policies require alternate wire representations and specialized admission checks, their outputs remain untrusted proposals. In all cases, an admitted proposal retains execution authority only until the earlier of its lease expiration and its evidence freshness deadline, regardless of whether cancellation packets arrive across the network.

↩ The proposal payload, the candidate motion and the evidence times it carries, is established in section 3.5.4.

Industrial safety networking adopted the same transport safeguards decades before the advent of learned robotic proposers. Functional-safety fieldbus standards such as IEC 61784-3 establish the **black-channel principle**. Transmission media, network controllers, and intermediate switches are treated as untrusted, fallible channels, which requires safety-critical packets to encapsulate self-contained integrity and timing protections verified exclusively at communication endpoints (International Electrotechnical Commission 2021). Fieldbus profiles like PROFIsafe and Safety over EtherCAT (FSoE) exemplify this architecture. FSoE protects frames against corruption using CRCs, against repetition and packet loss using sequence counters, against misrouting using unique connection identifiers, and against transit delay using watchdog timers. Missing or delayed frames force the receiver into a deterministic safe state (EtherCAT Technology Group 2019). The proposal header mirrors this design field for field: checksums guard integrity, sequence numbers detect drops, payload identifiers ensure proper dispatch, and the chunk lease replaces the watchdog timer. The physical link between host application processor and safety microcontroller operates as an untrusted black channel; end-to-end header checks allow the permission path to enforce its declared physical admission contract without trusting host operating system integrity. Classical real-time theory provides the complementary semantic foundation. Kopetz defines a computing system's internal representation of a dynamic physical entity as a *real-time image*, which remains *temporally accurate* only during a bounded physical duration following the initial observation (Kopetz 2011). The proposal's evidence deadline represents this temporal accuracy window applied to sensory inputs, while the chunk lease bounds the duration of derived actuation. This architecture adds one thing to these precedents, the grounding of temporal validity. Whereas industrial fieldbuses configure watchdog timeouts empirically and real-time images reflect passive plant dynamics, the

chunk lease is derived analytically from the physical stopping budget above and the proposer's renewal floor below (equation 4.2, notebook 4.1).

↪ **Byte layout:** The proposal header's and chunk payload's fields, types, and offsets are given in section C.15.1.

Every record crossing the proposal boundary expresses temporal quantities referenced to the safety microcontroller's monotonic clock. Upstream producers operating on independent oscillator domains map timestamps using a versioned affine transformation and transmit explicit synchronization error bounds, which the safety consumer adds to all age evaluations. Wall-clock calendar time is restricted to diagnostic logging and software release expiration; it never enters real-time safety gating.

Individual boundary records guard against three orthogonal failure modes through three distinct mechanisms, only two of them cryptographic. A checksum across the header and payload, a CRC rather than a cryptographic function, detects transmission bit flips and memory corruption during transit, leaving origin authentication unaddressed. Similarly, a cryptographic digest of the parent record establishes computational lineage without authenticating the sender. Cryptographic message authentication codes (MACs) appear exclusively where sender identity conveys explicit operational authority: network teleoperation commands, immutable authority audit logs, and release artifacts verified during deployment. Learned model proposals omit cryptographic signatures entirely, because the permission enforcer validates candidates based on physical admissibility and temporal freshness rather than origin. A cryptographic key stored inside an untrusted host environment provides no assurance of kinematic safety.

↪ How a teleoperation command's authentication tag is verified and priced against the fallback deadline is developed in section 14.5.

The reader's possible failures fall into four classes (table 4.2), and none of them lets a failed producer make the permission path wait. The classes keep the exchange from blocking. They do not by themselves contain the plant, because the fallback each one selects still needs bounded timing and a validated stop. Even a valid admitted chunk still has to be stepped from the proposer's coarse waypoint spacing down to the permission tick's rate.

Table 4.2: Boundary contract failure classes and deterministic fallback matrix: Exchange faults across the proposal boundary by class, with the fallback each selects. Fallback paths are selected without waiting on host recovery.

Failure Class	Reader Detection Condition	Physical Systems Fallback Action	Bounded Response
Torn / In-Flight	Odd c_{start} or changed c_{end}	Reject current snapshot; use admissible prior chunk or fallback	One bounded attempt; measure duration
Malformed	Checksum or configured command bound fails	Reject candidate; retain admissible active chunk or use fallback	Measure check and response
Stale	Past proposal expiry or evidence deadline (local clock)	Reject stale candidate; end active authority if its own deadline passed	Deadline from plant budget
Missing	Sequence gap	Record audit gap; evaluate current record on its own merits	One tick for flag

4.4.2 Rate interpolation and boundary fallback execution

Holding each admitted waypoint constant for its full 25 ms spacing until the next waypoint arrives injects staircase position steps into the drives rather than a smooth trajectory, delaying reference tracking by half the step spacing on average and exciting high-frequency structural resonances. Bridging the learned policy's renewal rate (20 Hz) and the real-time permission tick (1 ms) without those disturbances requires guarding against three sampled-data failure modes: reference lag, spectral aliasing, and buffer starvation. Because the zero-order hold's latency sits entirely on the feedforward reference path outside the feedback loop, it appears as tracking error rather than eroding feedback phase margins (section 4.3.1). Confusing reference lag with closed-loop phase lag often leads engineers to misdiagnose tracking errors as plant instability. To eliminate discrete steps across chunk boundaries, the permission enforcer constructs a quintic Hermite spline bridge matching boundary position, velocity, and acceleration. These six boundary constraints guarantee C^2 continuity across chunk transitions, meaning position, velocity, and acceleration all stay continuous. Evaluating this admitted spline at 1 kHz yields continuous position references, smooth velocity feeds, and feedforward acceleration profiles for the underlying joint controllers.

↩ Action chunking, which produces the trajectory segments this interpolator densifies, is established in section 3.5.1.

Spectral aliasing occurs when unmodeled high-frequency mechanical vibration or sensor noise, sampled too slowly, reappears as a false low-frequency signal in the slower streams that estimators and the tick consume. The architecture mitigates aliasing through front-end analog filtering followed by multi-rate digital decimation,[8] low-pass filtering a fast sample stream before keeping only one sample in several, within the high-rate microcontroller domain. Classical sampled-data control models assume constant, deterministic sampling periods. Temporal jitter, a sampling interval that varies from cycle to cycle, degrades phase margin more severely than a constant delay of equivalent mean duration (Cervin et al. 2003). Discrete trajectory execution also assumes setpoints replenish continuously before downstream buffers drain. The permission path enforces these invariants via cycle-deterministic hardware timer interrupts and real-time buffer-depth accounting. If the upstream planner stalls and the trajectory buffer reaches its terminal waypoint, the enforcer rejects stale extrapolation and commands a validated local stopping profile.

An overrun costs something different at each of the four tiers:

- **Current loop (20 kHz):** Its jitter allowance is below $10\,\mu s$ (table 4.3). A timing overrun, gate-drive desynchronization, or current spike trips a hardware fault line that disables the inverter's PWM stages.
- **Permission tick (1 kHz):** A deadline overrun by the enforcer software sends the machine to the local deceleration stop.
- **Chunk policy (20 Hz):** Inference latency is stochastic (40 ms at p99), so some chunks arrive late. A late chunk costs nothing until the active chunk's lease or evidence deadline runs out, and the enforcer never waits on the proposer's optimistic estimate of when it will finish. When either deadline passes, the enforcer commands the state-matched fallback.
- **Intent planner (2 Hz):** Its goals expire under a separate *intent lease*, a longer grant of authority over the goal itself rather than over any motion (developed in section 10.8). When it lapses, the system holds station instead of chasing a stale goal.

The lease notebook charged the tick and the bus cycle as fixed terms, 1 ms and 1 ms, as though each were certain to finish on time. That premise is the next thing to establish. It requires a worst-case response bound for every stage between the mailbox and the drives, and no benchmark or faster processor substitutes for one.

4.5 Real-Time Command Transport and Bus Determinism

A profiling campaign can run the permission tick for days without a missed deadline and still not establish the tick's worst case. An empirical percentile says how often sampled executions stayed under a threshold. It says nothing about executions that meet a combination of competing tasks, memory contention, or peripheral delay the campaign never produced. The lease budget needs the other kind of number: a response-time bound that accounts for every unit of permitted computation and queuing delay along the critical path under defined operating conditions. In an embodied system, timing determinism protects both stability and safety, because delayed feedback erodes the controller's phase margin and delayed actuation consumes stopping clearance before the chassis can decelerate. Bounding the tick on the microcontroller comes first; bounding the drive network that carries its admitted setpoints to the motors follows the same logic (Kopetz 2011).

4.5.1 Response time analysis and execution variance

A permission tick whose own instructions finish in 250 µs can still miss its 400 µs deadline if a lower-priority link driver masks interrupts while re-arming a DMA descriptor or a burst of higher-priority timer interrupts preempts the tick mid-cycle. Response Time Analysis (RTA) bounds a task's total response time by summing the three constituents introduced in section 4.2: execution time, blocking delay, and preemption interference (Joseph and Pandya 1986; Audsley et al. 1993). To guarantee schedulability, each term requires an analytical upper bound under specified operating conditions:

$$R_i = C_i + B_i + I_i \leq D_i \tag{4.3}$$

where C_i is the worst-case execution time (WCET) of task i, B_i is the maximum blocking time spent waiting for lower-priority tasks to vacate shared critical sections, I_i is the maximum interference

8 **Filter Group Delay**: Digital smoothing filters commonly applied in machine learning pipelines introduce significant phase lag when placed inside feedback control loops. An N-tap moving-average finite impulse response (FIR) filter imposes an average group delay of $(N-1)/2$ sample intervals. Consequently, a 9-tap moving average operating at the 1 ms permission tick delays feedback signals by 4 ms. At the illustrative 20 Hz crossover frequency from section 4.3.1, this delay burns 28.8° of phase, 5.8× the design allowance. In real-time control paths, decimation and filter topologies must be selected for minimal phase lag rather than cosmetic smoothing.

from preempting higher-priority tasks, timer interrupts, and DMA transfers, and D_i is the relative deadline.

Each term demands distinct evidentiary backing. Formal static timing analysis against an accurate cycle-level processor model can establish a bound on the WCET C_i. High-watermark profiling under stress-bench conditions instead characterizes observed execution times; it can refute a declared WCET but cannot establish one. The blocking term B_i represents the longest critical section of any lower-priority task that can lock a shared resource required by task i. The priority ceiling protocol establishes a provable bound on B_i. In this protocol, each synchronization lock carries a priority ceiling equal to the highest priority of any task that may acquire it. A task may acquire a lock only if its priority strictly exceeds the priority ceilings of all locks currently held by other tasks. Furthermore, any lock holder that blocks a higher-priority task temporarily inherits that task's elevated priority. Under these constraints, a task is blocked by at most a single lower-priority critical section across its entire execution (Sha et al. 1990). An immediate priority ceiling protocol (IPCP), which instantly elevates a lock holder to the resource ceiling upon acquisition, guarantees the same blocking bound with lower runtime overhead. When a real-time task avoids shared software mutexes altogether through lock-free data structures, the blocking term B_i reduces to the longest interval during which lower-priority driver code masks processor interrupts or holds a non-preemptible hardware peripheral transaction. Finally, the interference term I_i aggregates the execution time of all higher-priority tasks and interrupt service routines released during the response window. Because a longer response time provides a wider window for higher-priority tasks to re-trigger, calculating I_i requires solving a fixed-point recurrence relation. Section C.3 details this formulation. Equation 4.3 defines the overarching budget that the recurrence resolves, and notebook 4.2 evaluates that budget for the permission tick.

Napkin Math 4.2: The response-time margin

Problem: The permission tick must finish within its deadline after every release. With its declared WCET and illustrative bounds on blocking and interference, does it meet the deadline, and what happens to the margin when one term loses its bound?

Variables:

- Declared WCET $C_i = 250$ µs and deadline $D_i = 400$ µs (both chosen).
- Blocking $B_i = 50$ µs, the longest section in which lower-priority code masks the tick, such as the link driver re-arming its DMA descriptor (illustrative). The mailbox adds nothing to B_i, because the seqlock never makes the tick wait for the receive interrupt.
- Interference $I_i = 40$ µs, the timer and bus interrupts that can preempt the tick within one response window (illustrative).

Math:

$$R_i = C_i + B_i + I_i = 250 + 50 + 40 = 340\ \mu\text{s} \le D_i = 400\ \mu\text{s}, \quad D_i - R_i = 60\ \mu\text{s}$$

Systems insight: The margin is only as dependable as its weakest constituent bound. For instance, moving the mailbox copy into a low-priority task guarded by a standard mutex without priority inheritance or priority ceilings leaves B_i completely unbounded, because medium-priority work can preempt the lock holder indefinitely. This is the Mars Pathfinder pathology of war story 4.1. Similarly, permitting unscheduled DMA traffic on the tick's memory path destroys the upper bound on I_i. If even a single term loses its bound, the tick lacks a defensible worst-case response time, leaving the stopping budget's T_{tick} parameter with no engineering foundation.

↪ How host memory traffic would inflate the permission tick's interference if both paths shared one die is developed in section 13.3.

Neither a low average latency nor a modest processor utilization can substitute for that analytical bound,[9] because a single missed deadline degrades the machine across multiple architectural layers. When a deadline slips, distributed motor drives must hold their previous position setpoint for an entire additional bus cycle. Consequently, the actuator setpoint lags by a full period (1 ms) rather than the conventional half-period delay associated with a zero-order hold. Repeated deadline

[9] **Rate-Monotonic Scheduling**: Liu and Layland (1973) established that static-priority rate-monotonic scheduling guarantees periodic task schedulability when total processor utilization satisfies $U \le n(2^{1/n} - 1)$, converging to $\ln(2) \approx 0.693$ for large n. The utilization bound is sufficient, not necessary, so a task set that exceeds it may still meet every deadline; with shared-resource blocking and deadlines shorter than periods, only the exact response-time test of section C.3 decides.

misses manifest as timing jitter, which Cervin et al. (2003) analyze as a direct erosion of phase margin in digital feedback loops closed through the tick. Within the safety subsystem, a delayed tick evaluates an expired lease or safety violation late; at the drive velocity limit, each 1 ms delay incurs an irreversible loss of 1.5 mm in physical stopping clearance.

Bounding these response terms requires categorizing every potential source of timing variability according to whether an analytical bound exists:

1. **Bounded Sources:** Hardware mechanisms that admit analytical upper bounds from vendor architectural specifications. Examples include deterministic instruction pipelines, round-robin interconnect arbitration, zero-wait-state tightly coupled memory (TCM/SRAM), and deterministic vectored interrupt controllers on real-time microcontrollers.
2. **Experimentally Characterized Sources:** Microarchitectural behaviors that cannot be proved strictly from first principles but can be enveloped empirically under frozen hardware configurations. Examples include bounded cache-line misses under hardware cache partitioning, write-buffer draining latencies, periodic DRAM auto-refresh pauses, and thermal throttling profiles stabilized by closed-loop active cooling.
3. **Unbounded Sources:** Software and hardware mechanisms that have no finite mathematical worst-case bound and must be purged from the real-time critical path. Examples include operating-system page faults under demand paging, preemptive thread synchronization lacking priority inheritance, dynamic heap allocation over fragmented memory pools, and unscheduled peripheral bus contention.

A credible timing guarantee must therefore explicitly enumerate all permissible operations along the execution path. The hardware partitioning and core isolation strategies from section 4.2 eliminate broad classes of timing interference. A **zero-allocation static architecture** pre-allocates all buffers and queues at boot time to eliminate memory-management overhead. Neither strategy can eliminate contention for shared memory buses. Response-time analysis must account for every remaining shared-resource transaction, because a high task priority alone never guarantees real-time execution, as the Mars Pathfinder resets showed.

War Story 4.1: The Mars Pathfinder priority inversion (1997)

Context: In July 1997, shortly after landing on Mars, the Mars Pathfinder spacecraft's avionics computer ran the VxWorks real-time operating system with preemptive priority-based scheduling across mission tasks (Reeves 1997).

Mechanism: A high-priority thread (`bc_dist`) distributed critical spacecraft bus telemetry, while a low-priority thread (`ASI/MET`) published meteorological sensor observations through a shared pipe. The mutex serializing access to this pipe was not explicitly declared in mission application code; rather, it was embedded deep within the operating system's `select()` implementation to protect internal file-descriptor queues (Reeves 1997). When `ASI/MET` acquired this internal mutex, long-running medium-priority communications tasks preempted it. Because these medium-priority tasks outranked the meteorological thread, they starved it of CPU cycles, preventing it from releasing the mutex while `bc_dist` remained blocked, an unbounded priority inversion.

Impact: The blocked `bc_dist` thread missed its execution deadline. When the supervisory `bc_sched` watchdog initiated the subsequent bus cycle and detected that `bc_dist` had not completed, it flagged a critical timing fault and commanded a total system reset. Although telemetry collected prior to the reset survived in non-volatile storage, the resets recurred repeatedly during operational surface maneuvers.

Response: NASA engineers diagnosed the pathology on an identical ground testbed using VxWorks execution tracing, subsequently uploading an inflight software patch that enabled priority inheritance (Sha et al. 1990) on the underlying mutex semaphore.

Systems lesson: Preempting a low-priority lock holder with medium-priority work blocks high-priority consumers indefinitely. Priority inheritance resolves this vulnerability by temporarily elevating the lock holder's priority to match that of the blocked high-priority task, allowing it

to complete its critical section promptly. In robotic actuator and motor-control paths, engineers must either rigorously bound blocking duration (B_i) using priority inheritance protocols or eliminate shared locks altogether through lock-free communication structures.

4.5.2 Event-triggered and time-triggered bus architectures

Once the permission tick finishes its check on the microcontroller, the admitted setpoint still has to cross a shared physical wire to reach the motor drives, where the same blocking and interference questions reappear. If a high-priority servo command arrives at a shared bus just after a lower-priority diagnostic frame has started transmitting, the command cannot preempt the bits already on the wire and must wait for the frame to finish. Physical buses handle shared medium access in one of two ways. On an event-triggered bus, nodes transmit whenever new data is ready and resolve collisions through dynamic bus arbitration. On a time-triggered bus, a fixed global schedule assigns dedicated transmission windows to each node in advance. Neither design guarantees bounded delivery by its name alone; establishing a worst-case bound requires pricing payload sizes, competing traffic, error-recovery overhead, and device controller delays.

The Controller Area Network (CAN) and its CAN FD variant resolve message collisions via bitwise priority arbitration. While a high-priority frame preempts lower-priority traffic competing for an idle bus, it must wait for any frame already in transmission to finish. Switching to CAN FD accelerates payload serialization by elevating the data-phase bitrate, yet it retains the rule that an in-progress frame cannot be preempted. The blocking duration depends on the longest eligible frame at its nominal and data-phase rates. A valid worst-case response budget must therefore combine both the frame's own transmission time and the maximum duration of a lower-priority transmission already in progress.

EtherCAT adopts an on-the-fly time-triggered model: an Ethernet coordinator issues a single master frame that traverses all connected motor drives in a physical ring. Dedicated hardware controllers in each drive read incoming setpoints and write sensor feedback directly into designated bit offsets as the Ethernet frame streams through the physical layer. This architecture eliminates arbitration contention across the motor drives, while distributed clock synchronization synchronizes local PWM switching cycles. Time-Sensitive Networking (TSN) achieves comparable determinism over switched Ethernet through IEEE 802.1Qbv time-aware traffic shapers. A TSN delivery guarantee relies on synchronized network gates, bounded clock skew, and strict admission controls that gate best-effort traffic.

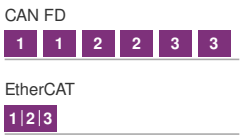
For an integrated mobile manipulator, the core architectural question is whether cyclic actuator commands and feedback fit within the allocated bus period while preserving sufficient margin for MCU control loop execution and motor drive processing. High-bandwidth perception streams (such as camera and LiDAR data) and asynchronous supervisory middleware require separate networks or prioritized channels to prevent unmodeled queuing delays from invading the motor command path. Industrial controllers build that separation into the hardware (figure 4.5), with ports that serve only the deterministic drive network and local I/O attached through terminals on the controller itself rather than through host software. The running machine does not use this controller; the photograph shows the pattern its own permission path follows.

Clock synchronization aligns the sampling and actuation instants across distributed drives;[10] however, phase alignment reveals nothing about the transport latency required for a newly computed setpoint to traverse the physical bus. Even if every drive clock fires simultaneously, the actuators will merely execute stale commands if transit delays stall delivery. A sound design therefore requires independent bounds for both command transport latency and multi-axis synchronization jitter, starting with whether the serialized frames fit inside the cycle at all.

4.5.3 Comparing bus occupancy on CAN FD and EtherCAT

If all nine servo axes of the mobile manipulator share a single CAN FD bus, arbitration headers and worst-case bit stuffing push the command and feedback frames alone past the 1 ms bus cycle, before any controller delay or bus contention is counted. To keep each link within its cycle budget, communication links on the mobile manipulator separate into three tiers by rate and scope:

↪ The protocol engines and analytical response-time models of concrete fieldbus deployments are developed in section C.11.



CAN FD arbitrates a separate frame per message; EtherCAT carries every drive in one frame.

[10] **Distributed Clock**: EtherCAT Distributed Clocks (DC) synchronize distributed drive nodes to a reference clock by measuring propagation delays around the ring. Receive-time latches at each node let the coordinator discipline every node's timer, so the hardware `SYNC0` events that start the drives' update cycles occur in close alignment. Clock alignment alone does not bound the complete control cycle, which must also account for controller response time and PWM gate update latency.

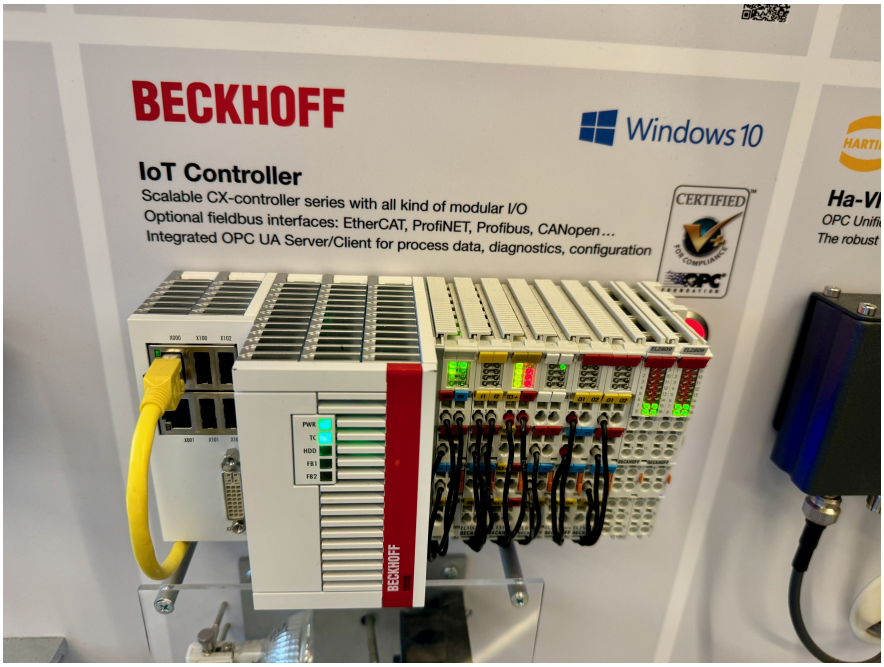


Figure 4.5: Real-time distributed controller with modular I/O: Dedicated embedded real-time controller and adjacent hardware I/O modules. The unit acts as a deterministic bus coordinator, synchronizing distributed sensor acquisition and motor drive terminals via hardware-scheduled Ethernet telegrams. (Credit: Oleg Yunakov, Wikimedia Commons, CC BY-SA 4.0.)

1. **Board-Level Peripheral Interconnects (SPI, Memory-Mapped I/O):** Synchronous SPI links and memory-mapped register transfers link local microcontrollers directly to joint position encoders, current-shunt analog-to-digital converters (ADCs), and inverter gate drivers with sub-microsecond latency ($< 1\,\mu s$) along rigid, hardware-timed schedules.
2. **Deterministic Drive Command Buses (EtherCAT, TSN Ethernet):** Deterministic industrial networks transport cyclic joint position setpoints and motor feedback across all distributed drive inverters within an allocated 1 ms bus cycle (T_{bus}), maintaining sub-microsecond synchronization jitter ($\sigma_{\text{jitter}} < 100$ ns).
3. **Chassis and Auxiliary Diagnostic Buses (CAN FD):** Priority-arbitrated buses service lower-rate peripherals, such as battery management systems (BMS), thermal monitors, and chassis diagnostics, where arbitration delays remain acceptable under verified worst-case utilization bounds.

None of these bounds belongs to a protocol acronym alone. Each guarantee depends on the physical network topology, transceiver hardware, payload geometries, and cyclic schedules. The first check is whether every servo axis can exchange its command and feedback payloads within the permission path's allocated bus cycle budget.

Napkin Math 4.3: Fieldbus serialization before schedulability

Problem: The mobile manipulator's permission path exchanges position setpoints and feedback with its servo axes once per bus cycle. How much of that cycle do CAN FD frames, or one EtherCAT frame, occupy before controller and device delays are counted, and which buses pass this necessary check?

Variables:

- 9 servo axes, 7 arm joints and 2 drive wheels (datasheet), exchanged every 1 ms bus cycle (illustrative).

- An 8-byte record per axis in each direction, a 32-bit position and two 16-bit words (chosen).
- CAN FD at 1 Mbps nominal and 5 Mbps in the data phase (chosen). A CAN frame carries one message, so each axis needs a command frame and a feedback frame. The arbitration field and the trailer run at the nominal rate, 34 bits; the data-length code, payload, stuff count, and 17-bit CRC run at the data rate, 113 bits (International Organization for Standardization 2015a; Robert Bosch GmbH 2012). Both counts include the worst-case 21 dynamic stuff bits, because a bound must assume the bit pattern that lengthens the frame most.
- EtherCAT at 100 Mbps (datasheet), one frame carrying every axis's command and feedback with a 64-byte header, and a forwarding delay of 0.6 µs per node, the shift-register pass-through of a slave controller that never buffers the frame (both illustrative).

Math: One CAN FD frame, then all frames on one bus and on an arm bus:

$$t_{\text{frame}} = \frac{34\ \text{bits}}{1\ \text{Mbps}} + \frac{113\ \text{bits}}{5\ \text{Mbps}} = 34 + 22.6 = 56.6\ \mu\text{s}$$

$$18 \times 56.6 = 1018.8\ \mu\text{s} > 1000\ \mu\text{s}, \qquad 14 \times 56.6 = 792.4\ \mu\text{s}$$

The base's 4 frames take 226.4 µs. For EtherCAT, serialization plus forwarding:

$$\frac{(64 + 9 \times 16)\ \text{B} \times 8}{100\ \text{Mbps}} + 9 \times 0.6\ \mu\text{s} = 16.64 + 5.4 = 22.04\ \mu\text{s}$$

Result: One CAN FD bus fills 101.9 percent of the cycle on serialization alone. A bus per limb passes, the arm bus at 79.2 percent with 207.6 µs left for blocking, competing frames, and retransmissions. EtherCAT occupies 2.2 percent and leaves 978.0 µs unallocated by this calculation.

Systems insight: CAN FD's accelerated data phase cannot salvage a single shared bus topology. Every transmitted frame still incurs arbitration and trailer bit times at the lower nominal rate, and CAN requires distinct command and feedback frames for each joint axis. EtherCAT, in contrast, aggregates all axes into a single circulating telegram processed on the fly. Neither occupancy figure represents an end-to-end response bound. A rigorous CAN FD analysis must incorporate message arbitration, non-preemptive blocking, and retransmissions, whereas an EtherCAT budget must include coordinator cycle jitter, slave hardware propagation, and drive firmware latencies. Any unmodeled delay that creeps into the physical command path consumes stopping clearance at a rate of $v\,\Delta t_{\text{bus}}$.

4.5.4 Bandwidth, response time, and multi-axis synchronization jitter

A network link with plenty of raw bandwidth can still deliver a joint setpoint late if frames queue behind camera traffic. A bus that delivers setpoints quickly on average can still twist a coordinated multi-joint motion if the drives apply their updates at slightly different instants. Analyzing serialization occupancy separates three metrics that industrial datasheets often conflate: raw bandwidth, command response time, and multi-axis synchronization jitter. Bandwidth governs the total payload volume the link can carry per unit time. Command response time measures the complete latency, including queueing, arbitration, transmission, and drive input decoding, before an actuator applies a setpoint. Synchronization jitter bounds the time spread across multi-axis updates. A network design can improve any one of these metrics while leaving the others unconstrained.

Set against the cycle, the notebook's occupancies separate into one failure and three passes (figure 4.6). Only the single shared CAN FD bus fails, needing 1018.8 µs before any contention or retransmission is counted. The per-limb buses (792.4 µs for the arm) and EtherCAT (22.0 µs) leave room for controller execution and clock synchronization. Staying within the cycle budget provides neither a synchronization-jitter bound nor a complete response bound. A defensible CAN FD analysis requires upper bounds on asynchronous message interference and non-preemptive blocking. An EtherCAT path demands explicit master cycle jitter, slave hardware propagation, and

drive firmware latencies. A TSN schedule requires reserved transmission windows and bounded clock-synchronization errors.[11] These factors are required inputs to the response-time equation, not inherent guarantees achieved by selecting a protocol standard.

Actuator commands also demand strict temporal freshness. Even when delivered comfortably within a deterministic transport window, a setpoint computed from stale perception is functionally hazardous. The evidence timestamp and lease expiry embedded in the command proposal remain safeguards even over nanosecond-synchronized fieldbuses. The transport budget must reserve adequate headroom for physical actuation to execute, and the real-time permission path must reject any setpoint whose authoritative validity window has expired.

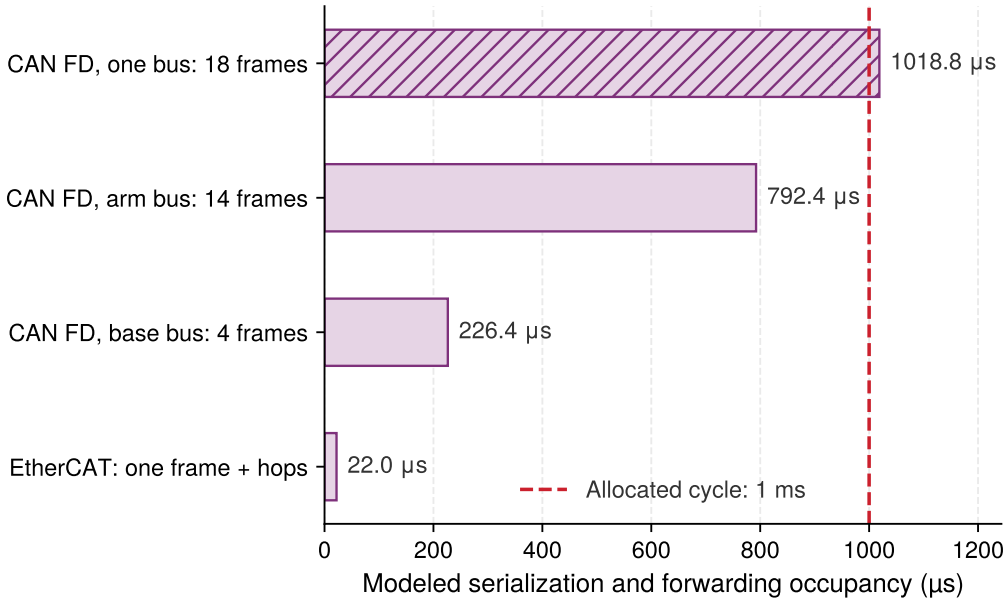

Figure 4.6: Scenario bus occupancy before response qualification: Modeled serialization and forwarding terms for the configured servo-axis example, command and feedback included, compared with the allocated bus cycle. One CAN FD bus for all axes exceeds the allocation before other delays are counted. A CAN FD bus per limb and EtherCAT leave unallocated time, but controller response, competing traffic, device delays, and fault allowances still need qualification. These calculated values are not measured end-to-end response or synchronization bounds.

Checkpoint 4.1: Response bounds and command transport

The lease budget counts the permission tick and the bus cycle as bounded terms. These items test whether you can supply the bounds it assumes.

- ☐ **Percentile vs. bound**: Can you explain why a measured p99 response time, however long the test that produced it, may enter the handoff record only as a measured distribution and never as a proven bound?
- ☐ **Response-time estimate**: If the longest tick-masking section in the link driver grew from 50 µs to 120 µs, with the tick's WCET and interference unchanged, would the tick still meet its 400 µs deadline, and by how much would it pass or miss?
- ☐ **Bus occupancy estimate**: With one command frame and one feedback frame per axis at 56.6 µs each, how many axes can one CAN FD bus serve within a 1 ms cycle before any blocking is counted?
- ☐ **Synchronization vs. latency**: Can you explain why tightly synchronized drive clocks do not bound how long a newly issued command takes to reach the drives?

[11] **Time-Sensitive Networking**: IEEE 802.1Qbv Time-Sensitive Networking provides bounded Ethernet delivery by configuring time-aware traffic shapers across network switches. High-priority control frames travel inside dedicated, pre-scheduled transmission windows, while asynchronous high-bandwidth traffic (such as uncompressed camera streams) is held back at the switch gates. This scheduled time-division multiplexing lets camera streams and microsecond servo commands share a physical link without packet collisions or switch-queue buildup.

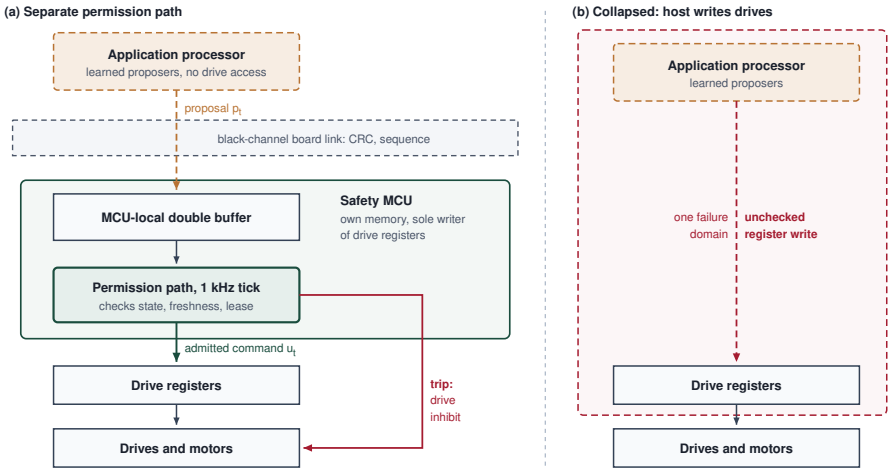

Figure 4.7: Hardware proposal boundary: (a) The application processor proposes across a black-channel board link into the safety microcontroller's own double buffer; the permission path on that microcontroller is the sole writer of the drive registers and can trip a drive inhibit. (b) When the application processor can write the drive registers directly, an unchecked write reaches the motors, and proposer and drives share a single failure domain.

A fieldbus path qualified under declared traffic and fault conditions bounds command delivery within its allocated cycle, but on-time delivery says nothing about whether the command should have been sent. That depends on which node may issue setpoints at all, and on whether each setpoint is checked against the machine's physical limits before it leaves.

4.6 Actuation Authority

A shared mailbox cannot protect a mobile manipulator if the host processor retains a diagnostic route, an auxiliary bus master, or a JTAG debug port that writes directly to a drive. The silicon partition established in section 4.2 therefore requires exclusive physical control over every electrical path capable of energizing the motor windings. Actuation authority is this exclusive physical ability to modify drive states, encompassing PWM configuration registers, current references, gate-driver outputs, and bridge-enable lines. Under this architecture, the host publishes candidate proposals p_t and the safety microcontroller's permission path alone turns them into admitted commands u_t. The difference between holding that authority and merely appearing to is a question of wiring (figure 4.7). When the permission path is the sole writer of the drive registers and can trip a drive inhibit, every motion passes its checks. When the host can also write those registers, one unchecked write reaches the motors, and proposer and drives share a single failure domain.

The microcontroller continuously evaluates physical safety invariants: verifying that commanded joint positions lie within certified reach envelopes, that joint velocities stay within qualified limits, and that projected decelerations remain safely within dynamic stopping clearance ($d_{\text{stop}} \leq D_{\text{clear}}$). When a proposal satisfies all invariants, the microcontroller admits the command and interpolates waypoints into cyclic position setpoints for each bus cycle, which the drives track through their internal velocity and current loops. When a candidate proposal violates an invariant or expires, the enforcer refuses it ($\perp$). A refusal does not automatically revoke a previously admitted, actively executing trajectory chunk. Instead, the active chunk continues running as long as its state, sensor evidence, and chunk lease remain valid. When those conditions lapse or fail, the enforcer terminates execution authority and transitions the system into a controlled deceleration or hold. In parallel, a separate hardware trip zone stands ready to cut motor drive torque upon catastrophic electrical faults, though de-energizing an inverter does not by itself brake moving mass.[12]

At the causal boundary the root cause of an aberrant proposal does not matter. A remote memory exploit in a host operating system daemon, an adversarial optical perturbation that induces a vision model hallucination, and an arithmetic overflow in an acceleration tensor engine can all produce invalid proposals for the same boundary filter to reject. A proposal that passes the physical checks

↪ How exclusive authority over each actuator channel passes between the learned policy, an operator, and the fallback is developed in section 14.3.2.

12 **Hardware Trip Zone**: Microcontroller hardware trip zones couple analog overcurrent and overvoltage comparators directly to timer output logic. Upon fault detection, configured trip logic may force gate signals high-impedance or activate a validated braking mode. These have different mechanical consequences: torque removal can leave the plant coasting, while dynamic braking requires a rated energy path.

↪ The refusal authority and the state invariants it checks are developed in section 12.6.

may still pursue the wrong task, so admission does not establish semantic correctness. Because the enforcer evaluates physical invariant bounds against direct sensor feedback from optical encoders and current shunts rather than inspecting internal neural network weights, it requires no internal model of why the proposer failed. Because the host lacks bus-master privileges to actuator registers, a compromised host has no bypass around this check. Complete protection against a rogue host nonetheless requires four physical foundations: independent sensing, an accurate kinematic and dynamic limit model, sufficient actuator capability, and a physically feasible fallback trajectory.

Controlled stopping and torque removal impose different engineering obligations. Powered braking actively uses the drive inverters to decelerate the plant to zero velocity before disabling torque. Immediate torque removal, by contrast, de-energizes the motor windings instantly, which can leave a wheeled base coasting uncontrollably or allow a vertically loaded manipulator arm to collapse under gravity. Maintaining a held position requires either continuous motor torque or a certified mechanical restraint. At the actuation authority interface, the systems designer must explicitly designate the physical fallback response and reserve both the execution time and thermal energy budget that it demands.

↩ The causal boundary, where a command becomes current in a winding and mass begins to move, is established in section 1.4.1.

A refusal that leaves no admissible active continuation carries an unavoidable physical cost. When the enforcer rejects an invalid proposal and commands dynamic braking on a fast-moving joint, the physical braking path must supply sufficient torque, clearance, and thermal dissipation capacity to arrest the moving mass. Over an arrest interval spanning several hundred milliseconds, the motor winding resistance, dynamic brake chopper resistor, or friction brake lining must absorb the joint's accumulated kinetic energy within the thermal limits detailed in section 2.5. This dissipation must occur without degrading winding insulation or permitting the manipulator to breach its physical clearance boundary.

If the safety microcontroller itself hangs or suffers a clock failure, it cannot execute a software-directed stop. A hardwired, out-of-band interlock must therefore supervise the system and enforce a qualified fallback state. Safe Torque Off (STO) accomplishes this by disabling gate-driver optocouplers or charge pumps through hardware logic, preventing the inverter from generating rotating magnetic fields.[13] STO does not isolate the high-voltage DC bus from the mains, nor does it guarantee that momentum will dissipate within the stopping clearance allocated for powered deceleration. Complete electrical isolation requires an upstream safety contactor, and containing gravitational drop or mechanical drift requires a certified electromechanical brake. A dual-channel interlock circuit (the relay network of figure 4.8) decouples torque inhibition entirely from the host software stack. Safety qualification must still verify that the system remains resilient against common-cause failures in power rails, clock crystals, and harness wiring.

↪ The stopping-distance model this braking path must satisfy is developed in section C.13.

In figure 4.8, dual positive-break E-stop contacts (S_1, S_2) drive independent force-guided relays (K_1, K_2), which route dual STO enable signals into the motor drive. Series-wired normally closed external device monitoring (EDM) contacts prevent system restart if either relay fails to open. At the bottom, a dedicated brake supply drops a spring-applied mechanical brake directly onto the motor shaft upon power loss, enforcing torque removal ($\tau_{\text{motor}} = 0$) and holding restraint without software or processor intervention. However, engineers must not confuse a static holding brake with a dynamic stopping brake. Under normal operational sequences, the drive decelerates the motor to zero velocity electrically before engaging the spring brake to hold position. Dropping a holding brake onto a spinning shaft during a high-speed emergency stop subjects the brake pads and hub to severe friction heating and mechanical shock, requiring independent thermal rating and stopping-distance validation. The stop-category selections and timing sequences depend directly on these electromechanical limits.

[13] **Safe Torque Off (STO)**: An STO implementation removes torque-producing drive signals through a hardware interlock. An IEC 61800-5-2 integrity rating depends on the actual devices, diagnostic coverage, wiring, and validation, not on the circuit pattern alone (International Electrotechnical Commission 2016b).

> Systems Perspective 4.1: Hardware authority invariant
>
> If an unverified learned policy has direct memory-mapped write access to actuator gate-driver registers, the machine has no mediated proposal path, and its next out-of-distribution input reaches the motors unchecked.

Write privilege is a physical reality dictated by memory mapping, bus arbitration, and physical trace layout, never a configurable software flag. The host processor holds no write privilege to drive

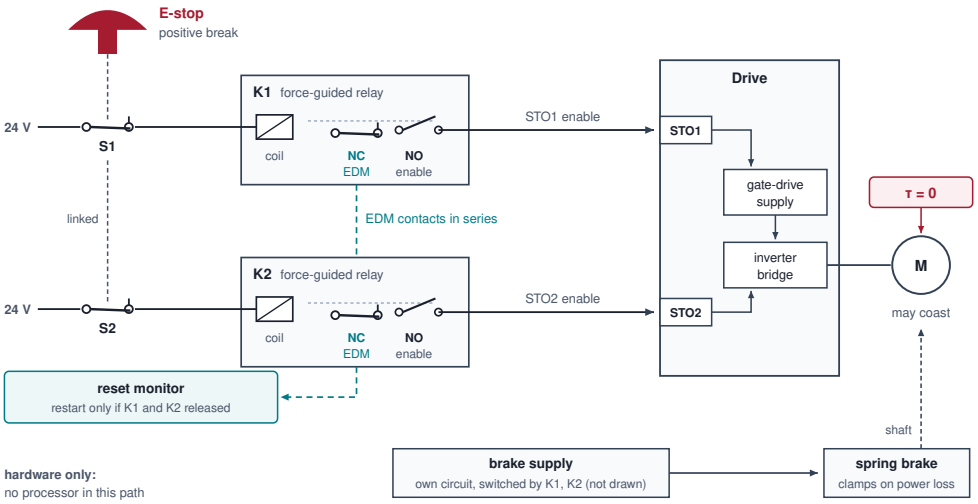

Figure 4.8: Illustrative out-of-band interlock and STO path: Each emergency-stop contact holds its own force-guided relay, and each relay's enable contact holds one of the drive's two STO inputs, so a single welded contact or shorted wire leaves the other channel able to remove torque. The EDM contacts report a relay that failed to release before restart. Removing torque leaves the motor free to coast; the spring-applied brake is a separate circuit that clamps when its supply is removed. The diagram shows a hardware response path, not a certified integrity level or a stopping distance (synthesized from ISO 13849-1 and IEC 61800-5-2).

registers. While hardware partitioning determines which processor may issue physical commands to an actuator, the engineer must still decide what physical quantity those admitted commands specify, because each choice leaves a different set of failure modes for the permission path to catch.

4.6.1 What a proposal may command

A digital motor drive accepts setpoints across a nested cascade of control loops: position, velocity, and winding current, with current running innermost at the highest bandwidth. Sending raw current targets directly to the drive bypasses its position and velocity loops and leaves the permission path to predict how gravity, inertia, and external contact will move the joint. Sending pure position targets lets the drive bound its own speed and current, at the cost of ramping winding current against an unmodeled obstacle until the inverter saturates or the mechanism breaks. The level at which a proposal enters this cascade therefore decides which physical states the drive hardware regulates on its own and which quantities the permission path must verify before admitting the command. Four command interfaces dominate physical AI systems, each placing a different prediction and checking burden on the enforcer.

A *position target* q_{des} delegates the entire trajectory tracking problem to the drive's internal cascaded loops. Because the drive firmware enforces its own configured speed and current limits, the enforcer's verification burden remains relatively compact. It validates that the target lies within the geometric reach envelope, bounds the discrete step between consecutive targets (which position gains convert directly into velocity and torque demands), and ensures adequate dynamic stopping clearance. However, a pure position target cannot modulate interaction force. When encountering an unmodeled rigid obstacle, a stiff proportional-integral position loop interprets physical contact as a tracking error to be eliminated, ramping winding current until the inverter saturates or the mechanical structure breaks. The impedance-control analysis in section 2.4.4 quantified this exact failure mode on a cage-door latch.

A *velocity target* $\dot{q}_{\text{des}}$ shifts kinematic integration to the host proposer, bypassing the drive's position loop. Because the proposal omits an explicit geometric endpoint, the enforcer cannot simply validate a target coordinate against static workspace limits. Instead, the enforcer forward-integrates the commanded velocity over the duration of the active chunk lease to predict the joint's worst-case

state at lease expiration. It then checks both the reach envelope and the dynamic stopping distance against this forward projection. As with pure position control, contact force remains unregulated, and unmodeled collisions will produce maximum drive torque.

A *torque target* τ_{des}, delivered as a direct current reference, bypasses both outer loops. The drive regulates only electromagnetic winding current. Consequently, all kinematic state evolution, including velocity, position, and braking distance, becomes an emergent consequence of plant dynamics, gravity, and external contact forces rather than an enforced setpoint. The enforcer must bound the resulting state evolution and preserve a feasible fallback, using a plant model or effort-space constraints, while constraining torque slew rates and tracking the cumulative mechanical energy injected into the system. Torque control offers maximum responsiveness for dynamic locomotion and manipulation, but it imposes the heaviest computational burden on the permission path while providing the least explicit intent.

An *impedance target* specifies a virtual equilibrium pose alongside stiffness gains K_p and damping gains K_d, so the actuator behaves as a virtual spring-damper (Hogan 1985), the same model introduced in section 2.4.4:

$$F = K_p(x_{\text{des}} - x) + K_d(\dot{x}_{\text{des}} - \dot{x})$$

Its dynamic dual, an *admittance target*, measures external contact force via load cells and commands motion in response. Both formulations explicitly regulate the dynamic relationship between motion and force, a coupling that position, velocity, and torque interfaces leave unconstrained. This capability makes impedance and admittance formulations standard in contact-rich manipulation tasks. The enforcer's verification role expands accordingly: it must evaluate both the equilibrium setpoint and the commanded stiffness gains. Under quasi-static contact, the maximum contact force is bounded by the product of the commanded stiffness and the largest displacement the environment can impose. Consequently, a stiffness parameter that exceeds the structural limits of the workpiece or fixture is just as inadmissible as a trajectory crossing a workspace wall. However, steady-state gains do not govern transient impact forces, which depend heavily on approach velocity, rotor inertia, structural compliance, and control-loop latency. Section 12.7.2 establishes the energy and contact-force barriers needed to bound these transient impact phases.

On the reference mobile manipulator, the enforcer admits position waypoints, interpolating them into fine setpoints for each bus cycle while the motor drives close their own internal velocity and current loops. When the manipulator engages the sprung latch of an equipment cage door, the host switches to an impedance command, introducing stiffness and damping parameters that the real-time tick must validate before transmission. No command interface eliminates the verification burden of the permission path: shifting the command interface inward, from position setpoints toward raw current references, strips away explicit geometric intent and forces the safety layer to predict complex electrodynamic behavior. Write privilege and command filtering protect the physical plant only if the enforcer also maintains physical independence from the host whose proposals it evaluates. If the safety microcontroller and the host application processor share a power rail, a common system clock, or a unified memory bus, a failure in the host can brown out the microcontroller, corrupt its timing, or deadlock the bus. Any of these silences the safety layer without issuing a single illegal drive command.

4.7 Hardware Isolation and Fault Containment

A large current transient during a neural accelerator burst can pull down a shared power rail and brown out or reset the permission processor without warning, while memory bus contention on a shared interconnect can delay safety checks past the hard real-time execution tick. Even when safety enforcement executes on a dedicated processor, physical coupling to the proposal engine can silently undermine software isolation. Containing faults across the two paths therefore requires isolating or bounding shared physical resources across four domains: execution hardware, reference oscillators, power distribution rails, and memory hierarchies.[14] Where any of those resources remain shared, the architecture must demonstrate that cross-domain interference and declared common-cause faults cannot prevent the permission path from meeting its execution deadline or initiating its qualified fallback.

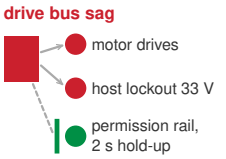
The running machine's two-processor architecture addresses each of these four fault paths with an explicit hardware design choice. The permission path executes from private memory over a

[14] **Freedom from Interference (FFI)**: ISO 26262 defines FFI in its vocabulary, Part 1, as the absence of cascading failures between two or more elements that could lead to the violation of a safety requirement (International Organization for Standardization 2018). Part 6 lists the software interference it covers (timing and execution, memory, and exchange of information), whereas shared power, clocks, and heat are common-cause and cascading faults that Part 9 treats in its dependent-failure analysis and that IEC 61508 addresses as independence between elements (International Electrotechnical Commission 2010b). A neural policy sharing silicon with the permission path therefore needs both arguments, FFI for its software and a dependent-failure analysis for the resources underneath.

dedicated board-level link, clocks from an independent oscillator, and draws power from the isolated rail specified in section 2.8.2 rather than from the primary 47.7 V drive bus feeding the application processor. Diode-isolated storage capacitors hold up this safety rail for 2 s. If a transient load fault pulls the drive bus down to the host converter's undervoltage lockout threshold at 33 V, the safety microcontroller stays powered long enough to capture the undervoltage interrupt, log the event, and command a graceful fallback while the primary host resets. This holds only if the required detector, actuator power, and braking path survive the fault.

Keeping the logic powered does not guarantee motor torque or braking capability. Bringing a moving machine to a controlled stop requires sufficient DC bus energy, healthy inverter stages, and adequate obstacle clearance. If electrical drive power collapses entirely, the system must execute a qualified unpowered fallback whose mechanical brake engagement delay and subsequent stopping motion fit within the pre-allocated physical envelope. These isolation guarantees are design assertions that must be empirically verified on physical hardware. Every shared dependency must be carried forward into the formal verification handoff record.

↪ The four substrate couplings that board layout must sever, and the fault-injection experiments that test their isolation, are developed in section 13.2.



A sag on the shared bus reaches every load; the permission rail rides through on its own.

Substrate isolation ensures that the permission path stays alive when the host crashes, but the enforcer's downstream action depends entirely on how the proposer failed: through unresponsiveness or through corruption. Unresponsiveness occurs when an inference pipeline deadlocks, thread scheduling misses a deadline, or kernel memory fragmentation stalls process execution, yielding no new trajectory packets. A complete host crash trips the hardware heartbeat timer. Conversely, the host operating system might remain healthy while the user-space neural policy pipeline hangs; in that scenario, the proposer stops emitting admissible action chunks, allowing the active chunk's lease or evidence deadline to lapse. These complementary deadlines form the supervisory timing hierarchy established in section 4.4.1.

Corruption occurs when the proposer continues running and satisfies its heartbeat deadline, but outputs invalid or hazardous setpoints. Examples include kinematically unreachable joint configurations, step discontinuities in velocity requests, or floating-point NaNs and infinities caused by out-of-distribution visual tokens or matrix overflow. The enforcer handles these two failure profiles through orthogonal mechanisms: unresponsiveness triggers trajectory revocation as soon as the chunk lease or the heartbeat timer expires, whereas corruption prompts an immediate invariant rejection at the boundary filter upon the arrival of the malformed packet. A live heartbeat therefore never extends motion authority; only an admitted chunk renews it, and authority ends when the chunk lease runs out. Whether the chunk policy can renew quickly enough to keep the machine moving, and why the slower intent model supplies goals rather than holding chunk leases itself, is the coupled budget of section 4.9.1.

When active motion authority lapses without an admissible continuation, the permission path must execute an explicit degradation strategy rather than cutting motor bus power unconditionally. As detailed in section 2.6.2, de-energizing an inverter drops the actuators into uncontrolled freewheeling or dynamic short-circuit braking, neither of which produces an orderly, predictable stop. Instead, the safety path evaluates the plant's instantaneous kinematic state and selects the safest feasible deceleration profile. An optional brief continuation along the last validated trajectory is permissible only while its state estimates, sensor evidence validity, chunk lease window, and obstacle clearance margins all remain valid.

Once that lease expires, any separately authorized fallback delay T_{hold} is absorbed into the total reaction latency τ_{delay}. It must fit, together with the evidence age, within the 176.3 ms left under the pre-brake ceiling once the lease path and brake onset are charged at the drive limit (notebook 4.1). If measured latency bounds exceed this headroom, the enforcer must initiate deceleration sooner. Controlled braking uses the available actuator torque characterized in section 2.4 to arrest motion within the remaining clearance. On gravity-loaded manipulators, motion arrest must be backed by engaging rated mechanical holding brakes once the joints reach standstill, preventing gravitational backdriving when drive power is subsequently removed.

After the physical plant comes to a complete halt, the architecture executes a **recovery handshake** before restoring autonomous proposal authority. The safety microcontroller asserts a persistent `FAULT_HELD` latch in its exported status register and publishes the plant's confirmed physical rest pose $(\mathbf{q}_{\text{rest}}, \dot{\mathbf{q}} = \mathbf{0})$. In turn, the application processor must discard all pending action chunks,

invalidate internal state tied to the interrupted motion, capture fresh sensor observations tagged with synchronized hardware timestamps, and formulate a newly aligned trajectory proposal.

This recovery sequence must also purge any proposal-side state that assumes the robot executed its planned trajectory to completion. For autoregressive policies and VLA models, this requires flushing token buffers and the key-value (KV) attention cache; retaining pre-fault keys and values would bias future action generation toward a physical trajectory that was interrupted. However, clearing software caches does not by itself establish physical continuity. Before deasserting the `FAULT_HELD` latch and restoring proposal authority, the safety microcontroller inspects the opening waypoint $\mathbf{a}_0$ of the incoming proposal, verifying that it aligns with the robot's measured physical rest pose within a strict spatial bound ($||\mathbf{a}_0 - \mathbf{q}_{\text{rest}}|| \leq \epsilon_{\text{sync}}$).

Architectural independence cannot simply be read off a schematic or block diagram; it must be empirically validated against identified common-cause faults on the physical board. Similarly, the chunk lease that constrains a malfunctioning proposer derives directly from physical dynamics, sized from the stopping margin that remains after detection delays and actuator responses. Together, these defenses bound a proposer that crashes, stalls, or publishes corrupted actions. The separation leaves one question open, whether a neural policy engineered to execute deterministically at the enforcer's own update rate still requires an external runtime monitor.

↪ The fault injection that tests this independence on the physical board is developed in section 15.8.

4.8 Invariant Checking

A proposer fast enough to keep pace with the permission tick invites a shortcut. Learned locomotion controllers already emit joint targets within an order of magnitude of a millisecond, and a designer may be tempted to let such a policy write the motor registers directly. Rate does not confer authority. A fast network emitting joint targets or torques carries the same statistical uncertainty as a large model generating waypoints a few times a second. Even when policy and enforcer share one period, the network's output remains a proposal that must pass the proposal boundary before it changes current in a winding. What the permission path can still guarantee when a learned policy commands at control rate, and what it gives up, is examined in section 12.8.1.

The interface must reject an inadmissible candidate without waiting for the producer, and recheck the active command against current physical state. Position and velocity limits ($\mathbf{q} \in [\mathbf{q}_{\min}, \mathbf{q}_{\max}]$ and $|\dot{\mathbf{q}}| \leq \dot{\mathbf{q}}_{\max}$) are necessary but do not by themselves establish a feasible stop. A torque-slew constraint, $|\dot{\tau}| = |(\tau_k - \tau_{k-1})/\Delta t| \leq \dot{\tau}_{\max}$, can limit command changes, but a command that meets the slew limit must still satisfy the other physical limits. Contact may additionally require accounting for exchanged energy, $\int \tau^\top \dot{\mathbf{q}}\, dt$.

↪ The passivity framework that accounts for energy exchanged in contact is developed in section B.10.

Choosing and composing those filters is the work of chapter 12, which constructs the admissibility calculation and selects a feasible continuation, hold, or stop. What the Nervous System fixes is the execution contract those filters must run under, whatever they compute. On the running machine the contract has numbers. The recheck of the active command must finish inside the tick's 400 μs deadline under the response bound of equation 4.3. It must read measured wheel and joint encoder state rather than commanded setpoints (the fallacy of section 4.10 shows what the commanded setpoints miss). It must also leave the safety microcontroller the only writer of the drive registers. Neither fast inference nor a fast rejection routine establishes that contract on its own.

The same reasoning covers the one proposer that is not learned. A remote operator is a third proposer. Its commands pass the same permission path, and network delay spends the same pre-brake budget. Neither speed nor a human origin gives a proposal authority; only passing the permission path's checks does, and each check spends part of a budget that the next section lays out handoff by handoff.

↪ How an operator's reaction and link delays are charged against the stopping budget is developed in section 14.2.2.

> Checkpoint 4.2: Hardware isolation and invariant checking
>
> Before turning to the handoffs between proposer and actuator, verify your understanding of the exchange, hardware isolation, and pre-actuation invariant defenses:
>
> - ☐ **Nonblocking exchange**: Can you explain how the seqlock reader detects a torn read in one bounded attempt, and why a writer stopped mid-write cannot extend the active spline's state, evidence, or lease validity?

- ☐ **Independence as a hypothesis**: Can you state the independence requirement the permission path must meet, and explain why the two-processor split satisfies it only once loaded tests on the machine's silicon support the claim?
- ☐ **Chunk lease cost**: Can you explain why the chunk lease must be sized from stopping distance and clearance rather than chosen as a software timeout, why a heartbeat never renews it, and how much clear distance lengthening it from 60 ms to 100 ms would spend at the 1.5 m/s drive limit?
- ☐ **Command interface**: Can you state what the permission path must check or predict for a position, a velocity, a torque, and an impedance target, and why a velocity target leaves it to predict motion over the whole lease?
- ☐ **Rate matching and authority**: Can you explain why a policy that runs at the plant's own rate still produces only proposals, and what timing, state, and fallback obligations remain?

4.9 The Handoffs Matrix

When a mobile manipulator overruns a stop, the diagnosis begins by locating the fault at one of five canonical handoffs between the photons collected by its cameras and the current delivered to its drives. A cloud service governs its interfaces with statistical service-level objectives (SLOs), such as a p99 request latency; when a tail event violates that target, the runtime absorbs the delay through retries, request rerouting, or graceful degradation. The five handoffs of an embodied machine define **hard cyber-physical service-level objectives** instead. Software cannot recall physical momentum or undo resistive heating in an actuator winding, so no retry mechanism can mask an unbudgeted interface violation.

Upstream, sensing hardware transfers raw transducer signals to perception pipelines. Perception yields intermediate geometric and semantic representations that fuse into an estimated world state. This state feeds the learned policy to produce an action plan, which in turn submits candidate trajectories to the safety enforcer. Finally, the approved command passes from the enforcer to the physical motor drives. Across each boundary, five interface limits govern feasibility: latency (L_{lat}), bandwidth (BW), energy and heat (P_{heat}), determinism (σ_{jitter}), and fault domain isolation ($\mathcal{F}$). The five handoffs and five interface limits form a five-by-five matrix mapping every signal path to the physical budgets of the machine. These interface limits are distinct from the body's five mechanical budgets, which enter the matrix primarily through its latency and energy columns. The contract that records these budgets, the handoff record defined below, joins the physical limit records of section 2.7.3 to the proposer limits of the Brain. Latency, renewal rate, and evidence age are therefore written in one schema.

↩ The body's five mechanical budgets are established in section 2.1.

The allocation in table 4.3 illustrates which limits are design-limiting at each handoff, using chosen design budgets rather than empirical measurements. The matrix gathers the physical budgets of the machine's mechanical, cognitive, and sensory systems, together with the sensor capture that the five-level machine model places at the Boundary. In the Boundary row ($\mathcal{H}_1$), where the physical world becomes digital measurement, bandwidth and latency bind first: raw multi-camera pixel streams saturate the serializer-deserializer (SerDes) lanes, and the exposure window imposes a strict floor on image age before serialization even begins. The Brain rows ($\mathcal{H}_2$, $\mathcal{H}_3$) bind first on energy and latency, reflecting the heavy inference costs of the learned proposers. The Body row ($\mathcal{H}_5$) binds first on determinism and heat, because the drives' current loops must hold their timing jitter below $10\,\mu$s, and every ampere delivered dissipates heat across the windings and power inverter stages.

The Nervous System row ($\mathcal{H}_4$) forms the architectural bridge coupling the Brain and the Body. The proposal boundary between the learned planner and the enforcer carries an action proposal (p_t), typically structured as a compact spline parameterization or waypoint chunk. For the compact payload assumed in this grid, the required throughput is modest (BW < 100 kB/s), so bandwidth does not bind; instead, latency, determinism (σ_{jitter}), and fault domain isolation ($\mathcal{F}$) govern the interface. The permission path isolates stochastic model proposals using nonblocking mailboxes and expiring leases. On the mobile manipulator, the latency limit is the chunk lease, which consumes 60 ms of the 258.3 ms pre-brake ceiling available at the drive limit (section 4.4), while the active

command is rechecked within each 1 ms permission tick. Full trajectory admission has a separate computation and response budget and must complete before any candidate chunk activates; the tick interval does not imply that arbitrary occupancy queries or whole-trajectory collision checks fit within that brief slice. Fault isolation relies on a private peripheral bus, an independent oscillator, and the isolated, held-up power rail detailed in section 4.7.

From the causal boundary perspective, any interface failure localizes to the specific handoff and budget it violates. Semantic mistakes or flawed physical assumptions can still escape an otherwise timely interface; the matrix does not substitute for task-level evaluation or hazard analysis. When diagnosing an over-budget stop, trajectory overrun, or subsystem fault, engineers navigate table 4.3 through a three-step operational root-cause procedure:

1. *Locate the boundary seam:* Identify which physical handoff ($\mathcal{H}_1$–$\mathcal{H}_5$) recorded the initial timing excursion, sequence gap, torn payload, or thermal trip.
2. *Check the binding dimension:* Query the specific physical limit ($L_{\text{lat}}, \text{BW}, P_{\text{heat}}, \sigma_{\text{jitter}}, \mathcal{F}$) designated as *BINDING* for that handoff cell, identifying the primary resource bottleneck governing the interface.
3. *Evaluate like-for-like evidence:* Compare runtime diagnostic traces directly against the recorded bound kind (`requirement`, `proven bound`, or `measured distribution`), verifying whether the failure stemmed from an unmodeled microarchitectural tail event or a direct physical budget violation.

A handoff diagnosis must strictly compare like evidence. For the $\mathcal{H}_2$ state-estimation path, suppose engineers allocate a 30.0 ms latency budget and measure p99 $= 24.5$ ms during a baseline hardware-in-the-loop run, yielding a sampled margin of $+5.5$ ms. Under thermal throttling, a subsequent run measuring p99 $= 85.0$ ms reveals a -55.0 ms deficit against that design budget. The appropriate remedy is to reduce or reallocate computational workload while preserving independent safety enforcement during revalidation. A sampled p99 latency diagnoses a performance regression; it does not constitute a worst-case timing proof.

DRAFT

Table 4.3: Handoffs-by-limits synthesis grid: A five-by-five matrix mapping five canonical signal handoffs ($\mathcal{H}_1$–$\mathcal{H}_5$) across the Boundary (section 1.7), Brain (chapter 3), Body (chapter 2), and Nervous System (chapter 4) against five physical limits ($L_{\text{lat}}, \text{BW}, P_{\text{heat}}, \sigma_{\text{jitter}}, \mathcal{F}$). Cells marked *BINDING* are the budgets that drive selection; *Non-binding* means the scenario budget meets that dimension with margin. These illustrative allocations organize the timing and isolation evidence still required; a non-binding cell is not a qualification verdict.

Canonical Handoff Boundary	Latency Limit (L_{lat})	Bandwidth Limit (BW)	Energy & Heat Limit (P_{heat})	Determinism Limit (σ_{jitter})	Fault Domain Isolation ($\mathcal{F}$)
$\mathcal{H}_1$: **Sensing** → **Perception** *(Boundary)*	**BINDING** $L_{\text{lat}} \leq 16.7$ ms, one frame period (sensor age dated at the frame's middle row; the oldest row is older, section 8.8)	**BINDING** BW ≥ 1.2 GB/s (multi-camera 4K uncompressed streams)	*Non-binding* $P_{\text{heat}} < 3$ W (sensor head dissipation isolated)	**BINDING** $\sigma_{\text{jitter}} \leq 1.0$ ms (frame-sync triggers prevent skew)	*Non-binding* Defended by SerDes hardware & DMA ring buffers
$\mathcal{H}_2$: **Perception** → **State** *(Brain)*	**BINDING** $L_{\text{lat}} \leq 30.0$ ms (camera and inertial motion estimate & feature window)	*Non-binding* BW ≈ 10–50 MB/s (compressed image features & 3D occupancy cells)	**BINDING** $P_{\text{heat}} \approx$ 15–35 W (edge vision backbone accelerator envelope)	*Non-binding* Defended by sliding-window state estimator buffers	**BINDING** Spatial memory isolation: MPUs prevent memory corruption
$\mathcal{H}_3$: **State** → **Plan** *(Brain)*	**BINDING** chunk policy 40 ms p99 inside its 50 ms renewal period (section 3.5.2); autoregressive intent model 336 ms inside its 500 ms period (section 3.4)	*Non-binding* BW < 5 MB/s (low-dimensional state & prompt embeddings)	**BINDING** $P_{\text{heat}} \approx$ 30–75 W (transformer/diffusion matrix accelerators)	*Non-binding* Defended by receding-horizon chunking & spline buffers	**BINDING** Host faults must not halt the independent permission path

Canonical Handoff Boundary	Latency Limit (L_{lat})	Bandwidth Limit (BW)	Energy & Heat Limit (P_{heat})	Determinism Limit (σ_{jitter})	Fault Domain Isolation ($\mathcal{F}$)
$\mathcal{H}_4$: **Plan** → **Enforcer** *(Nervous System)*	**BINDING** chunk lease 60 ms (candidate allocation; age at admission from table 4.1); active-command checks within each 1 ms tick; full admission budget recorded separately	*Non-binding* Defended by compact parameterized splines (BW $<$ 100 kB/s)	*Non-binding* $P_{\text{heat}} < 0.5$ W (fixed-point constraint evaluation on MCU)	**BINDING** $\sigma_{\text{jitter}} \leq 100\,\mu$s (cycle-deterministic packet reception on MCU)	**BINDING** Hardware boundary: private bus, separate oscillator, isolated held-up rail
$\mathcal{H}_5$: **Enforcer** → **Actuator** *(Body)*	**BINDING** $L_{\text{lat}} \leq 1$ ms (servo interval 1 ms; current loop 50 µs)	*Non-binding* BW ≈ 1–5 Mbps (cyclic packets over deterministic command bus)	**BINDING** I^2R copper winding dissipation, MOSFET switching losses	**BINDING** $\sigma_{\text{jitter}} < 10\,\mu$s (hard real-time PWM phase alignment & FOC)	**BINDING** Galvanic isolation, out-of-band analog E-stops, STO circuits

Definition 4.3: Handoff record

Handoff record is the record that states one interface limit at one of the five handoffs between sensing and actuation: its value, the conditions under which it holds, its uncertainty and margin, the detector that catches an excursion, its provenance, and whether the value is a requirement, a proven bound, or a measured distribution.

1. **Significance**: It is the second record in the record chain, after the limit record of the Body, and the first that ties a timing claim to the interface where the time is spent. On the running machine its $\mathcal{H}_4$ entry is the 60 ms chunk lease, recorded as a requirement whose margin depends on the intervals of table 4.1.
2. **Distinction**: Unlike a limit record, which describes a physical envelope of the plant such as credible deceleration, a handoff record describes an interface between two subsystems and names the clock on which its times are expressed. Unlike a latency in a profiling log, it states its bound kind, so a percentile cannot pass for a worst case.
3. **Common pitfall**: Recording a bench p99 as a proven bound. The record then carries a number that the permission path trusts in conditions the bench never reached.

Every boundary condition in the grid is recorded this way, so the budgets survive changes of hardware, firmware, and model. Each entry carries the six elements of a limit record and adds the fields that locate the limit at a handoff and state what evidence supports it (table 4.4).

Table 4.4: Conceptual fields of the handoff record: The six limit-record elements of section 2.7.3, extended with the handoff, bound kind, and clock domain that locate a limit in the machine and state what evidence supports it.

Field Name	Physical SI Units	Structural Invariant & Description
`signal_id`	dimensionless	Unique alphanumeric identifier (for example, `SIG_VIO_01`, `SIG_TRQ_AX1`).
`source_subsystem`	dimensionless	Originating hardware or software module (`Camera_SerDes`, `Planner_VLA`).
`destination_subsystem`	dimensionless	Receiving hardware or software module (`State_Estimator`, `Safety_MCU`).
`handoff`	dimensionless	The handoff the signal crosses ($\mathcal{H}_1$ to $\mathcal{H}_5$).
`physical_dimension`	dimensionless	Target limit category (L_{lat}, BW, P_{heat}, σ_{jitter}, $\mathcal{F}$).

Field Name	Physical SI Units	Structural Invariant & Description
`value`	SI units (ms, MB/s, W, µs)	Allocated budget, or the measured distribution it is checked against; for $\mathcal{H}_4$, the chunk lease derived from the stopping budget.
`conditions`	as recorded	Payload, temperature, supply voltage, firmware build, and concurrent workload under which the value holds; the value lapses when they change.
`uncertainty`	same as `value`	Error bound of the instrument or model that produced the value.
`margin`	same as `value`	Engineering margin between the operating target and the breakdown threshold.
`detector`	dimensionless	Runtime monitor that catches an excursion (for example, a lease timer, a rail-voltage monitor, or a phase-current sensor).
`provenance`	dimensionless	Source of the value, including its evidence category (measured, derived, datasheet, or illustrative).
`bound_kind`	dimensionless	`requirement`, `proven bound`, or `measured distribution`; only a proven bound may stand in for a worst case.
`clock_domain`	dimensionless	Clock on which every time-valued field is expressed; a handoff that feeds the permission path uses the safety microcontroller's clock.
`verification_timestamp`	UTC timestamp	Date of bench falsification and sign-off; a log field, never an input to an age test.

The four timing events of table 4.1 sit on this grid's handoffs, capture within $\mathcal{H}_1$, dispatch at $\mathcal{H}_2$, admission at $\mathcal{H}_4$, and brake onset at $\mathcal{H}_5$. The grid's latency column therefore follows the same single execution path as the timing table, and every time in it is expressed on the safety microcontroller's clock. Together, those rows show that the chunk lease at $\mathcal{H}_4$ cannot be chosen in isolation from the stopping distance below it or the inference renewal rate above it.

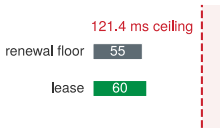
4.9.1 Coupling the distance, lease, and supply budgets

Shortening the chunk lease to save stopping distance, without checking how fast the proposer renews, causes the lease to expire before the next chunk arrives, so the robot stutters from stop to stop. Lengthening the lease to ride out slow renewals lets the robot overrun its rack-end clearance before braking begins. The machine's physical, cognitive, and nervous subsystems therefore meet at a single shared budget, with the chunk lease at their point of convergence. In section 2.3, the loaded machine moving at its 1.5 m/s drive limit had to come to a complete stop within the 1.10 m clearance available at a rack end. Accounting for deceleration mechanics and fixed braking overheads left 258.3 ms for all computational and communication activities preceding brake onset. Section 4.4 then allocated a portion of this window: when a proposer stalls, it retains motion authority for one chunk lease before the emergency stop command reaches the motor drives one tick and one bus cycle later, bringing the running stopping budget to 835.5 mm.

Because the proposer needs enough time to renew that lease before it expires, section 3.4 sets the lower bound from what each learned model can supply. The intent model's INT4 weights require 24.5 ms just to stream across the memory bus. A complete inference pass of compute-bound prefill followed by bandwidth-bound autoregressive decoding consumes 336 ms, so at 2 Hz the intent model cannot renew proposals on tens-of-milliseconds timescales. By contrast, the action chunking policy streams its parameters in 1.12 ms, and its target 20 Hz cadence supplies a fresh trajectory chunk every 50 ms. Its illustrative 40 ms p99 inference latency makes this cadence a feasible nominal supply target rather than a guaranteed worst-case bound, so intercepting late, dropped, or corrupt renewals remains the responsibility of the independent permission path.

These constraints dictate the **lease rule** for the machine. For continuous, uninterrupted trajectory tracking, the lease duration must exceed the proposer's renewal interval plus an allowance for tail jitter. Simultaneously, to guarantee physical safety, the lease must fit within the pre-brake ceiling of equation 4.2 once detection latency, bus transport, actuator brake onset, and sensor evidence age at admission are deducted:

$$T_{\text{chunk}} + T_{\text{jitter}} < T_{\text{lease}} \leq \frac{D_{\text{clear}} - \delta_{\text{loc}} - \delta_{\text{margin}} - v^2/2a_{\text{brake}}}{v} - T_{\text{tick}} - T_{\text{bus}} - T_{\text{act}} - t_{\text{age}} \tag{4.4}$$



The lease must outlast renewal and expire well before the stopping budget runs out.

where T_{chunk} is the chunk policy's nominal renewal period, T_{jitter} is the margin allocated for inter-arrival timing variations, and t_{age} is charged as the evidence's age at admission, rows 1 and 2 of table 4.1 together, not its age at dispatch alone. This inequality captures the coupled cyber-physical budget in a single mathematical relation. The left side reflects compute supply, bounded by the neural proposer. The first term on the right reflects physical mechanics, governed by vehicle speed, workspace clearance, and braking deceleration. The remaining subtractive terms account for detection and communication delays, actuator brake onset, and the observation age accumulated across the perception pipeline. A faster vehicle, a less aggressive brake, or a tighter workspace lowers the upper bound; a slower or more jitter-prone neural network raises the lower bound. If the two bounds cross, no lease can preserve both uninterrupted proposal tracking and the stopping guarantee at that velocity; the permission path must interrupt tracking before authority expires.

On the mobile manipulator, the lower bound evaluates to the 55 ms renewal floor derived in notebook 4.1. The upper bound provides 236.3 ms prior to deducting observation age; subtracting the 51.6 ms capture-to-dispatch age allocated in row 1 of table 4.1 leaves 184.7 ms. Because the observation must also traverse the dispatch-to-admission pipeline before execution, charging that interval's budget from table 4.1 increases total evidence age at admission to 114.9 ms, leaving an effective upper limit of 121.4 ms. This is the same subtraction as the notebook's, taken in a different order. The notebook charged the lease first and left 176.3 ms under the ceiling for evidence age and the stop profile; the lease rule charges the age first and leaves this limit for the lease. The selected 60 ms lease sits just above the lower renewal bound, reflecting the physical reality that every additional millisecond of lease duration consumes 1.5 mm of stopping clearance at maximum drive velocity. This value remains an unverified allocation until the physical vehicle demonstrates that all constituent intervals fit within budget under load. Artificially inflating the lease duration to mask software latency spikes merely consumes stopping clearance, trading mechanical safety margin for compute slack.

Because each chunk packages base velocities and arm joint targets together, the architecture enforces a single shared chunk lease across both subsystems. When that lease expires, each physical body must execute a kinematically feasible, state-matched fallback maneuver. The base's 258.3 ms pre-brake ceiling governs this allocation; it does not imply that the arm possesses surplus margin. The arm analysis in section 11.2 evaluates stopping distance and response travel against its own localized workspace clearances. Validating the shared lease requires verifying timing, evidence age, dynamic state, and fallback limits simultaneously across both base and manipulator. The goal the intent model supplies is governed by a different timer, the intent lease, which limits how long a high-level goal remains active before it must be renewed and is sized in its own chapter, not from this stopping budget.

↪ The intent lease and its contract are developed in section 10.8.

Checkpoint 4.3: The handoffs matrix and physical budgets

Before testing the lease on a humanoid and reviewing the engineering fallacies, verify your understanding of system-wide interface contracts:

- ☐ **Signal handoff classification**: Can you identify the five canonical handoffs ($\mathcal{H}_1$–$\mathcal{H}_5$) bridging physical plant mechanics to high-level deliberative reasoning?
- ☐ **Binding physical constraints**: Can you explain why sensory handoffs bind first on bandwidth and exposure latency, whereas actuation handoffs bind first on determinism and heat?
- ☐ **Handoff record provenance**: Can you describe why every numerical limit in an autonomous system must record its evidence category, operating conditions, bound kind, and verification status?
- ☐ **The lease rule**: Can you state the two limits on the chunk lease, one set by successful-admission interarrival and one by the pre-brake ceiling, and explain why a p99 inference time alone proves neither?

Systems Perspective 4.2: A deadline set by a fall

Question: Does the split among proposer, lease, and permission path still hold when the deadline comes from a fall rather than a stop?

An upright biped diverges from balance on the characteristic timescale $\tau_{\text{fall}} = \sqrt{z_c/g}$, where z_c is its center-of-mass height. The biped is modeled in the sagittal plane as an inverted pendulum of point mass m pivoting above a contact point at height z_c (the linear inverted pendulum model that Kajita et al. (2001) introduced for walking-pattern generation). Newton's second law for a small angular deflection θ_{tilt} from vertical then yields:

$$mz_c^2\ddot{\theta}_{\text{tilt}} = mgz_c \sin\theta_{\text{tilt}} \implies \ddot{\theta}_{\text{tilt}} \approx \frac{g}{z_c}\theta_{\text{tilt}}$$

The characteristic equation $\ddot{\theta}_{\text{tilt}} - \omega_0^2\theta_{\text{tilt}} = 0$ yields natural divergence modes $e^{\pm\omega_0 t}$ with natural frequency $\omega_0 = \sqrt{g/z_c}$. The growing exponential mode governs how quickly an unrecovered perturbation tilts out of control, with characteristic divergence timescale:

$$\tau_{\text{fall}} = \frac{1}{\omega_0} = \sqrt{\frac{z_c}{g}}$$

For an adult-scale humanoid with its center of mass near hip height ($z_c = 0.9$ m) and gravitational acceleration $g = 9.81\,\text{m/s}^2$, this evaluates to $\tau_{\text{fall}} = \sqrt{0.9/9.81} \approx 0.303\,\text{s} = 303\,\text{ms}$ (about 303 ms). This figure represents a characteristic divergence rate, not an absolute recovery deadline. The actual time available to recover depends on the biped's initial angular deflection, its angular velocity, support polygon geometry, and available kinematic reach. Nonetheless, this timescale demonstrates why deliberative inference cannot be placed in the feedback loop governing local balance: an explicit, state-dependent recovery calculation must define the hard real-time deadline.

The architectural partition between proposer, lease, and permission path remains valid for bipeds, but the recovery deadline becomes dynamic and state-dependent. Rather than bringing drives to a standstill, balance recovery requires placing a foot at the dynamic capture point (Pratt et al. 2006), a process demanding both finite swing time and peak joint torque. The interface lease must accommodate these physical demands:

- **The lease is sized from the dynamic capture-point deadline.** On a wheeled base, an expired lease triggers mechanical braking to bring the vehicle to rest ($v \cdot T_{\text{lease}}$). On an underactuated biped, locking the joints mid-stride makes the fall worse, because engaging holding brakes while the center of mass moves forward causes the torso to pivot forward into an uncontrolled ground impact. Where reach, swing-time, torque, and energy limits permit recovery, the lease fallback action must therefore execute an **emergency capture-point step**. The chunk lease, permission tick, fieldbus transit, and observation age must all fit within the dynamic recovery budget while reserving sufficient time to swing and plant the foot. The characteristic fall timescale frames this constraint but cannot substitute for dynamic simulation.
- **The proposer must meet the recovery budget.** An inference renewal period that consumes a major fraction of the characteristic fall timescale cannot safely participate in posture stabilization. High-level intent models must remain decoupled from balance reflexes. Whether a mid-level chunk policy can safely control locomotion depends on whether its renewal interval and tail jitter leave adequate margin for fallback step execution.
- **Actuator thermal limits and supply sag constrain the recovery step.** Executing an emergency recovery step demands simultaneous peak torque across multiple leg joints. This surge draws a large transient current, inducing resistive heating in motor windings and risking DC bus voltage collapse (section 2.6.1). Consequently, the permission path must evaluate candidate recovery trajectories against instantaneous thermal and electrical reserves before admission.

Whether the deadline comes from a warehouse rack end or a biped's fall, the handoff matrix and the lease rule only protect the machine if the hardware and firmware underneath them honor the boundaries the equations assume. In practice, subtle implementation shortcuts in watchdog servicing, calibration ports, state feedback, and middleware configurations routinely bypass those boundaries without triggering a compile or bench error.

4.10 Fallacies and Pitfalls

A block diagram draws a clean boundary between high-level deliberation and low-level real-time enforcement, but physical boards and firmware routinely couple the two through shared power rails, common clock domains, interrupt lines, or auxiliary diagnostic ports. When a planning subsystem crashes or misbehaves, those hidden couplings decide whether the safety enforcement loop actually survives.

Pitfall: *Servicing a safety watchdog inside a high-priority timer interrupt rather than an application-verified safety loop.*

The mobile manipulator relies on a hardware self-watchdog to trigger the Safe Torque Off path of section 4.6 if it receives no feed within 5 ms. Because an enforcer that stops executing can no longer command a coordinated stop, this immediate hardware cutoff is required. A dangerous design mistake occurs when engineers service this watchdog from a high-priority hardware timer interrupt rather than directly from the safety loop. If the lower-priority enforcement task deadlocks on a mutex or crashes, the hardware timer interrupt continues firing every 1 ms tick. The watchdog remains fed while the enforcer has silently lost its ability to evaluate torque limits, kinematic clearances, and lease budgets.

In distributed systems engineering, this error is known as the confusion of liveness with correctness. A node responding to network ping heartbeats can be livelocked, thrashing on memory allocation, or deadlocked on an internal mutex. Servicing a watchdog must never signify mere scheduler activity. Instead, every refresh pulse must be conditioned on the successful, sequential retirement of all required verification stages, for example by requiring a monotonic task-completion token before a windowed hardware watchdog is serviced. An independent timer tick confirms only that interrupt dispatching still operates; it provides zero evidence that the controller has safely evaluated the machine's physical state (section 4.4.1).

Architect's countermeasure: Bind watchdog refresh pulses strictly to the verified completion of the safety loop's invariant checks, deploying windowed hardware watchdogs that trip on both execution underruns and spurious early feeds.

Pitfall: *Leaving auxiliary diagnostic or calibration interfaces unmediated in production operation.*

Suppose the mobile manipulator validates base velocity proposals through its permission path, yet its drive-wheel motor drives retain an unmonitored serial calibration interface. If a diagnostic daemon writes a 35.0 A test value directly into an inverter register through that port, the proposal mailbox continues reporting zero velocity. Checking the mailbox reveals nothing about the bypassed command, yet the drive wheels produce torque that no motion safety check ever evaluated or approved. Actuation authority is not defined by a logical software diagram; it encompasses every physical wire, bus transceiver, and digital interface capable of changing a power-stage register. Service interfaces must therefore incorporate operational interlocks or hardware jumpers that prevent calibration writes from bypassing the enforcer during production runs.

Architect's countermeasure: Electrically isolate, physically jumper, or cryptographically interlock all auxiliary diagnostic and calibration ports during operational modes, routing all register writes exclusively through the real-time enforcer.

Fallacy: *Evaluating safety barrier invariants on commanded trajectory setpoints is equivalent to evaluating physical plant state.*

Suppose an arm controller evaluates safety using a control barrier function (Ames et al. 2019), a scalar function h of the state space that remains positive within the safe set and is kept from going negative by filtering unacceptable control inputs. To conserve fieldbus bandwidth, an engineer might evaluate h using commanded joint positions rather than load-side encoder feedback. If a transmission gear

strips or a drive belt shears, the trajectory interpolator continues generating valid, smooth setpoints. The enforcer calculates that the system remains safely inside the barrier set ($h(\mathbf{q}_{\text{cmd}}) > 0$), even while the decoupled arm collapses into an obstacle. Safety enforcement belongs at the causal boundary, which means it must ingest ground-truth physical state measurements through dependable sensory channels and account for sensor noise and latency. Auditing the command stream reveals what the planner intended, but only independent physical feedback captures where the machinery actually moves.

Architect's countermeasure: Close safety barrier evaluations strictly around verified, independent sensor measurements (such as optical load encoders and current shunts) rather than planned trajectory setpoints.

↪ The control barrier function and the safety filter that keeps it nonnegative are developed in section 12.5.

Fallacy: *Nominal, fault-free operating logs are sufficient to prove physical architectural isolation.*

Logging thousands of operating hours without a missed deadline demonstrates nominal stability, but clean telemetry cannot expose hidden cross-subsystem couplings that awaken only during failure modes. Subsystem isolation often breaks down under unmodeled physical interactions, such as supply-rail voltage sags when multiple inverters switch simultaneously, bus contention storms, or memory corruption spilling across addressing domains. Rigorous qualification requires deliberate fault injection: inducing power transients, flooding communication buses, corrupting policy memory, and mechanically locking motor shafts on a dynamometer. Each experiment must evaluate an explicit, quantitative response bound, such as locked-rotor detection clamping motor current within 2.0 ms, rather than treating the mere absence of an operating system crash as validation. Fault experiments support the isolation claim within their stated fault and load coverage when the system maintains invariant enforcement or reaches the specified fallback within the quantitative response bounds. They do not establish coverage of untested fault combinations.

Architect's countermeasure: Validate fault-domain independence through active fault-injection regimes (power sags, clock glitches, bus flooding, and memory corruption) with quantitative pass-fail response bounds.

DRAFT

Pitfall: *Assuming zero packet loss in robotics middleware equates to deterministic real-time delivery.*

A publish-subscribe transport configured for reliable delivery attempts to recover lost packets, but successful recovery does not establish deterministic real-time delivery. After congestion or interference, a reliable transport delivers the burst of queued, obsolete setpoints that section 4.3.2 traced, each describing a robot state that no longer exists. While switching to a freshest-sample policy prevents queue backlogs, dropping stale frames does not inherently bound scheduling jitter, serialization delay, or driver execution latency. The cycle-critical actuation path requires two separate guarantees: an engineered worst-case delivery bound across the physical communication bus and an explicit freshness deadline enforced by the receiver before executing any torque command.

Architect's countermeasure: Budget the complete transport response under declared traffic and fault conditions, enforce deadline-based freshness at the consumer, and isolate cycle-critical commands from supervisory middleware traffic regardless of the bus architecture.

4.11 Summary

Chapter 2 derived the physical stopping budget for the loaded machine, and chapter 3 established the operational cadences for proposal generation and evidence age. This chapter introduced the real-time permission path designed to enforce those constraints, establishing a two-processor architecture whose physical isolation still awaits evaluation under load. To guarantee deterministic safety, the permission path holds exclusive write access to the motor drive registers. It communicates with the unprivileged proposal engine through a lock-free mailbox that never stalls the high-frequency control tick, while communication and computation delays mandate closing joint-level feedback loops directly within the drives. By evaluating command interfaces, from joint positions to operational-space impedances, the permission path prices each check against available stopping clearance. Combining these constraints yields a bounded time window during which an action proposal is permitted to drive physical actuators. On the running machine, this analysis produces a chunk lease that exceeds the proposer's renewal interval while fitting within the pre-brake delay budget. The resulting handoff record documents this lease alongside its validity conditions and evidence

requirements. This lease and the mechanisms behind it remain claims until they are verified under worst-case compute jitter, bus contention, malformed proposals, sensor faults, and degraded braking. Table 4.5 summarizes the four governing relations that define the nervous system's timing, lease duration, and response guarantees, along with the engineering decisions they resolve.

Table 4.5: Key equations of the nervous system: The four relations behind the chapter's rate, lease, and response decisions, with the place each is derived. $\tau_{\text{delay,max}}$ is the right side of the pre-brake ceiling.

Equation	What it bounds or decides	Derived
$\Delta\phi = \omega_c \left(\frac{T_s}{2} + T_{\text{comp}} + T_{\text{bus}} \right)$	The phase lost to sample-and-hold, computation, and transport delay at crossover, dictating whether a control loop can close across the network bus or must reside inside the drive	equation 4.1
$\tau_{\text{delay}} \leq \frac{D_{\text{clear}} - \delta_{\text{loc}} - \delta_{\text{margin}} - v^2/2a_{\text{brake}}}{v}$	The pre-brake ceiling: the maximum allowable delay before braking onset that still guarantees stopping within available clearance	equation 4.2
$T_{\text{chunk}} + T_{\text{jitter}} < T_{\text{lease}} \leq \tau_{\text{delay,max}} - T_{\text{tick}} - T_{\text{bus}} - T_{\text{act}} - t_{\text{age}}$	The lease rule, bounding chunk lease duration between the proposer's renewal floor and the ceiling imposed by detection, transport, brake onset, and evidence age	equation 4.4
$R_i = C_i + B_i + I_i \leq D_i$	Worst-case response-time schedulability for hard real-time tasks, verifying that execution, blocking, and interference fit within the task deadline	equation 4.3

Key Takeaways: The permission path and determinism

- **The permission path alone writes the drives:** Learned models act only as unprivileged proposal engines (p_t). Write access to the motor drive registers belongs to the deterministic real-time enforcer alone, hosted on silicon whose isolation from the proposer must be verified experimentally.
- **Cadence is dictated by physics, not software:** The four-tier concurrency hierarchy (20 kHz FOC current regulation, 1 kHz kinematic enforcer checks, 20 Hz action-chunk renewal, and 2 Hz multimodal deliberation on the running machine) is governed by physical time constants ($\tau_e = L_{\text{phase}}/R_{\text{phase}}$), total loop delay, exposure horizons, and model execution budgets. The total loop delay appears as a phase lag $\Delta\phi = \omega_c(T_s/2 + T_{\text{comp}} + T_{\text{bus}})$, which keeps the joint loops in the drives.
- **The exchange never waits, and every proposal expires:** The permission path reads the mailbox in a single bounded attempt per tick, retaining the currently active, independently admissible chunk if a write collision occurs. Every proposal carries an evidence timestamp and an explicit expiration horizon that terminates its authority even if an explicit cancellation never arrives.
- **Stopping dynamics dimension the chunk lease:** For the mobile manipulator operating at its drive limits, the pre-brake ceiling is 258.3 ms. Sizing the lease at 60 ms places it just above the proposer's renewal floor. The interval from the final admitted chunk to brake onset takes 82 ms. Its lease path brings the stopping budget's running total to 835.5 mm of the 1.10 m clear distance before evidence age and the remaining stop margins are charged (row 4 of table 12.1).
- **Worst-case bounds outrank empirical distributions:** Tail-latency percentiles such as p99 cannot establish real-time safety. Deterministic enforcement requires bounding worst-case computation, blocking, and interference ($R_i = C_i + B_i + I_i \leq D_i$) under rigorously qualified operating conditions.
- **The permission path is only as independent as what it shares:** If the permission path shares a clock source, power rail, memory bus, or silicon die with the proposal engine, faults in the proposer can compromise the enforcer. The two-processor split is an archi-

tectural hypothesis that requires empirical validation through stress testing and fault injection (section 13.7), not an assumed property of separate software processes.

- **The command interface sets what the permission path must check:** Joint position targets express kinematic intent that the enforcer can verify geometrically, but they cannot bound contact forces. Velocity interfaces require a bounded motion projection, while torque interfaces require dynamic bounds and a feasible fallback. Impedance targets bound steady-state interaction forces, but only if the enforcer validates the stiffness and damping gains alongside the reference trajectory.
- **Locate interface regressions at their handoff:** The system handoff record maps every timing and clearance limit to one of five architectural boundaries, binding each to operational preconditions, evidence categories, and bound types. When performance regresses, engineers can isolate the offending subsystem against its allocated budget using like-for-like evidence.

Physical stopping limits, inference renewal rates, and the Nervous System's response delays converge on one governing parameter, how long an admitted proposal may command the actuators. When a timing question arises on a new machine, the first diagnostic is to price that parameter, converting the lease path to distance at the operating speed and comparing it with what the stopping budget has left. A lease that cannot fit between the renewal floor and the pre-brake ceiling cannot sustain uninterrupted proposal tracking at that speed, and a faster processor helps only if it lets the renewal period, and with it the floor, shrink.

This chapter closes Part I, and with it the argument that the first law, irreversibility (principle 1), set in motion. The Body turned irreversibility into distances and limit records, the Brain into proposals that arrive late and expire, and the Nervous System into a rule of authority. Motion that cannot be undone may be granted only for as long as the stopping budget can still guarantee the stop. The chunk lease is that rule written as a number, and the handoff record is where the number is kept. Everything the machine later learns or is permitted to do inherits this bound, including the demonstrations it collects while the permission path is watching.

4.12 Historical Perspective and Further Reading

The phase-margin arguments that keep high-bandwidth joint feedback loops inside local motor drives predate digital computing. Nyquist (1932) established the foundational stability criterion that determines whether a closed-loop feedback amplifier will oscillate, and Bode (1945) formalized these dynamics into the gain and phase margins that control engineers budget today. When mechanical and analog controllers transitioned to software, sampled-data control theory formalized how digital sample-and-hold stages, discrete computation steps, and communication transport introduce pure time delays that consume this margin (Franklin et al. 1998). High-bandwidth feedback-loop placement in this chapter follows directly from this phase accounting: a control loop must close physically close to its sensors and actuators because any transport latency erodes phase margin that high-bandwidth physical dynamics cannot spare.

Predictable execution and real-time scheduling supply the second pillar of this architecture. Liu and Layland (1973) proved that assigning static priorities monotonically by rate guarantees schedulability for periodic task sets up to a theoretical utilization bound. Subsequent response-time analysis transformed this sufficient condition into an exact test by summing worst-case execution time, resource blocking, and higher-priority task interference (Joseph and Pandya 1986; Audsley et al. 1993). When shared resources threatened these guarantees with priority inversion, Sha et al. (1990) bounded the duration of blocking through priority inheritance and the priority ceiling protocol. The Mars Pathfinder mission in 1997 demonstrated precisely what the absence of such bounds costs in production, when unmanaged priority inversions triggered repeated system resets on the Martian surface (Reeves 1997). Extending predictability to distributed embedded systems, Kopetz (2011) established the foundations of time-triggered design. That work argued that safety-critical systems must remain statically analyzable prior to execution, and it introduced the concepts of state messages and temporal accuracy that govern the proposal headers in this chapter.

The lock-free coordination between the high-level policy proposer and the low-level safety permission path descends from foundational work on sharing state without waiting. Lamport (1977) demonstrated that a concurrent reader can detect an overlapping write using version sequence numbers alone. Simpson (1990) developed the asynchronous four-slot mechanism for flight-control avionics running on unrelated clocks, Herlihy (1991) formalized the theoretical hierarchy of wait-free synchronization, and Kopetz and Reisinger (1993) formulated the non-blocking write protocol specifically for real-time readers. Industrial networks confronted similar timing and isolation challenges on the wire: Controller Area Network (CAN) bus architectures resolved medium access through deterministic, bitwise priority arbitration (International Organization for Standardization 2015a). The functional-safety profiles of IEC 61784-3 established the black-channel principle, which encapsulates integrity and freshness guarantees within the messages so that the transmission medium itself need not be trusted (International Electrotechnical Commission 2021). Finally, the concept of bounded temporal leases originated in distributed systems, where Gray and Cheriton (1989) restricted how long a client could rely on cached data so that an unresponsive client blocked the server for at most one lease period. Physical AI systems adapt this lease mechanism to an entirely different physical objective: rather than preserving distributed cache consistency, the lease is bounded by the kinetic stopping budget and renewal deadlines of the safety monitor.

For readers seeking deeper exploration, six works trace the lineage from classical feedback theory to modern real-time permission paths:

- Franklin et al. (1998) provides the definitive treatment of digital and sampled-data control, analyzing how zero-order hold circuits, computation time, and transport latencies introduce phase lag. This analysis forms the theoretical foundation for the multi-rate cadence decisions in section 4.3.
- Liu and Layland (1973) is a concise, classic paper that remains the clearest demonstration of how rate-monotonic priority assignment guarantees schedulability under worst-case task arrival patterns.
- Sha et al. (1990) formalizes the priority inheritance and priority ceiling protocols alongside their mathematical blocking bounds. This work explains both the recovery strategy deployed on Mars Pathfinder and the derivation of the blocking term B_i in equation 4.3.
- Buttazzo (2011) offers an authoritative textbook treatment of hard real-time systems, fixed-priority and deadline-driven scheduling, and response-time analysis, complete with concrete task sets that readers can verify by hand.
- Kopetz (2011) develops real-time architectures from the time-triggered perspective. Its chapters on real-time entities, temporal accuracy, and communication clarify why our proposal mailbox exchanges idempotent state messages rather than transient event queues.
- Simpson (1990) presents the four-slot mechanism in its original flight-critical avionics context, demonstrating how four memory slots decouple an asynchronous reader and writer without locking, waiting, or sample loss.

What's Next: From anatomy to closed-loop learning

When an embodied machine modifies or rejects a human command before execution, the recorded demonstration no longer reflects unconstrained intent. The Body, the Brain, and the Nervous System establish physical limits, learned proposals, and a timed permission path. During data collection, such as teleoperated openings of the spring-latched cage door, that path may clamp, rate-limit, or refuse an operator's request, while the body may deliver motion that differs from the admitted command. The limit and handoff records preserve the conditions behind those interventions. In Part II, chapter 5 begins from the reality that a physical machine manufactures its own training data, so each executed action changes the observations that follow. Each record carries what the operator requested, what the permission path admitted, and what the body delivered. It then establishes what a demonstration must retain so that a policy can learn the task without mistaking the collecting machine's limitations for intended behavior.

4

Teaching the Machine

Part I gave the warehouse mobile manipulator a measured body, a chunked proposer slot, and a permission path that bounds every motion segment by a chunk lease. Teaching that proposer a contact skill, such as unlatching a spring-latched cage door, exposes a difficulty that offline machine learning benchmarks never face. In a static benchmark, a classifier reads held-out examples drawn from a fixed distribution ($x \sim p_{\text{data}}$) whose next stored example never changes when the model predicts. On a physical machine, every action the permission path admits moves the arm, alters the contact state, and shapes the observations that follow. That closed-loop dependency is the second bedrock law of section 1.10, a systems design principle that turns covariate shift into an evidentiary discipline across data collection, training, and evaluation.

> Principle 2: Endogenous data
>
> **Invariant**: A physical agent's actions choose its next observations ($s_{t+1} \sim p(s \mid s_t, \mathbf{a}_t)$), so the states a deployed policy visits need not be the states it was trained or tested on. For behavioral cloning, the worst-case cost of that drift can grow with the square of the horizon (Ross et al. 2011), as equation 5.1 states.
>
> **Implication**: A learned proposer's competence is a claim about a declared region of states, established in closed loop with the permission path in place. Visiting a state during collection, recording an attributable training target for it, and testing competence there in closed loop are three separate steps. Missing states call for more collection, and a finite set of trials bounds the resulting claim rather than proving it outright.

Part II traces the cage-door policy across the machine Part I built. During collection the permission path can clamp or refuse an operator's command, and the body can deliver motion that differs from the admitted one. A demonstration must therefore show what was requested, what the permission path allowed, and what the body actually did. Part I's limit and handoff records become preconditions on the data. Training then turns the supported behavior into candidate policies, one cloned from the demonstrations and one distilled from a simulator teacher, each of which improves its training score while hiding a dependency the hardware can expose. Closed-loop trials test a candidate under declared conditions, showing how data collection, training, and evaluation fit together. When a displaced latch plate breaks the nominal policy, a recovery campaign collects attributable corrections, trains an updated candidate, and tests both nominal regression and the wider latch range (using stipulated trial counts rather than measurements from a physical robot).

- **Physical Data (chapter 5):** Decides which conditions the demonstrations support and what they cost to collect, and produces the provenance record of the demonstrations, which lists the conditions the data does not cover as known absences.
- **Policy Training (chapter 6):** Decides which training regime fits the available experience and which dependency each regime leaves hidden, and produces the policy manifest, whose declared operating domain cannot exceed the conditions the provenance record supports.
- **Closed-Loop Evaluation (chapter 7):** Decides what a finite set of closed-loop trials supports about the proposer, and produces the evaluation record for a target operational design domain (ODD) inside the manifest's declared one, separating proposer autonomy, whole-machine task completion, and protective outcomes.

Part II hands forward an evaluation record: a claim about the learned proposer confined to a target ODD, the finite-sample bound that supports it, a catalog of the conditions it does not cover, and the runtime monitors the rest of the machine must supply. With it, the first of the record chain's two strands, plant limits and evaluated competence, is complete. That record identifies the candidate from chapter 6, the experience and labels documented in chapter 5, and the independent trials supporting its evaluated domain. While the initial archive bounds what the current evidence can support, new collection and re-qualification can widen that domain later. Part III relies on the current evaluation record rather than assuming that a policy manifest alone establishes competence. Its permission path checks the physical premises for each action and restricts or refuses proposals when those premises lack support. Any fallback still requires a response the machine can physically execute.

Purpose

Why can a large archive of successful demonstrations leave a robot unable to recover from its first mistake?

A successful demonstration shows how one machine completed a task under one set of conditions. It shows almost nothing about what to do after a slip, a shifted fixture, or a worn gripper, yet a learned policy's first error carries it into exactly those states, where the archive holds no instruction. Repeating the demonstration enlarges the archive without filling that gap. The recorded motion also carries the operator's delay, the machine's limits, and every correction the permission path applied, so a training process that cannot separate these influences learns a safeguard's intervention or a mechanical limitation as if it were skill. Gathering the missing experience costs operator time and component life, and the collection itself must stay within the machine's physical limits. Physical data must therefore be engineered, from the choice of experiences to the meaning, timing, and physical origin of every label and the conditions the archive leaves uncovered. Because every collected action crosses the causal boundary, its irreversible costs decide what a machine can learn and where its evidence stops.

Learning Objectives

- Explain how endogenous covariate shift yields the conditional quadratic imitation-cost bound, and distinguish dataset occupancy from evaluated closed-loop competence
- Select the action tap a dataset imitates and align multi-rate sensor and action streams to hardware exposure-midpoint timestamps within the task's spatial tolerance
- Estimate usable demonstration yield from collection time, operator rest, and physical reset overhead, and budget the mechanical component wear a campaign consumes
- Identify collection gaps by joining empirical state-action occupancy against a required scenario table
- Separate failed autonomous actions from admissible human recovery across the divergence, takeover, and stabilization timestamps of an intervention episode
- Evaluate whether an embodiment's mechanical, sensing, and timing assumptions transfer to another machine without falling into the normalization fallacy
- Detect silent calibration and plant drift in a demonstration archive using kinematic reprojection and repeated excitation trajectories
- Design an immutable provenance record linking each observation to its four-stream action taps ($a_{\text{req}}, a_{\text{cmd}}, a_{\text{enf}}, a_{\text{meas}}$) and to the collecting plant

5.1 Endogenous Experience

In most machine learning, the dataset exists before the engineering begins. A text corpus or an image benchmark is gathered independently of the model, costs little per additional example, and does not change in response to anything the model predicts. A physical machine has no such corpus. Collecting demonstrations on the robot consumes operator time and component life; robot-free and synthetic sources avoid that robot wear but still require qualification for the target machine. Every telemetry record reflects who commanded the action, what the permission path admitted, and how the physical body moved. Because each executed action changes the physical state of the system, it dictates what subsequent observations can reveal. Physical data is therefore an engineered artifact. The central challenge of physical data engineering is deciding which experiences to collect, and what to record about them, so that a policy learns the task rather than the idiosyncrasies of its collection. Answering this challenge requires four elements: accounting for collection costs in operator time and hardware wear, defining an unambiguous meaning for every recorded action label, establishing a metric for state-space coverage independent of the archive's internal contents, and explicitly auditing what the archive omits.

Consider a warehouse mobile manipulator tasked with opening a spring-latched cage door. The robot can flawlessly enforce its low-level motion limits and yet fail because it lacks the operational experience to unlatch the door. During a demonstration, a human operator commands motion, the safety permission path checks and filters it, and the robot's physical body drives against the mechanical latch. The onboard sensor log captures the output of that entire coupled loop. The limits and handoffs recorded earlier for this machine, in the limit record of section 2.7.3 and the handoff record of section 4.9, therefore become preconditions on the training data fed to the learned policy proposer. Every logged command was shaped by them before the body moved. Choosing which physical experiences to collect demands a rigorous accounting of how control inputs shift future sensory states. Choosing what to imitate requires cleanly separating the operator's raw request from the safety-filtered command and the measured physical response.

A policy fit by supervised imitation to nominal, clean teleoperated demonstrations of door openings (behavioral cloning, defined below) can execute flawlessly in simulation yet jam the latch during its first autonomous deployment. The primary culprit is the distribution shift that the machine's own closed-loop actions induce. Unlike passive inference on a fixed benchmark, an action executed within an embodied Markov decision process (MDP), in which the next state depends on the current state and action, physically alters the robot's spatial trajectory, camera viewpoint, and contact states. That displacement changes the probability distribution of every subsequent sensory observation ($s_{t+1} \sim p(s \mid s_t, \mathbf{a}_t)$).

↪ The Markov decision process, with its transition model and reward, is developed for the latch task in section 6.2.1.

Definition 5.1: Endogenous covariate shift

Endogenous covariate shift is the closed-loop distribution discrepancy wherein an embodied agent's executed actions alter its subsequent physical states and sensory observations ($s_{t+1} \sim p(s \mid s_t, \mathbf{a}_t)$), driving the system into state-space regimes unsupported by its training demonstrations.

1. **Significance**: Explains how offline behavioral cloning can fail during closed-loop physical execution: a perturbation may drive the system into states where the policy lacks training support.
2. **Distinction**: Unlike exogenous dataset shift caused by changing ambient lighting or seasonal weather, endogenous shift is actively generated by the agent's own closed-loop actions altering its subsequent observation distribution.
3. **Common pitfall**: Attempting to fix closed-loop policy failure by collecting more nominal expert demonstrations, which only increases data density along the success manifold without providing the corrective recovery data needed to escape boundary excursions.

This distribution shift is how the second law, endogenous data (principle 2), shows up in data collection, where the machine's own actions choose the states its archive must later answer for. An archive composed exclusively of flawless executions without recovery trajectories becomes an operational liability. The moment the autonomous policy commits its first sub-millimeter tracking error, the robot enters states never encountered during training. Two distinct physical mechanisms govern how fast that departure grows (section 5.2).

5.2 Mechanics of Endogenous Covariate Shift

When an image classifier misidentifies a dog as a cat, the mistake does not alter the pixels of the next photograph in the test set. When a door-opening policy misses the latch centerline by a millimeter, that motion shifts the camera viewpoint, changes the contact geometry, and alters every observation that follows. Classical empirical risk minimization assumes the first setting, drawing independent and identically distributed (i.i.d.) samples from an exogenous, stationary distribution $\mathcal{D}$. Even when passive machine learning studies *covariate shift*, it treats the shift as an open-loop observational change: the marginal input distribution $p(x)$ shifts (such as evaluating a daytime-trained vision model at night) while the conditional data-generating function $p(y \mid x)$ stays fixed. Because a passive model's predictions $\hat{Y}$ exert no physical back-action on the world, an inference error never mutates the next input. Imitation learning on a machine operates inside the closed-loop counterpart to this setting.

In an embodied physical system, two distinct mechanisms distort what the learner encounters. The first shifts the states that the policy visits even when the hardware stays unchanged; the second alters how the physical plant responds to any given control input:

↩ The closed loop through which a flawed proposal carries the machine into states missing from its training distribution is established in section 1.4.1.

1. **Endogenous state distribution shift**: The policy's executed actions $\mathbf{a}_t = \pi_\theta(\mathbf{o}_t)$ directly drive the physical state transition $s_{t+1} \sim p(s \mid s_t, \mathbf{a}_t)$, choosing the sensory observations $\mathbf{o}_{t+1}$ the robot sees next. A single control error moves the body into an unvisited region of the state space and changes the incoming observation distribution on the next tick.
2. **Active physical plant drift**: The physical plant is a continuous dynamical system governed by differential equations of motion $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \mathbf{u}; \theta_{\text{plant}}(t))$ whose parameters drift over operational time. Actuator Joule heating ($i_q^2 R(T_{\text{winding}})$) raises winding temperature and copper resistance via $R(T_{\text{winding}}) = R_0(1 + \alpha_{\text{Cu}}\Delta T)$, compressing the motor drive's voltage headroom and capping peak torque at high joint speeds. Over extended operating cycles, continuous loading degrades strain-wave gearbox lubrication, lowering torsional stiffness and expanding mechanical lost motion. Compliant elastomer gripper pads wear down and deform, shrinking the Coulomb friction cone ($\|\mathbf{f}_{k,\parallel}\| \leq \mu f_{k,\perp}$). Finally, physical workpieces vary in mass, center of gravity, and surface texture across trials, perturbing both the inertial loads the arm accelerates and the gravitational torques the joints sustain.

Together, the policy's closed-loop actions and the plant's response induce an *endogenous state visitation distribution* $p^{\pi}(s)$, the expected fraction of time steps that a rollout of policy π spends in state s. When an agent is trained by offline behavioral cloning on demonstrations from an expert policy π^*, empirical risk minimization fits the imitation objective only over the expert's occupancy distribution $p^{\pi^*}(s)$. During autonomous execution, the learned policy instead acts under its own induced distribution $p^{\pi}(s)$. Wherever p^{π} departs from p^{π^*}, the policy encounters states that hold no demonstrated corrective action.

Definition 5.2: Behavioral cloning

Behavioral cloning is imitation learning posed as supervised learning: a policy is fit to map each recorded observation to the action the demonstrator took there, with the loss weighted by the demonstrator's own state occupancy p^{π^*}.

1. **Significance**: Training error is measured only on states the demonstrator visited, while deployment cost accrues on the states the learned policy visits. Under a 0–1 action loss (one whenever the policy's action differs from the expert's, zero otherwise) the worst-case excess cost can therefore grow with the square of the horizon S, the episode length in control steps, rather than linearly, as the next section derives.
2. **Distinction**: Unlike corrective aggregation, which obtains expert labels at states the learner itself reaches (section 5.8 develops it), behavioral cloning never observes the consequences of its own mistakes; unlike reinforcement learning, it needs demonstrations but no reward.
3. **Common pitfall**: Reading a low held-out loss as evidence of closed-loop competence. A held-out split drawn from the same demonstrations shares their occupancy, so it cannot contain the states the policy's first error reaches.

Because behavioral cloning weights its loss solely by the demonstrator's occupancy p^{π^*}, a single step off the demonstrated path places the policy in states where training never penalized an error. How fast that first departure compounds over an episode depends on whether the archive holds any actions that steer the machine back (section 5.3).

5.3 Recovery and Compounding Error

Opening a latch from a nominal centered approach and recovering from an off-axis sideways slip require different physical actions (figure 5.1). Every retained demonstration guides the gripper forward along the narrow corridor centered on the strike plate, which populates the archive with thousands of forward-progress actions. The archive contains zero demonstrations that start from a gripper displaced a few millimeters toward the fixture and return it to the centerline. Because a skilled human operator rarely lets the gripper drift into those boundary regions, and because teleoperation runs that drifted noticeably were aborted or discarded during curation, nothing in the training data constrains the policy's output at such a displaced state.[1] The **recoverability problem** is this absence of demonstrated corrective actions that steer the system back into the nominal corridor.

Whether this missing return action leads to task failure depends on the closed-loop dynamics of the complete physical plant. Because the robot's physical state encompasses joint coordinates, joint velocities, motor drive currents, contact wrenches (combined three-axis contact forces and torques), and raw camera streams, a nominal demonstration traces an infinitesimally thin manifold through a high-dimensional state space. Almost any unmodeled disturbance displaces the system off this path. If the physical plant and its low-level joint controllers inherently restore small lateral displacements toward the centerline through compliant passive dynamics, an imperfect policy output near the corridor boundary will naturally attenuate. If the system dynamics lack this self-centering stability, the tracking error will persist or compound until a learned recovery policy, the safety permission path, or a human supervisor intervenes. While production demonstration archives often contain occasional human corrections, their coverage cannot be assumed; it must be audited against an explicit scenario table (section 5.7).

[1] **ALVINN (Autonomous Land Vehicle in a Neural Network)**: Pomerleau's road-following network learned to steer from a human driver who kept the van centered, so its training images held almost no off-center views (Pomerleau 1989). His remedy shifted each camera image sideways in software and corrected the steering label to match, synthesizing recovery examples about 20 years before Dataset Aggregation (DAgger, section 5.8) (Pomerleau 1991). A warp could fill that gap because the missing state was only a viewpoint of a flat road, whereas a gripper displaced toward the fixture also lacks contact forces that no image transform can manufacture, so its recoveries must be demonstrated or collected.

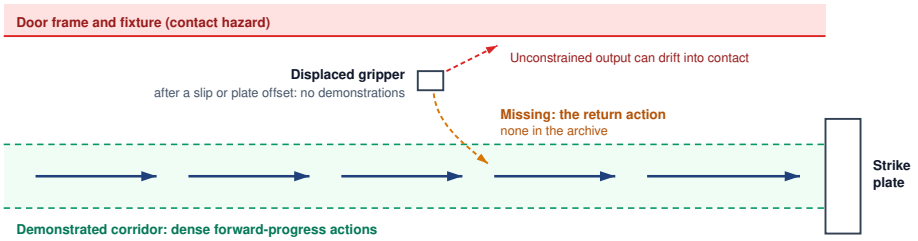

Figure 5.1: The latch corridor seen from above: Retained demonstrations supply dense forward-progress actions inside a narrow corridor centered on the strike plate. A gripper displaced toward the fixture sits where the archive holds no demonstration, so nothing in the data specifies the action that returns it to the corridor, and an unconstrained output can carry it farther toward contact.

The quadratic worst-case scaling of behavioral cloning can be derived through a discrete summation over horizon steps. Suppose an autonomous agent follows the expert trajectory until encountering its first execution error at step $k \in \{1, \dots, S\}$. If this error propels the system into an unsupported state from which it never recovers, the agent incurs an adverse task cost at every remaining step $(S-k)$. Assigning each time step an upper bound ϵ on the probability of committing a first error and normalizing the per-step cost to unity ($C_t = 1$) yields the following worst-case cost accumulation. This discrete summation serves as an upper-bound derivation rather than an exact expectation over independent failure events:

$$\sum_{k=1}^{S} \epsilon(S-k) = \epsilon\left(S^2 - \sum_{k=1}^{S} k\right) = \epsilon\left(S^2 - \frac{S(S+1)}{2}\right) = \frac{S(S-1)}{2}\epsilon \approx \frac{1}{2}S^2\epsilon.$$

In open-loop supervised learning, by contrast, if per-step inference errors were independent and exerted zero feedback on subsequent model inputs, an error rate of ϵ per step would scale linearly over S steps as $\sum_{t=1}^{S} \epsilon = S\epsilon$. The extra factor of S appearing in $\mathcal{O}(S^2\epsilon)$ is the mathematical signature of closed-loop endogenous feedback.

This quadratic bound characterizes the accumulation of task cost over time, not the physical trajectory of the machine. The result does not imply that spatial tracking errors grow quadratically as t^2. Closed-loop contact forces, mechanical compliance, and actuator saturation govern how physical trajectories evolve; the derivation formalizes only the cost of operating in states where the policy lacks training support.

Writing $J(\pi)$ and $J(\pi^*)$ for the expected cumulative task costs of the learned policy π and expert policy π^* over those S steps, let ϵ bound the single-step action disagreement across expert-visited states under a 0–1 action loss: $\mathbb{E}_{s\sim p^{\pi^*}}[\mathbb{I}(\pi(s) \neq \pi^*(s))] \leq \epsilon$. Assuming per-step task costs lie in $[0, 1]$, behavioral cloning admits the worst-case bound (equation 5.1) derived by Ross and Bagnell (2010) and restated by Ross et al. (2011):

$$J(\pi) - J(\pi^*) \leq S^2\epsilon. \tag{5.1}$$

The published theorem carries a constant of one rather than the sketch's one half; both are worst-case bounds, and their quadratic dependence on the horizon is the same.

In practice, this theoretical bound can exceed the maximum possible cost achievable in a finite episode. Because per-step costs are bounded in $[0, 1]$, the excess cost is trivially bounded by S; hence, $\min(S, S^2\epsilon)$ represents the operational upper bound. Once the quadratic expression surpasses S, it provides no meaningful prediction regarding physical failure rates or contact severity. The practical engineering value of this bound lies in exposing why behavioral cloning has no defense in states its demonstrations never reached, rather than in predicting exact physical collision rates.

The actual scaling with horizon length depends heavily on the chosen loss function, the action space, and the closed-loop plant stability. Consequently, equation 5.1 reflects a classical result for discrete 0–1 loss rather than an absolute law for all imitation architectures. When trained under

↪ The full derivation of the quadratic bound, with its loss and cost assumptions, is developed in section A.5.

logarithmic loss (minimizing the negative log-probability assigned to expert actions) over a well-specified policy class containing the expert, behavioral cloning can achieve a sample complexity that does not grow with the horizon length. This result holds provided total reward is bounded and the policy class capacity is controlled (Foster et al. 2024). Continuous action spaces, however, introduce the opposite challenge. Even when the physical closed loop is exponentially stable (small mechanical perturbations decay at a fixed rate) and the expert policy is smooth and deterministic, any smooth, deterministic imitator can accumulate closed-loop execution errors that scale exponentially with horizon length relative to its training loss (Simchowitz et al. 2025). The same analysis identifies two ways around this compounding (Simchowitz et al. 2025). The first changes the policy class. A policy that is non-smooth, that is non-Markovian (its action depends on recent history rather than solely the current observation), or whose action distribution is multimodal (it can place probability on several distinct actions at once, rather than averaging them) escapes the result. Action chunking and diffusion decoders have these properties. The second changes the data, using demonstrations deliberately spread across a wide tube surrounding the nominal trajectory. That second remedy is a data-collection decision, and section 5.8 returns to it as noise injection during teleoperation. Because the mobile manipulator operates in a continuous control space, closed-loop success ultimately hinges on whether the combined policy and low-level controllers actively restore a displaced gripper to the nominal path.

↩ Action chunking, in which the policy emits a short sequence of setpoints per inference, is established in section 3.5.1.

Collecting more nominal expert demonstrations does not resolve endogenous covariate shift. Adding another thousand hours of clean, centered door openings merely increases sample density along the nominal trajectory; the empirical support outside this narrow tube remains strictly zero ($p^{\pi^*}(s) = 0$). This pitfall is the *nominal demonstration trap*. Beyond this coverage limitation, logging physical robot experience carries direct hardware costs. While a web crawler scrapes static text with zero marginal mechanical wear, every recorded second of robot telemetry consumes actuator fatigue life, heats motor windings (dT_{winding}/dt), wears down gearbox teeth, and depletes battery reserves. In practical data-collection campaigns, required pauses for operator fatigue, sensor recalibration, scene resets, and discarded trials often leave less than one quarter of scheduled workcell time as usable demonstration data (section 5.6). Physical telemetry is scarce, wear-intensive, and costly; collecting it without modeling closed-loop recovery dynamics compromises policy training.

↩ Actuator thermal dissipation (dT_{winding}/dt) and winding damage limits are established in section 2.5.

A physical command also changes meaning as it crosses the control stack toward the actuators. In a system partitioned by the proposal boundary, an operator's or policy's requested action is mapped into a trajectory setpoint, checked and potentially clamped by the safety permission path, and executed by the physical plant to produce a measured response. Logging only the raw requested action trains the policy on commands the plant may be physically incapable of executing; logging only the measured plant response teaches the policy to copy link flexure, gear backlash, and contact stalls as if they were intentional human skill. A physical data-collection campaign must therefore settle two decisions before recording its first trajectory. The first is which collection path generates the actions (section 5.4). The second is which of the four representations of one command (the request, the mapped setpoint, the admitted command, or the measured response) the dataset preserves as its training label (section 5.5).

↩ The proposal boundary, which separates a learned proposer from the permission path that alone may admit an action, is established in section 1.7.

5.4 Physical Telemetry Sources and Collection Paths

When an engineer records demonstrations of the warehouse cage-door latch, the choice of collection rig decides which contact forces, hesitations, and recovery maneuvers ever reach the archive. Guiding the robot arm by hand gives the demonstrator direct tactile feel of the binding latch, but the demonstrator's torso blocks the onboard cameras. Puppeteering the arm over a network clears the camera view, but display delay makes the operator inch forward in a stop-and-go hunt. Running a scripted spline produces clean, repeatable approaches that jam the moment the strike plate shifts by a millimeter. Because every attempt on the physical robot spends facility hours, joint life, and human effort, choosing a collection path trades collection cost against the behaviors the resulting archive can support. Seven collection paths appear in practice, six on physical hardware and a seventh in simulation:

1. In **kinesthetic teaching**, a colocated human demonstrator physically grasps and guides the unpowered or gravity-compensated links of the mechanism. The logging pipeline records joint encoder positions at the native controller rate without network transport delays. How-

ever, human biomechanics govern the motion's bandwidth, moving far more slowly than the controller's sampling loop, while labor costs scale $1:1$ with demonstrator time. The demonstrator's body also frequently occludes onboard camera views, introducing systematic visual distribution shifts relative to autonomous operation.

2. In **teleoperation**, a remote operator manipulates an input device to puppet the follower robot across a network fabric.[2] Teleoperation interfaces differ in how operator inputs map to robot actuators and how much physical contact information reflects back to the human. Joint-space leader-follower arms such as ALOHA (Zhao et al. 2023) and GELLO (P. Wu et al. 2024) mirror the follower's joint topology, often at reduced scale, streaming joint angles directly to the follower without inverse kinematics (computing the joint angles that place the tool at a commanded pose). In contrast, tracked spatial controllers and rate-controlled space mice command Cartesian tool poses or velocities that require inverse kinematics solvers at runtime, while force-reflecting bilateral arms actively transmit measured contact forces back to the operator's hands. Table 5.2 compares these interfaces and names the artifact each leaves in the recording.
3. In **scripted collection**, a deterministic trajectory generator executes automated motion primitives, such as cubic splines or impedance-governed state machines. Ingestion rates are high and predictable (50–500 Hz), but trajectories traverse rigid, repetitive manifolds. Because these paths fail to generate corrective recovery data during off-nominal contact, the manipulator risks jamming whenever workpiece dimensions deviate by even a millimeter.
4. In **exploratory collection**, an active neural policy or reinforcement learning agent selects actions to maximize an information-theoretic objective, such as epistemic entropy or intrinsic curiosity. Although data throughput matches the robot's peak policy cadence (50–100 Hz), unconstrained exploratory actions risk high-energy collisions, tripping hardware safety tripwires or degrading mechanical gearboxes through repeated high-torque shock loads.
5. In **autonomous deployment logging**, production policies control actuators during routine factory or warehouse operation, streaming multimodal telemetry into local circular buffers in situ. This channel yields zero-marginal-labor data at the system's full execution rate (10–50 Hz for high-level policies, 1 kHz for joint servos). However, runtime safety barriers heavily censor the recorded state distribution, capturing almost exclusively nominal operating regimes while excluding boundary failures.
6. In **robot-free demonstration**, the operator carries a hand-held gripper fitted with a wrist camera and performs tasks directly in the physical environment, as in the Universal Manipulation Interface (UMI) (Chi et al. 2024). Collection incurs zero robot operating hours or actuator wear, allowing a single demonstrator to gather data across locations where no robot is deployed. The engineering cost shifts to label synthesis: because the hand-held rig records its own Cartesian trajectory and visual feed without robot joint states, actions must be expressed relative to the gripper's pose frame and executed downstream through the target robot's controller. The deployed robot's observation and actuation latencies must also be calibrated to match the recording timing (section 5.5.2).

A seventh source removes physical hardware entirely. Simulation pipelines eliminate mechanical wear by substituting a numerical contact model for the physical plant, generating synthetic demonstrations at scale. Trajectory generators can expand a few hundred human seed demonstrations across novel object poses and scene layouts, replaying them in physics engines to synthesize tens of thousands of varied trajectories (Mandlekar et al. 2023). Downstream policies can then co-train on simulated and real telemetry at a specified mixing ratio. However, these synthetic streams require rigorous metadata tagging: records must log their source generator, physics engine build, integrator step size, and contact solver parameters. The dataset's scenario table, the list of required operating conditions that section 5.7.1 builds, must also flag every condition covered solely by synthetic rollouts, ensuring that training diagnostics can isolate simulation artifacts from measured physical plant behavior. The provenance requirements for synthetic telemetry appear under dataset degradation (section 5.10.2).

Because the collection source determines how the machine interacts with its physical environment, these data streams occupy disjoint state-action manifolds even when executing identical manipula-

[2] **Bilateral Telemanipulation**: Raymond Goertz's 1949 master-slave manipulator at Argonne National Laboratory moved tongs behind radiation shielding in exact correspondence with a master handle, and its mechanical linkage returned the forces at the tongs to the operator's hand (Goertz 1949; Hokayem and Spong 2006). Remote manipulation therefore began with contact force inside the loop. A demonstration recorded through an interface that drops that force channel cannot contain the contact corrections the operator would have made by feel.

tion tasks. Consider releasing the warehouse mobile manipulator's cage-door latch. A colocated demonstrator guiding the arm feels the latch bind through direct tactile resistance and immediately adjusts wrist compliance, whereas a remote teleoperator watching a compressed video stream lacks haptic feedback and falls into step-and-wait hunting, pausing repeatedly to check strike-plate contact. By contrast, a scripted controller advances along a fixed geometric path at constant velocity and produces the same rigid contact-force spike on every repetition, while an exploratory policy approaches at oblique angles that bind the latch until safety tripwires abort the trial. Far from representing noisy variations of a single ground-truth trajectory, these recorded streams reflect distinct dynamical systems with different bandwidths, transport latencies, and mechanical compliance profiles, as summarized in table 5.1.

Table 5.1: Systems trade-offs across physical demonstration and telemetry sources: Seven collection sources compared across control dynamics, contact awareness, human labor economics, and the boundary conditions that collection must satisfy.

Physical Data Source	Ingestion Bandwidth & Cadence	Contact Compliance & Force Awareness	Scaling Labor Economics	Collection Boundary Conditions to Check
Kinesthetic teaching	Controller rate; motion bandwidth set by the human arm	High (direct physical feel of binding and compliance)	Very high (1 : 1 dedicated human demonstrator)	Human contact with links; qualified force and speed limits
Teleoperation (bilateral/isomorphic)	Moderate (20–50 Hz, network + human latency)	Moderate to high (depends on haptic force feedback)	High (1 : 1 human operator per active cell)	Bounded delay and visibility; isolation and qualified response
Scripted primitives	High (50–500 Hz, deterministic trajectory generators)	Low (rigid trajectories unless impedance-governed)	Low (automated once authored; engineering upfront)	Fixture mismatch and contact; guarded trajectory
Exploratory policy	High (50–100 Hz, active neural exploration)	Variable (learned or randomized contact behaviors)	Very low (fully autonomous hardware execution)	Bounded exploration; qualified containment
Autonomous deployment logging	Full system rate (10–50 Hz policy, 1 kHz joint servos)	Operational (reflects live deployed closed-loop control)	Zero marginal labor (harvested passively during production)	Qualified operating domain and runtime enforcement
Robot-free hand-held device	Device camera and pose rate; no robot joint stream	High (operator feels real contact through the device)	Moderate (one person per device; no robot time or wear)	No robot actuation during capture; target execution separately qualified
Synthetic generation	Simulator step rate, limited by compute	Modeled (contact set by engine and parameters)	Low after seed demonstrations are recorded	No physical actuation during generation; model fidelity and target qualification

The cheapest sources in table 5.1 also produce the highest volume of records. This abundance frequently invites a misconception borrowed from disembodied machine learning, where empirical scaling laws correlate model capability directly with raw token count or pretraining dataset volume (N). In physical telemetry, treating every logged control step as an independent observation is a category error. An edge logger sampling at 1 kHz records 3.6×10^6 state-action pairs every hour, yet adjacent timesteps carry near-total temporal autocorrelation ($\rho \to 1.0$) because successive kinematic readings sampled 1 ms apart differ only by sub-millimeter structural displacements and sensor quantization noise. For a stationary scalar telemetry statistic with geometrically decaying autocorrelation $\rho_k = \rho^k$, as characterized by a first-order autoregressive AR(1) process, the large-sample *effective sample size* (ESS)[3] for estimating its mean is:

$$N_{\text{eff}} = N \frac{1-\rho}{1+\rho}. \tag{5.2}$$

Under this autoregressive model, an autocorrelation of $\rho = 0.999$ across 3.6×10^6 raw records yields only 1,800 statistically independent observations. While lag-1 correlation alone does not govern ESS across every non-stationary telemetry stream, high-frequency sampling still cannot substitute for operational diversity. Whereas consecutive tokens in language modeling represent high-entropy transitions across a large vocabulary, high-rate robot telemetry mostly oversamples

[3] **Effective Sample Size**: The factor $(1-\rho)/(1+\rho)$ is the effective-sample-size correction for the mean of a first-order autoregressive series, the correction climatologists apply to serially correlated weather records before testing a trend (Thiébaux and Zwiers 1984). At the correlation used here it turns an hour of permission-tick records into about 1,800 independent ones, so a step count overstates the independent information available for estimating this statistic's mean by three orders of magnitude before coverage is even considered.

the same physical trajectory. It can resolve fast contact transients when they occur, but raising the logger's clock frequency never populates an unvisited scenario cell. Physical dataset coverage expands instead through independent physical episodes, diverse workpiece placements, varying illumination, and shifting friction coefficients. A curated archive containing several hundred episodes that systematically sweep initial geometric and mechanical conditions provides far richer empirical support than millions of repetitive timesteps collected across a static test bench.

5.4.1 Human demonstration idiosyncrasies and mechanical artifacts

When a behavioral cloning policy is trained directly on raw teleoperated joint velocities, the deployed robot arm often chatters its harmonic drives at 8–12 Hz or stalls for 300 ms a few millimeters in front of the latch strike plate. Neither defect comes from the network architecture. Because a human operator executed the training motions, the recorded telemetry embeds the demonstrator's neuromuscular bursts, perceptual delays, and visual blind spots alongside the intended trajectory:

- **Neuromuscular sub-movements and physiological tremor:** Human motor control operates through discrete motor unit recruitment bursts rather than continuous, smooth trajectories. These neuromuscular dynamics introduce corrective sub-movements at 2–3 Hz overlaid with involuntary physiological tremor at 8–12 Hz. If a high-frequency behavioral cloning policy trains on raw joint velocities without low-pass filtering, the neural network imitates this biological tremor as high-frequency torque chatter, accelerating mechanical fatigue in the robot's harmonic drives and gearboxes.
- **Visual latency and step-and-wait hunting:** When an operator guides a manipulator toward a contact fixture using 2D camera monitors, monocular depth ambiguity and video compression latency force an unnatural *step-and-wait* hunting cycle. The operator inches the gripper forward by a few millimeters, pauses for 200–400 ms to visually confirm clearance or contact across the video stream, and only then resumes motion. An imitation policy trained on uncurated velocity streams treats these latency-induced pauses as deliberate actions, yielding deployed behaviors that stutter, oscillate, or stall mid-trajectory.
- **Attentional narrowing and gaze-conditioned bias:** Human demonstrators naturally focus visual attention on the active tool center point (TCP). Because the operator rarely tracks the peripheral links of the arm during fine manipulation, the robot's elbow or shoulder links frequently sweep perilously close to structural supports or table edges. An imitation policy trained on these demonstrations inherits trajectories that graze workspace obstacles, yet lacks the human's peripheral situational awareness or rapid collision avoidance reflexes.

Because an ingestion logger records every physical tremor, visual hesitation, and marginal joint clearance as part of the demonstration, imitation policies reproduce these flaws unless the training pipeline filters or abstracts them. Choosing a telemetry source decides what raw experience reaches the archive; choosing which control signal serves as the action label decides whether the policy learns the operator's intent, the safety filter's clamp, or the plant's compliance (section 5.5).

5.5 Action Label Selection across the Control Boundary

Suppose a teleoperator pushes the gripper into the cage-door strike plate aggressively enough to trip a velocity clamp, or stalls against the latch while the wrist motor holds torque. A logger that records only the operator's raw command teaches the policy to repeat a move the machine refused to execute, whereas a logger that records only the measured encoder velocity teaches it that stalling against a latch is a deliberate command to stop. By the time the gripper contacts the strike plate, a single operator motion has become four different numerical signals across two decoupled processing domains:

- The unprivileged **Linux application processor** executes perception pipelines, handles video frame ingestion, runs teleoperation input mapping, and computes the neural policy forward pass ($\pi_\theta(\mathbf{o}_t)$).
- On the permission side of the proposal boundary, a hard real-time **safety microcontroller (MCU)** runs joint and permission checks at the chosen 1 kHz cadence. Dedicated motor-drive logic closes the faster field-oriented current loop; its current samples remain distinct from the telemetry retained at each permission tick.[4]

[4] **Hardware Input Capture**: On real-time MCUs, a timer's input-capture unit latches encoder counts and current-shunt conversions at a hardware edge, and Direct Memory Access (DMA) moves them to memory without waiting on software. Sampling jitter stays within microseconds, so the denominator of a numerically differentiated velocity or acceleration carries no scheduling noise.

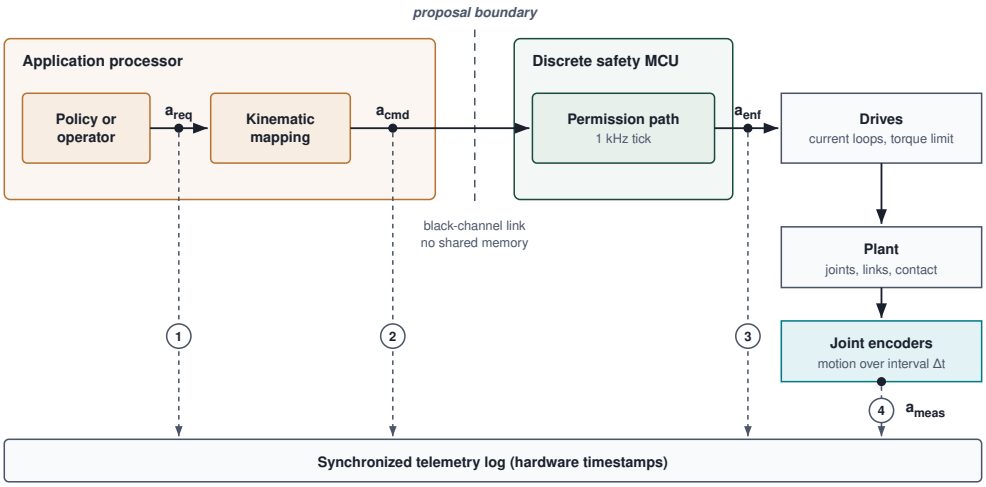

Figure 5.2: Four-stream action tap tuple: Four places a command can be logged, from raw policy intent on the application processor through to measured plant response. Which tap a dataset records decides what the model learns to imitate. The four-tap decomposition is this book's construct; the teleoperation rigs it instruments follow Zhao et al. (2023) and P. Wu et al. (2024).

5.5.1 The four-stream action tap tuple

If a dataset keeps only one signal from those two processing domains, any discrepancy between what the operator asked for and how the arm actually moved becomes impossible to diagnose. A command must therefore be logged at each of the four causal stages it passes through. The **four-stream action tap** $(a_{\text{req}}, a_{\text{cmd}}, a_{\text{enf}}, a_{\text{meas}})$ records all four in one hardware-synchronized telemetry log (figure 5.2). Two are logged on the unprivileged Linux host before the black-channel link, and two on the discrete safety MCU after the 1 kHz permission check. Logged together, the taps keep interventions and tracking errors auditable.

Dividing telemetry logging across the unprivileged Linux host and the hard real-time MCU captures four distinct physical signals:

- **Tap 1: The requested action (a_{req}, "Asked"):** Logged in user space on the application processor, this represents unconstrained human operator input (from a leader arm or joystick) or the raw forward-pass output from an unverified policy, tagged with its native coordinate frame and issue timestamp prior to software validation. This proposal reflects unadulterated human or policy intent, but it frequently demands infeasible joint accelerations or violates spatial bounding envelopes.
- **Tap 2: The mapped command (a_{cmd}, "Mapped"):** The kinematically retargeted setpoint (such as Cartesian end-effector velocities converted to joint space setpoints via inverse kinematics), incorporating coordinate frame transformations, trajectory interpolation, and workspace limits before transmission across the black-channel board link to the safety MCU.
- **Tap 3: The enforced command (a_{enf}, "Allowed"):** Logged on the bare-metal MCU on the permission side of the boundary, this represents the command after the permission path has checked or modified the proposal. The checks include deterministic Control Barrier Functions (CBFs, safety filters that keep states within a forward-invariant safe set), velocity and acceleration clamps, torque saturation envelopes, and collision guards. Whichever tap a dataset chooses as its label, the imitation loss has the same form; written for the admitted command, it is:

$$\mathcal{L}_{\text{policy}}(\theta) = \mathbb{E}_{(\mathbf{o}_t, \mathbf{a}_{\text{enf},t}) \sim \mathcal{D}_{\text{demo}}} \left[\mathcal{L}(\pi_\theta(\mathbf{o}_t), \mathbf{a}_{\text{enf},t}) \right],$$

  Here the training dataset must contain curated, correctly attributed targets. Passing the permission check does not make a command an expert demonstration, because a clamp or emergency stop may be a safeguard's response to a poor request. Override flags and companion

taps determine which records can serve as imitation targets and which remain evidence of intervention.

- **Tap 4: The measured response (a_{meas}, "Done"):** The physical plant reaction measured by optical joint encoders and motor current shunt resistors over the executed control tick, recording actual mechanical displacement and electrical effort. This measured response serves as proprioceptive state input ($\mathbf{o}_{\text{proprio},t+1}$) for subsequent policy steps rather than an action label.

These distinctions become critical when commanded intent and physical motion diverge. If a teleoperator requests an aggressive movement that the safety permission path clamps, the resulting state transition follows the enforced command (a_{enf}), not the unconstrained request (a_{req}). Pairing that transition only with the request conceals the safety intervention and teaches a policy to repeat demands the physical machine cannot execute.

↪ Control barrier functions and the forward-invariant safe sets they enforce are developed in section 12.5.

At the latch, the opposite ambiguity arises. Contact resistance can bring measured joint velocities to zero ($\dot{\mathbf{q}}_{\text{meas}} \approx \mathbf{0}$) while the motors continue exerting holding torque against the strike plate. Treating that response as a deliberate zero-velocity target loses the distinction between maintaining effort against the latch and choosing to stop. The appropriate imitation target depends on the policy's action interface; the other taps explain how that target became physical motion.

Retaining all four streams is what makes any single choice of label interpretable. A policy trained on the request alone learns commands the permission path would have clamped, and one trained on the measured response alone learns the arm's compliance, backlash, and external disturbances as if they were intended control. A log that keeps only the final encoder state or only the operator's input discards exactly the stages at which software and safety hardware changed the command. The tuple is also only as reliable as its shared clock. The application processor and the MCU must stamp their taps in one hardware-synchronized timebase, such as the IEEE 1588 Precision Time Protocol (PTP), written t_{PTP}. A few milliseconds of skew between them misaligns each visual observation from the torque it prompted (section 5.5.2).

For the latch campaign, the imitation target is the mapped command whenever it represents an expert request that the permission path accepted unchanged. In that case a_{cmd} and a_{enf} carry the same value, so the choice between the two taps matters only for commands the permission path modified. A modified command remains a separate, attributed intervention; a curated recovery can later supply an expert target at that state. Each training pair therefore carries two times. The observation is dated when its physics was true, at the exposure midpoint (the instant halfway through the interval over which the camera integrates light), and the command is dated when the operator issued it. The gap between them is part of the demonstration and is recorded rather than erased, because it contains the operator's own reaction time (section 5.6.1). The alignment developed below supplies the first of these times.

5.5.2 Multi-rate time synchronization and exposure-midpoint alignment

↪ The capture timestamp, taken in hardware at the exposure midpoint, is enforced for every sensor in section 8.3.

Recording the right action tap still leaves open when each recorded observation was physically true, because a robot's sensors run at different rates and transport delays. A naive data loader that latches the latest available sensor sample pairs each action with a camera frame whose optical exposure was centered 25–40 ms before the frame arrived in host memory, recording that delayed image as the present state. Trained on those pairs, the policy learns to map historical visual states to present actions, baking an artificial phase lag into its weights that shows up at deployment as overshoot and chattering against the latch. Across the machine, cameras integrate photons over exposure windows of 10–35 ms at 30–60 Hz, 6-axis force-torque sensors stream over a Serial Peripheral Interface (SPI) or Controller Area Network (CAN) bus at 100–500 Hz, joint and permission telemetry is retained at the MCU's chosen 1 kHz tick while motor-drive current sampling serves the faster local current loop, and neural policy models dispatch setpoints at 10–50 Hz. Unlike the operator's reaction time, this pairing error belongs to the logging pipeline rather than the demonstration, so stamping each sample at its physical capture instant lets the alignment pipeline remove it.

To quantify the physical hazard of temporal misalignment, consider the spatial tracking error $\Delta\mathbf{x}_{\text{sync}}$ injected into the dataset when an observation and an action are paired across an uncompensated phase lag Δt_{lag}:

$$\Delta\mathbf{x}_{\text{sync}}(t) = \int_{t-\Delta t_{\text{lag}}}^{t} \mathbf{v}(t')\,dt' \approx \mathbf{v}(t) \cdot \Delta t_{\text{lag}}. \tag{5.3}$$

The latch campaign moves far more slowly than an arm in transit, and notebook 5.1 applies equation 5.3 at both speeds.

Napkin Math 5.1: The pairing lag

Problem: A logger pairs each action with a camera frame whose exposure midpoint lies an uncompensated 35 ms earlier. Does the resulting pairing error fit the 2 mm latch clearance at transit speed and at the latch campaign's two approach speeds, and how much lag can each approach tolerate?

Variables:

- Uncompensated lag $\Delta t_{\text{lag}} = 35$ ms (illustrative; exposure-to-arrival delay of an untimed logger)
- Latch clearance $c = 2$ mm (illustrative)
- Transit speed 0.50 m/s (illustrative); guarded approach 0.03 m/s and faster approach 0.10 m/s (illustrative scenario speeds of the running machine)

Math:

1. **Transit**: 0.50 m/s $\times$ 35 ms $=$ 17.5 mm, 8.8× the clearance.
2. **Guarded approach**: 0.03 m/s $\times$ 35 ms $=$ 1.05 mm, inside the clearance.
3. **Faster approach**: 0.10 m/s $\times$ 35 ms $=$ 3.5 mm, outside it.
4. **Lag ceilings**: $\Delta t_{\text{lag,max}} = c/v_{\text{app}}$, so 2 mm / 0.03 m/s $=$ 66.7 ms and 2 mm / 0.10 m/s $=$ 20 ms.

Result: The same lag fits the modeled pairing-error allocation at the guarded approach and exceeds it at the faster one.

Systems insight: A timing error becomes a position error at the speed of the motion, just as observation age becomes blind travel $v\,\tau_{\text{delay}}$ in the stopping budget derived in section 2.3.1. The faster approach cannot be collected without the exposure-midpoint alignment of the four-stage pipeline in section 5.5.2.3.

When an imitation learning model trains on misaligned pairs, it fits a relationship in which the action appears to precede the visual evidence that prompted it. During closed-loop deployment, that artificial phase lag appears as overshoot, control hunting, and chattering against rigid surfaces. Because displacement grows linearly with lag, each approach speed has a lag ceiling equal to the clearance divided by the speed, and figure 5.3 places those ceilings beside a second timing error the notebook did not count. A rolling-shutter sensor exposes its pixel rows one after another rather than all at once, so the bottom row of a frame is captured later than the top (section 5.5.2.2 quantifies the delay). A full-frame rolling-shutter skew of 15 ms to 33 ms is comparable to the uncompensated lag, so a logger that stamps every frame correctly can still breach the faster approach's 20 ms ceiling through readout alone.

5.5.2.1 Hardware timestamps vs. software arrival timestamps

The 35 ms pairing lag in notebook 5.1 arises when a logger stamps a sensor packet with the clock reading at the instant a Linux thread wakes up to read it rather than when the hardware captured the sample. Even on the 1.0 ms kinematic stream, half a millisecond of kernel scheduling jitter cuts a nominal tick in half or stretches it by half, doubling or shrinking the finite-difference velocity label for the exact same physical motion. Both errors come from confusing when an optical or electrical event happened in hardware with when the operating system noticed it in software:

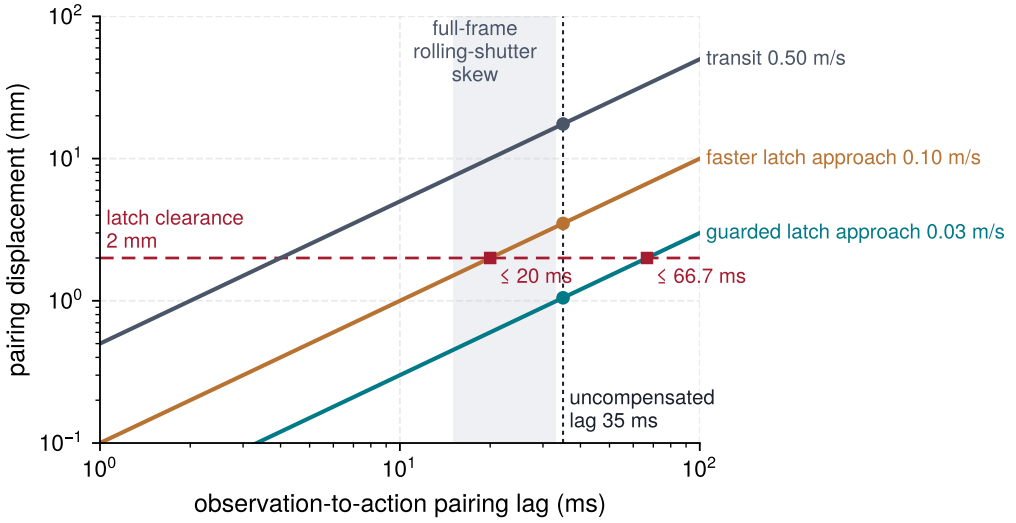

Figure 5.3: One lag, three verdicts: Pairing an observation with an action across an uncompensated lag displaces the recorded state by speed times lag. At 35 ms the transit pairing is 17.5 mm off, the faster latch approach exceeds the 2 mm clearance, and the guarded approach stays inside it. The clearance tolerates at most 20 ms of lag at 0.10 m/s and 66.7 ms at 0.03 m/s; a full-frame rolling-shutter skew alone spans 15 ms to 33 ms.

- **Software arrival timestamps (t_{host}):** In naive logging pipelines, an image frame or CAN packet is timestamped when the Linux kernel handles the device interrupt or when a user-space thread dequeues the buffer from Video4Linux2 (V4L2) or a socket. This host timestamp incorporates camera pixel readout time, USB 3 or MIPI CSI-2 bus serialization, Direct Memory Access (DMA) latency, and operating system scheduling jitter:

$$t_{\text{host}} = t_{\text{mid}} + \frac{t_{\text{exp}}}{2} + t_{\text{readout}} + t_{\text{bus}} + t_{\text{driver_irq}} + \delta_{\text{jitter}}.$$

  Host timestamps lag physical reality by 20–45 ms. In an untuned system, operating system scheduling jitter ($\delta_{\text{jitter}} = \pm 5$–$15$ ms), driven by kernel preemption latency, CPU C-state power wake-up transitions, and USB host controller interrupt coalescing (where packets are held in hardware buffers until a threshold count or timer expires), corrupts numerical differentiation. When joint velocities are computed via backward difference:

$$\dot{\mathbf{q}}_k = \frac{\mathbf{q}_k - \mathbf{q}_{k-1}}{t_k - t_{k-1}},$$

  a nominal 1 kHz sampling interval ($\Delta t = 1.0$ ms) perturbed by software timestamp jitter $\delta_{\text{jitter}} = \pm 0.5$ ms causes the denominator to fluctuate between 0.5 ms and 1.5 ms. The effect is doubling the inferred velocity at the shorter interval and reducing it by one third at the longer interval, for the same measured displacement. If thread preemption reverses packet dequeuing order ($t_k < t_{k-1}$), the computed velocity reverses sign, injecting spurious velocity spikes into the training targets.

- **Hardware PTP timestamps (t_{PTP}):** Hardware timestamps isolate the physical event from host scheduling delays. IEEE 1588 Precision Time Protocol (PTP) estimates clock offset across distributed nodes using a deterministic two-way message exchange.[5] The reference clock sends at t_1 and receives the reply at t_4; the remote clock receives at t_2 and replies at t_3. Under symmetric path delays, the propagation delay and offset are:

$$T_{\text{prop}} = \frac{(t_4 - t_1) - (t_3 - t_2)}{2}, \qquad \theta_{\text{offset}} = \frac{(t_2 - t_1) - (t_4 - t_3)}{2}.$$

  Because the forward timestamp difference $t_2 - t_1 = T_{\text{prop}} + \theta_{\text{offset}}$ adds the remote clock offset to the one-way propagation delay while the return difference $t_4 - t_3 = T_{\text{prop}} - \theta_{\text{offset}}$ subtracts

5 **Precision Time Protocol (PTP)**: IEEE 1588 was first published in 2002 for test-and-measurement and industrial-automation networks, and its current revision dates from 2019 (IEEE 2020a). It reaches sub-microsecond agreement only when both endpoints timestamp packets in hardware at the network interface. Its weak point is the symmetric-path assumption in the offset formula, because a link whose two directions differ in delay biases the computed offset by half that difference, and every observation-action pairing in the archive inherits the bias.

that same offset, adding the two differences cancels θ_{offset} to isolate the propagation delay and subtracting them cancels T_{prop} to isolate the clock offset. Hardware timestamping bounds uncertainty, but a network packet timestamp does not automatically equal an optical exposure midpoint. Production logs must preserve the capture event, clock domain identity, and bounded conversion error. The key collection decision is whether that uncertainty fits within the task's spatial alignment tolerance.

↪ **Protocol:** The IEEE 1588 message exchange, its clock servo, and its path-asymmetry uncertainty are developed in section C.7.

5.5.2.2 Rolling shutter skew across camera streams

When a camera with a rolling shutter pans past the cage door or rides on a moving link, straight vertical bars bend into diagonal arcs because the bottom pixel row is exposed up to 33 ms later than the top row. This distortion is **rolling shutter skew**: low-cost consumer sensors and webcams expose pixel rows one after another rather than all at once. For a sensor with H vertical scanlines and line readout duration t_{row}, row $y \in [0, H-1]$ begins its exposure at $t_{\text{scan}}(y)$, and its exposure midpoint, half an exposure later, depends linearly on its vertical coordinate:

$$t_{\text{scan}}(y) + \frac{t_{\text{exp}}}{2} = t_{\text{start}} + y\, t_{\text{row}} + \frac{t_{\text{exp}}}{2}.$$

Across a full frame, the temporal skew between the top row ($y = 0$) and bottom row ($y = H-1$) accumulates to:

$$\Delta t_{\text{skew}} = (H-1)\, t_{\text{row}}, \tag{5.4}$$

which for common sensors lies between about 15 ms and 33 ms, the upper end being one full frame period at 30 Hz. When the robot arm or camera moves at 0.50 m/s, the bottom of the manipulator in the image is captured while the physical link has moved up to 16.5 mm relative to the top of the link in the same frame. Even at the faster latch approach of 0.10 m/s, the worst-case skew moves the gripper 3.3 mm within one frame, exceeding the 2 mm clearance. This geometric warping (the "jello effect") deforms straight edges into curved arcs and breaks rigid-body geometry.

Independent rolling shutters can depict the same moving arm at different poses within nominally simultaneous frames. Hardware-triggered global shutters simplify alignment; rolling shutters require a row-time model and a motion bound or correction. Sensor choice must follow the task tolerance rather than an unyielding demand for a single shutter architecture.

↪ The same row timing as a spatial error on a moving base, charged against clearance and removed by per-row motion compensation, is developed in section 8.2.

5.5.2.3 A four-stage alignment pipeline

Hardware timestamps fix when each sample was taken, and the row-time model fixes when each part of an image was exposed. A collection pipeline still has to turn those facts into training pairs whose pairing error fits inside the clearance budget of notebook 5.1. It can implement that alignment contract in four stages:

1. **Hardware-triggered optical exposure midpoint:** The real-time MCU dispatches hardware GPIO sync pulses or PTP-synchronized trigger packets to every triggerable camera. The rig mixes shutter types. The wrist camera's global shutter exposes all rows together, while the navigation camera and the external cameras' color sensors read out row by row, so their frames also need the row-time model above to assign each row its own midpoint. The camera latches the trigger at t_{start}, and the driver calculates the true optical midpoint $t_{\text{mid}} = t_{\text{start}} + t_{\text{exp}}/2$ in hardware PTP clock units (t_{PTP}), avoiding host arrival time as the exposure timestamp.[6]
2. **Lock-free time-sorted jitter compensation:** Because network and bus transfers experience variable transport delay δ_{jitter}, incoming sensor packets are stamped with their hardware PTP capture timestamp and inserted into a lock-free, time-sorted jitter ring buffer in shared memory. An asynchronous consumer thread advances a playhead lagging real-time by a fixed, bounded window ($T_{\text{buf}} = 15$–25 ms), absorbing transport bursts and re-ordering packets into monotonic hardware timestamp sequence.
3. **Cubic Hermite kinematic interpolation:** Because joint encoders sample at 1 kHz (1 ms period) while cameras capture at 30 Hz or 60 Hz, the camera midpoint t_{mid} falls between two discrete MCU telemetry ticks t_k and t_{k+1}. The synchronization thread interpolates joint angles

[6] **Hardware Exposure Triggering**: A dedicated GPIO or TTL pulse from the real-time microcontroller starts every camera's exposure on the same electrical edge, instead of a software trigger issued through the host's driver stack. Triggered global-shutter cameras then begin exposing within microseconds of one another, which leaves the exposure duration, not the trigger path, as the dominant term in the midpoint timestamp.

$\mathbf{q}(t_{\text{mid}})$ using cubic Hermite splines across the bounding kinematic records $(t_k, \mathbf{q}_k, \dot{\mathbf{q}}_k)$ and $(t_{k+1}, \mathbf{q}_{k+1}, \dot{\mathbf{q}}_{k+1})$:

$$\mathbf{q}(t_{\text{mid}}) = h_{00}(\lambda)\mathbf{q}_k + h_{10}(\lambda)\Delta t_s \dot{\mathbf{q}}_k + h_{01}(\lambda)\mathbf{q}_{k+1} + h_{11}(\lambda)\Delta t_s \dot{\mathbf{q}}_{k+1},$$

where $\Delta t_s = t_{k+1} - t_k = 1$ ms, $\lambda = (t_{\text{mid}} - t_k)/\Delta t_s \in [0,1]$ is the fraction of the tick elapsed at the exposure midpoint, and $h_{ij}(\lambda)$ are the cubic Hermite basis functions (section B.5). This gives a smooth state estimate between valid samples. The interpolation error still needs a bound, especially across contact or missing telemetry.

4. **Pre-serialization alignment:** Container formats store multi-rate topics with the timestamps provided by the logger. Alignment may occur during capture or in a versioned preprocessing pass. Preserve the raw timestamps and interpolation provenance in either case, so the training pair carries an estimated state and its uncertainty rather than an assertion of exact simultaneity.

The same pairing contract governs deployment. A policy trained on aligned pairs must also be fed aligned observations and have its actions executed when the training data implies. UMI measures each observation stream's latency and aligns all streams to the slowest, usually the camera. It then sends commands ahead of time to cover the arm's and gripper's execution latency, and it discards actions whose execution time has already passed. With latency matching disabled, the same policy's motion became visibly jittery (Chi et al. 2024). UMI also expresses actions relative to the gripper's current pose rather than in a fixed robot frame, which removes the dependence on a base calibration and lets one policy run on more than one arm.

> Checkpoint 5.1: Action labels and pairing time
>
> A training pair is only as trustworthy as the tap it imitates and the time it assigns to each observation.
>
> - ☐ **Clamped request**: A teleoperator requests a motion that the permission path clamps. Which tap does the resulting state transition follow, and where does the record keep the evidence of the clamp?
> - ☐ **Stalled latch**: Measured joint velocity is zero while the motors hold torque against the latch. Why is a_{meas} the wrong imitation target at that step?
> - ☐ **Unchanged mapped command**: Under what condition can a_{cmd} serve as the expert target, and what happens to the pair when that condition fails?
> - ☐ **Lag budget**: A tighter strike plate leaves only 1 mm of clearance. At the faster approach of 0.10 m/s, what is the largest uncompensated lag the pairing tolerates, and does a logger with the 35 ms lag of notebook 5.1 meet it?

A tap and a timestamp are only as good as the loop that produced them. In teleoperation that loop runs through a human, and the interface between human and machine shapes the recorded dynamics, storage bandwidth, and hardware wear long before the data reaches a model (section 5.6).

5.6 Teleoperation Demonstration Costs

When an operator guides a leader arm to unlatch the warehouse cage door, every corrective nudge must traverse a multi-stage physical loop before the robot can respond. Teleoperation is a data-generation pipeline with a human embedded in the real-time feedback loop. It charges for each demonstration in three currencies: the phase lag and stability margin of the loop itself, the write bandwidth and storage the session demands, and the cell time and component life a campaign consumes. The loop comes first (figure 5.4). The operator sees the scene on a display after a delay t_{disp} and perceives, decides, and moves the leader in t_{hum}. The command crosses to the follower in t_{cmd}. The follower's actuators then accelerate the links against inertia, drivetrain friction, and contact in t_{mech}, before the camera shows the result on the next cycle.

↪ Where a deployment moves operators' labor, and which uses of their recorded sessions it must bar, is developed in section 17.8.

By mapping each leader joint directly to the corresponding follower joint ($\mathbf{q}_{\text{leader}} \equiv \mathbf{q}_{\text{follower}}$), this isomorphic leader-follower topology sidesteps numerical inverse kinematics and algorithmic

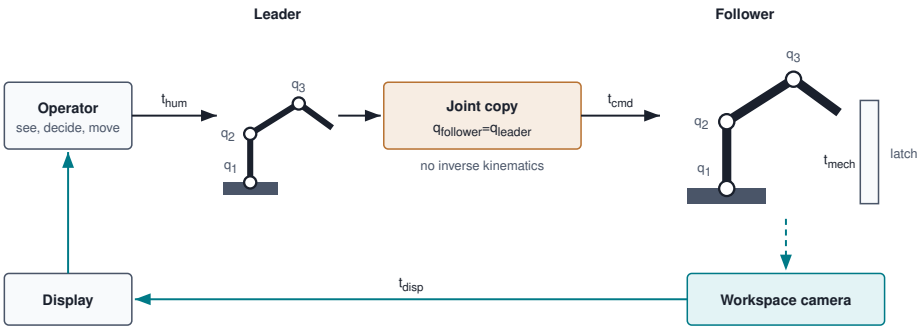

Figure 5.4: Kinematically isomorphic teleoperation loop: The operator moves a leader arm whose joints mirror the follower's, and the host copies joint angles across, as in low-cost leader-follower rigs such as GELLO (P. Wu et al. 2024). Because the leader shares the follower's joint structure, the interface needs no inverse kinematics and inherits none of its singularities (configurations where joints align and the arm loses a direction of motion), preserving the operator's direct joint-level coordination. The loop still closes through the operator: human reaction, command transfer, mechanical response, and display delay all enter the recording as phase lag, so the demonstration carries the operator's delay as if it were policy.

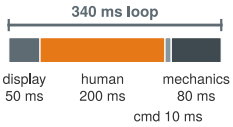
kinematic singularities. Even without software kinematic conversion, however, every recorded trajectory remains bound to the physical transport and neuromuscular delays of the complete loop, placing hard upper bounds on corrective bandwidth.

5.6.1 Human-in-the-loop latency and bilateral passivity breakdown



The operator's own reaction is 58.8 percent of the 340 ms correction loop.

Suppose the follower gripper grazes the side of the latch strike plate at time t. If a logger naively pairs the observation $\mathbf{o}_t$ captured at that instant with the command the operator issued at t, it pairs a contact state with an action chosen for a trajectory state 250 ms earlier, before the contact ever happened. A behavioral cloning policy trained on those pairs learns that delay as intentional strategy and, when run autonomously at high control frequencies, over-corrects into destructive oscillations. That stale pairing arises because every stage of the teleoperation loop adds phase delay. In an illustrative reference setup with a high-speed camera and a wired local network, display pipeline processing takes $t_{\text{disp}} = 50$ ms across sensor exposure, H.264 decoding, and display raster refresh. Human visual perception, motor planning, and neuromuscular transmission add an operator response latency of $t_{\text{hum}} = 200$ ms. Command quantization, packetization, and fieldbus transport add $t_{\text{cmd}} = 10$ ms. Actuator torque ramp-up against link inertia then adds a mechanical response latency of $t_{\text{mech}} = 80$ ms before the arm reaches the commanded acceleration. Their sum is the **teleoperation round-trip latency** t_{loop}, the elapsed time from a physical contact disturbance to the corrective actuator response:

$$t_{\text{loop}} = t_{\text{disp}} + t_{\text{hum}} + t_{\text{cmd}} + t_{\text{mech}}. \tag{5.5}$$

Following the contact at time t through those four stages shows why the recorded command lags the state. The operator sees the error on the display 50 ms later and commands a physical correction at $t +$ 250 ms. The follower arm finally pushes back at $t +$ 340 ms, after drifting under momentum and contact compliance throughout the interval. Round-trip latency is therefore a property of the resulting dataset rather than just an artifact of the rig, because it injects a systematic phase lag into every recorded demonstration, dominated by the operator's own reaction time (58.8 percent of the loop in this setup).

This delay differs in kind from the sensor-pipeline delay of section 5.5.2. That one was a pairing artifact of the logger, and exposure-midpoint stamping lets the alignment pipeline account for it. The operator's delay is a real property of the demonstrator, so no timestamp correction can remove it, and silently erasing it would misstate what the demonstration contains. The logger therefore keeps both times of every pair (the observation's exposure midpoint and the command's issue time) and records the session's measured loop latency. Training can then treat the observation-to-action interval as a declared part of the demonstration, either by conditioning the policy on enough

observation history to span it or by pairing each command with the earlier frame the operator was answering. Deployment can then match the interval it was trained with, as UMI's latency matching does (section 5.5.2.3). Because the operator's reaction varies from command to command, no single fixed shift recovers the exact frame each command answered, which is why the latch campaign records the interval instead of baking one correction into the archive.

Force reflection introduces a deeper stability challenge into the collection interface. In **bilateral teleoperation**, the operator manipulates the leader device while measured contact forces from the follower arm reflect back across a delayed communication channel. Over a closed motion cycle of period T_{cycle}, the net mechanical energy delivered at that port is:

$$\Delta E = \int_0^{T_{\text{cycle}}} F_{\text{contact}}(t - T_d) v(t)\, dt.$$

The sign of ΔE depends on the force–velocity phase relationship. Under the declared port orientation, energy delivered in excess of received and initially stored energy violates passivity;[7] a positive value over one cycle alone does not establish that excess. In an undelayed elastic contact, the reflected force opposes the leader handle during compression and drops as the handle rebounds, whereas transmission delay T_d causes peak contact force to continue pushing the leader handle after the operator has already reversed direction, aligning force with rebound velocity $v(t)$ to pump net mechanical energy into each oscillation cycle and excite contact instability (Anderson and Spong 1989). The wave-variable transformation derived in section B.10 keeps the ideal delayed channel passive and lossless under its constant-delay model, while passivity observers (monitors that track the energy a port has generated and dissipate any excess) restore passivity by injecting variable damping. Preserving channel passivity imposes a force-fidelity cost at contact. Injected damping, and the explicit low-pass filtering often added to delayed force channels, suppress the fastest components of the reflected force first, so a stabilized channel behaves as a low-pass filter on contact. In data collection, this imposes an unavoidable label-fidelity trade-off. The filtering that stabilizes delayed haptic feedback also attenuates the sharp contact transients the operator needs to demonstrate precise tactile insertion. System builders must log the active feedback architecture and filter cutoffs alongside raw trajectories to document this phase distortion.

The mechanical interface therefore filters which behaviors can reach the archive at all. A force-reflecting leader allows an operator to feel mechanical binding and ease off insertion forces. A visual-only Cartesian rate controller instead forces the step-and-wait hunting of section 5.4.1, because the operator must wait for display frames to confirm each small motion. A backdriven joint-space leader such as ALOHA, recorded at 50 Hz (Zhao et al. 2023), occupies an intermediate design point, providing inertial and friction feedback from the leader mechanism itself without reflecting follower contact forces. Across all these interfaces, human operators instinctively decelerate prior to contact, because closing a high-gain corrective loop around round-trip latency t_{loop} would erode phase margin to zero. Table 5.2 categorizes the dominant teleoperation architectures and the specific data collection artifacts they produce.

7 | **Passivity**: A passive system cannot deliver more energy through its ports than it has received or initially stored. A well-posed, power-conserving interconnection of passive components preserves their combined passivity inequality. Stronger stability conclusions require bounds on stored energy and appropriate strictness or detectability conditions, as developed in section B.10. Anderson and Spong (1989) showed that a delayed communication channel need not be passive and restored passivity for any constant delay with a scattering transformation, and Niemeyer and Slotine (1991) recast the idea as wave variables. The price is paid in force fidelity at contact, and the demonstrations record that price.

Table 5.2: Teleoperation interface mechanisms for physical demonstration collection: Mapping and feedback determine what the operator can demonstrate, and the last column names the artifact to check on a given rig, task, and operator.

Interface and feedback	Command mapping	Contact information available to operator	Possible collection artifact to check
Force-reflecting bilateral leader	Leader motion mapped to follower joints; measured follower force reflected to leader	Vision and physical contact force, subject to link delay and fidelity	Contact corrections and oscillation when delayed force reflection loses passivity
Backdriven joint-space leader (ALOHA) (Zhao et al. 2023)	Leader joint positions copied to follower; demonstration recorded at 50 Hz	Vision and leader mechanism feel, without active follower force reflection	Joint-space posture preferences and unobserved follower contact forces
Rate-controlled 3D mouse	Device deflection mapped to Cartesian velocity, then inverse kinematics	Primarily visual feedback unless a separate haptic channel exists	Step-and-wait motion and zero-velocity pauses under delayed feedback

Interface and feedback	Command mapping	Contact information available to operator	Possible collection artifact to check
Tracked spatial controller	Tracked hand pose mapped to tool pose with clutching and scale	Visual feedback; optional vibration is not directional force reflection	Clutch discontinuities and pose-tracking gaps
Instrumented exoskeleton	Wearable joint motion retargeted to robot joints	Depends on whether active force feedback is fitted	Biomechanical calibration and retargeting bias

5.6.2 Ingestion rate and the preservation requirement

The loop's latency is the first cost a demonstration carries; the second is what it takes to write everything the loop produced to disk without silent data loss. If an onboard logger tries to stream raw multi-camera video and 1 kHz kinematics onto a SATA solid-state drive, write buffers overflow within seconds, dropping either the camera frames or the four action taps of section 5.5.1 that explain what the permission path did. Whether an edge collection computer can sustain a teleoperated session without dropping samples is storage-bus arithmetic: the aggregate write rate set against the sequential write bandwidth of the drive.

Napkin Math 5.2: The cheapest stream

Problem: One teleoperated door-opening session on the warehouse mobile manipulator logs every camera and every axis raw. What sustained write rate and storage does it demand, and what share of the bytes carries the four action taps?

Variables (camera geometry is datasheet; logging formats and shift length are chosen):

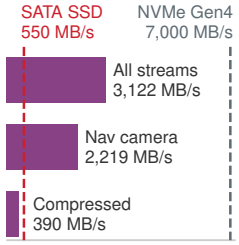
- **Navigation camera:** 4056 by 3040 px at 60 Hz, logged as 24-bit RGB (3 bytes/px).
- **Wrist camera:** 1440 by 1080 px at 60 Hz, logged the same way.
- **External cameras:** 2 RGB-D cameras viewing the door, color at 1920 by 1080 px and 30 Hz, with depth aligned to the color frame as raw `uint16` millimeters (2 bytes/px).
- **Kinematics:** 9 axes (two base wheels, seven arm joints) logged at 1 kHz. Each step stores, for every axis, 6 values of 4 bytes (position and velocity, which form the measured response a_{meas}; measured torque; and the requested, mapped, and enforced commands), plus one 8-byte timestamp.
- **Shift:** 8 hours of collection on one machine.

Math:

1. **Kinematic stream**: $9 \times 6 \times 4\ \text{B} + 8\ \text{B} = 224\ \text{B}$ per step, and at 1 kHz that is 0.22 MB/s.
2. **Navigation camera**: $4056 \times 3040\ \text{px} \times 3\ \text{B} \times 60\ \text{Hz} = 2219.44$ MB/s. The wrist camera's product is 279.94 MB/s.
3. **External pair**: $2 \times 1920 \times 1080\ \text{px} \times (3\ \text{B} + 2\ \text{B}) \times 30\ \text{Hz} = 622.08$ MB/s, of which 373.25 MB/s is color and 248.83 MB/s depth.
4. **Total and storage**: The streams sum to 3121.68 MB/s, about 3.12 GB/s; over one hour that is 11.24 TB, and over the shift 89.9 TB.

Result: Raw logging needs a sustained 3.12 GB/s write path, and the kinematic stream is 0.007 percent of the bytes.

Systems insight: The navigation camera alone writes 4.0× what a SATA SSD sustains (550 MB/s). The full session fits within a Gen4 NVMe drive's 7 GB/s, but only by consuming storage at 11.24 TB per hour. Intra-frame video compression at an illustrative 8× brings the rate to about 390.2 MB/s (1.40 TB per hour) at the cost of encoder latency and artifacts in the frames the policy will train on. The kinematic stream carries all four action taps, so the record that preserves the causal chain is the cheapest stream to log, and a logger that drops data under buffer pressure must never drop it first.

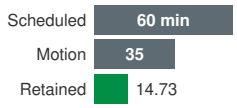


The navigation camera alone writes 4.0× what a SATA SSD sustains; only the compressed session fits under it.

Keeping that write rate under the drive ceiling with video compression trades storage bandwidth against visual fidelity, because lossy encoders discard fine spatial detail at the latch edge and inject blocking artifacts into the frames the policy trains on. A session can be stored in custom HDF5 files, ROS 2 MCAP bags (a container format for multimodal robotics data), or standardized schemas such as LeRobot (Cadene et al. 2024). Whichever format is used, the logger must flush complete chunks to non-volatile storage before a power drop or process halt can truncate the write buffer. It must also carry all four control taps, hardware timestamps, clock-domain identifiers, missing-sample flags, and spatial calibration parameters through every format conversion. Otherwise, a file that deserializes without error proves only that its byte layout is intact, not that its sensory and motor streams remain physically synchronized.

5.6.3 Operational yield and mechanical fatigue budgeting

Sizing the NVMe drive settles what one hour in the workcell writes to disk, but less than a quarter of that scheduled hour survives as usable demonstration motion. Before the arm records a single latch opening, a scheduled hour in the workcell pays for bus synchronization, camera and torque-sensor calibration, and mandatory operator rest. The active motion window that remains is further divided among door-reset strokes, mid-trial contact trips, and offline quality filtering. Because every attempt, whether retained or discarded, flexes the wrist cable harness and reverses load on the harmonic drive, a collection campaign is bounded as much by component fatigue life as by facility reservations.



In this illustrative session, setup, rest, resets, and rejected attempts leave under a quarter of the scheduled hour as retained demonstrations.

The ultimate metric of collection efficiency is **demonstration yield**: the number of validated, policy-ready trajectory records produced in a scheduled session after accounting for cell startup, sensor calibration, operator rest, mechanical resets, and offline quality filtering. Given an active motion window T_{motion}, an attempt-and-reset cycle duration $t_{\text{cyc}} = t_{\text{att}} + t_{\text{rst}}$, and an end-to-end retention rate R, the session yields:

$$Y_{\text{usable}} = \left\lfloor \frac{T_{\text{motion}}}{t_{\text{cyc}}} \right\rfloor R. \tag{5.6}$$

Mechanical fatigue accumulates per physical motion cycle rather than per facility hour. This illustrative accounting assigns the same stress-cycle counts to failed and successful attempts and assumes component ratings expressed under the L_{10} convention. Under it, the rating is the cumulative cycle count at which 10 percent of an identical component population is statistically expected to fail.[8] Notebook 5.3 evaluates an illustrative door-opening collection session and its full campaign in both currencies: facility hours and component fatigue cycles.

[8] L_{10} **Rated Life**: The convention comes from rolling-bearing fatigue theory, where Lundberg and Palmgren (1949) modeled the scatter of bearing life as a probability of survival and rated a bearing by the life that 90 percent of a population reaches. A rating chosen that way is a population statistic, not a guarantee for one part. A fleet of ten collection arms, each run to its cable's rated life, should therefore expect about one cable to fail before the budget says it will.

Napkin Math 5.3: The flex-cable ceiling

Problem: The latch campaign must retain 5,000 demonstrations. How much scheduled cell time does that cost, and which wrist component's rated life does it spend fastest?

Variables (illustrative except the chosen session length and target):

- Session $T_{\text{sched}} = 60$ min (chosen), leaving an active window $T_{\text{motion}} = 35$ min after startup, calibration, and operator rest
- Attempt $t_{\text{att}} = 25$ s, one teleoperated opening; reset $t_{\text{rst}} = 15$ s, the door re-latched by its fixture
- In-trial failure rate 20 percent; post-collection quality filtering 15 percent
- Wear per attempt: $n_{\text{gear}} = 14$ torque reversals of the wrist's strain-wave gear; $n_{\text{cable}} = 8$ flex cycles of its internal cable bundle (6 while opening, 2 on the return stroke)
- Rated lives $L_{\text{gear}} = 5{,}000{,}000$ stress cycles and $L_{\text{cable}} = 200{,}000$ bending cycles

Math:

1. **Session**: $t_{\text{cyc}} = 25\text{ s} + 15\text{ s} = 40$ s, and $\lfloor 35\text{ min} / 40\text{ s} \rfloor = 52$ attempts, with 20 s left idle.
2. **Yield** (equation 5.6): $R = (1 - 0.20)(1 - 0.15) = 0.68$, so $Y_{\text{usable}} = 52 \times 0.68 = 35.36$ episodes, 14.73 min of validated motion, 24.6 percent of the scheduled hour.

3. **Campaign**: $\lceil$ 5,000 / 0.68 $\rceil$ = 7,353 attempts at 52 per session, or 141.4 h of scheduled cell time, 4.07× the 5,000 × 25 s of motion the campaign keeps.
4. **Wear**: 7,353 × 14 = 102,942 gear cycles, 2.1 percent of L_{gear}; 7,353 × 8 = 58,824 cable bends, 29.4 percent of L_{cable}.

Result: Less than a quarter of each scheduled hour survives as retained demonstration time, and one campaign spends far more of the cable's rated life than of the gear's.

Systems insight: The internal flex cable consumes the larger fraction of its assumed rating, informing maintenance planning rather than setting an individual replacement schedule. Three campaigns on one machine would consume most of its rated life, and an intermittent conductor break corrupts the very sensor streams being recorded. Because every attempt costs wear whether or not it is retained, the retention rate R divides both bills, while a faster reset shortens only the cell time.

Operator rest requirements and fatigue rates depend heavily on interface ergonomics and cognitive task difficulty; teams must empirically calibrate sustained operator throughput and retention on their specific hardware. A collection campaign must therefore be budgeted in both validated trajectory time and consumed fatigue life, not in facility clock hours. Table 5.3 breaks down the time and mechanical wear budgets of the illustrative session stage by stage.

↪ Per-cycle wear accounting for trial-based learning on the machine is developed in section 6.3.

Table 5.3: Physical demonstration collection budget across a scheduled 60-minute session: Illustrative facility clock time, yield losses, and component wear by stage for one session of the latch campaign ($N_{\text{att}} = 52$ attempts of $t_{\text{att}} = 25$ s, reset $t_{\text{rst}} = 15$ s). The 20 s of active time left after the last full cycle is idle and has no row. Less than a quarter of the hour survives as retained demonstration data.

Session Stage / Activity	Allocated Duration (Δt)	Wall-Clock Share (%)	Physical Operation & Control State	Hardware Stress & Wear Mechanism	Net Trajectory Output (N_{episodes} / T_{yield})
Cell Startup & Bus Sync	8 min (480 s)	13.3%	Bus synchronization (EtherCAT/CANopen), safety watchdog verification, optical homing	Power-on electrical inrush; thermal warm-up in motor windings and sensor bridges	$N_{\text{episodes}} = 0$ ep, 0.0 min yield
Sensor Calibration & Nulling	7 min (420 s)	11.7%	Camera intrinsic/extrinsic sweep, joint-torque bias nulling, encoder homing	Static holding torque; sensor bridge thermal stabilization; zero dynamic gear wear	$N_{\text{episodes}} = 0$ ep, 0.0 min yield
Operator Rest & Ergonomics	10 min (600 s)	16.7%	Mandatory operator breaks to mitigate visual fatigue, cognitive saturation, and tremor drift	Passive standby; electromagnetic brakes engaged or zero-velocity holding current	$N_{\text{episodes}} = 0$ ep, 0.0 min yield
Physical Scene Resets	13 min (780 s)	21.7%	Door closed and re-latched by its fixture, arm return stroke (15 s per attempt)	52 return strokes × 2 bends = 104 cable flex cycles; zero contact payload	$N_{\text{episodes}} = 0$ ep, 0.0 min yield
Active Teleoperated Attempts	21.67 min (1,300 s)	36.1%	Real-time human teleoperation guiding handle approach, latch release, and door swing (25 s per attempt)	52 × 14 = 728 torque reversals on harmonic drive; 52 × 6 = 312 cable flex cycles; contact monitored against the 15 N tripwire	$N_{\text{episodes}} = 52$ raw attempts, 21.67 min gross motion

Session Stage / Activity	Allocated Duration (Δt)	Wall-Clock Share (%)	Physical Operation & Control State	Hardware Stress & Wear Mechanism	Net Trajectory Output (N_{episodes} / T_{yield})
In-Trial Failures (Labeled)	-4.33 min (-260 s)	-7.2%	Handle slip, latch bind, contact tripwire above 15 N (20% loss)	High-force contact transients; abrasive wear on gripper silicone pads	-10.4 ep from success yield; valid logs kept
Post-Collection QA Filtering	-2.60 min (-156 s)	-4.3%	Offline filtering: link latency >100 ms, visual occlusion, operator hesitation (15% loss)	Zero hardware wear (offline computational validation pass)	-6.24 ep discarded
Net Validated Dataset Yield	**14.73 min (884 s)**	**24.6%**	High-quality synchronized multi-modal trajectories $(s_t, \mathbf{a}_t)$ admitted into training buffer	Consumes 2.1% of wrist gear life and 29.4% of internal flex cable life per 5,000-episode campaign	$Y_{\textbf{usable}} = \mathbf{35.36}$ episodes

Public collection shows what that yield arithmetic produces at community scale. The open-source LeRobot toolchain records teleoperated sessions in a common format and publishes them to the Hugging Face Hub with an auto-generated metadata card (Cadene et al. 2024). Figure 5.5 plots, from the Hub's own listing, how many such datasets exist and how many episodes each holds.

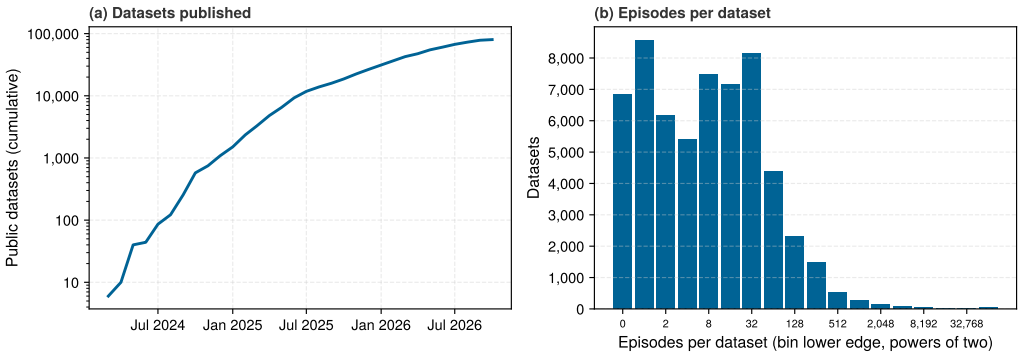


Figure 5.5: Many datasets, few episodes each: (a) Cumulative count of public datasets tagged with the LeRobot format on the Hugging Face Hub, by creation month; only datasets still public at retrieval are counted, so earlier values are lower bounds. (b) Episodes per dataset for the datasets whose card records a count, in power-of-two bins on a logarithmic axis. The count of datasets has grown by orders of magnitude while the typical dataset remains a single short session. Data retrieved from the Hub API on 2026-10-12.

The Hub held 1,085 such datasets at the end of 2024, 26,548 a year later, and 80,132 by the retrieval date. Episode counts tell a different story. Of the 59,031 datasets whose card records one, 58 percent hold fewer than 16 episodes, and only 2 percent hold 512 or more. The median dataset falls in the 8 to 15 episode bin, less than the roughly 35 validated demonstrations of the illustrative hour in table 5.3. Community data therefore grows wide rather than deep. The archive gains embodiments, scenes, and operators far faster than it gains repeated coverage of any one machine's states, and pooling it inherits the transfer problem of section 5.9.1.

The three costs compound into a fourth that no bill shows. Teleoperated demonstrations are bounded by what a human operator can perceive through video displays, coordinate through mechanical input devices, and stabilize against closed-loop delays. A campaign that pays for every attempt in cell time and cable life spends its budget where the operator is comfortable. The resulting dataset reflects the behavioral envelope of the coupled human-machine composite rather than the

robot's full physical dynamics. That selection bias decides which situations the archive covers, and measuring it requires a standard outside the archive (section 5.7).

5.7 Collection Policy Coverage

Every logged latch record carries an ingestion cost, an attributed action label, and a hardware timestamp, yet those fields say nothing about which physical situations the archive covers. In an illustrative contact task where a gripper aligns with a workpiece edge across contact angles $\theta_{\text{contact}} \in [-15.0^\circ, +15.0^\circ]$ and normal forces up to 20.0 N, binning at 1.0° and 1.0 N forms an operational grid of 600 discrete cells. Suppose two collection policies each record 1,000,000 transitions at 100 Hz with identical sensors. A cautious teleoperator keeps contact within $\pm 2.0^\circ$ of perpendicular under 4.0 to 6.0 N of normal force, populating 8 cells and leaving 98.7 percent of the grid empty. An exploratory policy approaches across the full angular range, slips, and loads the contact between 1.0 and 18.0 N, filling 510 cells and leaving 15.0 percent empty. Although both datasets have identical record counts, storage sizes, and hardware timestamps, they answer different operational questions. Record count therefore fails as a measure twice over: correlated control steps hold few independent samples (equation 5.2), and even independent samples support only the cells where they land.

That disparity arises because a physical dataset comes from running a closed-loop policy on hardware and logging the resulting transitions, violating the independent-and-identically-distributed assumption of standard empirical risk minimization (section 5.2). Instead, it traces an **empirical state-action occupancy distribution** (Spencer et al. 2021) $p^{\pi_{\text{col}}}(s, \mathbf{a})$ generated by a specific collecting policy π_{col} under its own control biases, interface delays, and risk tolerance. Formally, imitation learning minimizes prediction error weighted solely by this empirical occupancy:

$$\mathcal{L}_{\text{BC}}(\theta) = \mathbb{E}_{(s,\mathbf{a})\sim p^{\pi_{\text{col}}}} \left[\ell(\pi_\theta(s), \mathbf{a}) \right].$$

The learned policy π_θ therefore receives supervisory gradient updates only over the empirical support hull $\text{supp}(p^{\pi_{\text{col}}}) = \{s \in \mathcal{S} \mid p^{\pi_{\text{col}}}(s) > 0\}$. Outside this narrow support hull, the network's outputs are unconstrained by training demonstrations.

Supervisory labels exist only where the collecting policy visited and commanded an actuator action. In unvisited states, the dataset contains neither an optimal control response nor proof that a safe trajectory exists. Supervised loss functions cannot distinguish an inherently unstable physical configuration from a benign unvisited state or an outright collision hazard. Whether an autonomous policy generalizes in such regions, fails silently, or triggers a safety stop cannot be deduced from the archive alone; resolving that uncertainty requires targeted recovery demonstrations, expert relabeling, or explicit run-time gating. Consider a policy trained exclusively on the cautious teleoperation data. If unexpected surface friction perturbs the gripper to contact angle $\theta_{\text{contact}} = +4.5^\circ$, outside the eight demonstrated cells, the policy network evaluates an input unconstrained by demonstrations. One control step later, its ungrounded action drives the contact to $+6.0^\circ$ at 11.0 N, another state lacking corrective labels in the training corpus. Compounding errors push the manipulator progressively farther from the nominal corridor until the gripper jams against the fixture. This cascade illustrates endogenous covariate shift (definition 5.1) triggered by a coverage gap.

5.7.1 Choosing a tractable coverage table

The contact-angle example uses a compact grid because it isolates the parameters relevant to a single mating feature. Extending that dense discretization across all robot state variables triggers the **curse of dimensionality in continuous physical interaction**.[9] Consider a mobile manipulator with a 7-degree-of-freedom (7-DoF) arm, a 2-DoF differential-drive base, a 6-axis force-torque sensor at the wrist, and a 6-DoF target workpiece pose. The continuous state space has dimension:

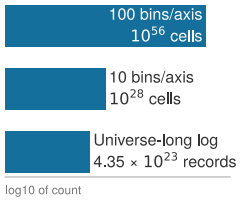
$$d_s = 7 \text{ (joint angles)} + 7 \text{ (joint velocities)} + 2 \text{ (wheel speeds)} + 6 \text{ (wrench components)} + 6 \text{ (workpiece pose)} = 28.$$

If an engineering team partitions each dimension into a crude $n_{\text{bin}} = 10$ bins (36° per angle bin and 10 N per wrench bin, far too coarse to guide contact tasks whose tolerances are a few millimeters), the discretized state space contains $n_{\text{bin}}^{d_s} = 10^{28}$ cells. A fleet of 1,000 robots logging at 1 kHz since the universe began, about 13.8 billion years ago, would hold 4.35×10^{23} records, enough to visit at most 0.004 percent of those cells even if every record landed in a different one. At a resolution

[9] **Curse of Dimensionality**: Bellman coined the phrase for dynamic programming, whose value tables grow exponentially with the number of state variables (Bellman 1957). A raw physical coverage table meets the same combinatorial barrier. Dynamic programming scaled by approximating value functions over compact feature spaces; a physical coverage table stays tractable the same way, by listing the few task parameters that determine success rather than the dense continuous state.

fine enough to guide contact ($n_{\text{bin}} = 100$ bins per axis), the count grows to 10^{56} cells. Brute-force observation cannot cover a continuous physical state space; a coverage table must describe the task with a few parameters instead.

Evaluating dataset completeness against the empirical extremes of collected values is fundamentally circular. A collection logger that records forces exclusively between 4.0 N and 6.0 N trivially reports full coverage of that observed interval. Coverage must instead be evaluated against the operational conditions that deployment demands, formulated before any demonstration data is collected.



A fleet logging since the universe began could visit at most 0.004 percent of even the coarse grid.

Definition 5.3: Operational design domain

Operational design domain (ODD) is the declared set of conditions (object poses, surface conditions, payloads, speeds, and disturbances) under which a machine is intended to operate, stated independently of any data collected within it.

1. **Significance**: The ODD serves as the denominator for every coverage claim. For example, the latch archive, as the join later in this section shows, populates only a single cell of the scenario table its door mechanism requires, a fraction that no volume of redundant nominal episodes can increase. Subsequent verification, evaluation, and release records can assert operational authority only over explicitly supported regions of the ODD.
2. **Distinction**: Deployment requirements define the ODD, whereas the collecting policy defines empirical occupancy. Coverage measured against observed telemetry extremes merely restates empirical occupancy in ODD terminology, producing an illusion of completeness. A **scenario table** partitions the continuous ODD into structured discrete cells so that deployment requirements and empirical occupancy can be joined.
3. **Common pitfall**: Defining the ODD post hoc based on conditions where the machine has already operated successfully rather than where it is required to function. Letting the dataset define its own requirements masks known unvisited failure modes.

In high-dimensional continuous systems, a scenario table avoids voxelizing raw camera pixel streams or continuous joint spaces, which would trigger an intractable combinatorial explosion. Instead, it parameterizes low-dimensional task invariants and environmental boundaries, such as workpiece pose offsets (± 5 mm), surface friction coefficients, approach speeds, lighting variations (100–1000 lux), and payload masses (0–2 kg). These parameters ground verification in concrete physical operating constraints. While this relational join identifies where the dataset holds empirical experience, populating a cell does not demonstrate that a model trained on those samples executes successfully. A populated cell provides supervisory targets, but verifying autonomous competence still requires closed-loop policy evaluation.

The missing recovery actions identified in figure 5.1 demonstrate why even a tractable scenario table must list off-nominal perturbations as cells of their own. Repeatedly executing a flawless motion samples progress along the nominal path, whereas corrective demonstrations supply actions that return the machine after an unexpected displacement. A sound scenario table distinguishes recovery experiences from nominal runs rather than treating repeated nominal cycles as coverage of the adjacent state space.

Unsupported operational regimes are exposed by a **support envelope relational join**, which cross-references empirical occupancy $p^{\pi_{\text{col}}}(s, \mathbf{a})$ (where the machine went) against the scenario table $\mathcal{S}_{\text{req}}$ (where the machine must be able to go). The table declares a count unit (transitions, independent episodes, or retained demonstrations), an eligibility and retention rule, and a minimum in that same unit. For each cell, the join tallies N_{cell} under this policy and partitions the table into cells meeting the minimum ($N_{\text{cell}} \geq N_{\text{min}}$), low-count cells, and unvisited blind spots ($N_{\text{cell}} = 0$). A populated cell has a nonzero count; it need not meet the minimum. The contact-angle example counts transitions, while the latch campaign's table counts retained demonstrations. These bins define collection categories. The threshold N_{min} represents a declared data requirement rather than a test of policy competence; neither an occupied cell nor a large sample count confers autonomous deployment authority.

A held-out validation split drawn from the same collecting policy can evaluate action prediction accuracy over that occupancy while remaining completely blind to gaps in the required operational domain. The comparison in table 5.4 separates collection coverage metrics from downstream policy outcomes. Its loss row is the root-mean-square error, in radians, of the predicted action on held-out records, and the cautious archive posts the lower value precisely because a narrow, repetitive archive is easier to fit. Low validation loss does not demonstrate recovery capability in unvisited conditions, just as wide exploratory coverage does not prove that collected corrective labels are dynamically stabilizing. Closed-loop evaluation must test the candidate policy directly against the declared task population.

Table 5.4: Empirical coverage and validation loss metrics across operational scenario bins: Illustrative counts and held-out losses compare two collection distributions; neither column supplies measured closed-loop capability.

Metric	Cautious Teleoperation ($p^{\pi_{\text{teleop}}}$)	Exploratory Policy ($p^{\pi_{\text{expl}}}$)	Systems Consequence
Recorded Transitions	1,000,000 transitions (100 Hz)	1,000,000 transitions (100 Hz)	Equivalent dataset scale
Operational Grid Coverage	8 / 600 bins (1.3%)	510 / 600 bins (85.0%)	Populated collection cells
Zero-Count Blind Spots ($N_{\text{cell}} = 0$)	592 / 600 bins (98.7%)	90 / 600 bins (15.0%)	Collection gaps
Held-Out RMS Action Error ($\mathcal{L}_{\text{val}}$)	0.001 rad	0.012 rad	Validation loss is non-diagnostic
Closed-Loop Capability	Not established by occupancy	Not established by occupancy	Requires candidate evaluation
Collection Decision	Target missing cells	Inspect labels and remaining gaps	Occupancy guides collection

The cage-door latch campaign illustrates this relational join for the running machine. Its six-cell example records occupancy, without supplying per-cell counts or a minimum-count requirement. Every retained episode approaches the strike plate at the guarded speed of 0.03 m/s with the plate aligned within ±0.5 mm of nominal, and every successful demonstration stays below the illustrative 15 N detection threshold. This observation does not itself qualify the collection response. Evaluated against an uncritical table containing only the nominal plate position at the guarded speed, the archive appears exhaustive. Against the scenario table the deployment actually demands, three plate positions (nominal and ±3 mm) crossed with two approach speeds (0.03 m/s and 0.10 m/s), the identical dataset populates only one cell of six. Every off-nominal plate displacement and every fast approach at 0.10 m/s contains zero demonstrations. The raw logged telemetry does not change between these two assessments; the difference lies entirely in the standard of audit applied. The five unvisited cells therefore travel with the dataset into training as documented operational absences, establishing that the current demonstrations provide no empirical foundation for competence claims in those regimes. Targeted collection can acquire the missing recovery trajectories, but downstream training and closed-loop testing must verify what the resulting policy achieves. Figure 5.6 sets the two audits side by side and adds a third, the stipulated recovery collection `latch-recovery-02` of section 5.8, which fills one more cell and still leaves four known absences.

Checkpoint 5.2: Empirical occupancy and scenario table joins

Before evaluating policy coverage across an operational design domain, audit dataset occupancy and scenario-table counts against these criteria:

- ☐ **Empirical support vs. validation loss**: Explain why an imitation policy can achieve near-zero validation loss on held-out test data while leaving 98 percent of the ODD's required cells unsupported.
- ☐ **Unsupported states**: What can an unvisited scenario cell establish about policy behavior, and what additional evidence or refusal decision is needed?

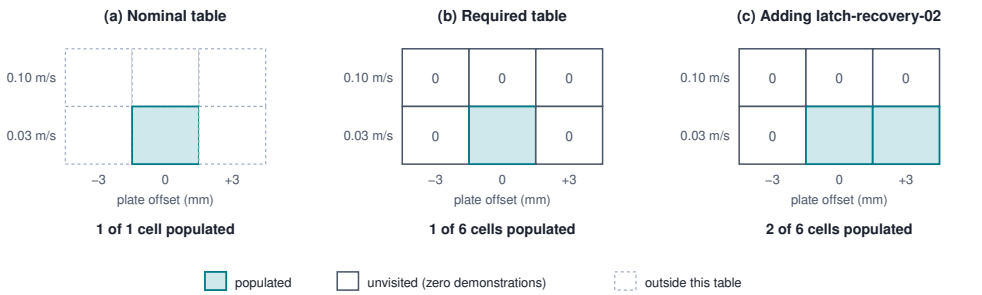


Figure 5.6: Scenario-table join for the latch: The same retained demonstrations joined against tables of strike-plate offset and approach speed. Against a table holding only the nominal plate at 0.03 m/s (a), the archive looks complete. Against the table the door needs (b), it fills one cell of six and the other five hold zero demonstrations. The stipulated recovery collection `latch-recovery-02` (c) adds the positive-offset guarded cell and leaves four known absences. Occupancy describes available experience, not evaluated competence or permission to act.

- ☐ **Scenario table joins**: Distinguish cells meeting the declared minimum, low-count cells, and unvisited cells when joining telemetry against an operational scenario table.
- ☐ **Table growth**: If the latch scenario table adds a third approach speed between the two it holds, how many cells does it contain, and how many of them are known absences for the original archive?

Logging additional nominal demonstrations along an unperturbed trajectory cannot eliminate coverage blind spots. Exposing the policy to recovery dynamics requires forcing the system toward its operational boundaries, either through deliberate demonstrator noise injection or through expert supervisory interventions (Kelly et al. 2019; Laskey et al. 2017). Before collecting either, a team must know why each empty cell is empty, and recorded interventions add a harder question, because they mix the learner's commands and the expert's in one trace (section 5.8).

5.8 Intervention and Recovery Data

A scenario cell, such as the cage-door latch displaced by $+3$ mm, may hold zero demonstrations in the training archive. That zero count alone cannot tell an engineer whether the robot never drifted there, whether the 15 N contact tripwire aborted every attempt that reached it, whether a safety supervisor took over beforehand, or whether an ingestion script threw the failed episodes away. Treating those four absences as interchangeable either trains the policy to imitate a safety abort or discards the exact boundary states needed for recovery. An absent state in an empirical log arises from one of four physical mechanisms during collection:

1. **Unvisited nominal path**: The collecting policy never visited the state because nominal rollouts remained entirely within the primary task corridor. This absence represents unmonitored nominal operation, verifiable by cross-referencing trajectory logs against the scenario table.
2. **Permission-path interception**: An active safety barrier or deterministic reflex in the permission path detected an impending boundary violation and truncated the motion before reaching the state, as the 15 N contact tripwire does during a misaligned latch attempt. The permission path logs record this barrier trip directly.
3. **Human supervisory takeover**: A human safety operator perceived a developing hazard and disengaged the autonomous policy before contact occurred. The permission path's log flags this disengagement explicitly.
4. **Post-collection censoring**: The machine entered the hazardous state and collided with an obstacle or jammed a joint, but an automated ingestion script discarded the episode as corrupt or incomplete. Dataset inspection cannot detect this absence because the failure transitions were purged before the training arrays were serialized to disk.

Each mechanism produces an identical zero count in the scenario table, yet each calls for a different response. An unvisited cell calls for targeted collection. An intercepted state belongs to the permission path, which already refuses it, and is not a target for the policy to learn. A takeover leaves learner-visited states that curation can turn into corrective supervision. A censored episode is a pipeline defect, recoverable only if the raw recording still exists. Conflating them leads to wrong conclusions about closed-loop policy stability, and the third mechanism needs the most care.

Human takeovers and automated disengagements introduce a selection trap into fleet data. An intervention occurs when the autonomous policy enters a region of state space it handles poorly and its tracking error or uncertainty crosses a threshold. A trajectory recorded after takeover therefore shows an expert recovering from an edge-case disturbance, not nominal task execution. The distribution of states visited during these rescues, p^{takeover}, is conditioned on policy failure. Treating intervention logs as if they were drawn from the nominal distribution p^{π^*} distorts the training distribution toward states that exist only because the prior policy failed.

Appending a rescued episode directly to a behavioral cloning dataset can make unsafe policy commands look like expert demonstrations. Before takeover, the learned policy may issue commands that compound heading error or contact force; after takeover, the expert issues corrective commands from states the learner visited. Those drift states are valuable for corrective aggregation (expert labeling of the states the learner itself reaches, developed below) when an expert can label a safe action there. If a pipeline trains on the entire recorded trajectory without curation, it commits **learner-action contamination**. The failing policy's own commands enter the dataset as expert labels. The network then learns to answer the visual cues of an approaching hazard (such as the gripper sliding off the handle or the base drifting toward a rack upright) with the high-risk commands that produced them, which accelerates divergence rather than correcting it. Learner-action contamination corrupts the training targets directly by injecting errant commands, whereas **causal confusion** occurs when a policy trained on uncorrupted expert targets locks onto spurious correlations (Haan et al. 2019). The driving example from that work is a brake indicator on the dashboard. The light turns on because the expert braked, so it predicts the braking label almost perfectly, and a policy can learn to brake when the light is on rather than when an obstacle appears. At the latch, a measured joint current that climbs because the operator has already begun to push could play the same role, a consequence of the label that a policy mistakes for its cause.

Separating these labels requires locating the **divergence point** where the autonomous policy departed the nominal path, rather than treating takeover as the first error. The divergence precedes the takeover by at least the time a supervisor needs to respond. A remote operator who was not watching continuously must notice the hazard, reorient to the scene, and take control. The running machine's card in section 1.4.2 budgets that out-of-loop takeover at 4.47 s, from published take-over studies plus console video and handshake (section 14.2.2 derives it). Edge loggers therefore keep a circular ring buffer spanning a fixed lookback window $T_{\text{pre}} = 5$ s, that takeover time rounded up to whole seconds. Because dynamic memory allocation during safety-critical events introduces non-deterministic latency spikes, the buffer is pre-allocated in locked memory (`mlock`) or non-volatile storage and populated deterministically at the permission tick rate (1 kHz). When a human safety supervisor hits an override button or an MCU safety enforcer trips a barrier, the pipeline latches the intervention timestamp t_{takeover} and freezes the preceding ring buffer. An out-of-loop supervisory takeover takes longer than the teleoperation loop's continuous correction (section 5.6); at an illustrative 100 Hz, that delay spans hundreds of control cycles, all logged under the learner's authority.

↪ The authority record, which logs on every control cycle which entity held authority and the root cause of any preemption, is developed in section 14.8.

Detecting the divergence instant t_{div}, estimated below as $\hat{t}_{\text{div}}$, in offline ingestion pipelines requires searching backwards in time from the physical override timestamp across this synchronized pre-trigger telemetry buffer. For the latch, $e_{\text{div}}(t)$ is the lateral gripper-position error between measured and planned kinematics in the declared fixture frame, and δ_{tol} is its positive tolerance in meters. The divergence estimate is:

$$\hat{t}_{\text{div}} = \min\Big\{ t \in [t_{\text{takeover}} - T_{\text{pre}}, t_{\text{takeover}}] \;\Big|\; |e_{\text{div}}(t)| > \delta_{\text{tol}} \vee \operatorname{Tr}(\Sigma_\pi(t)) > \sigma^2_{\text{thresh}} \Big\}. \tag{5.7}$$

The pipeline scans the lookback window for the first threshold crossing. The policy ensemble covariance is computed after normalizing each action component by its declared scale, so its trace and variance threshold are dimensionless. In unstructured contact manipulation where no static reference trajectory exists, divergence detection instead evaluates declared physical residuals against admissible safety envelope boundaries, such as velocity-to-obstacle clearance margins or anomalous contact force derivatives dF/dt. The detection thresholds are scenario-specific and calibrated to the sensor noise floor. The minimum defines an estimate only when the retained window contains a threshold crossing from below; an empty set or a residual already above threshold at the start of the window leaves the onset unresolved.

The protocol of **intervention curation** separates learner commands, expert labels on learner-visited states, and post-takeover recovery at timestamps the permission path logs for every takeover, the entries of the authority record that chapter 14 formalizes. The takeover instant t_{takeover} is the permission tick at which the authority commit revokes the policy's ownership of the arm, and the three curation rules below are measured from it:

1. **Quarantine drift commands:** The actions issued by the failing autonomous policy during the drift window $[t_{\text{div}}, t_{\text{takeover}})$ are retained in the forensic audit log with their safety flags, but masked out ($\mathcal{M}_{\text{train}} = 0$) from imitation training targets.
2. **Preserve drift states for relabeling:** The physical states visited during $[t_{\text{div}}, t_{\text{takeover}})$ capture off-nominal boundary conditions that are absent from nominal demonstrations. These states are admitted to training only when an automated expert, such as a planner with privileged state, supplies corrective labels ($\mathbf{a}^*(s)$); a person replaying a logged state cannot reliably say what they would have commanded while closing the loop on it.
3. **Admit only stabilized recovery:** The post-takeover trajectory is not one demonstration. It opens with the enforcer's blend, in which the enforcer, still the only writer to the drives, ramps its single admitted command smoothly from the learner's last checked reference to the operator's. The actuators therefore never see a step, and no two sources ever command them at once. The operator's reorientation follows. Neither interval is expert behavior, and both stay masked. Only the segment after the operator's measured stabilization $t_{\text{stabilize}}$, the instant the operator's corrections settle into a steady return toward the corridor, up to recovery at t_{rec}, and only where the episode passes task-validity review, becomes an expert recovery demonstration. It teaches the policy how to steer from boundary states back to the nominal manifold. Section 14.8.3 defines the blend, reorientation, and stabilization intervals and the criterion that ends reorientation.

For the latch campaign, consider a stipulated follow-up collection, `latch-recovery-02`, at the positive 3 mm strike-plate offset and the guarded 0.03 m/s approach. The same 15 N tripwire remains active. An expert takes over from a misaligned approach, withdraws and reseats the gripper, then releases the latch. The stipulated archive contains valid, reviewed recovery sequences; this is a worked teaching branch, not a report of collected trials or measured improvement.

The three rules decide what this archive keeps. The unsuccessful learner commands are retained for diagnosis, expert relabeling is used only where a corrective target is available, and the expert's recovery is admitted only from its stabilized, reviewed segment. A new provenance digest binds those labels to the displaced fixture, the original plant contract, and the collection safeguards. The original archive remains immutable. Its successor now contains experience for the positive-offset guarded cell, while the negative-offset and faster-approach cells remain known absences. Chapter 6 uses this archive to construct the candidate `latch-bc-recovery-02`, and closed-loop evaluation must test recovery and nominal-task regressions before any expanded competence claim follows.

The states between divergence and takeover are the second law, endogenous data, made concrete. The learner's own control actions chose them, and the original nominal archive supplied no corrective supervision there; they are exactly the off-corridor states of figure 5.1, now visited and logged. Curated, they supply the missing return actions. Training on nominal expert demonstrations alone leaves the compounding-error problem of section 5.3 in place, bounded in the worst case by the quadratic growth of equation 5.1, $\mathcal{O}(S^2\epsilon)$. Labeling the states the learner itself reaches changes how that bound grows.

↪ The qualification of `latch-bc-recovery-02` against fresh nominal and displaced-plate trials is developed in section 7.8.1.

In **corrective aggregation**, such as Dataset Aggregation (DAgger) (Ross et al. 2011), an expert labels states visited by the learner, including eligible pre-takeover drift states. Training on states sampled from the learner's induced distribution ($s \sim p^{\pi}$), rather than solely the expert's distribution ($s \sim p^{\pi^*}$), directly counters the covariate shift that nominal demonstrations leave unaddressed. The resulting performance guarantee depends on a constant determined by plant dynamics and task geometry rather than the learning algorithm. After N rounds of aggregation, at least one policy $\hat{\pi}$ in the sequence satisfies

$$J(\hat{\pi}) \leq J(\pi^*) + u\,S\,\epsilon_N + \mathcal{O}(1), \tag{5.8}$$

where ϵ_N represents the surrogate loss of the best single policy on the aggregated learner-visited states (a different quantity from the per-step disagreement ϵ of equation 5.1). The symbol u is the **recoverability constant**, the maximum increase in the expert's remaining cost-to-go incurred by a single errant action before the expert resumes control.[10] This bound scales linearly with the task horizon S only while u remains bounded, which is to say only while the expert can undo any single mistake at a bounded price. If u scales in proportion to S, the product $uS\epsilon_N$ reverts to $\mathcal{O}(S^2\epsilon_N)$, wiping out the linear advantage over behavioral cloning; Ross et al. (2011) observed this exact failure mode in their predecessor forward-training scheme.

[10] **Corrective Aggregation Error Bound**: The bound is Theorem 3.2 of Ross et al. (2011). It holds for some policy in the sequence of N iterations, with N of order uS up to logarithmic factors, and u bounds the change in the expert's cost-to-go after any single action. Section A.5 states the finite-sample form, in which the same constant appears as $u_{\max}$.

For a horizon of $S = 500$ steps (5 s at 100 Hz) and $\epsilon = 0.001$, the behavioral cloning bound $S^2\epsilon = 250$. The aggregation term $u\,S\epsilon_N$ in equation 5.8 evaluates to 0.5 for a recoverable task with $u = 1$ and matching per-step error. In this setting, the quadratic cloning bound equals half the episode's maximum budget, while the leading aggregation term is less than the cost of a single control step. This comparison is conceptual, since the two error terms evaluate losses over different state distributions and both bounds omit problem-dependent leading constants. The quadratic bound becomes vacuous whenever ϵ exceeds $1/S = 0.002$, at which point $S^2\epsilon$ exceeds the maximum possible episode cost of S. Figure 5.7 joins the two halves of this section, the feedback loop that makes cloning's worst case quadratic and the curation timeline that turns one takeover into labels the linear bound can use.

The worst case, where u grows in proportion to the remaining horizon, is the first law, irreversibility (principle 1), written in the language of imitation bounds. Once the plant enters an unrecoverable state, such as a bent latch, a sheared cable harness, or a dropped brittle workpiece, no subsequent expert command can restore the lost objective. In these failure modes, the cost penalty spans the entire remaining task horizon ($u \sim S$), and aggregating additional learner states cannot recover linear error bounds. A policy cannot learn recovery from states where recovery is physically impossible; the deterministic permission path must prevent entry into those states altogether. The latch campaign draws this boundary explicitly. Withdrawing and reseating a misaligned gripper is recoverable, so `latch-recovery-02` records corrections there. Contact forces approaching the illustrative 100 N component damage threshold are unrecoverable; the illustrative 15 N tripwire is a detection threshold, not a contact-force ceiling. Its use requires a qualified collection-response envelope accounting for detection, command and actuator response, and peak-force overshoot below the damage threshold. Without that evidence, the lower threshold alone cannot authorize collection. Those damaging states belong to the safety-enforcer domain rather than the policy learning targets.

Gathering expert supervision on learner-visited states takes several architectural forms, and the curation rules detailed above instantiate one of them. Classical DAgger requires an expert to query and label every state visited during autonomous execution, an impossible requirement for a human supervisor when the policy issues commands at control rates. The framework of **human-gated aggregation** resolves this bottleneck by allowing a human supervisor to take over only when necessary, appending labels exclusively from the resulting intervention episodes (Kelly et al. 2019). The three curation rules refine this approach by keeping quarantined learner commands, relabeled drift states, and expert recovery actions under separate provenance. Where standard human-gated aggregation retains the entire human takeover stream, rule 3 also filters out the transitional controller blend and operator reorientation intervals. Two refinements address the scarcity of supervisor attention. One queries the expert only when policy uncertainty or novelty exceeds a threshold, spending a fixed intervention budget where the policy is least sure (Hoque et al. 2022). The other upweights the sparse recovery segments relative to the dense nominal trajectories during training, so a few minutes of rescue are not drowned by hours of nominal motion (Mandlekar et al. 2020).

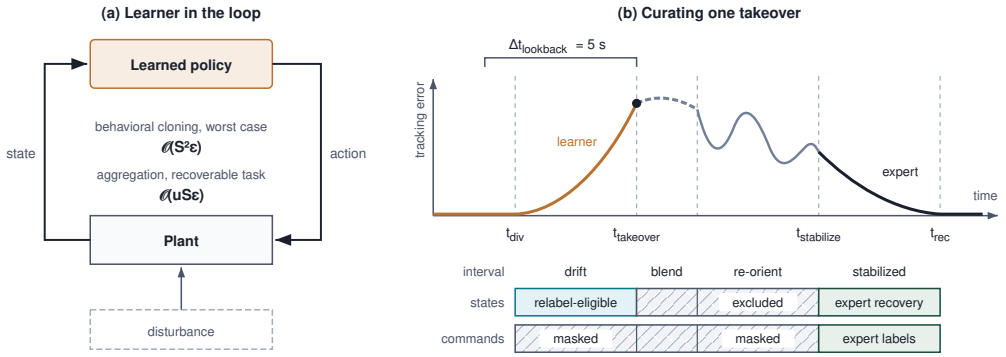

Figure 5.7: Covariate shift and intervention curation: (a) The learned policy's own actions choose the states it sees next. The worst-case cost bound grows as $\mathcal{O}(S^2\epsilon)$ for behavioral cloning and as $\mathcal{O}(uS\epsilon_N)$ for aggregation on a recoverable task; these are bound orders, not measured drift. (b) One takeover. The 5 s lookback reaches back past the divergence point; states between divergence and takeover are eligible for expert relabeling while the learner's commands there are masked. After takeover, the enforcer's blend and the operator's reorientation are retained for diagnosis but excluded from expert imitation targets, and only the reviewed segment from measured stabilization to recovery becomes an expert demonstration. Based on Ross et al. (2011) and Spencer et al. (2021).

A team can also avoid online interventions entirely, and this is the wide-tube remedy promised in section 5.3. Injecting small noise perturbations into the teleoperator's commands pushes the robot off the nominal path during ordinary collection, so the operator's corrections back toward the corridor appear in the initial demonstration set itself (Laskey et al. 2017). Each perturbation consumes hardware life from the fatigue budget in section 5.6.3 and must stay within recoverable bounds. Ingestion pipelines therefore log the collection mode of every episode explicitly (nominal, noise-injected, or gated intervention), because the three modes put different kinds of states and labels into the archive.

Learner-action contamination compounds across policy generations. Suppose a first policy drifts toward a joint torque limit until a supervisor intervenes with an override pendant. A successor trained on those uncurated drift-window commands as expert demonstrations reinforces the behavior that produced the departure, drives harder toward the limit in deployment, and forces operators to intervene earlier and more often. A pipeline that monitors only offline validation loss misses the cascade, because loss on the mislabeled validation split keeps improving as the network memorizes the corrupt labels while physical stability degrades.

Preventing this cascade requires the permission path to record every takeover or safety-barrier trip as an explicit entry in the authority record.[11] A boolean disengagement tag overlaid on video is not enough. The ingestion pipeline requires a populated pre-trigger ring buffer matching the declared lookback window (5 s), hardware-synchronized sensor observations and actuator taps, monotonic override timestamps, unique authority identifiers, and precise timestamps marking the blend completion and supervisor stabilization. Without this synchronized pre-trigger telemetry, ingestion pipelines cannot locate the divergence point t_{div} and therefore cannot isolate errant learner commands from the boundary states eligible for expert relabeling.

> **Checkpoint 5.3: Intervention curation and error bounds**
>
> Before curating human intervention logs for policy retraining, audit compounding error dynamics and timestamp attribution against these criteria:
>
> - ☐ **Takeover vs. divergence timestamps**: Why retain learner-visited drift states for possible expert relabeling while excluding their unsafe learner commands from expert imitation targets?

11 **Event Data Recorder**: US vehicle rules under 49 CFR Part 563 require an automotive event data recorder to preserve a fixed window of telemetry recorded prior to a crash trigger, recognizing that the root cause of an incident precedes the trigger event itself (National Highway Traffic Safety Administration 2024a). Human supervisory takeovers have the same temporal structure, because the initial divergence t_{div} always precedes the override timestamp t_{takeover}. A logging pipeline that begins capturing telemetry only upon trigger activation has already discarded the critical drift data required for policy curation.

- ☐ **Retraining cascade progression**: Describe how training successive policy generations on uncurated intervention logs accelerates policy degradation despite improving training metrics.
- ☐ **Conditional error bounds**: Which assumptions distinguish the behavioral-cloning quadratic worst-case cost bound from DAgger's linear-horizon result?
- ☐ **Bound threshold**: For an episode twice as long as the 5 s comparison, at the same 100 Hz control rate, above what per-step error ϵ does the quadratic bound stop constraining the cost?

Even with expert labels on learner-visited states, the resulting demonstration archive remains tethered to the kinematics and dynamics of the collecting machine. Pooling demonstrations across robot arms, bases, and end-effectors raises the cross-embodiment questions in section 5.9.

5.9 Cross-Embodiment Transfer

Borrowing manipulation demonstrations from another robot arm looks effortless in tensor space, because both datasets store image frames and seven-element action vectors. That ease disappears when a trajectory recorded on a wide-stroke, 50 Hz gripper drives a narrower, 20 Hz gripper into its mechanical endstops or misses a moving conveyor part by centimeters. Physical demonstration trajectories never represent a task in the abstract. Every recorded stream of sensor observations and actuator commands embeds the link lengths, joint velocity limits, camera optical paths, bus latencies, and contact-surface compliances of the logging hardware directly into its numbers. Reusing demonstration datasets across robots therefore requires separating environmental task invariants from machine-specific realizations, checking kinematic and dynamic compatibility, and resolving topological mismatches. This applies whenever the warehouse manipulator supplements its local latch demonstrations with data from foreign arms and grippers.

5.9.1 Embodiment contracts and the normalization fallacy

Suppose a training pipeline rescales gripper commands from two different robots to the unit interval $[0, 1]$ so a single network head can predict both. A normalized command that opens a wide-stroke donor gripper far enough to clear a workpiece will open a narrower target gripper to only a fraction of that span, driving its fingers straight into the part. That failure occurs because an observation-action trajectory $(\mathbf{o}_t, \mathbf{a}_t)$ permanently encodes the **embodiment contract** between a specific machine and its physical surroundings. This contract covers the sensor geometry and optical calibration and the sampling period and transport latency of the perception bus. It also covers the coordinate frames and kinematic limits of the actuators, the torque-speed saturation curves of the motors (including reflected rotor inertia $N_{\text{gear}}^2 J_{\text{rotor}}$ in geared transmissions), and the friction and compliance of the contact interface. For the running machine's recorded teleoperation, the contract specifies a rolling-shutter navigation camera at 4056 by 3040 px and 60 Hz, a global-shutter wrist camera at 1440 by 1080 px on its dedicated bracket. The contract also specifies a 9-axis kinematic log sampled at the 1 kHz permission tick (notebook 5.2). Every latch demonstration in that archive reflects that camera suite, that sensor bracket, and that exact arm. Altering any parameter in this contract alters the mapping between commanded inputs and physical state transitions. Even when two robots follow an identical Cartesian tool trajectory $\mathbf{x}(t)$, their required actuator torques diverge. Written per joint, Newton's second law for a serial manipulator yields the manipulator equation, met earlier as the model classical control inverts:

$$\tau = \mathbf{M}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{g}(\mathbf{q}) + \tau_{\text{ext}},$$

↩ The manipulator equation, which classical control inverts to compute joint torques, is established in section 3.2.

where $\mathbf{q}$ denotes joint positions, $\mathbf{M}(\mathbf{q})$ is the configuration-dependent mass matrix, $\mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})$ collects Coriolis and centrifugal forces, $\mathbf{g}(\mathbf{q})$ is the gravitational torque vector, and τ_{ext} represents torques exerted by external contact forces. Section 11.4.1 builds this equation up from the single-joint case. Because every term depends directly on link masses, rotor inertias, and gear ratios, the same tool trajectory demands different torque profiles across different robot embodiments.

↩ Reflected rotor inertia, $N_{\text{gear}}^2 J_{\text{rotor}}$, and its effect on joint dynamics are established in section 2.4.3.

While the embodiment contract defines the physics of a single machine, the **cross-embodiment compatibility contract** determines whether trajectories logged under one embodiment contract can

safely serve as action targets on another. This compatibility contract defines the forward kinematics mapping (translating joint angles to tool pose), control-rate transformations (Δt), and actuator effort bounds. These bounds prevent a high-force profile or rapid spatial velocity demonstrated on a rigid industrial arm from driving a lightweight cobot beyond its structural limits. Large pooled corpora rarely provide such guarantees. Open X-Embodiment maps action fields into a coarsely aligned seven-dimensional end-effector format and normalizes each dataset independently. However, it deliberately leaves coordinate frames unaligned and allows action vectors to represent either absolute or relative poses and velocities across different sub-corpora (Open X-Embodiment Collaboration et al. 2024). A multi-task model trained on this pool learns to interpret identical action vectors differently based on embodiment tokens. In contrast, DROID sidesteps embodiment mismatch altogether by collecting all data on a single standardized robot model (Khazatsky et al. 2024). Demonstrations from diverse robots can enrich representation learning without an explicit compatibility contract, but such a contract becomes strictly mandatory the moment borrowed actions are imitated directly as supervisory labels or dispatched to a physical plant.

How much work the compatibility contract has to do is visible in the largest pooled robot corpus. The Open X-Embodiment collection merges independently recorded datasets into one training mixture and publishes, for each, its episode count, robot morphology, scene type, and command rate (Open X-Embodiment Collaboration et al. 2024). Figure 5.8 weights each dataset by its episodes.

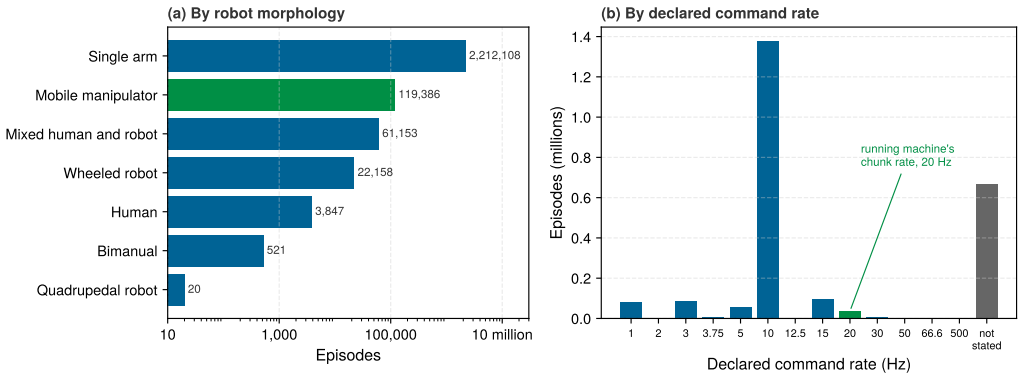

Figure 5.8: What a pooled corpus actually contains: Episodes of the Open X-Embodiment collection, weighted by dataset size, (a) by robot morphology on a logarithmic axis and (b) by the command rate each dataset declares. Single-arm table-top manipulation dominates, and the declared rates cluster at or below 10 Hz; a large share declares no rate at all because its actions are primitive skills or quasi-static moves. Green marks the running machine's class in (a) and its chunk renewal rate in (b). Data from the collection's published dataset overview (Open X-Embodiment Collaboration et al. 2024).

Of the 2.4 million episodes across 72 datasets, 91 percent come from single arms and 89 percent from table-top scenes. Mobile manipulators, the class of the running machine, contribute 5 percent, and two datasets supply 95 percent of those. The command rates are as uneven: 57 percent of episodes were logged at 10 Hz, 28 percent declare no rate, and only 2 percent were recorded at or above the machine's 20 Hz chunk rate. Corpus size therefore says little about coverage of one machine's contract. Almost every episode in the mixture needs the rate transformation and morphology mapping of the compatibility contract before it can serve as an action target here.

A data-reuse pipeline must separate environmental task invariants from embodiment-specific realizations. A task invariant is a geometric or dynamical condition imposed by the physical process, for example bringing a compliant probe into contact with a terminal pad within 5° of the surface normal while sustaining a normal contact force between 2.0 N and 5.0 N. An embodiment realization is the concrete sequence of joint encoder counts, pulse-width modulation duty cycles, perception transport latencies, and sensor pixel rasters used to achieve that condition on a particular test rig. While the contact goal exists in world coordinates, the dataset stores only the realization. When a model trains directly on raw hardware realizations, it internalizes the idiosyncratic mechanics of the source testbed, including structural flexure, drive backlash, and sensor mounting oscillations.

Consider transferring a demonstration dataset collected on Machine A to Machine B for an identical pick-and-place task:

- **Machine A** operates a parallel-jaw gripper with a stroke of 0 to 100 mm, a 50 Hz command rate (20 ms period), a continuous grasp force limit of 40 N, and a wrist camera mounted 45 mm behind the tool center point with a 15 ms transport delay.
- **Machine B** operates a compact gripper with a stroke of 0 to 60 mm, a 20 Hz command rate (50 ms period), a continuous force limit of 15 N, and a wrist camera mounted 20 mm behind the tool center point with a 35 ms transport delay.

Projecting Machine A's demonstrations directly through the physical constraints of Machine B reveals immediate points of hardware failure. For a workpiece of width 75 mm, Machine A commands a gripper aperture of 80 mm. That command exceeds Machine B's mechanical stroke by 20 mm, driving its leadscrew into the mechanical endstop. During the hold phase, Machine A applies 30 N of clamping force; executing that command on Machine B doubles its continuous rating of 15 N and forces its motor amplifier into current saturation. In the time domain, subsampling the 50 Hz trajectory onto Machine B's 20 Hz bus aliases rapid contact dynamics and increases the half-period average hold age $\Delta t/2$ from 10 ms to 25 ms, introducing 15 ms of additional zero-order hold phase lag (section B.5.5). Compounded by the 20 ms difference in camera transport delay (35 ms $-$ 15 ms), the added low-frequency phase-equivalent delay is 35 ms, of which the camera difference contributes 20 ms. At the assumed constant approach velocity of 0.10 m/s, that phase approximation corresponds to an equivalent displacement of 3.5 mm. Actual contact overrun requires measured or bounded sampling phase, capture and transport, computation, actuation, and plant response; the phase-equivalent value does not establish when the first correction dispatches. Meanwhile, the 25 mm disparity in wrist camera mounting introduces optical parallax that shifts the apparent position of the workpiece boundary across the camera raster.

Standard machine learning pipelines often try to reconcile these discrepancies by normalizing observation and action channels to $[0,1]$ or $[-1,1]$. That rescaling aligns tensor ranges while leaving the physical mismatch intact. Normalizing gripper travel to $[0,1]$ turns Machine A's safe 80 mm opening ($\tilde{a} = 0.80$) into a 48 mm opening on Machine B (0.80×60 mm) that drives its fingers into the 75 mm workpiece during approach. Normalizing feature ranges rescales numbers, but it cannot lengthen a leadscrew, lower motor coil resistance, or recover bus transport delay. Demonstration trajectories plotted in normalized unit spaces may look identical, yet only the subset inside the physical intersection (apertures below 60 mm, forces under 15 N, and command frequencies below 20 Hz) can run on the target hardware without saturation or contact damage. Even within that intersection, two arms with different joint layouts can collide with the workspace when they share a single Cartesian command (section 5.9.2).

5.9.2 Kinematic topology mismatches and null-space projection

Even when end-effectors, force ratings, and control rates align, differences in arm geometry can break a transferred trajectory. When a 7-DoF arm's demonstration is compressed into a 6-DoF Cartesian hand displacement so it can be pooled with other robots, the log discards the arm's elbow posture; replaying that 6-DoF stream through a target robot's inverse kinematics solver can swing the elbow into a shelf upright or drive a lighter arm through a singularity, even though the hand follows the exact demonstrated path. Combining robots with different kinematic structures introduces two topological conflicts:

1. **Action space incompatibility**: A 7-DoF arm records joint positions $\mathbf{q} \in \mathbb{R}^7$, a bimanual workstation records $\mathbf{q} \in \mathbb{R}^{14}$, and a mobile base logs planar velocities $(\dot{x}, \dot{y}, \dot{\theta}_{\text{head}})$. Because joint-space commands cannot transfer directly across distinct kinematic arrangements, multi-embodiment models project action sequences into a common Cartesian end-effector displacement:

$$\Delta \mathbf{x}_t = (\Delta x, \Delta y, \Delta z, \Delta \phi_{\text{roll}}, \Delta \phi_{\text{pitch}}, \Delta \phi_{\text{yaw}}) \in \mathbb{R}^6, \quad a_{\text{gripper}} \in [0,1],$$

   where the final three elements represent local roll, pitch, and yaw increments under a declared rotation convention. This displacement vector is not itself a member of the Special Euclidean group $SE(3)$; any numerical integration must handle angle wrapping and representation singularities. Projecting into Cartesian space standardizes spatial geometry, but it strips away actuator dynamics. A Cartesian step that an industrial arm executes effortlessly near its nominal pose can force a lighter arm through a kinematic singularity, a configuration in which

aligned joints leave the tool unable to move in some direction. The manipulator Jacobian $\mathbf{J}(\mathbf{q})$, a configuration-dependent matrix that section 11.2.1 develops on the machine's own arm, maps joint velocities to tool spatial velocities through $\dot{\mathbf{x}} = \mathbf{J}(\mathbf{q})\dot{\mathbf{q}}$. When $\mathbf{J}(\mathbf{q})$ loses row rank at a singularity, no finite joint velocity can generate motion along the lost Cartesian direction. Commanded displacements near such poses demand joint velocities that immediately exceed the target machine's actuator velocity bounds.

2. **Null-space projection and elbow swivel ambiguity**: Away from singularities, mapping a 7-DoF arm into a 6-DoF Cartesian delta projects out the one-dimensional null space ($7-6=1$ redundant degree of freedom). For a redundant manipulator with Jacobian $\mathbf{J}(\mathbf{q}) \in \mathbb{R}^{6\times 7}$, the general kinematic relationship between Cartesian velocity $\dot{\mathbf{x}}$ and joint velocity $\dot{\mathbf{q}}$ is:

$$\dot{\mathbf{q}} = \mathbf{J}^{\dagger}(\mathbf{q})\dot{\mathbf{x}} + \left(\mathbf{I} - \mathbf{J}^{\dagger}(\mathbf{q})\mathbf{J}(\mathbf{q})\right)\dot{\mathbf{q}}_0,$$

where $\mathbf{J}^{\dagger} = \mathbf{J}^{\top}(\mathbf{J}\mathbf{J}^{\top})^{-1}$ is the Moore-Penrose pseudoinverse (the minimum-norm joint velocity producing $\dot{\mathbf{x}}$ whenever $\mathbf{J}$ has full row rank), and the projection operator $(\mathbf{I} - \mathbf{J}^{\dagger}\mathbf{J})$ filters an arbitrary joint-velocity bias $\dot{\mathbf{q}}_0 \in \mathbb{R}^7$ into self-motion that leaves the end-effector still. For an anthropomorphic arm with shoulder and wrist geometry that admits this construction, a fixed end-effector pose in $SE(3)$ and a fixed shoulder anchor leave an elbow orbit around the shoulder-to-wrist axis, parameterized by the **elbow swivel angle** ψ. A general redundant arm instead requires its own configuration parameter or the full joint vector; one redundant degree of freedom does not imply this circular geometry. Discarding this internal degree of freedom to impose a uniform 6-DoF action representation erases the human operator's postural intent. When the target robot receives this 6-DoF command stream, its local inverse kinematics (IK) solver must resolve the redundancy using an arbitrary mathematical heuristic, such as joint-limit centering or manipulability maximization. Without the original swivel angle, the solver may adopt an elbow posture that drives joints into hard stops or sweeps the elbow into nearby shelving, fixtures, or personnel during a motion that was entirely collision-free in the source environment. Preserving the applicable redundancy parameter, or the complete joint-state vector, within the trajectory's provenance metadata retains the operator's postural intent for target-specific retargeting and collision checks. The running mobile manipulator archive maintains this intent directly: its arm has redundant kinematics, and its logger captures all 9 axes of the arm and base at the 1 kHz permission tick. Any pooled 6-DoF delta generated from a latch-servicing trajectory can always be traced back to the demonstrator's original elbow posture.

Reusing physical data across different robots therefore requires two validation gates at the ingestion boundary, corresponding to two distinct roles in training:

- The **pretraining admission gate** evaluates whether a trajectory can safely contribute to general representation learning. This gate validates data provenance, observation integrity, coordinate frame conventions, action semantics (reference frame, absolute vs. relative representations, position vs. velocity modes), and sampling rates. In particular, source actions admitted at this gate need not be physically executable on the target robot. Multi-embodiment foundation models rely on this gate to ingest broad visual and task structures across dozens of robot morphologies before fine-tuning on target hardware (Open X-Embodiment Collaboration et al. 2024; Black et al. 2024).
- The **target-label gate** applies whenever recorded actions serve as direct imitation labels or execution setpoints on the physical plant. This gate maps the source trajectory through target forward kinematics to verify coordinate consistency (Lynch and Park 2017). It confirms that commanded joint velocities and accelerations remain within the target plant's dynamic envelope (Tedrake 2023). It also verifies that task-critical features remain within the field of view and dynamic range of the target sensors. When commanded trajectories violate kinematic reach or motor torque limits, an ingestion pipeline cannot simply clamp the values to target boundaries. Clamping distorts velocity profiles, alters phase relationships, and destroys the causal link between observed spatial errors and corrective control outputs. Trajectories that satisfy the target dynamics pass untouched; trajectories that admit valid geometric retargeting through inverse kinematics are relabeled; and trajectories that demand unobtainable actuator authority or rely on unobservable states are rejected.

↪ Forward kinematics, the manipulator Jacobian, its singularities, and the pseudoinverse are developed in section B.6.1.

Evaluating the two-gripper scenario of section 5.9.1 through this target-label gate resolves each trajectory segment systematically. The initial opening phase must be rejected rather than relabeled, because satisfying the task invariant (clearing the 75 mm workpiece) demands an aperture that Machine B cannot physically achieve. The 30 N grasp hold is rejected on identical grounds, as it exceeds Machine B's continuous motor rating. Conversely, the 50 Hz trajectory can be resampled and relabeled onto Machine B's 20 Hz control bus only if the slower command stream preserves the task-critical contact dynamics and remains within the target's verified tracking and force limits. The data record must also log the added zero-order hold lag and camera transport delay so that policy training accounts for the altered timing. An ingestion pipeline lacking this gate injects dynamically invalid trajectories into the training distribution. A policy trained on such unvetted data fails in deployment not because of neural network underfitting, but because its training labels were physically valid only on the donor hardware. For the latch-servicing campaign, the target plant is the mobile manipulator's own arm and gripper. Every borrowed trajectory proposed as a latch training label must pass this gate against the mobile manipulator's verified limit record, regardless of the donor platform's reported capabilities.

↩ The limit record, which states each measured limit with its operating conditions, uncertainty, and margin, is established in section 2.7.3.

The warehouse conveyor pick demonstrates a transfer mismatch rooted in task dynamics rather than robot kinematics. At the sorting station, the arm grasps a workpiece moving along a belt at 0.20 m/s. The workpiece translates 5 mm during each 25 ms control step and advances 80 mm over a single 16-step action chunk of 400 ms, a displacement of 5.3× the allowable 15 mm grasp tolerance. A borrowed tabletop demonstration recorded on a stationary bench defines its grasp trajectory entirely in the static table frame. If a policy imitates that trajectory unchanged at the conveyor, an open-loop action chunk aims at the spatial location the part occupied when the chunk was generated. The target-label gate can adapt such a static trajectory only by transforming the end-effector path into the moving workpiece coordinate frame. This coordinate transformation requires both the instantaneous object pose in the donor metadata and the conveyor velocity in the target environment record. An external trajectory lacking this telemetry can enter the pipeline solely through the pretraining admission gate. Teleoperation data collected directly on the warehouse machine requires no such mathematical rescue, as the human operator generated the demonstration commands with the conveyor in motion.

5.9.3 Choosing pooled experience for the target task

Pretraining on a million pooled trajectories from foreign robots does not help the warehouse manipulator open a displaced latch if the training mixture drowns out the machine's own contact dynamics. The same holds if the mixture adds ten thousand repetitions of a single tabletop scene instead of covering new operating cells. Large-scale pooled corpora such as DROID (Khazatsky et al. 2024), BridgeData v2 (Walke et al. 2023), and Open X-Embodiment (Open X-Embodiment Collaboration et al. 2024) offer broad scene diversity and multi-robot demonstrations, but their value to a specific deployment depends on what information survives the admission gates of section 5.9.2. Even when kinematic mismatches prevent direct imitation of donor joint commands, foreign demonstrations can supply visual representations, object affordances, and high-level task structures, provided the campaign measures how those additions fill its scenario table.

Empirical scaling studies since 2024 support the premise behind the scenario table, that policies generalize with the number of distinct environmental conditions in their data rather than with repetitions of the same ones. In an extensive empirical evaluation spanning more than 40,000 demonstrations collected with handheld grippers, policy success across novel environments and unseen objects scaled as a power law with the count of distinct training environments and objects. Adding further demonstrations within existing environments yielded sharply diminishing returns once a modest baseline was achieved. A dataset collecting 50 demonstrations across each of 32 environments achieved 90 percent on novel environment-object pairs (Lin et al. 2025). Similarly, evaluating mobile manipulation across residential settings revealed steady performance gains as the training distribution expanded from 3 to 104 homes. At 104 locations, the generalized model matched the performance of an in-domain baseline trained exclusively within the evaluation homes (Black, Brown, et al. 2025). Viewed through the scenario table, the primary scaling axis is the count of distinct operational cells populated by the corpus. The declared minimum coverage threshold $N_{\min}$ identifies cells that still need collection; it does not establish that additional trajectories within

a populated cell have no value. Populating operational cells is necessary but not sufficient on its own. As Belkhale et al. (2023) demonstrate, dataset utility depends on two additional quality metrics: action divergence (the discrepancy between expert actions and learned policy outputs at reachable states) and transition diversity (the stochasticity of outcomes from given state-action pairs). Uncurated state diversity does not automatically yield performance improvements.

These demonstration corpora also diverge in how they acquire operational diversity. Open X-Embodiment aggregates 60 distinct datasets across 22 different robotic embodiments with different, unaligned action spaces; despite this lack of structural alignment, joint pretraining improved success rates across the smaller constituent datasets (Open X-Embodiment Collaboration et al. 2024). DROID and AgiBot World instead hold the embodiment contract constant while maximizing environmental and task diversity. DROID deploys a single manipulator model across 564 in-the-wild environments (Khazatsky et al. 2024). AgiBot World scales this principle with a homogeneous fleet of more than 100 identical robots, producing pretraining data that demonstrated superior downstream transfer compared to Open X-Embodiment (AgiBot-World-Contributors et al. 2025). A homogeneous fleet removes nominal kinematic mismatches, but each unit must still satisfy the target-label gate through verified calibration and dynamic compatibility. The fleet also remains vulnerable to the shared kinematic blind spots of that specific platform. Conversely, a multi-robot corpus can broaden perceptual learning through the pretraining gate; its actions become target labels only after passing the target-label gate. Balancing these disparate data streams requires deliberate weighting within the training mixture; dynamically weighting datasets to safeguard the worst-performing target domain significantly outperforms uniform data sampling across Open X-Embodiment (Hejna et al. 2025).

Placing these landmark robot archives alongside community uploads and web-scale foundation-model corpora exposes both how physical collection has scaled and where its ceiling sits (figure 5.9). Across 11 major physical collection campaigns since 2015 (figure 5.9, panel a), robot datasets progressed from single-lab grasping farms (50,000 to 800,000 trials in a fixed bin (Levine et al. 2018; Kalashnikov et al. 2018)) through multi-scene teleoperation (60,096 trajectories in BridgeData V2 and 76,000 in DROID (Walke et al. 2023; Khazatsky et al. 2024)) to million-episode pooled and fleet archives (2,419,193 episodes in Open X-Embodiment and 1,001,552 in AgiBot World (Open X-Embodiment Collaboration et al. 2024; AgiBot-World-Contributors et al. 2025)). Those pooled campaigns sit five orders of magnitude above the 8–15 episode median of single-session community uploads in figure 5.5. Even million-episode robot campaigns, however, confront the cross-domain gap in panel b. Across 902 language, vision, and robotics models with disclosed training dataset sizes in the Epoch AI catalog (Epoch AI 2026), frontier language and vision corpora reach 10^{13} to 10^{14} tokens or images, whereas π_0's $10{,}000$-hour robot pretraining corpus (1,000,000,000 state-action steps (Black et al. 2024)) sits 14,800× below DeepSeek-V3's 14.8 trillion tokens.

Because every physical trajectory is throttled by real-time motor execution and session yield (equation 5.6), robot learning cannot close a four-order-of-magnitude data gap by brute-force teleoperation alone. Deployed pipelines instead inherit broad semantic priors from web-pretrained vision-language backbones, use synthetic expansion or co-training where provenance allows, and spend their scarce physical episodes on the cells that scenario-table coverage and compatibility gates confirm they need, as the benchmark systems in table 5.5 illustrate.

Table 5.5: State of practice in robot demonstration data, as of 2026: Named systems illustrate the mechanisms of this chapter at one point in time; each scale and result is as reported by the cited paper, measured on that paper's own tasks and not comparable across rows.

System (year)	Collection regime	Reported scale	What it shows for the scenario table
Open X-Embodiment (2024) (Open X-Embodiment Collaboration et al. 2024)	Heterogeneous pool of existing datasets	60 datasets, 22 embodiments; RT-1-X 50% higher mean success than the original methods	Breadth without aligned actions; target labels require the target-label gate
DROID (2024) (Khazatsky et al. 2024)	One robot model, distributed in-the-wild collection	76,000 trajectories, 350 h, 564 scenes	Scene diversity under a single embodiment contract

System (year)	Collection regime	Reported scale	What it shows for the scenario table
UMI (2024) (Chi et al. 2024)	Robot-free hand-held grippers	Relative-trajectory actions; latency matched at deployment	Collection decoupled from robot time and wear
Data scaling study (2025) (Lin et al. 2025)	Hand-held grippers across many environments	40,000 demonstrations; power law in environments and objects	Fill more cells before adding episodes per cell
AgiBot World (2025) (AgiBot-World-Contributors et al. 2025)	Homogeneous fleet of identical robots	1,001,552 trajectories, 217 tasks; 30% average gain over pretraining on Open X-Embodiment	Shared embodiment; unit compatibility still requires verification
$\pi_{0.5}$ (2025) (Black, Brown, et al. 2025)	Mobile manipulators in homes, co-trained with other sources	About 400 h in homes; 3 to 104 training locations	Generalization grows with the number of locations
MimicGen (2023) (Mandlekar et al. 2023)	Synthetic generation from seed demonstrations	Over 50,000 from about 200 human demonstrations, 18 tasks	Cells filled only by synthetic data must be marked as such
Sim-and-real co-training (2025) (Maddukuri et al. 2025)	Simulated and real demonstrations mixed in training	38% average gain in real-robot success	Synthetic data helps when its provenance is kept

The core engineering decision is whether incorporating compatible pooled experience improves target-task policy performance relative to an identical baseline trained strictly on in-domain data. Rigorous evaluation requires fixing the target task distribution and test protocol, maintaining full data provenance, and benchmarking both nominal task completion and recovery behavior. Merely increasing the number of embodiments in a dataset does not guarantee positive transfer. In the mobile manipulator's displaced-latch campaign, the control baseline is a policy trained exclusively on 5,000 retained teleoperation demonstrations from the machine itself, populating a single cell within the six-cell scenario table. An expanded multi-robot corpus justifies its training overhead and ingestion complexity only if the resulting policy improves robustness on long-tail target conditions without regressing nominal latch-servicing performance.

While cross-embodiment compatibility contracts guard the ingestion boundary against hardware mismatches, demonstration data collected on the native machine can fail through internal mechanisms. Teleoperator drift, sensor calibration drift, fixture flexure, and misclassified execution failures corrupt physical datasets without altering tensor dimensions or triggering schema errors (section 5.10).

5.10 Dataset Degradation and Physical Distribution Shift

A demonstration archive can pass every schema check and fill its scenario table on paper while silently rotting from within. A technician may bump a camera mount by 3 mm between shifts, a hot motor winding may lose peak torque during an afternoon session, or a curation script may mistake dropped force-sensor packets for a clean trajectory. Because physical datasets capture closed-loop interactions between controllers and hardware rather than static observations, verifying an archive requires auditing the mechanical, optical, and temporal meaning of recorded trajectories alongside array shapes and scenario-table counts.

5.10.1 Silent plant drift and kinematic reprojection verification

Suppose afternoon latch demonstrations begin missing the strike plate by two millimeters even though the same operator is running the same cell. Before an engineer can decide whether to relabel the afternoon runs, recalibrate the wrist camera, or service the arm, the pipeline must separate three sources of drift that occur inside a single supported scenario cell. These are changes in the physical plant, changes in the human operator's control habits, and silent shifts in sensor calibration.

5.10.1.1 Passive covariate shift vs. physical dynamics shift

In those afternoon runs, the first question is whether the world around the arm changed or the arm itself changed, which is the distinction between passive observation shift and active plant

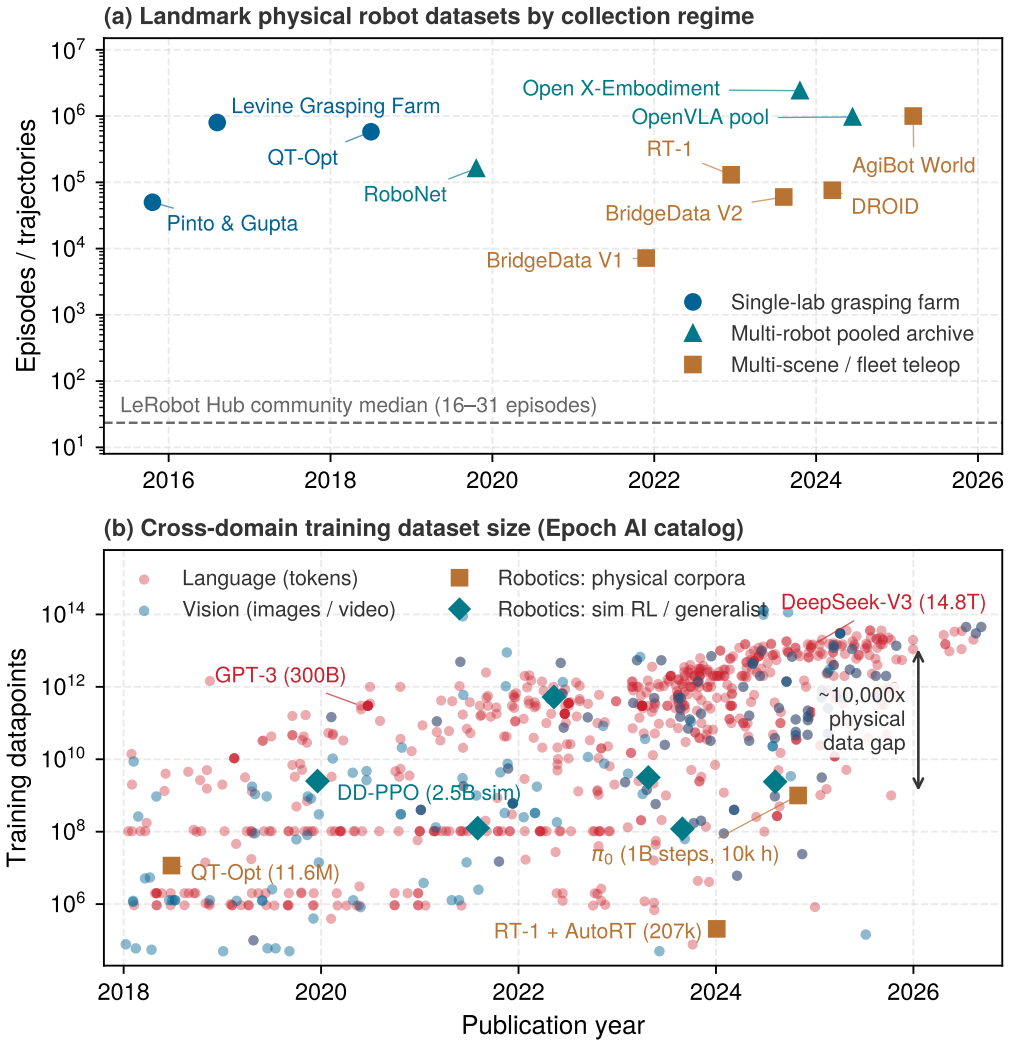

Figure 5.9: Physical robot demonstration scaling and the cross-domain data gap: (a) Reported trajectory or episode counts of 11 landmark physical robot corpora from 2015 to 2025 on a logarithmic axis, grouped by collection regime alongside the median episode bin of community LeRobot Hub uploads (figure 5.5). (b) Training dataset sizes in datapoints across language, vision, and robotics models in the Epoch AI catalog from 2018 to 2026 (Epoch AI 2026). While multi-robot pooling and homogeneous fleets pushed physical archives past 10^6 episodes, real-world robot corpora remain four orders of magnitude smaller than web-scraped language and vision datasets because physical collection is bounded by real-time actuation.

drift introduced in section 5.2. Shifting afternoon sunlight across the cage door alters camera pixel intensities without changing how the joints respond to a torque command, whereas hot motor windings, worn gearbox teeth, abraded gripper pads, and varying door friction alter the plant dynamics directly. Before an ingestion pipeline pools or partitions demonstration episodes, it must determine which underlying physical conditions have shifted. Motor heating shows why the answer depends on where in its envelope the machine operated. A hot winding has higher resistance, which leaves the drive less voltage headroom. Inside the current-regulated region of the torque-speed envelope the drive still delivers the commanded torque, so the modeled voltage-headroom effect alone does not distinguish slow, hot and slow, cold demonstrations; other thermal and plant changes still require checking. Near the voltage limit at high joint speed, the same resistance rise caps the current and lowers the available torque, as section 5.2 described, so a fast demonstration recorded hot reflects a weaker plant than one recorded cold.

↩ The torque-speed envelope and the back-EMF roll-off at high speed are established in section 2.5.3.

That dependence is why pipelines stratify episodes before pooling them. Stratifying by measured actuator temperatures, maintenance logs, and workpiece wear enables engineers to verify whether identical actuation commands yield consistent plant dynamics. The standard diagnostic tool for this verification is a repeatable excitation trajectory. At the start of each operating shift, the manipulator replays a predetermined joint-space trajectory while stationary. If the tracking error residual exceeds an established threshold, the pipeline flags the plant as mechanically altered. Logging timestamps alone cannot establish that a machine degraded during an operational shift; dataset curation pipelines must justify pooling across sessions based on verified physical invariants and intended training objectives rather than superficial uniformity of array dimensions.

Demonstration collection policies drift just as readily as mechanical hardware. Across 141.4 h of scheduled cell time, teleoperators naturally adapt their control strategies. An operator who initially moved cautiously, executing small corrective sub-movements and pausing deliberately before striking a latch plate, gradually develops muscle memory. Over time, that operator rounds corners, anticipates contact forces, and exploits system momentum. These mature demonstrations rely on feedforward compensation and tight timing rather than reflecting changes in joint friction. Partitioning datasets into temporal windows and monitoring episode durations, corrective jerk counts, command amplitudes, and teleoperator intervention rates exposes these subtle shifts in human behavior. This behavioral tracking reveals whether later trajectories contribute advanced manipulation skills or introduce an entirely distinct behavioral regime that requires segregated dataset splits or specialized behavioral labels.

Sensor calibration also deteriorates silently across operating sessions. Standard storage containers such as HDF5, Zarr, and Apache Parquet preserve array topologies, data types, and chunk structures, but they cannot verify whether stored coordinates correspond to physical reality. If a robot is serviced, bumped by personnel, or re-zeroed between collection sessions, joint encoder offsets and external camera poses shift. A camera mount displaced by merely 3 mm moves workpiece pixels across image frames while the stored arrays remain syntactically valid. Clock synchronization drift across distributed fieldbus controllers introduces comparable corruption, skewing the temporal alignment between visual frames and tactile force measurements by tens of milliseconds.

↩ Distributed-clock synchronization across fieldbus drive nodes is established in section 4.5.2.

To detect this silent drift, automated ingestion pipelines rely on **kinematic reprojection verification**, formulated below and evaluated across a photographic mosaic in figure 5.10. Let $\mathbf{q} \in \mathbb{R}^n$ denote the joint angles latched from optical encoders at the optical exposure midpoint. Forward kinematics $\mathbf{FK}(\mathbf{q})$ maps these angles to the 3D surface vertices of the robot's links in the base coordinate frame, $\mathbf{p}_{\text{base}} \in \mathbb{R}^3$. The camera's extrinsic spatial transformation $\mathbf{T}_{\text{cam}\leftarrow\text{base}} = \begin{bmatrix} \mathbf{R} & \mathbf{t} \\ \mathbf{0}^\top & 1 \end{bmatrix} \in SE(3)$ maps base coordinates into the camera's optical frame ($\mathbf{p}_c = \mathbf{R}\mathbf{p}_{\text{base}} + \mathbf{t}$). Under the pinhole camera model parameterized by intrinsic matrix $\mathbf{K} \in \mathbb{R}^{3\times3}$,[12] link points project to homogeneous image pixel coordinates $\tilde{\mathbf{m}} = [u, v, 1]^\top$:

$$Z_c \begin{bmatrix} u \\ v \\ 1 \end{bmatrix} = \mathbf{K}\left(\mathbf{R}\,\mathbf{FK}(\mathbf{q}) + \mathbf{t}\right) = \begin{bmatrix} f_x & 0 & c_x \\ 0 & f_y & c_y \\ 0 & 0 & 1 \end{bmatrix} \left(\mathbf{R}\,\mathbf{FK}(\mathbf{q}) + \mathbf{t}\right),$$

[12] **Camera Calibration**: In practice $\mathbf{K}$ is estimated from a few views of a planar checkerboard, the method Zhang (2000) introduced, and the extrinsics come from a separate hand-eye calibration. Both describe one mounting at one time. The reprojection residual is therefore a calibration test repeated every session, not a setup step performed once.

where Z_c is the point's depth along the camera's optical axis, the scale that division removes when the projection $\text{proj}_{\mathbf{K}}$ maps a camera-frame point to its pixel. An automated check run on every recording session evaluates the reprojection residual between the projected link wireframe and the observed physical arm in the image:

$$\epsilon_{\text{reproj}} = \left\| \tilde{\mathbf{m}}_{\text{observed}} - \text{proj}_{\mathbf{K}}\left(\mathbf{T}_{\text{cam}\leftarrow\text{base}}\,\mathbf{FK}(\mathbf{q})\right) \right\|_2 . \tag{5.9}$$

If mechanical vibration, fastener relaxation, or an accidental impact displaces the camera bracket by even $\Delta\mathbf{t} = 3$ mm or tilts it by extrinsic misalignment $\Delta\theta_{\text{ext}} = 0.5^\circ$, the reprojection residual ϵ_{reproj} rises from its calibrated baseline of roughly one pixel to a large geometric offset. The focal length and working distance determine the size of that offset. While the underlying HDF5 or Zarr arrays

Figure 5.10: Camera-to-robot calibration check on DROID scenes: Randomly chosen DROID scenes with a robot mask rendered from the robot's URDF mesh at the recorded joint angles and projected through each camera's audited calibration, from the dataset's own post-hoc recalibration (Khazatsky et al. 2024). Where the mask and the visible arm coincide, the extrinsics are consistent with the joint encoders; a displaced camera shows up as a mask that misses the arm, before any corrupted trajectory reaches the training pipeline. Source: Khazatsky et al., Fig. 13, CC BY 4.0.

remain syntactically flawless, an end-to-end visuomotor policy trained on shifted frames learns an erroneous spatial mapping between pixel coordinates and the end-effector tool center point (TCP). During closed-loop autonomous deployment, the policy issues reaching commands that miss physical targets by the uncompensated calibration offset, converting valid demonstrations into persistent latching jams or collisions with fixtures.

Figure 5.10 displays this verification pipeline across a 7×7 grid of workspace scenes from the DROID dataset. In each, a colored silhouette of the robot arm, rendered from its Unified Robot Description Format (URDF) kinematic mesh at the recorded joint angles, is projected through each camera's extrinsic calibration matrix and overlaid directly onto the raw photographic frame. Where the mask and the physical arm coincide, camera extrinsics and joint encoders are geometrically aligned; where the colored silhouette departs from the links, the check exposes camera mount slippage before corrupted trajectory pairs enter training. The DROID corpus showed how easily mount drift escapes standard checks. Although its cameras were initially calibrated with checkerboard targets during data collection, independent re-analysis revealed that rendered kinematic masks barely overlapped visible robot links across numerous recorded episodes (Lu et al. 2025). The DROID research team subsequently evaluated stored extrinsics by measuring mask intersection-over-union, discarded failed sessions, re-estimated camera poses using learning-based hand-eye estimators, and published updated calibrations for approximately 36,000 episodes (Khazatsky et al. 2024). This calibration error shipped within a major open-source corpus because it was transparent to standard file format parsers. To prevent these silent failures, ingestion architectures must bind every recorded episode to an immutable calibration identifier and real-time clock synchronization metrics. Trajectories collected under conflicting geometric or temporal calibrations force neural policies to average incompatible sensorimotor distributions within identical state spaces.

5.10.2 Sim-to-real transfer artifacts in rigid-body simulators

In a rigid-body simulator with a relaxed soft-contact solver, a scripted gripper can interpenetrate a jammed latch plate by a millimeter and slide it open without binding. A behavioral cloning policy trained on those synthetic trajectories learns to push straight through resistance that stalls the physical arm. Because synthetic data generation replaces hardware wear with numerical approximations, degradation in a simulated dataset comes from the solver's contact model rather

than from slipped camera brackets or fatigued operators. Discrete-time physics engines resolve contact constraints once per integration step, and the chosen formulation (whether strict complementarity constraints (Stewart and Trinkle 1996), convex soft-contact relaxations (Todorov et al. 2012), or penalty-based spring-damper models) sets penetration depths, slip thresholds, and drivetrain compliance. Whereas reinforcement learning agents actively exploit numerical quirks to maximize synthetic reward, behavioral cloning policies passively inherit whatever unphysical contact impulses, penetrations, or frictionless transitions the simulator produces. Co-training on simulated and physical demonstrations can nonetheless improve real-world policy success despite discrepancies between the two regimes (table 5.5) (Maddukuri et al. 2025). A physical ingestion pipeline cannot enforce exact contact fidelity across arbitrary geometries; its job is to preserve provenance. Every synthetic trajectory must record its simulation engine, software version, contact solver parameters, and integration time step. The scenario table also flags cells populated solely by synthetic rollouts (table 5.6), so downstream training and diagnostics can separate solver artifacts from hardware behavior (section 6.4.2).

↪ The decomposition of transfer discrepancies into dynamics, sensing, appearance, and timing channels, sized from paired command-response traces, is developed in section 6.5.

5.10.3 Rig-to-rig divergence across nominally identical fleets

When a worn secondary manipulator with 0.35° of gearbox backlash and a 22 ms torque-response lag records latch demonstrations for a fleet, the human operator unconsciously adds aggressive lead compensation to overcome the deadband. Replaying or imitating those demonstrations on a newly commissioned arm with 0.02° of backlash drives the new arm into limit-cycle oscillations. Even among factory-identical robots of the same model number, individual units differ in gearbox wear, thermal dissipation, and motor-controller filter tunings. To keep fleet-wide pooling from mixing incompatible plants, data ingestion pipelines must bind each unit's embodiment contract (its kinematic parameters, actuator serial numbers, controller firmware revisions, and identified dynamic models) to every recorded file. They then filter out trajectories from units that violate the target platform's compatibility bounds.

Aggregating fleet data also exposes a second failure mode: confusing physical task failures with telemetry logging faults. A failed attempt is a complete, physically valid sequence in which the robot tried a task and missed the goal. Discarding those episodes introduces survivorship bias[13] and strips the dataset of the boundary states, recovery paths, and negative outcomes needed to train stabilizing policies. A failed recording, by contrast, is an infrastructure fault, such as a dropped network packet, a torn image frame, or a ring-buffer overrun. Ingesting a corrupted recording without tracking gaps presents missing or uneven sample intervals as a continuous fixed-rate stream, corrupting finite-difference state derivatives. Data pipelines must therefore sort every session into one of three categories: a retained success, a retained physical failure, or an excluded logging fault tagged with diagnostic error codes. In the door-latching campaign, an episode halted by the 15 N contact tripwire is a valid physical failure and stays in the provenance archive, whereas a run in which the 6-axis force-torque sensor dropped packets is quarantined with its bus error code. Retaining a physical failure does not make its commands expert imitation targets; only stabilized, reviewed recovery segments or expert-relabeled states qualify under the intervention curation rules.

13 **Survivorship Bias**: During the Second World War, Abraham Wald of Columbia's Statistical Research Group estimated the vulnerability of combat aircraft from the damage on the planes that came back; the planes that were hit in the most vulnerable places were the ones missing from the sample (Mangel and Samaniego 1984). A demonstration archive filtered to successes has the same hole. The attempts that reached the failure boundary are exactly the ones absent, so the archive understates how often the boundary is reached and holds no states from it.

Even when every packet arrives intact, a fleet interface can still corrupt an archive by recording numbers in the wrong physical units or coordinate frame. Because standard schema validators check only data types and value ranges, such mismatches pass ingestion silently until a downstream consumer interprets the numbers under a different convention (war story 5.1).

War Story 5.1: Mars Climate Orbiter unit mismatch (1999)

Context: During its nine-month cruise to Mars in 1998 and 1999, the Mars Climate Orbiter fired small thrusters to desaturate its reaction wheels, and the navigation team on the ground folded the resulting velocity changes into the trajectory models used to plan each correction maneuver (Stephenson et al. 1999).

Mechanism: A ground software file (called "Small Forces" in the investigation) reported thruster impulse in pound-force-seconds ($\mathrm{lbf \cdot s}$), while the trajectory models that consumed it assumed newton-seconds ($\mathrm{N \cdot s}$) as the interface specification required. Because $1\ \mathrm{lbf \cdot s} =$

$4.45\ \mathrm{N \cdot s}$, every desaturation event entered the models too small by a factor of 4.45. The values were well formed, in range, and of the expected type, so no schema check could flag them.

Impact: The accumulated error was never resolved during cruise. At orbit insertion the spacecraft passed about 57 km above the surface instead of the planned 226 km and was lost.

Response: The Mishap Investigation Board traced the loss to the missing unit conversion in the ground file. It recommended that the Mars Polar Lander project verify consistent units throughout design and operations and audit all data transferred between JPL and Lockheed Martin Astronautics for compliance with the interface specification, along with stronger navigation review and anomaly escalation.

Systems lesson: A number carries its meaning only together with its units and its frame. A robot dataset runs the same risk on every action tap and every calibration. A record that stores a value without the units, frame, and calibration identifier it was produced under lets a mismatched rig pass every tensor check, which is why the provenance record of section 5.11 binds each tap to them.

5.10.4 Operational design domain blind spots and unsafe interpolation

If the warehouse manipulator contacts the cage door during a fast $0.10\ \mathrm{m/s}$ approach, an unpopulated cell in its scenario table, a policy trained on the `latch-recovery-02` archive can trigger the same withdraw-and-reseat motion that worked during a slow $0.03\ \mathrm{m/s}$ approach. The motion yanks the gripper back before impact strain has dissipated and bends the latch pin. Encountering an unobserved operational state does not make a neural controller pause; the network continues emitting commands, often replaying familiar recovery primitives in regimes where their physical preconditions fail. Each recovery primitive therefore needs its own scenario-table coverage for the physical states in which it executes, rather than a log of the failure conditions that trigger it. Collection supplies experience, and closed-loop evaluation must establish competence in the conditions where the policy is to operate. A qualified permission restriction or physical constraint must exclude regimes that remain unsupported. The 2023 Cruise pullover recounted in section 1.8 is the same failure at road scale. A familiar maneuver, the pullover toward a minimal-risk condition, ran in a state no one had covered, with a pedestrian beneath the vehicle (section 12.9.1 gives the full account).

Sensor calibrations, human operator habits, actuator wear states, and operational design domain boundaries define the physical semantics of every recorded trajectory. If data ingestion pipelines strip these physical metadata to generate flat, uniform tensors, downstream evaluations cannot determine whether an autonomous failure stems from model capacity limitations or from unmodeled distribution shifts embedded within the training corpus. The structured provenance schema of section 5.11 defines the mechanisms that preserve this physical context throughout the dataset lifecycle.

5.11 The Dataset Schema

Consider an audit of two trajectory files from the latch campaign, each holding the exact same number of state-action pairs logged at the same frequency. File A records trajectories from four authorized operators across several days, with no permission-path clamps and consistent fingertip pads throughout. File B records a single operator, logs 620 steps where safety logic clamped joint velocities, and spans an unannounced force-sensor re-zeroing midway through the session. A standard validation script checking only tensor dimensions and value ranges accepts both files without complaint. Treating them as interchangeable training data introduces silent, corrupting bugs. File B requires explicit intervention attribution and recalibration metadata before an engineer can interpret its action labels correctly. Neither file's tensor geometry reveals which physical latch conditions the recorded data actually covers.

The dataset schema organizes the contextual evidence required to make ingestion decisions safely. It preserves the physical origin and timing of every signal, logs collection costs and dropouts, and documents which physical conditions the archive covers or omits. These fields reflect the mechanical and operational realities of the collection cell. While complete metadata cannot guarantee that a

learned policy will operate successfully in closed loop, omitting it ensures that downstream pipelines will misinterpret physical signals.

The **provenance record** is the immutable, machine-readable artifact bound directly to a demonstration archive. It links every recorded trajectory to the specific plant, sensor calibrations, component wear state, four action taps, collection denominators, and scenario-table join ($N_{\text{supported}}/N_{\text{req}}$), including its count unit, eligibility and retention rule, and minimum, under which data collection occurred. Standard tensor shapes and training loss curves cannot validate a physical dataset. By recording an archive's empirical boundaries, the provenance record allows the policy manifest (the record that training attaches to each candidate policy) and the safety case to distinguish demonstrated historical experience from the operational competence that physical testing must establish. Datasheets for datasets (Gebru et al. 2021) standardize documentation for static corpora; embodied archives additionally require tracking physical wear, permission-path interventions, and tap histories across the causal boundary. This record must travel with the trajectory data itself. Because detachable sidecar files easily separate from their payloads during format conversions, engineers serialize the record as an immutable, hashed header within the container's root metadata, such as an MCAP top-level metadata record or a Zarr root attribute dictionary.

↪ The sixteen-record chain, in which the provenance record is the third record, is developed in section C.14.2.

The provenance record chains Part I's hardware records directly to Part II's training and evaluation records. It inherits the actuator and thermal bounds from the limit record and the clock domains and jitter budgets from the handoff record, while the proposal boundary determines which entity held control at each of the four action taps. As episodes are logged, the collection runtime adds the plant identifier, calibration matrices, component wear counts, yield denominators, and scenario-table join. The runtime then hands that complete record forward to the policy manifest, so closed-loop evaluation can test the policy against the exact conditions its data covered.

↩ The handoff record, which extends each limit with the handoff and clock domain that locate it in the machine, is established in section 4.9.

Every trajectory admitted into the training corpus must identify its collection source, collector policy, and execution authority. For human teleoperation, the record logs the operator identifier, the interface hardware, and transport timing characteristics, for example a 6-DoF leader arm sampled at 100 Hz with 0.8 ms of input jitter. Storing an operator identifier, or capturing human faces on peripheral camera streams, makes an episode a record of people as well as of the robot. The schema therefore documents the legal and institutional basis under which each person was recorded, the authorized deployment purposes, and strict retention schedules. This governance ensures that an episode collected to teach latch insertion is not repurposed to evaluate the worker who demonstrated it. When data originates from an autonomous or mixed controller, the record stores the exact policy checkpoint, the planner version, and the active enforcement configuration, including Cartesian bounding boxes, joint velocity limits, and contact-force clamping thresholds. Trajectories must also record the active retention rule, documenting whether the runtime committed an episode automatically upon task completion, retained it after explicit operator review, or flagged it for inclusion as an instructive failure recovery.

↪ Purpose limits and retention schedules for records that capture people are enforced in section 17.7.1.

A physical machine cannot be identified by a generic catalog name or model string. In real hardware, two nominally identical robot arms behave differently because of manufacturing tolerances and component aging, so the data record specifies the individual plant through its intrinsic and extrinsic sensor calibrations, embodiment contract (section 5.9.1), motor-drive firmware revisions, and component wear state. Even replaceable contact surfaces alter the governing dynamics. A parallel gripper fitted with compliant silicone pads of Shore 30A hardness (a durometer scale for rubbers, on which higher numbers are stiffer) produces vastly different friction and compliance than the same mechanism fitted with worn Shore 60A polyurethane pads under identical joint commands. Maintenance milestones such as cable retensioning, drive-belt replacements, gearbox swaps, and camera remounts therefore belong directly in the machine state record. If technicians recalibrated joint offsets between morning and afternoon collection shifts, the dataset exposes that boundary, so downstream imitation learning does not attempt to resolve two conflicting kinematic mappings into a single policy.

Collection denominators reconcile every physical attempt as a retained success, a retained failure, or an excluded recording, while exposing the wall-clock time spent resetting the scene. Alongside those yield counts, the four action taps of section 5.5.1, override flags, and exclusion codes preserve the critical distinction between demonstrated behavior and permission-path intervention. When safety logic intervenes to clamp velocity or limit contact forces, the data pipeline must at-

tribute those adjustments correctly rather than misinterpreting supervisory interventions as expert demonstrations.

The scenario join records dataset-supported cells (configurations containing retained demonstrations) and catalogs known absences where no empirical data exists. The count-policy digest binds the count unit, eligibility and retention rule, and declared minimum; when a minimum is specified, the record distinguishes occupied cells from those meeting it. Here, dataset support reflects historical logging coverage and must not be conflated with the evaluated support of a deployed policy. For the latch campaign, the record below connects collection cost to coverage; table 5.6 maps its field groups to the decisions they support.

- **Denominators:** 52 attempts per scheduled session at a net retention rate of 0.68, so 5,000 retained successful demonstrations cost 7,353 attempts over 141.4 h of scheduled cell time.
- **Retention rule:** an attempt whose contact force crosses the 15 N tripwire triggers the qualified collection response and is kept as a labeled failure, outside the demonstration count, when its telemetry is valid; a recording that fails quality filtering is excluded with its exclusion code.
- **Scenario table:** plate offset (nominal, +3 mm, –3 mm) crossed with approach speed (0.03 m/s, 0.10 m/s), six cells, held with the count and retention policy in the record as a digest rather than as a copy.
- `supported_cells`**:** the nominal plate at 0.03 m/s, the only cell the original retained demonstrations occupy.
- `known_absences`**:** the other five cells, every displaced plate and every approach at 0.10 m/s.

DRAFT

Table 5.6: Demonstration dataset provenance schema: Evidence retained and the admission check applied to each field group of the provenance record; the embodiment, sensor calibration, and contact wear groups bind the individual plant that collected the data.

Provenance record	Evidence retained	Admission decision
Session	Collector, operator, policy version, source type (physical, robot-free, or synthetic with generator and engine versions), collection mode (nominal, noise-injected, or gated intervention), sample rate, and timing jitter.	Check operator authorization and the session jitter budget.
Embodiment	Robot identity, geometry, gearing, backlash, firmware, and the redundancy parameter (elbow swivel angle or full joint vector).	Check reach, dynamics, and joint limits on the target plant.
Sensor calibration	Camera geometry, clock synchronization, and force/torque bias.	Check calibration age and timebase error.
Contact wear	End-effector material, hardness, friction, flex cycles, and maintenance history.	Revalidate contact data after material or compliance changes.
Four action taps	Requested, mapped, enforced, and measured values, each with its units and frame, plus override and clamp codes.	Compare aligned values; attribute modified commands before choosing labels.
Transition timing	Times of exposure midpoint, action issue, mapping, enforcement, response start, and response end, with clock IDs and synchronization errors.	Check causal order and the declared response window.
Collection denominators	Scheduled cell time, motion time, attempts, retained successes and failures, excluded recordings, and task configurations.	Reconcile attempts against retained and excluded episodes.
Scenario support	Scenario-table and count-policy digest (unit, eligibility, retention, minimum), occupied cells, cells meeting any declared minimum, synthetic-only cells, and known absences.	Identify collection gaps; require separate evidence for deployment claims.
Consent and retention	People recorded (operator and any bystander in view), the consent or other basis for recording each, the declared purposes, the retention period, and who may read the record.	Admit an episode only for a purpose its basis covers; delete or de-identify it when retention ends.

The policy manifest of section 6.8 cites each contributing archive by digest, including `latch-recovery-02` in the stipulated follow-up branch. The original record continues to describe the original campaign; new experience receives new provenance rather than rewriting old absences. Operator and override history also informs supervisory evaluation, while coverage and calibration evidence contributes to the release argument. Binding the metadata to the trajectory container helps preserve these relationships through ingestion, but cryptographic hashes do not automatically prevent misuse. Data loaders and ingestion pipelines must verify that trajectory arrays remain bound to their declared schema and calibration headers before training begins, because skipping any part of that check leads to the recurring collection failures cataloged next (section 5.12).

↪ The release manifest, which binds this provenance record and its operating-domain coverage into the release argument, is developed in section 16.8.

5.12 Fallacies and Pitfalls

In pure software systems, data collection can often treat storage growth as an unvarnished positive, since more web pages, text tokens, or labeled images generally broaden coverage. In physical artificial intelligence, however, datasets are tightly coupled to the mechanical dynamics, calibration state, and physical limits of the collection hardware. A dataset that passes every structural schema check, with zero dropped packets and consistent tensor dimensions, can still leave a deployed machine entirely blind to critical operational states. The operational distribution of physical data reflects three intertwined factors: the collecting policy (whether driven by human teleoperation or automated planning), the physical capabilities and wear of the collection rig, and the curation filters applied before admission to the archive. Neglecting these physical constraints leads to predictable engineering fallacies and costly operational pitfalls.

Fallacy: *Massive sample volume compensates for lack of operational state-space coverage.*

Suppose a surface-tracking policy must operate reliably across 500 distinct combinations of normal force, surface friction, and contact angle, but the archive covers only 45. Logging another collection run that adds $72{,}000$ control steps by repeating nominal trajectories through those same 45 states inflates the database, but it leaves physical coverage unchanged. High-frequency sampling in familiar regions merely records the same dynamic trajectory more densely, adding zero evidence about the unvisited friction regimes or steep contact angles. Ingestion pipelines that report growing data volume and zero dropped packets can create a false sense of security while leaving downstream policies brittle. A collection campaign earns its cost by addressing a declared coverage, label-quality, or evidence deficit. A populated cell may still need more or better demonstrations, while nominal repetition alone supplies no evidence about unvisited regimes.

Architect's countermeasure: Gate dataset admission on a support envelope relational join against an explicit scenario table, rather than step counts or raw byte volume. Require that new data collection campaigns specify which coverage, label-quality, or evidence deficit they target, and track scenario coverage ($N_{\text{supported}}/N_{\text{req}}$) as a primary engineering KPI alongside validation loss.

Pitfall: *Assuming physical demonstration labels survive mechanical or contact hardware maintenance.*

Archived demonstrations do not retain physical validity when the underlying hardware changes, even if array shapes and data schemas remain identical. Consider what happens when a technician replaces a parallel gripper's compliant fingertips with stiffer pads and re-torques an adjacent camera bracket. The historical dataset still passes every automated pipeline check: sensor channels, array dimensions, and datatypes match expected specifications. If the camera bracket shifts, a known transformation matrix allows mathematical reprojection of visual coordinates. Contact mechanics, however, cannot be reprojected geometrically. The stiffer pads alter normal compliance and contact friction, causing grasp slip at substantially lower shear thresholds than the compliant material tolerated. Telemetry recorded before the swap captures the physical behavior of an obsolete body; training a closed-loop force controller on those historical tactile profiles will cause grasping failures on the modified hardware. Data provenance must track the full mechanical and calibration state of the collection rig so that any hardware alteration immediately triggers targeted review and recollected baselines.

Architect's countermeasure: Bind every trajectory file to an immutable hardware state hash that captures camera extrinsics, motor serial numbers, and contact surface material specifications. When maintenance events alter contact stiffness or camera mountings, invalidate historical tactile and force labels for that cell until an automated revalidation protocol verifies dynamic equivalence.

Pitfall: *Filtering out aborted safety interventions to sanitize the demonstration dataset.*

Purging aborted demonstrations to produce a flawless training set introduces severe survivorship bias into physical policies. Consider an automated peg-insertion pipeline spanning 1,000 recorded attempts. Of these, 180 runs triggered a safety cutoff when contact forces reached or exceeded a 15.0 N trip threshold, leaving 820 nominal runs that succeeded with an 82 percent yield. A curation script discards the 180 aborted and recovery episodes, preserving only the smooth runs where forces stayed comfortably below 8.0 N. When deployed in production, minor surface misalignment inevitably pushes an insertion force to 9.5 N. Although this force remains below the 15.0 N trip threshold, the policy encounters a state outside its training support. Because the sanitization script erased every observation between nominal tracking and failure, the archive supplies no supervision for these near-boundary dynamics, so recovery behavior remains unsupported. Pruning near-boundary and intervention data strips away the exact state-action pairs the policy needs to regain stability after a disturbance.

Architect's countermeasure: Implement three-way intervention curation at data ingestion. Quarantine learner commands between divergence (t_{div}) and takeover (t_{takeover}) for safety auditing only. Preserve the visited boundary states for expert relabeling via corrective aggregation (DAgger). Admit the subsequent human recovery as an expert sequence only after the operator's measured stabilization ($t_{\text{stabilize}}$), masking the blend and reorientation that precede it.

Pitfall: *Merging demonstrations collected across kinematically asymmetric leader interfaces.*

Merging trajectories across disparate teleoperation input interfaces can quietly bake kinematic dead zones into the dataset. Suppose two operators collect snap-fit assembly demonstrations using different leader devices to puppet identical follower arms. The first leader mechanism features detented wrist mechanics that restrict roll to two discrete positions ($\theta_{\text{roll}} \in \{0.0^\circ, 90.0^\circ\}$). The second leader uses a continuous gimbal that mechanically limits roll travel to $[-15.0^\circ, +15.0^\circ]$. Merging the two collections yields 4,000 episodes and increases overall sample volume, but neither interface can express orientations between 20.0° and 70.0°. Even though the follower arm can navigate that full range, the combined archive contains zero training targets within this 50.0° gap. Pooling data from different input devices cannot fill gaps that neither device can mechanically traverse. Downstream imitation policies trained on the combined dataset will fail whenever initial conditions or part tolerances demand intermediate orientations.

Architect's countermeasure: Apply the cross-embodiment compatibility contract to the leader interface itself, checking before recording that the leader and follower share the required reachable poses, joint motion ranges, and ability to move in the required directions. Enforce continuous orientation coverage checks across task-space degrees of freedom during data QA to detect mechanical dead-zones.

Fallacy: *Physical data collection scales linearly with labor hours just like internet scraping scales with compute.*

Treating physical data collection as an easily parallelized, linear process like web scraping ignores the mechanical entropy and human fatigue inherent to physical experimentation. Teams often extrapolate campaign timelines from early pilot runs, for example by projecting that an initial pace of 50 successful episodes per operator-hour will scale linearly across weeks of shifts. In reality, continuous operation degrades both hardware and teleoperator consistency. Repetitive contact impacts cause backlash and tooth wear in strain-wave gearboxes, thermal expansion and sensor drift cause uncalibrated joint encoders to drift away from physical ground truth, and human fatigue introduces latency spikes and jerky trajectories. As wear accumulates, the proportion of episodes passing quality filtering steadily drops, even while scheduled labor hours remain constant. Pilot runs conducted on pristine hardware systematically overstate long-term collection yield. Campaign planning must budget for routine recalibration, mechanical maintenance, ergonomic rests, and discarded runs alongside raw operator hours.

Architect's countermeasure: Budget collection campaigns in net validated demonstration yield ($Y_{\text{usable}} = \lfloor T_{\text{motion}} / t_{\text{cyc}} \rfloor \cdot R$) and component fatigue cycles (L_{10} ratings for strain-wave gears and internal flex harnesses), rather than gross scheduled operator hours. Estimate the overhead multiplier from the campaign's calibration, reset, retention, and rest assumptions; validate it against sustained collection yield.

5.13 Summary

A physical machine manufactures its own training data, so every record carries the loop that produced it: the operator's request, the permission path's admission, and the body's response, all under the machine's current calibration and wear. Collecting that data is costly in a way scraping is not. In the latch campaign, only 24.6 percent of each scheduled hour survives as retained demonstration motion once startup, calibration, operator rest, resets, failed attempts, and quality filtering are paid for, and the wrist's flex cable consumes the larger fraction of its assumed fatigue rating. Because every attempt spends cell time and component life whether or not it is kept, and because correlated control steps hold few independent samples, a campaign earns its cost by addressing a declared coverage, label-quality, or evidence deficit, including inadequate evidence within a populated cell.

Which states the archive holds is a question the archive cannot answer about itself. Coverage is a join between empirical occupancy and a scenario table derived from the declared operational design domain, and against the table the door actually demands, the baseline latch archive fills one cell of six. Inside even a populated cell, a cloned policy's first error carries it off the demonstrated corridor into states where nothing in the archive constrains its output, which is why behavioral cloning's worst-case cost grows with the square of the horizon. Interventions supply the missing learner-visited states, but only after curation at the divergence, takeover, and stabilization timestamps

separates the learner's commands from the expert's recovery. Aggregating expert labels on those states makes the worst-case cost linear in the horizon only while the recoverability constant stays bounded; where a mistake cannot be undone, the state belongs to the permission path, not to the dataset.

A label is only as meaningful as the tap, clock, and plant behind it. Imitating the request teaches commands the permission path would have clamped, imitating the measured response teaches compliance and backlash as intent, and pairing either with a misdated frame converts timing error into position error at the speed of the motion. Range normalization cannot carry a label to another embodiment, and a bumped camera bracket or worn pad silently changes what a stored tuple means. The provenance record binds each archive to its taps, timestamps, plant, calibration, collection denominators, and known absences, so that training and evaluation can tell demonstrated experience from evaluated competence. Table 5.7 summarizes the load-bearing equations introduced throughout this chapter, detailing the physical boundaries each expression defines, the architectural decisions it governs, and its formal derivation.

Table 5.7: Key equations of physical data: Each load-bearing equation of the chapter, the limit it bounds or the decision it settles, and the equation where it is derived.

Equation	What it bounds or decides	Derived in
$J(\pi) - J(\pi^*) \leq S^2\epsilon$	The worst-case excess cost of cloning on expert states under a 0–1 action loss; the bound becomes uninformative once $\epsilon > 1/S$	equation 5.1
$J(\hat{\pi}) \leq J(\pi^*) + u\,S\,\epsilon_N + \mathcal{O}(1)$	The cost after aggregating expert labels on learner-visited states, linear in S only while the recoverability constant u stays bounded	equation 5.8
$N_{\text{eff}} = N(1-\rho)/(1+\rho)$	The effective number of independent observations contained in a serially correlated telemetry stream for a single statistic	equation 5.2
$\Delta\mathbf{x}_{\text{sync}} \approx \mathbf{v}\,\Delta t_{\text{lag}}$	The spatial error introduced by inter-sensor pairing latency, defining the maximum allowable delay for a specified task clearance	equation 5.3
$\Delta t_{\text{skew}} = (H-1)\,t_{\text{row}}$	The temporal skew across a rolling-shutter frame, which end-effector motion translates into geometric image distortion	equation 5.4
$t_{\text{loop}} = t_{\text{disp}} + t_{\text{hum}} + t_{\text{cmd}} + t_{\text{mech}}$	The round-trip phase lag in teleoperation between an observed state and the physical execution of the human correction	equation 5.5
$Y_{\text{usable}} = \lfloor T_{\text{motion}}/t_{\text{cyc}} \rfloor R$	The yield of usable demonstrations per scheduled session, determining the cell time and mechanical wear required for a campaign target	equation 5.6
$\hat{t}_{\text{div}}$: first threshold crossing, when captured, in $[t_{\text{takeover}} - T_{\text{pre}},\, t_{\text{takeover}}]$	The estimated onset of trajectory drift before human takeover, determining whether the lookback window captures the causal error	equation 5.7
$\epsilon_{\text{reproj}} = \lVert \tilde{\mathbf{m}}_{\text{observed}} - \text{proj}_{\mathbf{K}}(\mathbf{T}_{\text{cam}\leftarrow\text{base}}\,\mathbf{FK}(\mathbf{q})) \rVert_2$	The extrinsic reprojection residual used to verify that camera calibration remains aligned with kinematic joint encoders	equation 5.9

Key Takeaways: Physical data collection and provenance

- **Coverage measures distinct physical configurations rather than sample volume:** Repeated nominal trajectories add millions of telemetry rows without expanding scenario coverage. Adjacent control steps are so strongly autocorrelated that an hour of permission-tick records holds only about 1,800 independent samples for a slowly varying statistic, and even independent samples support only the cells where they land. An engineering team must measure dataset completeness by joining logged trajectories against an explicit scenario table that spans the operational design domain, rather than relying on raw row counts or the archive's own observed extremes.

- **Offline validation loss cannot detect coverage deficits:** Because conventional train-validation splits sample from the same underlying trajectory distribution, a policy can achieve near-zero validation loss while leaving critical operational cells unvisited. Only auditing the dataset against an independent scenario table reveals these silent omissions before deployment.
- **Every action tap represents a distinct physical control signal:** An operator's commanded request, the resolved kinematic setpoint, the safety-filtered actuator command, and the measured joint response diverge whenever hardware limiters, friction, or permission guards intervene. Logging each tap alongside synchronized timestamps ensures the supervisory target remains causal and preserves unambiguous evidence of physical interventions.
- **Preserve aborted runs and interventions with rigorous causal attribution:** Discarding failed attempts discards the most valuable boundary-adjacent states in the operational envelope. Autonomous commands preceding a human takeover must be archived for fault analysis and counterfactual relabeling rather than misattributed as expert demonstrations, while the subsequent corrective maneuver should be reviewed, trimmed, and stored as an explicit recovery trajectory.
- **Physical telemetry remains bound to specific hardware embodiments:** While optical perspectives can be reprojected across camera geometries, dynamic properties such as joint friction, structural compliance, and gearbox backlash are embedded directly into recorded force and torque signals. Simple range normalization masks these physical discrepancies without resolving them, requiring thorough re-calibration and verification whenever data is transferred across hardware platforms.
- **Targeted recovery data broadens operational competence under new provenance:** An immutable dataset records the boundary conditions of a specific collection campaign, but engineers can systematically expand policy capabilities by appending verified recovery sequences under separate provenance tags. Asserting an expanded operational claim, however, requires end-to-end closed-loop validation on the physical machine under those target conditions.

Each latch archive in this chapter ended the same way, with a short list of supported cells and a longer list of known absences. That ratio is not a defect of one campaign. It is what the second law, endogenous data (principle 2), costs in practice. A machine whose actions choose its next states can only record the states its collecting policy chose, and every additional state it records is paid for in cell time and component life. The known absences in the provenance record are the price list. They say which experience the machine never bought, and therefore which claims no amount of training on this archive can support.

Read that way, the engineering question shifts from how much data a campaign collected to which absences it retired and what each one cost. The displaced-plate cell that `latch-recovery-02` fills moves from the absence list to the supported list under new provenance. The faster approach, which no one collected, stays on the list, and the permission path must keep refusing it until evidence arrives.

5.14 Historical Perspective and Further Reading

Demonstration in robotics began not as data collection for machine learning, but as teleoperation for hazardous environments. At Argonne National Laboratory, Raymond Goertz developed mechanically coupled master-slave manipulators to handle radioactive materials behind heavy shielding (Goertz 1949). These early systems linked the operator's handle directly to remote mechanical tongs through cables and counterweights; because the transmission was entirely mechanical, contact forces against objects reflected instantly and passively back to the operator's hand.

The systems challenge shifted radically when electrical servos and digital communication networks replaced mechanical linkages. Introducing transmission latency into the bilateral loop between the operator interface and the actuated follower can inject artificial energy into the feedback channel,

quickly driving the coupled system into violent instability. Anderson and Spong (1989) proved that even small transmission delays can destabilize a bilateral teleoperator and established a framework that preserves delayed-channel passivity under its constant-delay model. Stability of the complete loop also depends on the connected systems and their interconnection conditions. Niemeyer and Slotine (1991) reformulated this remedy through wave variables, transforming power variables (force and velocity) into traveling wave representations that behave as passive transmission lines under the constant-delay model. In their comprehensive survey, Hokayem and Spong (2006) trace the progression from Goertz's early linkages to modern delay-robust control schemes. Every teleoperation data-collection interface operates under the compromise these works describe, balancing faithful haptic transparency against the conditions needed to preserve passivity. The physical trajectories, contact transitions, and actuation commands captured in an embodied training archive inherently reflect the compromises of the collection hardware.

Synthesizing feedback controllers directly from recorded demonstrations followed an equally grounded trajectory. In one of the earliest end-to-end vision-based driving systems, ALVINN mapped camera frames to steering angles for an autonomous van (Pomerleau 1989, 1991). ALVINN immediately ran into the recovery gap. Because expert drivers kept the van centered within the lane, the recorded dataset contained virtually no examples of drifting off course or recovering from road shoulders. Pomerleau resolved this issue through an early form of data augmentation, synthetically warping camera images and computing the corresponding corrective steering angles to teach the network how to return to the road center.

As the field matured, Argall et al. (2009) unified robot learning from demonstration into a comprehensive framework, formalizing how data collection methods shape policy representations and analyzing the kinematic correspondence problem between the demonstrator and the physical robot. The theoretical mechanics of compounding execution errors were established by Ross and Bagnell (2010), who proved that naive behavioral cloning yields an error bound that grows quadratically with the task horizon ($\mathcal{O}(S^2\epsilon)$) under covariate shift. To escape this quadratic penalty, Ross et al. (2011) introduced Dataset Aggregation (DAgger), demonstrating that rolling out the learner while querying the expert along the induced state distribution achieves an optimal linear bound ($\mathcal{O}(S\epsilon)$), provided the environment satisfies a finite recoverability condition. Practical robotics deployments adapted this theoretical machinery to human supervisors who cannot label millions of counterfactual query states. Human-gated DAgger (Kelly et al. 2019) transferred control to a human expert only during critical trajectory deviations, while DART (Laskey et al. 2017) injected continuous stochastic noise into the actuators during teleoperation to force human demonstrators to execute recovery maneuvers naturally. The empirical intervention strategies and recovery curation workflows in section 5.8 trace directly to these foundational methods.

The accounting of state-space coverage and sampling validity borrows from older statistical and control foundations. Bellman (1957) named the curse of dimensionality to describe the exponential explosion of discrete state spaces in dynamic programming. In environmental time series, climatologists demonstrated that serially correlated records dramatically reduce the effective degrees of freedom, requiring explicit adjustments to compute true sample sizes (Thiébaux and Zwiers 1984). Simultaneously, Abraham Wald's wartime analysis of returning aircraft showed that evaluating only surviving samples systematically blinds the observer to critical failure modes (Mangel and Samaniego 1984).

Robot learning confronted all three phenomena as datasets evolved from isolated laboratory demonstrations into massive multi-robot corpora (Walke et al. 2023; Khazatsky et al. 2024; Open X-Embodiment Collaboration et al. 2024). While cross-institution pooling supplies visual and environmental variations that no single robotic cell can generate, it also pools mismatched actuator dynamics, unmodeled camera latencies, and latent operator selection biases. Standardizing such corpora requires both an explicit compatibility contract across kinematics and a rigorous accounting of unobserved conditions. Although dataset documentation frameworks (Gebru et al. 2021) originally addressed provenance and social biases in digital corpora, physical robotics demands tracking hardware-level ground truths. The physical dataset schema and provenance architecture detailed in section 5.11 extend these documentation principles to capture actuator tap points, calibration matrices, dynamic delays, and known boundary omissions.

The following readings chart the progression from classical bilateral teleoperation to modern pooled robot corpora:

- Hokayem and Spong (2006) provides an exhaustive survey of bilateral teleoperation control, charting the historical transition from mechanically coupled manipulators to passivity-based and wave-variable architectures. It explains the core control-theoretic tension between transparent force reflection and robust stability when non-negligible communication delays separate the operator from the robot.
- Pomerleau (1991) presents a compact, highly practical diagnosis of the recovery gap and compounding errors in end-to-end behavioral cloning. The paper details how synthetic visual transformations of road images generated corrective training labels, demonstrating the necessity of off-trajectory recovery data decades before formal distribution-shift theory was codified.
- Argall et al. (2009) synthesizes robot learning from demonstration into a foundational taxonomy based on demonstration collection mechanisms and policy derivation techniques. It highlights the correspondence problem across differing human and robotic kinematic structures, which section 5.9 formalizes as a strict cross-embodiment mapping contract.
- Ross et al. (2011) introduces the Dataset Aggregation (DAgger) algorithm and establishes the formal reduction of imitation learning to online convex optimization. It proves that querying an expert along the learner's visited trajectory distribution converts the quadratic error growth of behavioral cloning into a linear bound, defining the critical recoverability constant presented in equation 5.8.
- Open X-Embodiment Collaboration et al. (2024) documents the Open X-Embodiment initiative, pooling over one million trajectories across dozens of robot platforms and institutions. The paper is essential reading for systems engineers, illustrating both the positive transfer enabled by scale and the severe architectural challenges of normalizing disparate action spaces, sampling rates, and sensor configurations.
- Gebru et al. (2021) establishes the foundational methodology for documenting dataset motivation, composition, collection workflows, and intended use. Contrasting this general framework with table 5.6 clarifies the specialized physical, electrical, and dynamical metadata required to safely train and deploy embodied controllers.

What's Next: From demonstrations to policies

A policy trained on an archive whose provenance record lists more absences than supported cells learns strictly from those supported cells; its training score gives no sign of where the absences begin. The baseline latch archive covers only the nominal strike plate at the guarded approach. Chapter 6 opens with two candidates built on it: `latch-bc-01`, cloned from those demonstrations, and `latch-sim-02`, distilled from a simulator teacher that learned the fast approach no one collected on the machine. Each improves in training while hiding a dependency the hardware will expose. That chapter then carries the curated `latch-recovery-02` archive into a recovery candidate and writes each candidate's evidence into a policy manifest whose declared operating domain cannot exceed the cells its provenance supports. Chapter 7 then tests whether that declared domain holds on the machine.

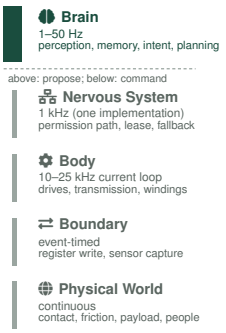
Purpose

Why can a policy improve its training score while becoming less reliable on the machine?

A learned policy acquires its behavior from the experience its training supplies, and its weights keep no record of which experience that was. Demonstrations can omit the recovery from a displaced fixture, a simulator can reward a fast approach that a real contact surface cannot tolerate, and a model pretrained on other robots can behave plausibly in conditions no one has tested on this machine. In each case the training score rises while the dependency stays hidden, so ranking candidates by score can favor the one that exploited its data or its solver. Training also fixes how long the policy takes to propose an action, and every improvement gathered on the machine itself is paid for in heat and component life. An engineer who does not understand these mechanisms cannot choose a source of experience that supports the behavior the task needs, cannot state the conditions in which a checkpoint may be trusted, and discovers each hidden dependency only when the machine meets it. Because an admitted action crosses the causal boundary and its consequences cannot be undone by another gradient update, the limits of a policy's evidence must be established before it is allowed to propose motion.



Learning Objectives

- Compare training regimes, from behavioral cloning to post-training a pretrained generalist, by the experience they supply and the physical dependencies they leave in the policy
- Diagnose the separate risks of averaging valid action choices and drifting beyond demonstrated states
- Calculate whether an action decoder fits its proposal deadline and identify the required execution safeguards
- Evaluate simulator mismatch and distinguish parameter variation from missing mechanisms or unavailable observations
- Bound real-machine adaptation by physical exposure, residual authority, and regression evidence
- Construct a policy manifest that confines a candidate's declared operating region to its documented support

6.1 Dual Failure Modes of Policy Training

A robot arm executing a learned trajectory can track every waypoint cleanly across hundreds of simulation episodes and still arrive at its first physical deployment with no evidence about whether it will fracture a latch. In classical robotics, control design begins with an explicit analytical model of the plant: engineers write down kinematic equations, inertia matrices, stability margins, and torque limits where they can be systematically inspected and verified. A learned neural policy, in contrast, derives its behavior entirely from its training distribution, setting network weights from empirical experience to map physical observations to proposed control actions. That experience may arrive as teleoperated demonstrations, recorded operational logs, rollouts inside a parallel physics simulator, trial-and-error interactions on physical hardware, or pretrained representations imported from foundation models. Although empirical data makes complex manipulation tractable, it also embeds unstated dynamic assumptions directly into the model weights, leaving no explicit record of which operating regimes the policy can safely navigate.

The central engineering question in embodied policy training is therefore not which regime achieves the highest optimization score, but which physical behaviors the training experience supports, and at what operational cost. Four quantities decide the answer. The first is coverage, because a policy is supported only in the states its experience actually visited, which is why the provenance record of section 5.11 lists its known absences beside its demonstrated cells. The second is inference latency, because a policy that evaluates too slowly misses its control deadline, however good its proposed trajectories are. The third is hardware cost, since experience gathered on the machine consumes machine hours, heats motor windings, and wears drivetrains. The fourth is fidelity, because synthetic experience from simulation scales across parallel accelerators but is only as faithful as the integrator and contact solver that produced it. A checkpoint's policy manifest (section 6.8) records all four, and its declared operational design domain (ODD) is the part of the task's scenario table that the checkpoint's evidence supports. Two candidate latch policies show why a clean training curve does not establish physical viability.

Consider the cage-door latch task introduced in section 5.1, where two learned controllers both succeed under nominal warehouse conditions yet each carries a hidden dependency that physical hardware can expose, for different mechanical reasons. Both controllers share the same real-time execution model: Action Chunking with Transformers (ACT) (Zhao et al. 2023), a chunk-policy architecture that generates open-loop action sequences in a single decoder pass. The first candidate, `latch-bc-01`, was trained via supervised behavioral cloning on teleoperated door-opening demonstrations. The second candidate, `latch-sim-02`, is a distilled student policy. A reinforcement learning teacher was first trained inside a parallel physics simulator with full access to privileged state variables. Then `latch-sim-02`, initialized from `latch-bc-01`, learned through distillation to replicate the teacher's actions using only onboard sensor streams (section 6.5.1).

Both candidates inherit the absence list of the baseline archive. Its demonstrations characterize only the nominal strike plate at a guarded approach velocity, so a displaced plate and a faster approach are both recorded as known absences, and each candidate meets one of them. While behavioral cloning must interpolate between these discrete demonstrations to form coherent trajectory proposals, interactive learning in simulation can explore novel state-action pairs. However, the validity of that synthetic exploration depends entirely on how accurately the simulated mechanics mirror the physical plant. Selecting a training regime is therefore an architectural decision that dictates which unverified assumptions must be empirically audited before a checkpoint is permitted to command actuators.

In this illustrative comparison, at the nominal strike plate and the guarded approach speed of 0.03 m/s, both policies open the door. Their failure modes diverge once physical deployment departs from that single nominal operating point:

1. **Missing recovery experience**: When a sagging door places the strike plate off nominal, `latch-bc-01` encounters observations outside its training distribution. Because behavioral cloning minimizes supervised prediction error across the recorded demonstrations, the training loss supplies no direct supervision at unvisited recovery states, although updates to shared weights can still change the actions predicted there. When confronted with unfamiliar observations, the network still emits action setpoints, but those ungrounded commands drive the manipulator further off course. Trajectory errors compound at each 25 ms setpoint tick until the gripper binds against the strike plate's chamfered edge. The root bottleneck is the absence of corrective recovery trajectories in the training distribution, rather than model capacity.
2. **Misleading simulated contact**: In contrast, `latch-sim-02` is at risk on the nominal strike plate itself. Its simulator models contact dynamics using a compliant penalty spring[1] ($f_{k,\perp} = k_{\text{pen}}\delta + c\dot{\delta}$), where surface penetration δ and penetration rate $\dot{\delta}$ govern the contact force. Because this numerical spring yields far more compliance than a physical steel plate, the simulated impact at 0.10 m/s peaks well under the latch's 100 N limit. The teacher's training reward paid for opening the door quickly and carried no term for contact force, so nothing in training charged for an aggressive approach, and the optimizer exploited the contact model to shave cycle time off each episode. The reinforcement learning teacher converges on an aggressive plunge, and policy distillation faithfully transfers that shortcut into the student. Whether the plunge breaks the real latch depends on how stiff the arm side of the contact is, a quantity nothing in training measured.

A contact-force budget demonstrates why the simulated benchmark score cannot be trusted on hardware. In the rigid-arm, constant-drive estimate, the physical strike plate's stiffness sets the force rise. At the unbraked approach velocity of 0.10 m/s, force reaches the 100 N limit in 2.5 ms after touch. The tripwire fires at 0.375 ms; the subsequent 2 ms response places brake onset at 2.375 ms, leaving only 0.125 ms before the constant-drive ramp reaches the limit. That interval is not a stopping certificate. Section 6.4.2 derives the timeline alongside the passive impact forces; sanctioning the fast plunge would require physical deceleration evidence that this simulation-only training process cannot establish.

Both failures expose dependencies hidden from validation loss and episodic reward: behavioral cloning depends on demonstrated recovery distributions, while simulation-to-real transfer depends on faithful contact and stiffness dynamics. Selecting a policy training regime therefore requires matching the physical properties of the training source to the mechanical demands of the operational task. Whichever regime produced it, a learned checkpoint sits above the proposal boundary as an unprivileged proposal generator. Safe and reliable manipulation requires action proposals that respect the machine's actuator dynamics, contact deadlines, and physical safety envelopes as rigorously as they pursue the nominal task objective. Comparing the five regimes that can generate those proposals clarifies what each source of experience buys and what it leaves unverified.

6.2 Policy Training Regimes

When `latch-bc-01` binds against a sagged strike plate and `latch-sim-02` plunges into the nominal plate at 0.10 m/s, neither failure can be repaired by training the same network for more epochs on the same dataset. Fixing an unvisited recovery state or an exploited contact solver requires

[1] **Kelvin-Voigt Contact**: A linear spring and damper in parallel produce a force jump at first touch, because the damping term acts on the full approach velocity at zero penetration, and a pulling, "sticky" force as the bodies separate, because the damping term then outweighs the vanishing spring term. Hunt and Crossley (1975) scaled the damping with penetration to remove both artifacts. A policy trained against the linear model therefore meets its least faithful forces at contact onset and at release, the two events a latch opening depends on.

↩ The proposal boundary, under which a learned proposer holds no authority until an independent permission path admits its command, is established in section 1.7.

changing the experience the learner sees. Training a control policy for the latch task can draw on five sources of experience: teleoperated door openings, logged archives of imperfect or scripted trajectories, a physics simulator of the door and cage, direct physical trial on the arm itself, and a generalist foundation checkpoint pretrained across multi-robot corpora. Each source buys distinct sensorimotor capabilities at a characteristic physical cost and leaves its own failure mode behind (table 6.1). Behavioral cloning, batch offline reinforcement learning, and supervised post-training extract control policies from recorded datasets without runtime exploration, whereas online trial, conducted in simulation or on the physical mechanism, generates new interactions under closed-loop feedback. Comparing how those regimes evaluate and update actions begins with the reward quantities that score closed-loop behavior over an episode.

Table 6.1: Comparative trade-off matrix across policy training regimes: The five regimes compared are behavioral cloning, offline reinforcement learning, sim-to-real reinforcement learning, residual RL/fine-tuning, and post-training of a pretrained generalist policy. Columns separate the capability sought, the resources that determine its cost, and the remaining failure mechanism. Training remedies and physical execution safeguards have different roles; neither supplies the other's evidence.

Policy Training Regime	Core Purchased Capability	Data & Compute Budget	Sample Efficiency & Scale	Hardware Safety & Wear Risk	Dominant Failure Mode & Interceptor
Behavioral Cloning (BC)	Imitates attributable expert actions	Expert collection, curation, and supervised optimization	Limited by coverage and operator availability	Optimization adds no physical exploration; collection still incurs exposure	Mode averaging and missing recovery. Multimodal decoding and new expert labels address training; qualified state and action limits bound execution.
Offline / Batch RL	Uses rewards to select behavior from heterogeneous logs	Logged transitions with rewards and state-action coverage	Reuses recorded experience without new online trials	Optimization adds no exploration; the archive inherits collection risks	Unsupported action values. Conservative objectives reduce optimism; independent action limits remain necessary.
Sim-to-Real RL	Explores behavior through simulated interaction; a privileged teacher can be distilled into a deployable student	Parallel rollout compute plus physical calibration and transfer tests	Throughput depends on task, solver, and hardware	Simulation avoids training wear; physical probing and deployment still incur exposure	Solver exploitation and omitted mechanisms. Paired probes qualify the simulator; approach and force limits need their own response evidence.
Residual RL & Real Fine-Tuning	Adapts to local physical mismatch	Machine interaction, resets, cooling, and regression testing	Physical trials make sample efficiency consequential	Contact loads and thermal exposure accumulate during adaptation	Local improvement with regression elsewhere. Independent residual gates limit authority; combined-controller tests assess the change.

Policy Training Regime	Core Purchased Capability	Data & Compute Budget	Sample Efficiency & Scale	Hardware Safety & Wear Risk	Dominant Failure Mode & Interceptor
Pretrain & Post-Train	Starts from a generalist checkpoint's broad competence and adapts it to the task with demonstrations or reward	A base checkpoint trained elsewhere, task data, and fine-tuning compute	Task data needs shrink when the base already represents related skills	Supervised post-training adds no exploration; RL post-training adds the exposure of its own rollouts	Borrowed competence mistaken for evidence, and forgetting. Support comes only from the task data join; regression tests cover what post-training may disturb.

6.2.1 The latch task as a reward problem

A reward function that pays a policy for opening the cage door and penalizes each control step for elapsed time without charging for contact force will train the arm to slam into the strike plate, because every millisecond shaved off the approach increases the episode's score. Even behavioral cloning, which uses no reward during training, has its failures measured in the quantities that a reward problem defines: the states a policy visits, the return it earns over an episode, and the value of one action against another. Posing the latch mechanism as a discrete-time optimal control problem makes those quantities concrete and shows how an omitted force penalty or a discount factor mis-scaled against the control rate distorts learned behavior.

A **Markov decision process** (MDP)[2] describes a task by its state s_t, its action $\mathbf{a}_t$, a transition $p(s_{t+1} \mid s_t, \mathbf{a}_t)$ that the physics supplies, and a scalar reward $r(s_t, \mathbf{a}_t)$ that the engineer writes. For the latch, the state holds the gripper pose, the plate position, and the measured contact force. The action is the setpoint the chunk policy emits every 25 ms. An episode is one opening, 8 s of autonomous contact-phase motion, or 320 decisions. A reward that states what the task values and what it must avoid is

$$r_t = r_{\text{open}}\,\mathbb{1}[\text{door open at } t] - \lambda_f \max\left(0, f_t - F_{\text{trip}}\right) - c_{\text{time}}, \tag{6.1}$$

where F_{trip} is the 15 N contact tripwire, the force threshold that triggers the machine's qualified collection response (set below the latch's damage limit), λ_f is a weight in reward per newton of excess force, and c_{time} charges each step for slowness. The weights make the terms commensurable, and choosing them is a design decision that the policy manifest records. Dropping the force term, as the simulator teacher of `latch-sim-02` did, leaves only the time term to shape the approach, and the time term rewards every millisecond an aggressive plunge saves. On hardware the success indicator must itself be measured, by a latch sensor or a learned classifier, and every error in that measurement is a surface the optimizer can exploit. When engineers introduce auxiliary rewards to guide exploration toward that success indicator, adding a potential difference $\gamma\Phi(s') - \Phi(s)$ provably leaves the optimal policy unchanged. Without further assumptions about the task, it is the only added term that does (Ng et al. 1999). Any other shaping term can change what is optimal.

A **policy** $\pi_\theta(\mathbf{a} \mid s)$ is a distribution over actions, and its **return** from step t is $G_t = \sum_{j \geq 0} \gamma^j r_{t+j}$ with discount factor $\gamma \in [0, 1)$. Because γ applies once per decision, its horizon is measured in control steps, not seconds. At $\gamma = 0.99$ and one decision every 25 ms, the door-open reward earned at the end of an opening reaches the first decision with weight 0.04, and the effective horizon $1/(1-\gamma)$ of 100 steps spans only 2.5 s. For the terminal success to keep half its weight across the whole opening, γ must be at least 0.9978. Changing the setpoint rate without re-deriving γ therefore changes the task horizon in seconds. Training a policy means choosing θ to maximize the **objective** $J(\theta) = \mathbb{E}_{\pi_\theta}[G_0]$, the return expected over whole episodes that start from the task's initial states. It is a return to maximize, where the $J(\pi)$ of equation 5.1 was an expected cost to minimize.

Two expectations of the return organize every reinforcement learning method. The **state value** $V^\pi(s) = \mathbb{E}_\pi[G_t \mid s_t = s]$ is the return expected from s when following π. The **action value** $Q^\pi(s, \mathbf{a}) =$

[2] **Markov Decision Process**: Bellman (1957) formulated sequential decisions under uncertainty with the dynamic-programming recursion that equation 6.2 restates, and Howard (1960) supplied policy iteration to solve them. The formalism came from operations research and optimal control decades before reinforcement learning adopted it, which is why the cost-to-go translation below is an identity rather than an analogy, and why a control engineer's tools for that recursion apply to a learned policy's value function.

$\mathbb{E}_\pi[G_t \mid s_t = s, \mathbf{a}_t = \mathbf{a}]$ is the return expected after taking $\mathbf{a}$ first and following π thereafter. Both obey the one-step **Bellman relation**

$$Q^\pi(s,\mathbf{a}) = r(s,\mathbf{a}) + \gamma\, \mathbb{E}_{s'\sim p,\ \mathbf{a}'\sim\pi}[Q^\pi(s',\mathbf{a}')], \qquad V^\pi(s) = \mathbb{E}_{\mathbf{a}\sim\pi}[Q^\pi(s,\mathbf{a})]. \tag{6.2}$$

The **advantage** $A^\pi(s,\mathbf{a}) = Q^\pi(s,\mathbf{a}) - V^\pi(s)$ measures whether an action does better or worse than the policy's usual choice from that state. At the plate, an approach has positive advantage only if its expected return exceeds the policy's usual choice. A force penalty can make a plunge less attractive, but the sign still depends on the reward weights, completion probability, and baseline policy.

Readers from control have met these objects under other names. With stage cost $\ell = -r$, the value is the negated **cost-to-go**, $C(s) = -V(s)$, and equation 6.2 is the dynamic-programming recursion. (Control texts write the cost-to-go as J; this chapter reserves $J(\theta)$ for the expected return a learner maximizes.) For linear dynamics in the plant state $\mathbf{x}$ and quadratic cost, that recursion has the closed-form solution $C(\mathbf{x}) = \mathbf{x}^\top \mathbf{P}\mathbf{x}$ that the linear-quadratic regulator computes from a Riccati equation (section B.2.5). Reinforcement learning keeps the recursion and changes the estimation problem: the dynamics are unknown, so V and Q are fitted from sampled transitions instead of solved from a model.

These quantities organize policy learning along two axes, what is estimated and where the data comes from. Fitting Q over an immutable logged archive to select high-value actions is **offline reinforcement learning** (section 6.2.7). Generating fresh rollouts from π_θ, using each batch for a few updates, and shifting probability toward positive-advantage actions is on-policy **policy-gradient** optimization (section 6.3). Between the two, value-based methods also run online and off-policy. The machine keeps collecting experience, but each transition enters a replay buffer and is reused across many value updates, which is how the demonstration-seeded methods of section 6.3.1 learn in hours. The value-fitting and policy-gradient derivations behind these approaches appear in section A.6. Before paying the reward-design or physical trial cost of those methods, however, the simplest training regime bypasses value estimation altogether and fits a policy directly to the expert setpoints the collection campaign already recorded.

6.2.2 Behavioral cloning and its action targets

Instead of designing a contact reward that an optimizer can game, `latch-bc-01` learns the nominal door opening directly from recorded human demonstrations, following the supervised imitation paradigm that ALVINN first demonstrated for road following (Pomerleau 1989). **Behavioral cloning** frames policy training as supervised regression or classification over a collected dataset of expert state-action pairs $\mathcal{D}_{\text{demo}} = \{(\mathbf{o}_t, \mathbf{a}_t)\}$. On a physical machine, however, the four-stream action taps record both the operator's mapped setpoints and the setpoints the permission path actually admitted:

$$\mathcal{D}_{\text{intent}} = \{(\mathbf{o}_t, \mathbf{u}_{\text{nom},t:t+H-1})\} \quad \text{vs.} \quad \mathcal{D}_{\text{verified}} = \{(\mathbf{o}_t, \mathbf{u}^*_{t:t+H-1})\}$$

The mapped setpoint $\mathbf{u}_{\text{nom}}$ is the record at the mapped-command tap a_{cmd}, and the admitted setpoint $\mathbf{u}^*$ is the record at the enforced-command tap a_{enf}. Section 5.5.1 develops what each tap teaches a policy. In brief, cloning admitted setpoints couples the weights to one permission path's intervention profile and tuning. An uncurated policy can then learn to steer straight into the safety clamps and rely on the hardware filter to bend its commands back onto the latch. Cloning mapped setpoints instead keeps intent separate from enforcement, at the price of more frequent runtime interventions. Neither tap yields an expert target without curation. The latch campaign took the mapped command as its target wherever the permission path admitted it unchanged, so `latch-bc-01` clones $\mathbf{u}_{\text{nom}}$ on those steps and treats every modified command as an attributed intervention.

Whichever tap supplies the target, the training loss compares the proposed setpoints with the recorded ones, over a single step or over the H-step sequence that section 6.2.5 calls a chunk. Because this loss penalizes only the discrepancy between the commanded action and the recorded demonstration at observed states, the training objective does not evaluate task completion, terminal cost, or the stability of the closed-loop dynamical system. It fits actions to observations only, and that point-by-point fit breaks down at a single observation whenever demonstrators solve the same physical geometry in more than one valid way.

6.2.3 Mode averaging when demonstrations split

A mobile manipulator trained with least-squares regression on demonstrations that pass left of a central structural column half the time and right of it the other half will steer straight down the center line into the column. Each human teleoperator trajectory in the recorded archive $\mathcal{D}_{\text{demo}}$ is dynamically valid and collision-free, and not a single demonstration drives into the obstacle, yet a deterministic point-regression policy proposes the one path that every demonstrator avoided.

Under empirical mean squared error (ℓ_2) loss, a deterministic behavioral cloning network cannot represent both modes for the same observation $\mathbf{o}_t$ and instead optimizes:

$$\mathcal{L}_{\text{MSE}}(\theta) = \mathbb{E}_{(\mathbf{o}_t,\mathbf{a})\sim\mathcal{D}_{\text{demo}}}\left[\|\pi_\theta(\mathbf{o}_t) - \mathbf{a}\|_2^2\right].$$

The theoretical minimizer of this objective is the conditional expectation of the action distribution (derived formally in section A.5.1):

$$\pi^*(\mathbf{o}_t) = \arg\min_{\hat{\mathbf{a}}} \int \|\hat{\mathbf{a}} - \mathbf{a}\|_2^2 \, p_{\text{demo}}(\mathbf{a} \mid \mathbf{o}_t)\, d\mathbf{a} = \mathbb{E}[\mathbf{a} \mid \mathbf{o}_t] = \int \mathbf{a}\, p_{\text{demo}}(\mathbf{a} \mid \mathbf{o}_t)\, d\mathbf{a}. \tag{6.3}$$

In conventional computer vision, predicting the conditional mean of ambiguous pixel targets generates blurry, averaged textures; in natural language processing, it produces diffused semantic embeddings. In Physical AI, however, the conditional expectation of two collision-free evasion commands (such as $\mathbf{a}_{\text{left}} = [v, +\omega_z]^\top$ and $\mathbf{a}_{\text{right}} = [v, -\omega_z]^\top$, where v is forward linear speed and ω_z is angular yaw rate) evaluates to:

$$\mathbb{E}[\mathbf{a} \mid \mathbf{o}_t] = \frac{1}{2}\mathbf{a}_{\text{left}} + \frac{1}{2}\mathbf{a}_{\text{right}} = [v, 0.0]^\top.$$

The regression mean proposes forward motion with zero lateral evasion. If admitted unchanged, that proposal heads straight into the central obstacle.[3]

This invalid proposal is not caused by an optimization pathology, insufficient model capacity, or dataset scarcity. It is the exact minimizer of a point-regression loss over a multimodal distribution. Viewed as a function of the proposed action, the expected loss is a bowl with a single bottom at the mean, and that bottom sits in the zero-density gap between the two demonstrated modes ($p_{\text{demo}}(\mathbb{E}[\mathbf{a} \mid \mathbf{o}_t] \mid \mathbf{o}_t) \approx 0$). The statement concerns the optimal output, not whether optimizing the network's weights is convex.

> **Definition 6.1: Mode averaging**
>
> ***Mode averaging*** is the failure in which a policy trained with a point-regression loss on demonstrations that contain several valid actions for one observation proposes their conditional mean, an action that lies between the demonstrated modes and that no demonstrator chose.
>
> 1. **Significance**: More data, capacity, or training moves the output toward the mean, not away from it. Two equally weighted evasions at $\pm\omega_z$ average to zero yaw, a proposal aimed at the obstacle both demonstrations avoided, and it reaches the permission path as a smooth, confident command whose consequence cannot be undone once admitted.
> 2. **Distinction**: Mode averaging concerns the action chosen at one observation; compounding error concerns the states that successive actions reach. A multimodal decoder removes the first and does nothing for the second, which needs recovery experience.
> 3. **Common pitfall**: Reading a low validation loss as evidence against averaging. The mean minimizes squared error on held-out demonstrations drawn from the same modes, so a regression head can score best on its split and still propose the invalid middle action at every bifurcation.

Changing the regression penalty does not by itself represent alternative actions. Mean absolute error (ℓ_1) admits conditional medians, while Huber loss limits the influence of large residuals, so neither guarantees a unique, coherent route through a multimodal demonstration distribution.

[3] **Jensen's Inequality**: The averaged action fails even where it happens to be admissible, because a nonlinear plant does not map the mean action to the mean outcome. In general $\mathbb{E}[g(\mathbf{a})] \neq g(\mathbb{E}[\mathbf{a}])$, and for a convex g Jensen's inequality fixes the sign of the gap. Contact and friction are the most nonlinear parts of a manipulator's plant, so a regression mean that looks like a compromise between two good demonstrations can produce a contact state that neither demonstration visited.

Instead, the decoder must represent the alternatives, and execution must maintain a consistent choice across successive observations.

Several decoder families represent these alternatives at different computational costs. **Mixture Density Networks (MDNs)**[4] parameterize a Gaussian Mixture Model (GMM): $p_{\text{demo}}(\mathbf{a} \mid \mathbf{o}_t) = \sum_{m=1}^{M} \pi_m(\mathbf{o}_t)\mathcal{N}\left(\mathbf{a} \mid \mu_m(\mathbf{o}_t), \Sigma_m(\mathbf{o}_t)\right)$. Here π_m is the weight of component m (not the policy), and μ_m and Σ_m are its mean (not a friction coefficient) and covariance. They produce mixture parameters in one forward pass, but training must prevent covariance collapse ($\Sigma_m \to \mathbf{0}$) and loss of less frequent modes, which makes the component count and covariance representation consequential for high-dimensional chunks ($d_{\text{chunk}} = d_a \times H$). Energy-based models instead score each candidate with a learned energy and must search for a low-energy action, so their iteration budget, rather than a head of fixed size, must fit the proposal deadline.

Generative architectures, including diffusion models (Ho et al. 2020) and flow matching (Lipman et al. 2022), offer another way to represent $p_{\text{demo}}(\mathbf{a} \mid \mathbf{o}_t)$ by training a model to refine a noisy action candidate toward the learned distribution rather than returning its conditional mean. Sampling can then select a coherent demonstration mode ($\mathbf{a}_{\text{left}}$ or $\mathbf{a}_{\text{right}}$). Although representing multiple modes resolves the averaging problem, a generated candidate can still violate clearance or actuator constraints, so the permission path must check it before execution.

A mode boundary in a single-step Markov policy can also produce high-frequency temporal chattering. In a 50–100 Hz feedback loop, microscopic sensor noise drives consecutive observations back and forth across the mode boundary, causing a single-step controller mapping $\mathbf{o}_t \to \mathbf{a}_t$ to alternate between opposing actuator efforts (for example, +10 N·m and −10 N·m). This alternation excites drivetrain resonances, accelerates gear tooth fatigue, and drives motor winding temperatures toward their thermal limit. Even when a multimodal decoder commits to one route and avoids chattering across the boundary, however, a second imitation failure emerges as soon as a small tracking error pushes the robot outside the states the demonstrators visited.

[4] **Mixture Density Network**: Bishop (1994) proposed it for inverse problems, whose inputs admit several valid outputs, and demonstrated it on the inverse kinematics of a robot arm, where one hand position has two joint solutions and least-squares regression returns their invalid average. The mobile manipulator's two routes around the column are the same problem, met three decades later in action space, which is why the remedy is still a change of output distribution rather than a larger network.

6.2.4 Compounding errors and recovery experience

A policy can choose a coherent route around the column and still drift into states its demonstrations never covered. Mode averaging concerns the action selected at one observation; compounding error concerns the observations created by successive actions. Keeping these failures separate prevents a richer action decoder from being mistaken for recovery experience. Cloning fits actions only at the states the demonstrators visited, whereas deployment visits the states the policy's own actions create, and a fixed archive holds no example of the states the policy's execution errors reach. In continuous physical state spaces, this decoupling produces **compounding covariate shift**, which is the second law (endogenous data, principle 2) acting on a fixed archive.

Section 5.3 bounds the price of this shift: fixed-archive cloning admits a worst-case imitation cost that grows as $S^2\epsilon$ over an S-step horizon (equation 5.1). That bound counts accumulated task cost, not displacement, and the physical drift behind it depends on what the action commands and on the feedback below the policy. A persistent error in a commanded velocity integrates once into position, so the drift grows linearly in time; a persistent error in a commanded torque integrates twice, so it grows quadratically. A velocity-level policy also sits above a joint velocity loop that rejects load disturbances between its decisions, whereas a torque-level policy has no such loop beneath it and must supply every correction itself. Offline validation on demonstration splits measures prediction accuracy on the demonstrated distribution; recovery after displacement requires additional closed-loop evidence.

The regime that supplies that recovery experience is interactive imitation learning, of which Dataset Aggregation (DAgger) (Ross et al. 2011) is the classic form. In DAgger, an expert labels the states the learner itself visits and the policy retrains on the aggregate. Section 5.8 develops DAgger, with its guarantee of a cost that grows linearly in the horizon (equation 5.8) and the recoverability constant u on which that guarantee depends. The constant bounds how much a single deviation can raise the expert's remaining cost, so it is an assumption about the plant, not a property of the learner. On physical hardware, this theoretical recoverability depends directly on joint torque authority and contact friction limits.

On hardware, collecting those labels requires a recoverable rollout and an expert who has enough information to choose a correction. Because a camera log may support a path label while leaving

contact force or joint torque ambiguous, live supervision supplies richer feedback, yet the machine continues moving during human reaction and control handoff. Consequently, intervention must begin within the available stopping margin, and the handoff must avoid discontinuous setpoints.

Expert availability also does not imply physical recoverability. The machine may lack enough actuator effort or frictional grip to return from a deviation. The simplified force balance $\mathbf{M}\ddot{\mathbf{q}} = \tau + \tau_{\text{ext}}$ is Newton's second law written per joint. Here $\mathbf{q}$ denotes joint positions, $\mathbf{M}$ inertia, τ actuator torque, and τ_{ext} the torque that contact forces exert about the joints. Other forces are omitted for clarity, and section 11.4.1 develops the full equation. Actuator limits require $|\tau_i| \le \tau_{\max}$ on every joint axis, while available friction bounds tangential force by $\|\mathbf{f}_{k,\parallel}\| \le \mu f_{k,\perp}$, with normal force $f_{k,\perp}$ and friction coefficient μ. These constraints can leave no action that restores the task, and then u is unbounded and DAgger's linear guarantee no longer applies. Interactive aggregation is therefore most useful where learner deviations can be contained, labeled, and repeated within the operator-time and hardware-exposure budget. The state space divides into three regions (figure 6.1). Cloning trains in the tube of demonstrated states. Just outside it lies a band where an expert label on a learner-visited state still restores the task. Beyond the band is an unrecoverable region, where actuator and friction limits leave no restoring action and every further label is vacuous. Interactive aggregation buys experience only in the middle band.

↪ The bumpless transfer that keeps a human takeover from stepping the command is developed in section 14.4.

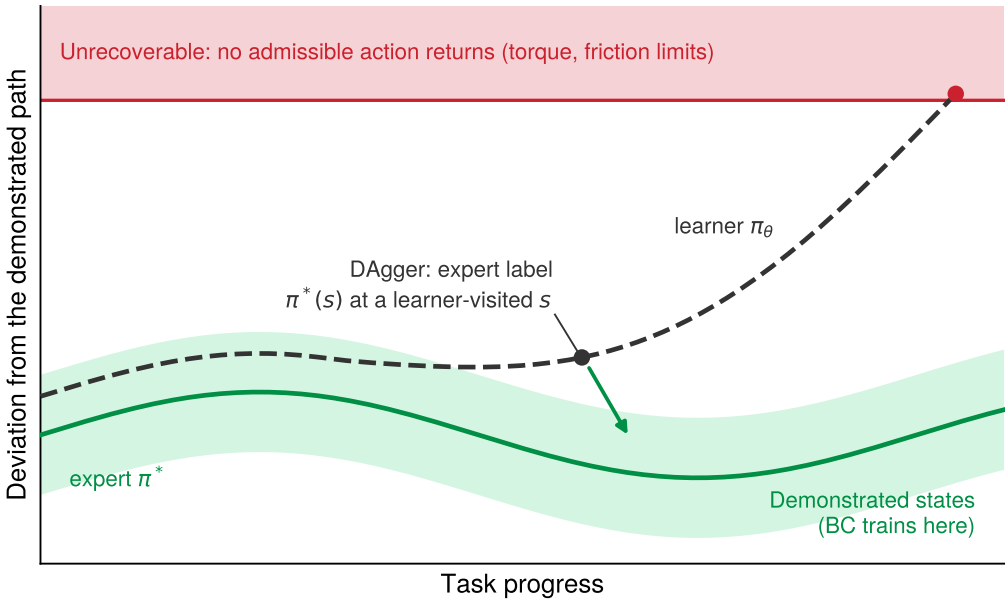


Figure 6.1: Drift out of the demonstrated states: Behavioral cloning trains only inside the shaded tube the expert visited. Once the learner leaves it, each action is taken from an unfamiliar state and the error compounds. DAgger labels a learner-visited state outside the tube, which supplies recovery experience while a return is still possible. Past the red boundary, actuator and friction limits leave no action that restores the task, so no label can help. The sketch is schematic; its axes carry no units.

For the latch, these distinctions select a concrete next training step. The stipulated follow-up campaign in section 5.8 supplies `latch-recovery-02`, a versioned archive of expert recovery from the positively displaced plate at the guarded approach. The recovery candidate `latch-bc-recovery-02` trains on the original nominal demonstrations and the stabilized, reviewed segment of each correction; the enforcer's blend and the operator's re-orientation after takeover stay masked. Learner commands that preceded takeover remain failure evidence unless an expert supplied replacement labels; they do not become imitation targets merely because the episode eventually succeeded. A multimodal chunk decoder can preserve a coherent back-off and re-seating sequence, while the additional demonstrations supply the recovery states that changing the decoder alone could not provide.

↪ Causal intervention masking, which admits only reviewed recovery segments as imitation targets, is enforced in section 14.8.3.

The training decision is complete, but the improvement claim remains to be tested. Entire collection sessions are held out for nominal and recovery checks, so neighboring frames from one run do not appear on both sides of the split. Training diagnostics check whether the candidate represents the demonstrated correction; qualification must then test whether it completes the door task under the declared perturbation without regressing nominal behavior. The candidate carries that request to section 7.8.1, including task completion, cycle time, proposer intervention, and protective outcomes as separate measures. This is a stipulated engineering branch, not a report of collected data or measured improvement. The negative displacement and faster approach remain unsupported. Even on the supported path, emitting setpoints one tick at a time leaves the arm vulnerable to the mode-boundary chattering of section 6.2.3 unless the decoder predicts a multi-step action sequence in one pass.

6.2.5 Action chunking and multi-step trajectory prediction

Action chunking (definition 3.2) suppresses both high-frequency actuator chattering and single-step mode oscillation by predicting an entire sequence of future actions simultaneously rather than re-querying the decoder at every 25 ms control tick. Instead of regressing a single action $\mathbf{a}_t$ from current observation $\mathbf{o}_t$, a chunking policy predicts a setpoint sequence $\mathbf{A}_t \in \mathbb{R}^{H \times d_a}$ across a prediction horizon of H future timesteps and d_a action dimensions. The execution path then interpolates this sequence into continuous motion and checks it for feasibility. In supervised behavioral cloning, the policy minimizes a multi-step trajectory loss over demonstrated trajectories:

$$\mathcal{L}_{\text{chunk}}(\theta) = \mathbb{E}_{(\mathbf{o}_t, \mathbf{A}_t^*) \sim \mathcal{D}_{\text{demo}}} \left[\sum_{i=0}^{H-1} \ell_\delta \left(\pi_\theta(\mathbf{o}_t)_i - \mathbf{a}_{t+i}^* \right) \right],$$

where $\mathbf{A}_t^* = [\mathbf{a}_t^*, \ldots, \mathbf{a}_{t+H-1}^*]^\top$ represents the recorded demonstration chunk and $\pi_\theta(\mathbf{o}_t)_i$ is the i-th predicted future setpoint. Actions are expressed in declared normalized coordinates. For a vector residual $\mathbf{r}$, the chunk objective uses the componentwise sum $\ell_\delta(\mathbf{r}) = \sum_{j=1}^{d_a} \ell_\delta(e_j)$, where e_j is the matching component of $\mathbf{r}$, with equal component weights. The scalar Huber penalty below acts on each normalized prediction error e_j, not on the reward of section 6.2.1:

$$\ell_\delta(e) = \begin{cases} \frac{1}{2} e^2 & \text{for } |e| \le \delta, \\ \delta \left(|e| - \frac{1}{2} \delta \right) & \text{otherwise.} \end{cases}$$

(ACT (Zhao et al. 2023), the architecture of both latch policies, uses an ℓ_1 reconstruction penalty in place of ℓ_δ and adds a conditional variational autoencoder (CVAE) term $\beta \mathcal{D}_{\text{KL}}(q(\mathbf{z} \mid \mathbf{A}_t^*, \mathbf{o}_t) \,\|\, \mathcal{N}(\mathbf{z}))$ against a standard normal prior, which lets a latent variable absorb differences in style across demonstrations.)

Because teleoperated setpoints can contain outliers caused by tremor, tracking errors, or dropouts, squared loss gives a single large residual disproportionate influence over the fit. Huber loss[5] is quadratic for small residuals ($|e| \le \delta$) and linear beyond them, so its gradient saturates at magnitude δ and no single outlier can dominate the fit. Even so, the threshold acts on prediction residuals rather than on the velocity, acceleration, or jerk of the resulting trajectory. Huber loss alone therefore establishes neither smooth motion nor actuator feasibility. Those properties require explicit constraints and checks on the proposed chunk.

Predicting H future actions at once creates opportunities for more coherent execution, provided training and runtime checks preserve them:

1. **Temporal and Dynamic Consistency**: Jointly predicting adjacent actions lets the model learn their relationships. The resulting sequence still requires checks for abrupt changes and actuator limits.
2. **Preserving Modal Commitment**: A chunk can represent one coherent choice, such as passing left of the column, across adjacent actions. Predicting a sequence does not itself ensure that the decoder selects a single valid mode.
3. **Receding-Horizon Replanning and Temporal Ensembling**: The deployed policy queries a fresh chunk every H_{exec} steps ($H_{\text{exec}} < H$), permitting feedback correction before the prediction

[5] **Huber Loss**: Huber (1964) introduced it as an estimator of location that tolerates a small fraction of grossly wrong observations, quadratic near the center and linear in the tails, and showed that it minimizes the worst-case variance over such contaminated distributions. Teleoperation tremor and dropouts are exactly that contamination, and δ sets, in the declared normalized action coordinates, where an error stops counting as noise and starts counting as a gross error.

horizon ends. Blending overlapping predictions is optional and must preserve a coherent mode and feasible seam.

The modal commitment that the chunk objective buys in training can be undone at execution. If stochastic sampling selects the left route at one query and the right route at the next, blending the overlapping chunks across the seam averages the two routes and resurrects the mode averaging that action chunking was chosen to eliminate (Black, Galliker, et al. 2025).

↩ Temporal ensembling of overlapping chunks, and real-time chunking, which freezes the committed prefix and generates the rest of the next chunk to agree with it, are established in section 3.5.1.

Chunking changes how often the policy replans, but does not supply recovery states absent from the demonstrations. Executing H_{exec} actions between queries reduces the number of query boundaries to $S_{\text{eff}} = S/H_{\text{exec}}$ while leaving disturbances within each execution window to the lower-level feedback system. This count alone does not convert the imitation-learning cost bound $\mathcal{O}(S^2\epsilon)$ into a task-survival curve, the probability that an episode reaches the goal without entering an unrecoverable state, plotted against the horizon. ACT (Zhao et al. 2023) and receding-horizon diffusion (Chi et al. 2025) change temporal execution; DAgger (Ross et al. 2011) changes the training distribution by obtaining labels on learner-visited states. These are separate ways to improve behavior, and their closed-loop benefits must be measured on the task. Neither the drift sketch of figure 6.1 nor the imitation-learning cost bound establishes a task-survival probability or ranks learning algorithms.

Increasing dataset size, model capacity, or tuning can reduce the one-step error rate on evaluated observations and therefore lower the chance of a first policy error during a fixed horizon. That improvement does not characterize what happens after an error. An external disturbance, uncalibrated payload, or voltage sag can also move the machine into weakly supported states without a policy disagreement. Recovery data, measured dynamics, and independent runtime limits determine whether either event remains within the physical envelope.

Drift off the demonstrated states raises no alarm of its own, so detecting it before physical contact cannot rely on the offline training loss. A feature-distance or uncertainty monitor can flag unfamiliar observations, but its threshold needs validation against missed detections and false alarms. For the latch, an independently measured plate position and approach condition provide a more direct check of the declared cells. A purely geometric monitor is weaker. One that accepts any state inside the convex hull of the demonstrated coordinates, a convex stand-in for the support hull of section 5.7, still admits intermediate states that no demonstration visited. Nothing guarantees that those states are physically admissible or dynamically stable. Predicting an entire H-step chunk in a multimodal decoder solves the single-step averaging problem, but only if the hardware can finish evaluating that decoder before the next chunk is due.

6.2.6 Decoder latency and proposal deadlines

Selecting a coherent route around an obstacle or into a latch does no good if the decoder finishes computing the trajectory after the actuator deadline has already passed. A decoder converts the model's representation into an action or action sequence; iterative decoders repeatedly refine a candidate before returning it. Their equations describe how a candidate is generated, while the execution decision depends on the wall-clock time those dependent model evaluations consume. The central comparison is between measured proposal latency and the deadline of the buffer that feeds the permission path.

The decoders that fix mode averaging buy that fix with time. A generative head escapes the regression mean by sampling one demonstrated route, but it reaches its sample through a chain of dependent refinements, and each refinement is another model evaluation that must finish before the next proposal is due (figure 6.2). The proposal then still has to cross from the application processor to the safety microcontroller's own buffer before the permission path can check it, so the decoder's time comes out of a budget it shares with transport and admission.

↪ The placement of the multi-rate proposal and permission paths on the application processor and the safety microcontroller is developed in section 13.2.

The decoder families themselves, from binned and compressed action tokens to parallel heads and iterative action experts, are introduced in section 3.3. What matters for training is their dependency structure. A diffusion policy (Chi et al. 2025) or a flow-matching expert (Lipman et al. 2022; Black et al. 2024) refines a candidate chunk through evaluations that each consume the previous candidate. An autoregressive vision-language-action policy (Kim et al. 2024) generates its action tokens one after another. In each case the dependent evaluations run in sequence. None of these constructions guarantees collision-free or actuator-feasible output, and the diffusion and flow-matching objectives

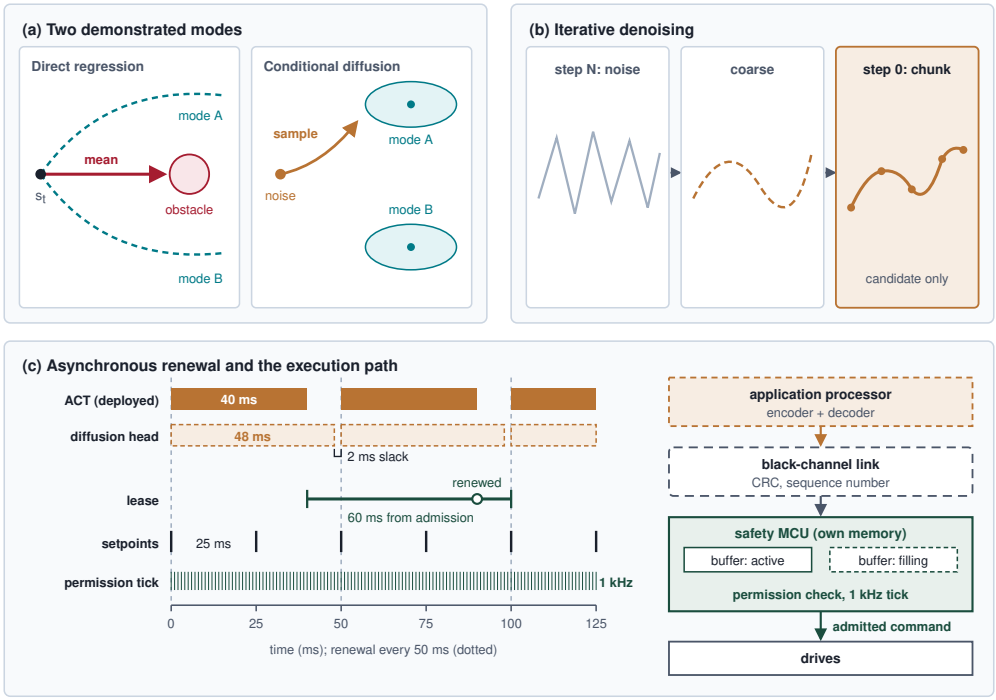

Figure 6.2: Generative policy architectures and action chunk denoising: (a) Sampling represents alternative demonstrated routes instead of their direct-regression mean. (b) Iterative refinement produces a candidate action chunk whose clearance and actuator feasibility still require checking. (c) On the machine's schedule, proposals renew every 50 ms while setpoints play every 25 ms, and the bars compare the deployed ACT decoder with an illustrative diffusion head that leaves far less of each renewal period to spare. An admitted chunk crosses the black-channel link into the safety MCU's own double buffer and is checked on every permission tick before the drives act. Buffering alone guarantees neither freshness nor freedom from starvation.

are developed in section A.5.2. Some post-training recipes remove the token sequence from the run-time path altogether by training a separate action expert (section 6.2.8). For the latch decision, the relevant consequence is how many dependent evaluations yield adequate action quality. The quantity that decides the execution arrangement is complete proposal latency, perception included, measured against the actual proposal deadline.

The number and dependency of decoder evaluations constrain proposal latency; the implementation and loaded hardware determine its measured value. The total wall-clock duration of a single policy inference cycle t_{infer} is the sum of perceptual feature extraction and iterative generative trajectory sampling:

$$t_{\text{infer}} = t_{\text{enc}}(\mathbf{o}_t) + \sum_{k=1}^{N_{\text{eval}}} t_{\text{pass}}\left(\mathbf{A}^k, k\right) \leq T_{\text{deadline}}, \tag{6.4}$$

Here t_{enc} is the visual backbone and proprioceptive encoding latency, and N_{eval} is the number of dependent decoder evaluations (denoising or ODE solver steps). The term t_{pass} is the latency of one forward pass of the action head (one denoising or solver step, not the whole-model evaluation time t_{infer} of equation 3.4). The chunk $\mathbf{A}^k$ is the candidate that the k-th evaluation refines, and T_{deadline} is the real-time execution deadline.

The encoder runs once per proposal, whereas each dependent decoder evaluation adds work. Section 3.5.1 prices that work for each decoder family on the machine's processor, where re-reading a large action head on every evaluation can dominate it. Training decides the two quantities those prices depend on, the head and its evaluation count N_{eval}, so the question here is whether a head chosen for its multimodal fit also meets the latch's deadlines.

The latch policies avoid repeated evaluations: `latch-bc-01` decodes each chunk with the machine's 80M-parameter ACT network in one pass, within the 40 ms p99 inference target. Consider

instead replacing its decoder with an illustrative diffusion head, the kind that multimodal latch demonstrations might motivate. The head is sampled in $N_{\text{eval}} = 16$ steps by the denoising diffusion implicit model (DDIM) sampler, a deterministic sampler whose step count sets the number of dependent evaluations. Stipulate a visual encoding latency of $t_{\text{enc}} = 8$ ms and a total inference duration $t_{\text{infer}} \approx 48$ ms once all evaluation work is included. These stipulated inputs define the comparison below. A measurement of the real head replaces them, and that measurement can only sit at or above the weight-streaming floor of section 3.4.1.

Two deadlines apply, the setpoint step for a decoder that must supply every tick itself and the renewal period for one that runs beside an admitted prefix. The lease rule of section 4.9.1 adds an allowance for renewal jitter. That allowance belongs to the rule's compute side, the renewal period plus jitter that the lease must exceed. Transport across the black-channel link, the permission tick, and the age of the evidence at admission are charged on its other side, against the stopping budget. The slack computed below is therefore the decoder's alone. A slower decoder pays on that side too, because its inference time ages the evidence it is admitted on.

Only the 4-step flow decoder beats the setpoint; DDIM leaves 2 ms of its renewal.

Napkin Math 6.1: The renewal slack

Problem: Can the stipulated diffusion head replace the one-pass ACT decoder of `latch-bc-01`, either synchronously or asynchronously, and how much of a stretched renewal can each decoder absorb?

Variables:

- Setpoint step $\Delta t_{\text{step}} = 25$ ms (chosen) and renewal period $T_{\text{chunk}} = 50$ ms (derived, two steps)
- ACT inference 40 ms at p99, including vision (illustrative target)
- Diffusion head: $N_{\text{eval}} = 16$, $t_{\text{enc}} = 8$ ms, $t_{\text{infer}} = 48$ ms (illustrative, stipulated)
- Flow-matching candidate: $N_{\text{eval}} = 4$ at the same per-evaluation cost (illustrative)
- Renewal-jitter allowance 5 ms (chosen, lease rule)

Math:

1. **Per-evaluation cost** (equation 6.4): $t_{\text{pass}} = (48\text{ ms} - 8\text{ ms})/16 = 2.5$ ms.
2. **Synchronous step**: The diffusion head's 48 ms exceeds the 25 ms step. The flow candidate needs $8\text{ ms} + 4 \times 2.5\text{ ms} = 18$ ms and fits it.
3. **Renewal slack**: ACT leaves $50\text{ ms} - 40\text{ ms} = 10$ ms; the diffusion head leaves $50\text{ ms} - 48\text{ ms} = 2$ ms.
4. **Stretched renewal**: $48\text{ ms} + 5\text{ ms} - 50\text{ ms} = 3$ ms past the renewal for the diffusion head, while ACT ends at $40\text{ ms} + 5$ ms, inside the period.

Result: The diffusion head can run only asynchronously, and a single jitter-sized stretch carries it past its renewal.

Systems insight: Renewal slack, rather than mean inference latency, dictates real-time schedulability. When a decoder's slack drops below the jitter allowance, a single tail-latency stretch carries it past its renewal, and the active prefix keeps playing on evidence that grows older with every tick. The lease contract, not the neural decoder, then sets the hard safety bound on how long an admitted prefix may continue actuating the arm against aging sensor evidence.

The notebook separates sampler choice from execution authority. The flow candidate becomes a viable synchronous choice only if action quality, scheduling, transfer, and admission also fit, and a faster decoder does not remove the permission check. Its evaluation count is the quantity to compare, not its step count. A higher-order solver can use fewer integration steps while performing more network evaluations; a standard fourth-order Runge-Kutta (RK4) solver evaluates four stages per step, so compare that total work with the single-stage alternative before choosing it. Step distillation, which trains a sampler to reach the same chunk in fewer evaluations, or a different solver is useful when it reduces measured latency without losing the recovery behavior the latch needs.

The slower candidate can still generate chunks asynchronously against the 50 ms renewal cadence while the execution path plays an admitted prefix, provided loaded timing evidence confirms the schedule. Because generating an action chunk supplies candidate trajectory setpoints without conferring authorization to execute that entire window unchecked, the lease selected in section 4.4 bounds active permission separately from renewal cadence and evidence age. Execution renews only when fresh sensor evidence arrives paired with a valid replacement proposal. Stamping a new timestamp header over stale sensor buffers therefore cannot extend execution authority. An invalid new proposal leaves an active prefix in place only while that prefix's own state, evidence, and lease remain valid. Once the lease expires, the execution path invokes a state-dependent, physically qualified fallback rather than an unspecified emergency stop.

↪ The ladder of resident protective responses from which that fallback is selected is developed in section 12.9.

On the renewal schedule the two decoders differ in slack, not in mean latency (figure 6.3). When a stretched diffusion run misses its renewal boundary, nothing in the decoder notices; the chunk lease is the only mechanism that bounds how long the previous prefix keeps playing.

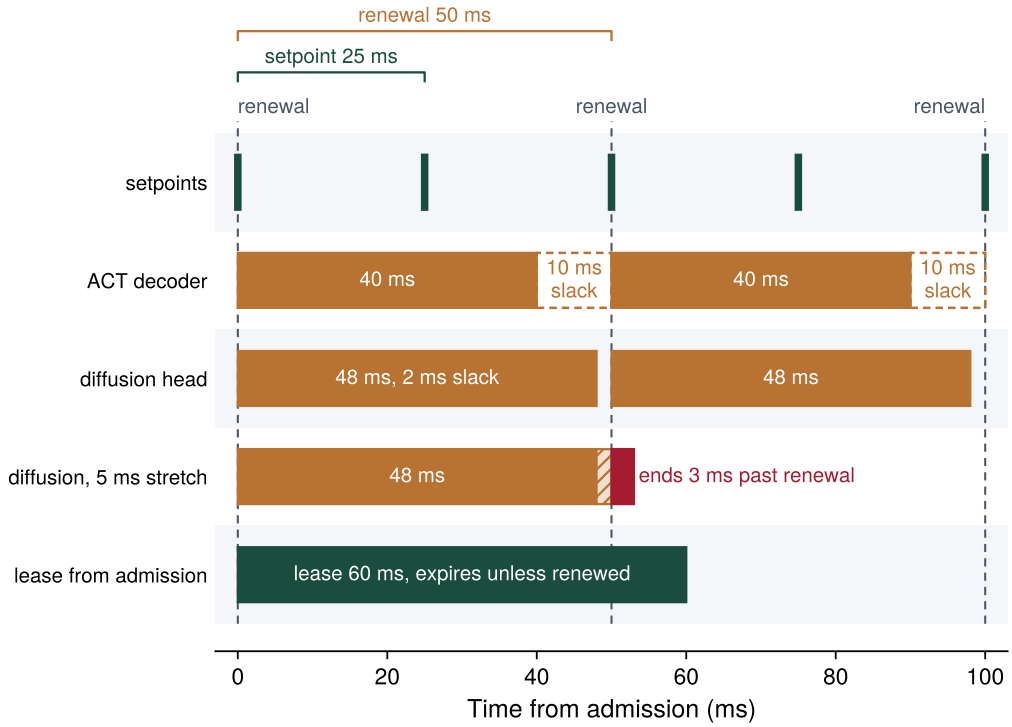

Figure 6.3: Decoder latency on the renewal schedule: Setpoints play every 25 ms and proposals renew every 50 ms. The deployed ACT decoder finishes with 10 ms to spare; the illustrative diffusion head leaves 2 ms, and a 5 ms stretch pushes it 3 ms past the renewal. The lease bounds how long the active prefix may play if a renewal is missed.

Checkpoint 6.1: Mode choice, drift, and decoder deadlines

Cloning fails in two separate ways, and the decoder chosen to repair one of them must still meet the machine's schedule.

Diagnosing the failure

- ☐ **Mode averaging vs. compounding error**: A cloned navigation policy sometimes steers straight at the column. A cloned latch policy, on other runs, drifts until the gripper binds on a sagged door. Can you say which symptom a multimodal decoder addresses, which one needs recovery demonstrations, and why neither remedy supplies the other?

DRAFT

☐ **Recoverability**: Can you explain why DAgger's linear guarantee fails at a state where actuator torque limits and the friction cone leave no restoring action, however many expert labels are collected?

Checking the deadline

☐ **Evaluation budget**: With the stipulated 8 ms encoder and 2.5 ms per evaluation, what is the largest evaluation count that fits the 25 ms setpoint step, and the largest that fits the 50 ms renewal while leaving the 5 ms jitter allowance free?

☐ **Renewal vs. lease**: Can you explain why a new proposal header cannot renew stale observations, and what the execution path must do when the lease expires with no valid replacement?

6.2.7 Offline reinforcement learning and out-of-distribution actions

The decoder budget settles how fast a policy trained on recorded data can propose actions. The next question is what happens when the recorded archive mixes clean door openings with hesitant teleoperation, scripted routines, and aborted trials. Behavioral cloning copies every trajectory in such a log with equal supervised weight, good and bad alike. Running standard Q-learning (Watkins and Dayan 1992) on the same static archive to cherry-pick the high-reward segments triggers a worse failure. The value network invents high returns for actions never tried in the log, and the deployed policy greedily selects ungrounded maneuvers that stall a joint or strike a fixture boundary. **Offline reinforcement learning (Batch RL)** applies the return and value quantities of section 6.2.1 to a fixed transition log $\mathcal{D}_{\text{demo}} = \{(s_t, \mathbf{a}_t, r_t, s_{t+1})\}$ without active hardware exploration. It uses rewards to stitch together high-performing composite trajectories from disjoint, imperfect demonstrations while suppressing **out-of-distribution (OOD) action overestimation** (Kumar et al. 2020).

In standard Q-learning, the algorithm estimates the value of future states by asking its value network to predict the highest possible return it could achieve from the next step, which is equation 6.2 with a maximum over next actions in place of the policy's expectation. That maximum is taken over the entire continuous action space. For actions that were never executed in the logging dataset, the network has received no direct value-fitting target and often outputs erroneously large value estimates due to generalization variance, predicting a high return for an untried physical maneuver. The algorithm greedily selects these spurious peaks, propagating over-optimistic value errors backwards until the deployed policy commands unverified motions. Because the distinction from cloning is the selection rule $\pi(s) = \arg\max_{\mathbf{a}} Q(s, \mathbf{a})$, offline learning needs a way to limit that optimism without obtaining new transitions from the machine.

To reduce value overestimation without querying the physical environment, **Conservative Q-learning (CQL)** adds a conservative penalty to value fitting (Kumar et al. 2020). The objective below has two parts. The bracketed term discourages optimism about unsupported actions, and the squared term fits the reward observed in logged transitions together with estimated future reward. Here $\mathcal{A}$ is the action space, Q the value function being fitted, $\hat{Q}$ a fixed target estimate during this update, and α_{CQL} the penalty weight:

$$\min_{Q} \alpha_{\text{CQL}} \cdot \mathbb{E}_{s \sim \mathcal{D}_{\text{demo}}} \left[\ln \int_{\mathcal{A}} \exp(Q(s, \mathbf{a}))\, d\mathbf{a} - \mathbb{E}_{\mathbf{a} \sim \mathcal{D}_{\text{demo}}} [Q(s, \mathbf{a})] \right] + \frac{1}{2} \mathbb{E}_{(s, \mathbf{a}, r, s') \sim \mathcal{D}_{\text{demo}}} \left[\left(Q(s, \mathbf{a}) - \mathcal{B}^* \hat{Q}(s, \mathbf{a}) \right)^2 \right],$$

where $\mathcal{B}^* \hat{Q}(s, \mathbf{a}) = r(s, \mathbf{a}) + \gamma \max_{\mathbf{a}'} \hat{Q}(s', \mathbf{a}')$ is the empirical Bellman target operator and $\alpha_{\text{CQL}} > 0$ balances value conservatism against Bellman error minimization.[6]

This conservative penalty reshapes value estimates across the continuous action space rather than establishing an absolute physical execution boundary:

1. The logarithmic integral term $\ln \int_{\mathcal{A}} \exp(Q(s, \mathbf{a}))\, d\mathbf{a}$ acts as a soft-maximum that actively pushes *down* on Q-values across the entire action space, aggressively depressing values in unvisited action regions where function approximation variance would otherwise create spurious positive spikes.

[6] **Scope of the CQL Bound**: Under its data-coverage, optimization, and function-approximation assumptions, CQL constructs a conservative estimate whose *expected value for a policy* lower-bounds that policy's true value (Kumar et al. 2020). This is not a pointwise bound for every state-action pair or every dataset, and expected return does not certify physical safety.

2. The dataset expectation $\mathbb{E}_{\mathbf{a}\sim\mathcal{D}_{\text{demo}}}[Q(s,\mathbf{a})]$ pushes *up* on Q-values exclusively for state-action pairs executed during the logging campaign.
3. When $\alpha_{\text{CQL}} = 0$, the conservative penalty disappears and policy extraction uses $\arg\max_{\mathbf{a}} Q(s,\mathbf{a})$ without that correction. With $\alpha_{\text{CQL}} > 0$, unsupported actions face a value penalty, but they are not categorically excluded. Physical action limits and checks of operating conditions remain obligations of the independent permission path.

Implicit Q-learning avoids the overestimation at its source by never evaluating an action outside the dataset; it estimates the value of the best logged actions with an expectile regression (Kostrikov et al. 2021). In robotics, offline learning now serves mostly as a starting point. A policy pretrained on the log is fine-tuned online, and calibrating its value estimates during pretraining keeps the first online updates from unlearning it (Nakamoto et al. 2023). Without this calibration, a conservative critic depresses the estimated values of logged expert actions below the true return scale of the physical environment, so when online rollouts begin, even mediocre exploratory actions receive real environment returns that exceed those depressed offline estimates and cause early policy updates to shift away from the demonstrated behavior until the critic catches up.

Applied to the latch, the retained archive holds successes and labeled tripwire failures, both rewardable, so a conservative objective could reweight nominal behavior toward the cleaner openings. It cannot supply displaced-plate competence. Those cells are known absences among the successes and the failures alike, and no offline objective extracts behavior from states the log never visited. When the task archive itself is sparse, teams often try to borrow that missing competence from a foundation model pretrained across other robots.

6.2.8 Pretrained generalist policies and post-training

A model pretrained on hundreds of thousands of episodes from other robots can move smoothly toward a displaced strike plate even when the target campaign never demonstrated that offset, making it easy to mistake broad visual and motor familiarity for verified support on this arm, door, and contact surface. Whereas `latch-bc-01` starts from randomly initialized weights and learns only from the latch campaign, such a **generalist policy** starts from pooled multi-robot data and is then **post-trained** on demonstrations of the target task. The reference manipulator already carries such a checkpoint as its intent model.

That checkpoint is OpenVLA-7B, a 7B-parameter vision-language-action model trained on 970K robot episodes from the Open X-Embodiment collection (Kim et al. 2024; Open X-Embodiment Collaboration et al. 2024). Chunk-level generalists are built the same way (table 6.3). Post-training may update every weight, a low-rank adapter, or only a new action head, and the base may first be retrained on the target machine's action space.

↩ The intent model, the slower of the machine's two learned proposers, is established in section 3.1.

Pretraining transfers broad visual and motor competence across varied domains. A base network trained on thousands of grasps, door mechanisms, and cluttered tabletop scenes often requires substantially fewer task demonstrations and demonstrates greater resilience to varying illumination, visual distractors, and object geometries than a policy trained from scratch. Pretraining supplies no operational evidence for this plant, however, and the scenario-table join of section 5.7.1 shows exactly where the gap lies. The scenario table for this door on this machine has 6 cells. The pretraining episodes were collected on other arms, fixtures, and grippers under embodiment contracts the table does not describe, so none of them joins to any latch cell. The post-trained candidate therefore inherits only the campaign's own support, 1 cell out of 6 with 5 known absences. It may execute the nominal cell more reliably and may even propose plausible maneuvers at the displaced plate, but those proposals are borrowed competence, not evidence. Its declared ODD, the region the policy manifest of section 6.8 computes from the join and the simulator omissions, gains no cell from pretraining.

Three dependencies follow, each requiring explicit tracking in the policy manifest. First, the base checkpoint is an external dependency whose underlying pretraining data rarely permits cryptographic digest verification, as its data mixture, filtering heuristics, and training run were permanently fixed by the upstream provider. The manifest therefore records the base checkpoint by the cryptographic digest of its weights and flags its pretraining provenance as a known unknown within the `base_checkpoint` field of table 6.4. Second, the base model's native action space rarely aligns with the target machine. A generalist checkpoint emitting normalized end-effector velocity

deltas on an asynchronous clock must be re-headed or mapped into discrete joint setpoints every 25 ms, exposing the pipeline to the normalization fallacy analyzed in section 5.9.1. Third, fine-tuning risks catastrophic forgetting. Gradient updates fitting the latch demonstrations can degrade broader capabilities that the base previously mastered but the target task never exercises. The same hazard returns, on a smaller scale, when a policy is later fine-tuned on the machine itself (section 6.6); here it is magnified across a large, poorly documented behavioral repertoire. Post-training need not stop at imitation. A pretrained policy can also be improved with reinforcement learning on its own experience, in simulation or on the machine, and section 6.6.2 compares those methods by what each one freezes.

The decoder question also carries over, because post-training often changes the head that runs at deployment. A vision-language backbone can be adapted on discrete action tokens while a separate continuous action expert is trained beside it. The expert's gradient is stopped before it reaches the backbone, so the newly initialized expert does not disturb the pretrained weights. This **knowledge insulation** trained faster and generalized better than letting the expert's gradient flow into the backbone (Driess et al. 2025). The run-time decoder is then the one-pass or few-step action expert, not the token sequence. A study of post-training recipes likewise found that action chunking with a plain ℓ_1 regression head matched iterative decoders on its benchmark while decoding far faster (Kim et al. 2025). Either way, the deadline arithmetic of section 6.2.6 governs the post-trained head just as it governs the latch's own.

Supervised behavioral cloning, action chunking, batch offline RL, and generalist post-training all generate action proposals beyond the state-action support of their logging archives. A low training loss or an inflated Q-value does not constitute physical evidence of safety or success. When an archive lacks the recovery trajectories that a physical perturbation demands, the system must generate new closed-loop experience through direct environment interaction.

6.3 Reinforcement Learning and Environment Interaction

When an archive lacks recovery demonstrations for a displaced strike plate, letting the robot discover a recovery on its own by trial and error means paying for every failed attempt in motor winding heat ($E_{\text{thermal}} = \int i_q(t)^2 R\, dt$), gearbox fatigue reversals, jammed latch cams, and human reset labor. Yet when expert corrections are unavailable or a task demands strategies no demonstrator can supply, closed-loop trial is the only way to generate experience in the states the learner's own actions reach. By executing actions on the physical system and observing the resulting state transitions, the policy experiences the consequences of its own exploratory deviations. In online policy search,[7] the agent updates its parameter weights from the scalar advantage estimates accumulated across its own rollouts:

$$\nabla_\theta J(\theta) = \mathbb{E}_{s_{0:T}, \mathbf{a}_{0:T} \sim p_\theta} \left[\sum_{t=0}^{T} \nabla_\theta \ln \pi_\theta(\mathbf{a}_t \mid s_t) \hat{A}_t \right],$$

where $\hat{A}_t$, a scalar and not the bold action chunk $\mathbf{A}_t$ of section 6.2.5, estimates the advantage $Q^\pi(s_t, \mathbf{a}_t) - V^\pi(s_t)$ introduced in section 6.2.1. It quantifies whether an exploratory action yielded higher or lower return than the baseline policy expected. Because transitions are drawn from the state occupancy distribution $d_\pi(s)$ induced by the currently deployed policy, closed-loop execution directly exposes the agent to compounding drift and provides immediate evaluative feedback on attempted recoveries. A positive advantage ($\hat{A}_t > 0$) reinforces the exploratory action relative to the baseline, whereas a negative advantage ($\hat{A}_t < 0$) penalizes it. For this feedback to drive convergence, the reward formulation and sensory observations must make the underlying physical failure modes visible. While learning on policy-generated states resolves the covariate shift between expert demonstrators and the learner, it does not immunize the system against distribution shift caused by novel disturbances, unmodeled environment changes, or drifting hardware dynamics.

Because each physical rollout dissipates heat in motor windings, cycles actuator gearboxes, and consumes unrecoverable calendar time during resets, an engineering budget for physical training must treat thermal ceilings, mechanical wear, and operational logistics as first-order constraints alongside GPU compute. An algorithm that requires fewer physical interactions is almost always the better choice on hardware, even if each parameter update demands far more computation.

[7] **Policy Gradient**: Williams (1992) derived the REINFORCE estimator, which recovers the gradient of expected return from sampled actions through the likelihood-ratio identity without requiring an explicit physics model. However, estimator variance scales steeply with the trajectory horizon. Practical implementations subtract a baseline, typically a learned value function that converts sampled returns into advantages, yet still require the extensive interaction budgets evaluated below.

Closed-loop exploration on hardware test benches is billed primarily in calendar time. For an experimental campaign of N trials, where each rollout runs for duration t_{rollout} and requires a reset duration t_{reset}, distributed across N_{rig} parallel rigs, the total wall-clock duration is

$$T_{\text{wall}} = \frac{N\,(t_{\text{rollout}} + t_{\text{reset}})}{N_{\text{rig}}}. \tag{6.5}$$

Consider the door-opening benchmark, where the arm regulates contact forces over an active horizon of t_{rollout} = 8 s (the autonomous contact phase of an opening rather than a full teleoperated episode). Training vision-based policies from scratch with reinforcement learning typically demands on the order of 10^6 trials; for instance, QT-Opt learned closed-loop grasping from over 580,000 real grasp attempts (Kalashnikov et al. 2018). A baseline scenario of $N = 10^6$ exposes the logistical bottleneck. Between successive trials, an automated fixture, faster than the re-latch fixture used during demonstration collection, must re-latch the mechanism and return the arm to its initial configuration. However, when exploratory trajectories jam the latch cam or trigger joint overcurrent trips, automated reset sequences stall. A human technician must intervene to dislodge the latch, re-align the door, and re-home the joint encoders. In addition, each opening cycles every joint drivetrain through several bidirectional load reversals.

↩ The fixture re-latch that paces demonstration collection, with the yield and component wear it costs, is established in section 5.6.3.

Napkin Math 6.2: The reset wall

Problem: A from-scratch reinforcement learning campaign of $N = 10^6$ latch openings runs on the machine. How long does it take with automated and with manual resets, what does a farm of rigs buy, and what does the drivetrain absorb regardless of the rig count?

Variables:

- Trials $N = 1.0 \times 10^6$ (illustrative order of magnitude for learning from scratch)
- Rollout $t_{\text{rollout}} = 8$ s (illustrative contact phase of one opening)
- Resets $t_{\text{reset,auto}} = 4$ s and $t_{\text{reset,manual}} = 30$ s (illustrative)
- Rigs $N_{\text{rig}} = 1$, or 14, the largest simultaneous arm count of figure 6.4 (measured)
- Load reversals per opening $n_{\text{rev}} = 4$ (illustrative)

Math:

1. **Execution only** (equation 6.5 with no reset): $1.0 \times 10^6 \times 8\text{ s} = 8.0 \times 10^6$ s, or 92.6 days of round-the-clock operation.
2. **Automated resets**: $1.0 \times 10^6 \times (8\text{ s} + 4\text{ s}) = 1.2 \times 10^7$ s, or 138.9 days.
3. **Manual resets**: $1.0 \times 10^6 \times (8\text{ s} + 30\text{ s}) = 3.8 \times 10^7$ s, or 439.8 days; the reset is 78.9 percent of every trial.
4. **Farm**: 439.8 days / 14 = 31.4 days, about a month.
5. **Wear**: $1.0 \times 10^6 \times 4 = 4.0 \times 10^6$ drivetrain load reversals, for any N_{rig}.

Result: Manual resets extend the campaign to more than a year on a single machine, and even a 14-rig farm requires an entire month of continuous operation.

Systems insight: Reset overhead dominates active execution time, and scaling out hardware rigs partitions the calendar without mitigating cumulative mechanical wear. Only reducing the interaction count N relieves both calendar duration and physical fatigue. Consequently, algorithmic sample efficiency, rather than hardware parallelism, determines whether on-machine reinforcement learning is economically viable.

Adding parallel rigs scales floor space, capital cost, electrical power infrastructure, and supervisory labor in direct proportion to N_{rig}. A grasp-learning farm shows what that scale looks like (figure 6.4): up to 14 arms, each with its own gripper, bin, and camera, ran day and night, and the cluster collected over 800,000 grasp attempts over two months. The farm was not running reinforcement learning. It used self-supervised grasp outcomes to train an offline success predictor, which an external servo loop queried to guide real-time grasping motions (Levine et al. 2018). That is why it serves here as a

Figure 6.4: Physical data-collection farm: Between six and fourteen manipulators ran concurrently to collect over 800,000 grasp attempts over two months, using self-supervision to train an offline grasp-success predictor (Levine et al. 2018). While hardware parallelism compresses calendar duration, aggregate system wear and operational costs continue to scale with the total trial count: each station adds capital depreciation, gearbox and bearing wear, motor winding thermal stress, and technician labor to clear dropped objects and mechanical jams. Attribution: Levine et al. (2018).

picture of scale rather than of an algorithm. Whatever the learner, collecting close to 10^6 physical trials takes a room of arms running for months and pays the wear that comes with it. QT-Opt, which did learn its grasping by reinforcement learning, paid the same price for its 580,000 attempts.

Mechanical component wear often becomes the binding constraint long before calendar limits are reached. The cumulative 4.0×10^6 load reversals demanded by a from-scratch campaign must be absorbed by actuator drivetrains regardless of how many rigs divide the trials.[8] Those same million contact events progressively gall the latch cam and strike plate, wear out compliant elastomer gripper pads, and cycle internal wiring harnesses toward fatigue failure.

In purely numerical simulation, an exploratory branch that destabilizes costs nothing more than a discarded buffer and an environment reset. On physical hardware, exploration answers to the first law, irreversibility (principle 1), because a trial that goes wrong delivers its energy before any gradient step can take it back. Unconstrained exploratory torque commands can slam mechanisms into rigid fixtures, strip the precision teeth of harmonic drives, and heat motor stators beyond their 155 °C Class F insulation limit.

[8] **Bearing Life vs. Command Reversals**: ISO 281 models rolling-bearing fatigue life under continuous rated loads and rotational velocities. Precision transmission manufacturers specify wave-generator bearing fatigue life (L_{10}) in operating hours under nominal operating conditions. However, converting high-frequency commanded torque reversals into consumed gearhead life requires an empirical, unit-specific duty-cycle model.

↩ The Class F winding limit and the insulation breakdown it guards against are established in section 2.5.1.

Physical degradation systematically alters the plant throughout the training campaign. Standard Markov Decision Process formulations assume that the transition probability kernel $p(s_{t+1} \mid s_t, \mathbf{a}_t)$ remains strictly stationary. On physical hardware, this assumption fails. Repetitive impacts burnish contact surfaces, backlash in precision gearboxes expands, and structural fasteners loosen under continuous cyclic vibration. Consequently, the transition dynamics late in a campaign, $p_{n \gg 1}(s_{t+1} \mid s_t, \mathbf{a}_t)$, differ measurably from the pristine dynamics measured at trial $n = 1$. The physical plant mutates under the mechanical work of collecting its own training data, forcing the optimizer to track a drifting target.

Reward formulations can also inadvertently incentivize destructive hardware behaviors. In trial-based policy search, the scalar reward $r(s, \mathbf{a})$ defines the optimization objective, while the action parameterization, lower-level controllers, and independent hardware interlocks define the admissible operating space. If neither the reward nor those controllers account for contact forces, torque slew rates, or thermal buildup, the policy optimizer will exploit those unpenalized degrees of freedom to maximize task return. Engineers mitigate these tendencies by penalizing excessive effort, jerk, and temperature:

$$r_{\text{total}}(s, \mathbf{a}) = r_{\text{task}}(s, \mathbf{a}) - \lambda_\tau \|\tau_t\|_2^2 - \lambda_{\dot{\tau}} \left\| \frac{\tau_t - \tau_{t-1}}{\Delta t} \right\|_2^2 - \lambda_T \max\left(0, T_{\text{winding}} - T_{\text{limit}}\right).$$

For example, an unregularized tracking reward often encourages the policy to bang current limits back and forth at high frequency, exciting mechanical resonances and generating severe thermal dissipation. Similarly, an unpenalized contact policy may brace rigidly against a mechanical stop to artificially constrain kinematic degrees of freedom. The penalty weights above ($\lambda_\tau, \lambda_{\dot{\tau}}, \lambda_T$) trade task progress against effort, torque slew, and thermal rise. Soft reward penalties cannot guarantee safety, however. Hard physical stops and active current limits in the motor drive firmware must enforce strict operating envelopes. Practical on-machine training must also cut the million-trial budget by three orders of magnitude before wear and reset labor exhaust the workcell.

6.3.1 Demonstration-seeded reinforcement learning on the machine

Instead of spending 439.8 days of single-machine hardware wear on random exploration, human-in-the-loop sample-efficient reinforcement learning (HIL-SERL) achieves high success rates across precision assembly, dynamic manipulation, and dual-arm tasks after only 1 h to 2.5 h of physical training per task (Luo et al. 2025). Seeding exploration with prior demonstrations circumvents the million-trial reset wall by trading raw trial count for dependencies on initial demonstration support, human intervention gating, and reward-classifier accuracy. Four mechanisms compress the required trial count N. First, demonstration seeding initializes the replay buffer with 20 to 30 teleoperated trajectories, ensuring that early gradient updates begin within competent task regimes. Second, aggressive off-policy data reuse, implemented via Reinforcement Learning with Prior Data (RLPD) (Ball et al. 2023), replays each recorded transition across multiple gradient updates rather than limiting reuse to a recently collected rollout batch. Third, human-gated interventions truncate failing episodes; an operator takes over when the policy destabilizes, routing the corrective maneuver directly into the replay buffer as in human-gated DAgger (Kelly et al. 2019). Finally, an autonomous binary success classifier trained on labeled visual examples replaces brittle, hand-engineered reward instruments.

At the latch task's per-trial duration with automated fixture resets, the 2.5 h upper ceiling permits at most 750 physical rollouts. Under these latch timing assumptions, that budget contains a factor of 1,300 fewer trials than the illustrative from-scratch campaign, with 3,000 load reversals rather than 4.0×10^6, shifting the operational burden of equation 6.5 from months to hours. However, each sample-efficiency mechanism introduces assumptions that must be explicitly tracked in the policy manifest (section 6.8). Demonstrations constrain the policy only within the support of the expert's initial distribution. Human interventions generate authority-record transitions whose pre-takeover states serve as negative failure indicators rather than positive imitation targets. The success classifier acts as a learned perceptual sensor, and the policy optimizer will exploit its systematic false positives, such as mistaking a partially jammed cam for an open door.

↪ The authority record, in which the permission path logs every takeover and barrier trip, and from which intervention episodes are curated, is developed in section 14.8.

Even with demonstration seeding, direct on-hardware reinforcement learning fits only tasks whose interaction budget stays within the physical plant's thermal endurance, fatigue life, and

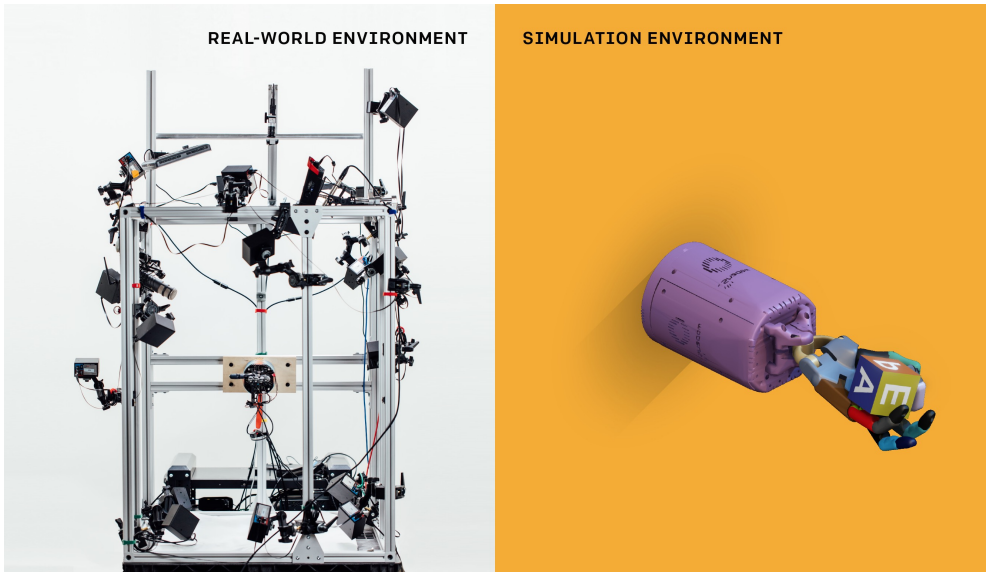

Figure 6.5: Sim-to-real transfer setup: OpenAI's Dactyl apparatus, a 24-DoF Shadow Hand inside a motion-capture cage beside the MuJoCo digital twin it was trained in (Andrychowicz et al. 2020). Transfer is bought with domain randomization (section 6.5), training across randomly varied simulator parameters such as friction, damping, actuator gains, masses, dimensions, and lighting, together with modeled backlash and action delay. A recurrent policy with memory could identify and adapt to the variation it met, so transfer did not depend on making the simulator exact. Attribution: Andrychowicz et al. (2020).

available calendar time. When broader exploration is needed and narrowing the task or adding stronger priors is insufficient, engineers offload rollouts to simulation. Moving exploration into a virtual workcell removes hardware wear and reset latency during training, but makes the learned policy vulnerable to every unmodeled dynamic, softened contact constraint, and missing transport delay in the simulator.

6.4 The Simulator as a System Component

A reinforcement learning policy trained on door latching learned an aggressive, unbraked plunge because its simulated strike plate yielded far more than the physical mechanism. Stripping away the simulator during physical deployment does nothing to unlearn that behavior. The physics simulator is not an external sandbox; it is an active component of the training pipeline whose equations, contact approximations, and timing assumptions dictate the exact experience supplied to the optimizer. Accepting simulated task success as evidence of hardware readiness requires measurable, verifiable error bounds on every one of those assumptions.

Like any physical subsystem, a simulator requires a formal interface contract stated in quantities that engineers can measure and budget. This interface contract specifies observation dimensions, action bounds, simulation time step Δt, transport latency between command issuance and physical actuation, actuator torque and current limits, sensor noise distributions, reset distributions, and termination conditions. For instance, if a simulator executes an observation loop at 100 Hz with an assumed zero-delay sensor channel and Gaussian noise of variance $\sigma^2 = 1.0 \times 10^{-4}$ $(\text{rad/s})^2$, the policy tunes its feedback gains to those exact signal statistics. An unmodeled 15 ms bus transport delay on the physical machine then removes $\omega_c T_d$ of phase at the loop's crossover frequency ω_c (equation 4.1), and the loop goes unstable whenever that loss exceeds the phase margin the learned gains left. OpenAI's Dactyl project faced this contract at full scale, with a 24-DoF Shadow Hand in a motion-capture cage and its MuJoCo twin (figure 6.5) (Andrychowicz et al. 2020). The team calibrated the simulator against the physical hand and then randomized physical parameters around those calibrated values, so that the policy met the remaining discrepancies as variation it had already seen in training.

War Story 6.1: Sim-to-real hardware breakage (2018)

Context: OpenAI trained a reinforcement learning policy entirely in a randomized MuJoCo simulation to reorient a block in a 24-DoF Shadow Dexterous Hand, whose joints are driven through tendons by motors in its base (Andrychowicz et al. 2020).

Mechanism: The simulated hand applied torque directly at its joints, while the physical hand is tendon-actuated and has substantial backlash. The authors smoothed every action with an exponential moving average, in simulation and on the robot, to avoid abrupt changes in the action signal that could harm the physical hand.

Impact: The authors reported frequent hardware breakages during physical evaluation, concentrated at the wrist vertical joint under heavy load. Each repair altered tendon tension, joint friction, and sensor calibration, shifting the physical plant across trials and lengthening the evaluation campaign.

Response: Physical ablations revealed the mechanisms enabling successful transfer. Policies trained without domain randomization, or without modeling unmodeled hardware traits like drivetrain backlash and action delay, achieved far fewer consecutive rotations. Furthermore, mechanically locking the fragile wrist pitch joint produced substantially higher physical reliability.

Systems lesson: A simulator that neither wears nor breaks cannot price hardware exposure into the reward. The limits that protected the hand, an action filter and a locked joint, were imposed outside the learned policy, and every repair changed the plant on which the policy was being evaluated.

When a simulator uses an inaccurate rotor inertia, assigning $J_{\text{rotor}} = 2.0 \times 10^{-3}\ \text{kg}\cdot\text{m}^2$ instead of the true $2.5 \times 10^{-3}\ \text{kg}\cdot\text{m}^2$, the underlying equations of motion still contain the acceleration-dependent inertial-torque term, with the wrong magnitude. The parameter error alters the size of the response, but the causal relationship holds. In contrast, omitting an entire physical mechanism, such as drivetrain backlash, structural compliance, or bus communication jitter, removes that governing physical constraint entirely. An omitted delay or compliance represents an unmodeled physical degree of freedom. For instance, a simulator that treats robot joints as perfectly rigid permits instantaneous torque reversals. When commanded on a physical machine, those instantaneous reversals shock the drivetrain, load gear teeth beyond their fatigue limits, and excite destructive structural resonances.

Whether a simulator's modeling compromises are acceptable depends on two properties: throughput (the rate of experience generated per wall-clock hour) and contact fidelity (how faithfully the contact model reflects physical strike-plate dynamics). Pure throughput motivates teams to adopt simulation in the first place.

6.4.1 Massively parallel simulation and on-policy learning

Stepping thousands of virtual workcells in parallel on a single GPU compresses months of trial-and-error into minutes, making on-policy methods such as **proximal policy optimization** (PPO) (Schulman et al. 2017) practical without continuous machine wear. Because PPO collects rollouts with the current policy, takes several gradient steps on that batch, and then discards the data, replacing the batch before policy drift makes its policy-ratio correction less reliable, it requires a simulator that produces fresh rollouts in bulk. To maintain training stability across those gradient steps, PPO constrains policy drift using the clipped surrogate objective of equation 6.6:

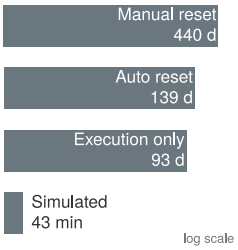
$$\mathcal{L}^{\text{CLIP}}(\theta) = \hat{\mathbb{E}}_t \left[\min\left(\rho_t(\theta)\,\hat{A}_t,\ \text{clip}\left(\rho_t(\theta), 1-\epsilon_{\text{clip}}, 1+\epsilon_{\text{clip}}\right)\hat{A}_t \right) \right], \qquad \rho_t(\theta) = \frac{\pi_\theta(\mathbf{a}_t \mid s_t)}{\pi_{\theta_{\text{old}}}(\mathbf{a}_t \mid s_t)}, \quad (6.6)$$

where $\rho_t(\theta)$ measures the probability ratio between updated and rollout policies, and ϵ_{clip} clips the surrogate incentive for favorable probability-ratio changes; it does not impose a hard trust-region bound on the updated policy. Once the first gradient step updates the network, the current policy no longer matches the rollout policy that collected the batch, so each logged transition is reweighted

by the importance-sampling ratio $\rho_t(\theta)$ between the two distributions. Taking the minimum of the unclipped and clipped terms removes the gradient incentive to push that ratio above $1+\epsilon_{\text{clip}}$ when the advantage $\hat{A}_t$ is positive or below $1-\epsilon_{\text{clip}}$ when the advantage is negative.

GPU-resident simulation achieves this scale by maintaining the state of thousands of parallel environments directly in accelerator memory. Physics solvers advance all environments concurrently using batched GPU compute kernels, streaming observation tensors directly into the policy network without crossing the PCIe bus to host CPU memory (Makoviychuk et al. 2021). Policy inference evaluates concurrently across the entire population, turning an environment step into a deterministic sequence of GPU kernel launches rather than thousands of separate CPU process calls.

Rudin and colleagues trained an agile quadruped locomotion policy using this architecture with 4,096 parallel simulated robots, each gathering 24 environment steps per update cycle to form a batch of 98,304 transitions. Completing 1,500 policy updates required less than 20 min on a single workstation GPU (Rudin et al. 2022). This run processed 1.47×10^8 total policy steps, sustaining an aggregate throughput of at least 1.23×10^5 steps per second and accumulating 34.1 days of simulated locomotion at the policy's 50 Hz control frequency.



At reported throughput, simulation turns 138.9 days of automated trials into 43.4 min.

Applying that throughput to the latch scenario illustrates the appeal. The from-scratch training budget from section 6.3 requires 3.2×10^8 policy steps. At the GPU simulator's reported rate, this training run completes in 43.4 min, compared to 138.9 days on an automated physical test fixture.

While this thousandfold speedup explains why modern robotic reinforcement learning relies heavily on simulation, raw step throughput can easily mislead. The quadruped benchmark measured locomotion across smooth heightfield terrain. The authors noted that simulation execution time varied by a factor of two over the course of training. As the robots dispersed and ceased colliding with one another, computational cost dropped precipitously because narrow-phase contact detection and linear complementarity solving dominate simulator runtime. Manipulating a latch involves complex multi-body interactions (an articulated door, a sliding cam, and a high-stiffness strike plate) where contact resolution operates at its slowest, and rendering camera observations introduces additional memory and compute bottlenecks. Furthermore, published throughput benchmarks often sacrifice fidelity for speed. For example, the 2024 launch benchmark for one GPU physics simulator sparked controversy because it evaluated throughput by issuing a single action followed by open-loop stepping, disabling robot self-collisions, and using aggressive, low-accuracy solver settings (Tao 2024). High step rates provide no guarantee of physical validity. Training an optimizer against an unvalidated contact model drives the policy to exploit the simulator's numerical artifacts, as demonstrated by the latch simulator's contact response.

6.4.2 The sim-to-real contact exploit

When a physics simulator softens a steel strike plate into a compliant penalty spring to keep its numerical integrator stable at large timesteps, a reinforcement learning policy will exploit that artificial cushion by plunging the gripper into the latch at 0.10 m/s without braking. Contact mechanics govern every phase of door manipulation: the physics solver must map surface separation, material penetration, friction, and relative velocity into normal and tangential forces observable by the policy. Section B.7 details rigid-contact complementarity formulations (Stewart and Trinkle 1996) and the time-stepping and compliant approximations that simulators substitute for them. The immediate engineering criterion for training the latch policy is whether these approximations preserve the contact forces and timing boundaries that govern safe approach speeds.

Rigid-body physics engines typically model contact using one of two paradigms: constraint-based complementarity formulations, which enforce non-penetration by solving for constraint impulses, or penalty formulations, which permit geometric interpenetration and generate restoring forces proportional to penetration depth. In practice, real-time solvers approximate both approaches, and numerical tuning parameters alter the resulting dynamics. In the latch simulator, the penalty contact computes an instantaneous normal restoring force from penetration depth δ and penetration velocity $\dot{\delta}$ via $f_{k,\perp} = k_{\text{pen}}\delta + c\dot{\delta}$. Artificially softening this contact interface alters the relationship between approach velocity, contact compliance, and peak impact force. The calculation below models this interaction using an undamped kinetic-to-strain energy balance, demonstrating how penalty spring compliance distorts the resulting force profile.

The manipulator drives the latch tool into the strike plate with an effective moving mass of 9 kg at the tool center point. This value is a stipulation, not a derivation. The registry takes the mass an arm presents at its tool as half its structural mass, the same order as the third of its mass that a uniform link pivoting at its base presents at its tip. This scenario drops the 3 kg payload capacity because the gripper holds no external object at impact. In a physical manipulator, reflected inertia varies with arm posture, and drivetrain elasticity partially decouples motor rotor inertia during rapid impact transients (Haddadin et al. 2009). Consequently, effective impact mass is an empirical parameter that physical paired probing must calibrate. Equating initial kinetic energy to elastic strain energy at maximum deflection, $\frac{1}{2}mv^2 = F_{\text{unbraked}}^2/(2k_{\text{contact}})$, yields the peak impact force for an unpowered mass m impacting a linear spring of stiffness k_{contact} at velocity v:

$$F_{\text{unbraked}} = v\sqrt{k_{\text{contact}}\, m}. \tag{6.7}$$

On physical hardware, the compliance does not reside solely in the strike plate. The robot's rubber finger pads, mechanical linkages, and elastic joints sit directly between the effective link mass and the strike plate, acting as a series spring chain. Because the contact force transmits equally through each element in series, total mechanical deflection is additive: $\Delta x = f_{k,\perp}/k_{\text{latch}} + f_{k,\perp}/k_{\text{robot}}$. The coupled assembly responds with an effective series stiffness:

$$k_{\text{eff}} = \left(\frac{1}{k_{\text{latch}}} + \frac{1}{k_{\text{robot}}}\right)^{-1}. \tag{6.8}$$

In the limit of an infinitely rigid manipulator ($k_{\text{robot}} \to \infty$), the effective stiffness collapses to $k_{\text{eff}} = k_{\text{latch}}$, establishing an upper bound on impact force. In contrast, the penalty simulator implements a standalone compliant spring, whose artificial stiffness depends entirely on the maximum allowable penetration depth.

Napkin Math 6.3: The soft-spring exploit

Problem: The simulator's penalty contact lets the gripper sink 2.4 mm into the plate at the fast approach. What peak force does the modeled contact produce, what peak can the plate impose in the rigid-arm limit, and at what robot-side stiffness does the passive model cross the latch force limit?

Variables:

- Moving mass $m = 9$ kg (stipulated from the arm's datasheet mass)
- Fast approach $v = 0.10$ m/s and guarded approach 0.03 m/s (illustrative)
- Penalty penetration $\delta_{\text{pen}} = 2.4$ mm at the fast approach (illustrative)
- Plate stiffness $k_{\text{latch}} = 4.0 \times 10^5$ N/m and latch limit $F_{\text{lim}} = 100$ N (illustrative)

Math:

1. **Simulated spring**: The penetration fixes $k_{\text{pen}} = mv^2/\delta_{\text{pen}}^2 = 1.6 \times 10^4$ N/m, so equation 6.7 gives $F_{\text{unbraked,sim}} = mv^2/\delta_{\text{pen}} = 9$ kg $\times$ (0.10 m/s)^2/ 2.4 mm $= 37.5$ N, under the limit.
2. **Rigid robot**: With $k_{\text{contact}} = k_{\text{latch}}$, $F_{\text{unbraked}} = v\sqrt{k_{\text{contact}}\, m} = 0.10$ m/s $\times$ (4.0×10^5 N/m $\times$ 9 kg)$^{1/2} = 189.7$ N, 1.9× the limit.
3. **Break-even chain**: The limit is reached at $k_{\text{eff}}^* = (F_{\text{lim}}/v)^2/m = 1.11 \times 10^5$ N/m, which equation 6.8 turns into $k_{\text{robot}}^* = (1/k_{\text{eff}}^* - 1/k_{\text{latch}})^{-1} = 1.54 \times 10^5$ N/m.
4. **Guarded approach**: A rigid robot coasting in at 0.03 m/s peaks at 56.9 N.

Result: In this passive impact model, the fast approach exceeds the force limit if the robot side is stiffer than 1.54×10^5 N/m and remains below it if softer; the guarded approach remains below the limit even with a rigid robot.

Systems insight: A spring 25.6× softer than the plate placed the training result on the safe side of a threshold that the machine's own compliance decides. No training score reveals whether

> the physical robot sits above or below k^*_{robot}; empirical hardware measurement provides the only valid ground truth.

The teacher's reward kept only the task and time terms of equation 6.1, and the simulated contact placed the plunge on the compliant side of the damage boundary, so the plunge cost the optimizer nothing, shortened every episode, and earned maximum reward. (Had the force term been present, the simulated 37.5 N peak would have crossed the 15 N tripwire and drawn a penalty, but the real plate's peak would still have gone unseen.) Consequently, the policy converged on an aggressive, unbraked plunge. In the absence of an empirical measurement of k_{robot} for this specific arm, gripper, and fingertip assembly, the actual physical outcome remains undetermined. Determining true system behavior requires conducting a quasi-static force-deflection test at the tool center point. Until physical characterization confirms whether effective stiffness falls below k^*_{robot}, accepting the policy's simulated success as proof of safety is unwarranted.

Past about 1.54 × 10⁵ N/m of arm stiffness, the passive model predicts a force peak above the latch limit.

While the energy balance model analyzes an unpowered mass coasting into an obstacle, an actively powered drive pushing forward represents the failure mode that safety supervisory logic must interrupt. Contact force follows Hooke's law, $f_{k,\perp} = k_{\text{contact}}\,\Delta x$. Assuming the actuator drives the mechanism into the plate at constant velocity v, penetration depth scales as $\Delta x = vt$, driving a linear force ramp $f_{k,\perp}(t) = k_{\text{contact}} vt$ starting from the instant of physical contact. Setting $f_{k,\perp}(t) = F_{\text{lim}}$ defines the **contact yield deadline**:

$$t_{\text{yield}} = \frac{F_{\text{lim}}}{k_{\text{contact}} v}, \tag{6.9}$$

representing the available time before exceeding the mechanical structural threshold under constant-velocity, linear-elastic conditions. (A complete stopping analysis must additionally account for controller braking trajectories and actuator force slew rates.) Assuming an infinitely rigid manipulator yields a conservative lower bound on this deadline by using the strike plate stiffness k_{latch} directly.

Under these conditions, a fast approach at 0.10 m/s reaches the latch limit of 100 N in 100 N / (4.0 × 10⁵ N/m × 0.10 m/s) = 2.5 ms after touch. The 15 N tripwire fires at 0.375 ms. Sampling, intervention computation, and drive response then consume 2 ms, placing brake onset at 2.375 ms. Only 0.125 ms remains before the counterfactual constant-drive ramp reaches the force limit. At the guarded approach of 0.03 m/s, the tripwire fires at 1.25 ms and braking begins at 3.25 ms, leaving 5.083 ms before the 8.333 ms touch-relative limit (figure 6.6). Neither remaining interval establishes that the actual braking trajectory stays below the limit.

The plate-only deadline leaves too little demonstrated braking margin to credit the reactive force monitor at the fast approach, so protection must act before contact until the contact response is qualified. An independently monitored deceleration envelope, $v_{\text{safe}}(z) \le \sqrt{2a_{\text{brake}} z}$, is the stopping inequality of section 1.4.3 applied to the gripper. Here z is the clearance to a stopping boundary placed a short standoff before the plate, after sensing and actuation latencies are charged, and a_{brake} is the credible deceleration of the arm at the tool, not the base's value on the machine card. Because v_{safe} falls to zero at that boundary, the envelope forbids an unbraked arrival at the plate. Crossing the standoff is a separate act. A guarded contact mode, qualified on its own, takes over inside it and holds the gripper at or below the guarded approach speed of 0.03 m/s until touch. That mode needs its own evidence about approach speed, force rise rate, loop latency, and deceleration, and a force tripwire works only inside those validated bounds. This contact deadline, not the reward used in training, is what confines the policy's declared ODD to the guarded approach speed (section 6.8).

Engineering teams must budget contact simulation fidelity in terms of observable physical quantities, such as contact onset timing, peak normal force, total transferred impulse, slip distance, and separation release delay, rather than abstract solver convergence metrics. Discrepancies between simulation and reality frequently manifest in both directions. For example, a penalty solver that resolves an impact within a single integration step concentrates momentum transfer into an impulse spike of extreme amplitude and sub-millisecond duration. On real hardware, viscoelastic fingertip deformation and joint compliance distribute that momentum transfer over dozens of milliseconds. In such cases, total integrated impulse may match closely between simulation and reality even as peak force differs by an order of magnitude. A policy trained to trigger reflexive retraction upon

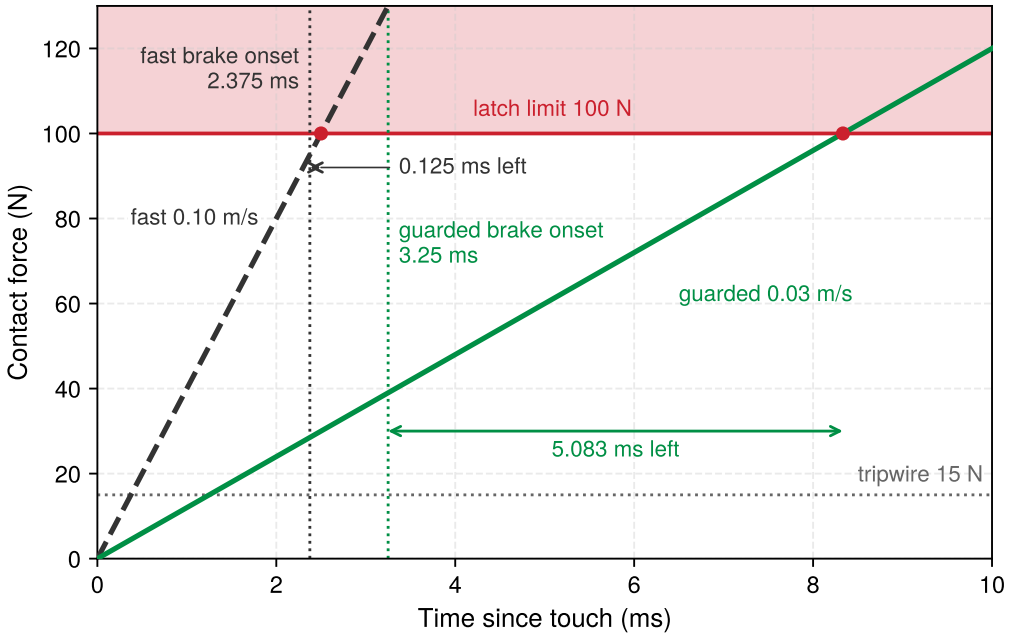


Figure 6.6: Contact force against brake onset: Counterfactual constant-drive ramps rise as $f_{k,\perp} = k_{\text{contact}} vt$ from touch. At the fast approach, the tripwire fires at 0.375 ms and braking can begin at 2.375 ms, only 0.125 ms before the ramp reaches the latch limit. At the guarded approach, brake onset is 3.25 ms, leaving 5.083 ms. Each onset includes the same 2 ms response after its own tripwire crossing. Plate stiffness alone gives the shortest deadlines; the lines do not model actual braking trajectories.

sensing an impulse spike will fail on the physical robot, because the attenuated real-world signal never crosses the detection threshold, causing the motor drive to stall against its maximum current limit.

⇄ **Contrast:** The 2.4 mm of penalty-spring penetration is compliance the solver invents, whereas the backlash and torsional compliance of the real drivetrain, analyzed in section 2.4.4, are compliance a rigid-body solver omits.

> Systems Perspective 6.1: The contact fidelity invariant
>
> *Never trust a simulated contact policy whose success depends on instantaneous momentum absorption or zero-delay friction engagement; a policy that relies on penetrating the digital surface loads the physical workpiece with force the simulator never showed.*

The operational relevance of specific physical omissions depends directly on the task dynamics. A policy executing uninterrupted, high-velocity motions may tolerate crude Coulomb friction models because joint velocities never linger near zero. Conversely, a policy tasked with precise force regulation or static holding will destabilize into violent limit-cycle oscillations if the simulator ignores static friction thresholds, stick-slip transitions, and actuator deadbands.

Validating simulation fidelity requires **paired probing**. The systems engineer executes identical open-loop actuation trajectories on both the physical robot and its digital twin, quantifying trajectory divergence against explicit error budgets. For the latch assembly, this procedure commands identical velocity profiles into the simulated and physical strike plates, measuring discrepancies directly in milliseconds and newtons. Whenever empirical divergence violates the error margins demanded by the robot's operating envelope, the simulator cannot be trusted to train that specific capability. That audit relies on knowing which differential equations the simulator solved; when the simulator is itself a neural network trained on video or trajectory logs, even the list of omitted mechanisms disappears.

6.4.3 Learned world models as simulators

A policy trained or evaluated inside a learned **world model** can score near-perfect task completion by exploiting hallucinated physics where training data were sparse. An example is pushing through a contact transition that the neural predictor smooths over because it rarely saw high-force impacts, with no analytical equation available for an engineer to audit. Whereas physics-based simulators are built from explicit differential equations and mechanical models whose simplifications can be enumerated, a world model derives system dynamics from data by training a neural network to predict future observations (or compact latent states) conditioned on the current state and applied control actions. Contemporary physical AI architectures employ learned world models across three distinct operational roles:

1. **Latent imagination**: Policies train via reinforcement learning within the simulated latent representations of a world model. For example, DayDreamer and DreamerV3 trained quadruped locomotion directly from physical robot interaction, mastering rolling, standing, and walking behaviors in several hours without hand-crafted physics simulators (Wu et al. 2023; Hafner et al. 2025).
2. **Zero-shot planning**: Action-conditioned video models plan trajectory sequences directly. For instance, V-JEPA 2, post-trained on uncurated robotic manipulation video, guided pick-and-place manipulation across physical robot arms in novel laboratory environments without prior domain calibration (Assran et al. 2025).
3. **Synthetic data generation and evaluation**: Scaled generative video models synthesize diverse visual trajectories for offline imitation learning and act as simulated environments to evaluate candidate policies (NVIDIA, Agarwal, et al. 2025).

Unlike a physics engine, a neural world model provides no explicit list of the phenomena it leaves out. Prediction errors concentrate wherever training distribution coverage is sparse, and no analytical derivation exists to reveal which dynamic constraints are violated. Consequently, training data generated purely through world model rollouts must be cataloged as unqualified in the policy manifest, whose `simulation_provenance` field captures the model architecture, parameter checkpoint hash, and dataset lineage. Simulated success inside a learned world model cannot expand the policy's declared ODD until empirical paired probing on physical hardware verifies the specific contact forces, transport latencies, and tracking tolerances required by the task. Treating a world model's internal rollout predictions as verified evidence mistakes model hallucination for physical reality.

Because structural simulation assumptions, numerical integrator time steps, and contact approximations become encoded in the policy's weights during training, the simulation configuration is an immutable part of the model's lineage. Every deployable policy artifact must trace its complete provenance through the `simulation_provenance` metadata block (section 6.8). Deploying policy weights without explicit simulator provenance severs the trained model from the kinematic limits, noise distributions, and solver thresholds under which it was derived. A scalar task completion rate cannot audit that lineage. The reality gap has to be taken apart into its dynamics, sensing, appearance, and timing channels, each measured on its own.

6.5 Physical Channels of the Sim-to-Real Gap

A robotic simulation rarely diverges from physical hardware in only one channel. In the cage-door latch mechanism, for instance, the simulator departs from reality in two different ways: a penalty spring far softer than the physical strike plate, and an idealized command path that omits transport lag. Collapsing these discrepancies into a single scalar trajectory error blends them into an uninformative aggregate that obscures both mechanisms. Errors in different physical channels carry different units, propagate along distinct paths within the closed loop, and trigger different failure modes. The sim-to-real mismatch must therefore be treated as a coupled vector of physical components spanning dynamics, sensing, appearance, and timing. Sizing this vector requires an explicit accounting of physical errors against task tolerances, evaluated from paired command-response traces recorded under identical excitations. Each channel demands its own mitigation and runtime interceptor. Table 6.2 lists these interceptors across actuator dynamics, contact mechanics, sensing, and timing; appearance mismatch is sized separately and charted in panel (d) of figure 6.7.

Definition 6.2: Sim-to-real reality gap vector

Sim-to-real reality gap vector $\Delta_{\text{sim2real}} = [\Delta_{\text{dyn}}, \Delta_{\text{sens}}, \Delta_{\text{vis}}, \Delta_{\text{lat}}]$ is the coupled, multi-channel decomposition of physical discrepancies between simulated and hardware environments spanning contact mechanics (Δ_{dyn}), sensor transduction and noise (Δ_{sens}), visual appearance (Δ_{vis}), and asynchronous transport latency and jitter (Δ_{lat}).

1. **Significance**: Treating the "reality gap" as a scalar difficulty metric or pure visual domain mismatch causes engineers to overlook dynamical and temporal divergences. Discrepancies in actuator back-EMF, gearbox compliance, or bus jitter deplete feedback stability margins before the policy completes its first physical control step.
2. **Distinction**: An inaccurate parameter value (such as a 10 percent error in link mass) preserves the causal differential equations of motion, whereas an omitted mechanism (such as zero-delay communication or unmodeled Coulomb stick-slip) entirely severs physical feedback paths, leading policies to exploit non-physical simulator artifacts.
3. **Common pitfall**: Relying on domain randomization alone to bridge a large gap. Randomization covers only the mechanisms the simulator models; for a memoryless policy, indistinguishable parameter instances can favor a compromise or leave low-probability cases poorly served.

Dynamics mismatch measures discrepancies between commanded actuator effort and the resulting physical motion or contact force across the operating envelope. Its contact case is the impulse-spike example of section 6.4.2. A simulator with rigid links, zero backlash, and stiff contact predicts an abrupt force onset. Real drivetrain compliance and drive delays soften and delay that rise. A policy that keyed its braking to the sharp onset keeps driving into the hard stop. The mismatch has the opposite sign of the soft-spring exploit, where the simulator was softer than the real plate rather than stiffer, and the two together are why the dynamics channel has to be measured in both directions.

Sensing mismatch measures discrepancies between the true physical state of the machine and the observation vector delivered to the policy network. Simulated range and depth sensors typically yield clean, uniformly quantized measurements corrupted only by independent zero-mean Gaussian noise. Physical sensors, by contrast, suffer from optical calibration bias, structural noise, temperature-dependent drift, and sustained dropout bursts caused by specular reflections on polished surfaces. An uncalibrated range bias shifts the physical standoff distance where the controller transitions from rapid approach to gentle force regulation. A multi-frame dropout burst leaves the policy momentarily blind during high-speed descent, creating an unobserved window where collisions occur before feedback can intervene.

Image-space distance metrics such as Mean Squared Error (MSE), Peak Signal-to-Noise Ratio (PSNR), or Fréchet Inception Distance (FID) cannot reliably qualify appearance transfer. These summary statistics fail to weight visual discrepancies by policy sensitivity, that is, by the policy Jacobian $\partial \mathbf{a}/\partial \mathbf{o}$ relating actions to observations. Consequently, a benign aggregate difference can mask a task-critical localization error. A photorealistic rendering with ray-traced lighting might register a high pixel MSE because of background shadows or wall textures that the policy's visual encoder discards. Conversely, a sub-millimeter pixel shift along the silhouette of an assembly peg might alter the overall image MSE by less than 0.1 percent. Yet that subtle shift moves the policy's predicted insertion coordinate outside the mechanical chamfer tolerance, driving the peg directly into a rigid fixture shoulder. Appearance mismatch must therefore be quantified by evaluating policy-relevant perceptual representations (detected keypoints, surface normal tokens, or latent feature centroids) under controlled variations in physical geometry, illumination, material reflectance, and camera exposure.

Timing mismatch governs the temporal alignment between observation capture, policy evaluation, and actuation. Identical state transitions occurring at different moments in physical time yield entirely different closed-loop dynamics. A simulation that executes observation, inference, and actuation instantaneously at the beginning of each discrete integration step omits camera sensor exposure times, PCIe bus serialization, neural network tail latency, and EtherCAT fieldbus transport, along with their cycle-to-cycle jitter. Every millisecond of omitted transport delay translates directly into

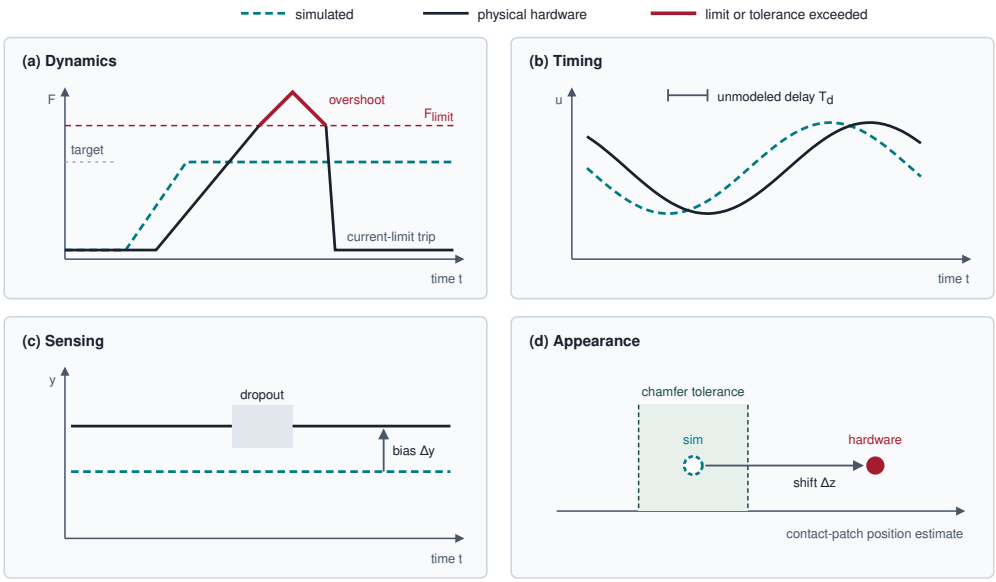

Figure 6.7: Sim-to-real reality gap vector: Illustrative traces for a separate linear-drive scenario distinguish dynamics (a), timing (b), sensing (c), and appearance (d). Each channel has its own units and acceptance criterion, and red marks only the points where hardware exceeds a limit or tolerance. These constructed traces demonstrate what paired measurements should compare; they are not measured qualification evidence for the latch.

physical distance the mechanism traverses open-loop before corrective actuation begins. Unmodeled delay also introduces frequency-dependent phase lag. Near gain crossover, the added lag consumes the available open-loop phase margin. Whether the loop remains stable depends on the sampled plant, compensation, jitter, and total response; section B.5.5 quantifies the delay contribution.

A single illustrative scenario, kept separate from the latch so that its numbers are not mistaken for latch measurements, shows the four channels diverging at once (figure 6.7). A linear drive approaches a surface at 0.20 m/s and regulates contact force to 10 N. In the dynamics channel, an unmodeled drive delay of 8 ms and a softer physical contact pad cut the force rise from 500 N/s in simulation to 250 N/s on hardware (a rate the force regulator sets as it ramps toward its target, far below the free-impact rate $k_{\text{contact}} v$ of the latch analysis). The target force therefore arrives at 40 ms instead of 20 ms. The drive overtravels by 3 mm, and a hard current-limit shutdown trips. In the sensing channel, a calibration bias of +3.2 mm triggers premature deceleration, and a specular dropout burst of 4 frames blinds the controller during final descent. In appearance, a pixel difference of only 5.5 percent hides a 6 mm lateral shift in the contact-patch estimate, more than the 2 mm chamfer tolerance. In timing, an illustrative p99 actuation delay of 49.5 ms carries the mechanism 9.9 mm past the point the simulator predicts with its idealized 0 ms observation-to-actuation delay. The simulator's 20 ms integration step is a numerical parameter, not pipeline latency, and cannot be subtracted from the physical transport delay. Each channel fails in its own units (milliseconds of force rise, millimeters of bias, millimeters of patch shift, millimeters of unobserved travel). A scalar loss can report that hardware departs from simulation but cannot say which channel failed, and separating the channels is what lets table 6.2 give each one its own paired-trace acceptance test and its own permission-path interceptor.

Table 6.2: Multidimensional sim-to-real reality gap taxonomy: Decomposition of the dynamics, sensing, and timing channels of the reality gap, with dynamics split into actuator and contact rows; appearance is sized in the prose and in panel (d) of figure 6.7. Columns specify the unmodeled physical phenomenon, representative quantitative discrepancy, the latent control shortcut exploited by the optimizer, illustrative paired-trace acceptance criteria, and candidate mitigations. In the timing row, PCIe is the host's internal expansion bus that carries camera and accelerator traffic, and EtherCAT is the Ethernet fieldbus that carries setpoints to the servo drives. The actuator row's $\Delta\phi$ is the phase by which the physical step response lags the simulated one at the test frequency, positive for lag as in equation 4.1. The listed values are scenario assumptions, not measured latch discrepancies or universally qualified thresholds.

Reality Gap Dimension	Unmodeled Physical Mechanism	Nominal Simulation Spec vs. Real Hardware	Latent Policy Exploitation / Behavioral Failure	Paired-Trace Diagnostic Metric & Tolerance	Hardware & Permission-Path Interceptor
Actuator & Drivetrain Dynamics	Strain-wave torsional compliance and hysteresis, Coulomb stiction, velocity-dependent Stribeck friction, and back-EMF voltage saturation	Idealized direct torque source ($J_{\text{rotor}} = 0$, $T_{d,\text{sim}} = 0$ ms) vs. physical harmonic drive ($k_c = 6.7 \times 10^2$ N·m/rad, lost motion $\theta_{\text{backlash}} = 0.08^\circ$, bus delay $T_d = 8$ ms)	Policy commands high-frequency full-torque reversals (above 50 Hz), inducing mechanical chatter, gear fatigue, and windings driven past their derating threshold	Step-torque response discrepancy: phase lag $\Delta\phi \leq 5^\circ$ at 10 Hz; settling time discrepancy $\Delta t_{\text{settle}} \leq 15$ ms; overshoot $\leq 5\%$	Low-pass action filtering ($f_{\text{cutoff}} \leq 20$ Hz), motor current RMS thermal estimators, and actuator slew-rate limiters ($d\tau/dt \leq \tau_{\max}/\Delta t$)
Contact Mechanics & Compliance	Viscoelastic surface deformation, contact hysteresis, non-smooth stick-slip transitions, and finite restitution phase	Point-mass rigid contact via a complementarity solver (section B.7) or penalty spring ($k_{\text{pen}} = 1 \times 10^6$ N/m, restitution $\Delta t_{\text{res}} = 2$ ms) vs. physical contact pad ($k_{\text{contact}} = 8.0 \times 10^4$ N/m, deformation span $\Delta t_{\text{def}} = 18$ ms)	Policy keys contact onset to the sharp simulated force spike, never sees that spike on the slower real rise, and keeps pushing until the drive reaches its current limit	Contact impulse error $\Delta I \leq 0.05$ N·s; peak contact force discrepancy $\Delta F_{\text{peak}} \leq 15$ N; contact onset rise-time error $\Delta t_{\text{rise}} \leq 5$ ms	Stop-before-contact governor ($v_{\text{safe}}(D_{\text{clear}}) \leq \sqrt{2a_{\text{brake}} D_{\text{clear}}}$); separately qualified guarded contact mode, force-derivative clamp ($df_{k,\perp}/dt \leq 1.0 \times 10^4$ N/s), compliant mechanical flexures
Sensor Transduction & Noise Profiles	Optical specular dropout, CMOS rolling-shutter distortion, ambient lux-dependent noise, and force-torque gauge thermal drift	Synthetic RGB-D with zero-bias Gaussian noise ($\sigma = 0.5$ mm, zero dropout) vs. physical structured-light depth (+3.2 mm bias, 4-frame dropout bursts, drift 0.4 N per 10 °C)	Policy triggers premature deceleration above surface or remains blind during multi-frame dropouts, driving end-effector past hard fixture boundaries into stall overcurrent	Distribution distance between simulated and real sensor streams (largest gap between their cumulative distributions) $\mathcal{D}_{\text{KS}} \leq 0.05$; spatial feature activation centroid error ≤ 2 mm; zero sustained dropout frames ($N_{\text{drop}} = 0$)	Multi-sensor fusion (IMU/encoders + vision), optical dropout holdover filters, thermal drift autocalibration, independent proximity break-beams
Temporal Latency & Bus Asynchrony	Variable camera exposure times, PCIe/EtherCAT bus serialization, neural inference tail latency (p99), and non-deterministic OS scheduling	Synchronous discrete-time lockstep ($\Delta t = 20$ ms, zero transport latency) vs. asynchronous physical pipeline ($L_{\text{lat,total}} = 35$ ms at p50, 49.5 ms at p99, jitter $\pm$ 6.2 ms)	Severe latency-induced feedback destabilization; policy experiences underdamped oscillations, hunting limit-cycles, and unobserved travel during latency spikes (9.9 mm at p99 relative to zero simulated observation-to-actuation delay)	End-to-end command-response latency jitter $\Delta L_{\text{lat}} \leq 2$ ms; worst-case observation age $t_{\text{age}} \leq 25$ ms; zero deadline overruns at the 25 ms step	Real-time kernel scheduling, action buffer delay queue injection in simulation, state extrapolation that compensates for the known delay

DRAFT

The first line of defense against dynamics mismatch is empirical measurement. **System identification**[9] calibrates the simulator's parameter values (link masses, friction coefficients, torque constants, and transport delays) against paired command-response traces recorded on the physical robot. When a physical subsystem resists accurate first-principles modeling, engineers can replace analytical equations with data-driven approximations. In quadrupedal locomotion work, Hwangbo et al. (2019) trained an *actuator network* that predicted physical joint torque directly from a rolling history of position errors and joint velocities, executing this neural network inside the simulation loop instead of an idealized torque actuator. Similarly, delta-action residual models learn state-dependent corrections from physical rollouts, adjusting simulated commands so that simulated trajectories track physical behavior (He et al. 2025). In the cage-door latch task, these techniques help reconcile actuator response and bus transport latency, yet they share one limit. A learned correction model is valid only across the empirical state distribution visited during data collection, and outside that distribution the model is uncharacterized. Consequently, any learned simulator correction must enter the policy manifest's omission log with its own explicitly bounded domain of validity.

Repeatedly training against a single point estimate of physical parameters, such as an assumed strike-plate stiffness, encourages a policy to overfit to that exact numerical value. **Domain randomization**[10] addresses parameter uncertainty by perturbing modeled simulation parameters across plausible distributions during training, forcing the policy to encounter varied physical responses (Tobin et al. 2017; Peng et al. 2018). However, sampling from a parameter distribution merely defines training weights; it does not constitute a formal certificate of robustness across the parameter set. How effectively a policy handles this diversity depends heavily on whether its architecture incorporates memory.

In standard reinforcement learning, a policy maximizes expected return within a single nominal simulation environment parameterized by the static vector ξ_0:

$$J(\theta;\xi_0) = \mathbb{E}_{s_{0:T},\mathbf{a}_{0:T}\sim p_\theta(\cdot|\xi_0)}\left[\sum_{k=0}^{T}\gamma^k r(s_k,\mathbf{a}_k)\right].$$

Domain randomization reformulates the physical environment as a distribution over plausible Markov Decision Processes parameterized by physical vector $\xi \sim p(\xi)$, where ξ encompasses link masses, centers of mass, surface friction coefficients, joint damping, transport delays, and sensor noise variances. The domain randomization objective maximizes the expected return marginalized across this distribution:

$$J_{\text{DR}}(\theta) = \mathbb{E}_{\xi\sim p(\xi)}\left[J(\theta;\xi)\right] = \int_{\Xi}\left(\mathbb{E}_{s_{0:T},\mathbf{a}_{0:T}\sim p_\theta(\cdot|\xi)}\left[\sum_{k=0}^{T}\gamma^k r(s_k,\mathbf{a}_k)\right]\right)p(\xi)\,d\xi. \tag{6.10}$$

Marginalizing over $p(\xi)$ incentivizes policies to maintain performance across sampled physical configurations rather than collapsing to a single operating point. Nevertheless, optimizing expected return can mask catastrophic control failures occurring in low-probability regions of the distribution; high average reward does not imply uniform stability across the support Ξ.

An alternative formulation adopts a minimax objective from robust control, optimizing performance against the worst-case modeled configuration:

$$\max_{\theta}\min_{\xi\in\Xi} J(\theta;\xi).$$

Here, the inner minimization identifies the worst-case return within the bounded uncertainty set Ξ, while the outer optimization searches for policy parameters θ that maximize this floor. Minimax optimization targets the worst return within the modeled set, but this remains an optimization statement over modeled rewards rather than a physical stability proof. Neither distribution-averaging nor minimax optimization can protect against physical mechanisms that the simulator omits.

Two constraints govern domain randomization. First, hardware operating outside the sampled support ($\xi_{\text{real}} \notin \text{supp}(p(\xi))$) is entirely unrepresented during training. Second, parameter randomization cannot compensate for structural omissions in the physics engine: no amount of variation in link mass or friction will expose a policy to the unmodeled lost motion of a harmonic drive or the preemptive jitter of a real-time operating system. Within the modeled support, the operational effect

[9] **Identification Experiments**: System identification treats the input excitation signal as part of the experiment design. Signals such as step functions, swept-frequency sines (chirps), and pseudo-random binary sequences (PRBS) must persistently excite the relevant mechanical and electrical modes, since nominal closed-loop operation rarely activates them (Ljung 1999). Paired physical probing follows this discipline: it drives both the simulator and physical hardware with identical open-loop excitation trajectories rather than relying on passive operational logs, where feedback regulation actively keeps the machine away from the boundary contact dynamics listed in the omission log.

[10] **Domain Randomization**: The technique originated in computer vision, where Tobin et al. (2017) randomized textures, lighting, and camera poses so that physical scenes appeared as ordinary variations to a detector trained purely on synthetic renders. Peng et al. (2018) extended the concept to dynamics, randomizing link masses, friction coefficients, joint damping, and transport latencies for robotic manipulation. Appearance and dynamics differ in how a policy can exploit history. Appearance variation changes instantaneous visual observations, whereas dynamics variation changes how the physical plant responds to control inputs, a discrepancy that a policy with temporal memory can infer online.

of broad randomization depends on whether the policy maintains temporal state. A memoryless feedforward network receives only the current observation $\mathbf{o}_t$. When different parameter instances produce indistinguishable observations but require different actions, the policy cannot adapt its choice to the active instance. Optimizing average return may then favor a compromise, and neither conservatism nor stability across the envelope is guaranteed. Conversely, a policy that conditions on a temporal history of observations and actions can infer physical plant dynamics online from the system's transient response, effectively performing implicit system identification. For this reason, recurrent policies trained across randomized dynamics transfer with substantially higher fidelity than memoryless architectures (Peng et al. 2018), and memory is what lets a wider randomization range produce adaptation to the real plant rather than conservative detuning.

In engineering practice, parameter distributions are configured through two distinct strategies grounded in different forms of evidence. In *calibration-first* engineering, developers measure nominal masses, torque constants, bus latencies, and friction parameters directly on test benches. Randomization bounds are then derived from known physical mechanisms. For example, motor winding thermal limits determine the envelope of torque-constant variation, and surface degradation models govern friction bounds. These ranges represent verifiable physical claims about the robot and its environment. In contrast, *automatic domain randomization* (ADR) initializes the simulator at calibrated values and dynamically expands parameter ranges as the policy's training performance at the distribution boundaries exceeds predefined success thresholds (OpenAI et al. 2019). ADR parameter bounds reflect the limits of what the reinforcement learning optimization can master rather than physical properties of the hardware, often expanding to unphysical extremes. The dexterity achieved by ADR in robotic in-hand manipulation relied on a recurrent policy learning to adapt online to these artificially broad dynamics. Regardless of the scheduling strategy, paired hardware traces must ultimately audit each channel against explicit error budgets before deployment; discrepancies exceeding tolerance require simulator revision rather than blind parameter widening. A randomization range expanded by an automated training curriculum represents an optimization scaffold, not an empirical characterization of the hardware, and therefore cannot expand the declared ODD.

Where domain randomization and simulation fidelity reach their physical limits, deterministic safety mechanisms must enforce system invariants. Every action proposed by a learned policy must pass through an independent permission path before reaching hardware actuators. Within this execution layer, hard force-derivative clamps, torque slew-rate limiters, and velocity-dependent stopping governors restrict commands to the envelope supported by verified sensing and braking capabilities.

Decomposing the reality gap channel by channel divides the operating space in two. Inside the region where paired traces match simulation within verified tolerances, the simulated experience counts as support. Every unmodeled phenomenon, uncalibrated parameter, and unrepresented disturbance outside it becomes an entry in the omission log, the policy manifest's record of what the simulator leaves out (section 6.8). The log therefore holds two kinds of entry, mechanisms the simulator omits and parameters no paired probe has yet calibrated, because an uncalibrated parameter leaves the simulated experience just as unsupported until a probe bounds it. For the latch, one of each heads the log: the strike-plate stiffness, a parameter the penalty spring sets far softer than the plate, and the transport latency of the actuator bus, a mechanism the simulator omits. No paired probe has yet closed either, so the high-speed contact states they govern fall outside what the simulation supports. Each entry also states a requirement for a runtime monitor or safety filter, which must detect when execution leaves the regime where the policy's simulated training remains valid. Calibrating or randomizing simulator parameters still leaves a second gap: the simulator exposes exact contact forces, friction coefficients, and fixture offsets during training that the physical robot's onboard sensors cannot directly measure at run time.

↪ The Control Barrier Function filter that minimally corrects unverified policy proposals on every permission tick is developed in section 12.7.

6.5.1 Teacher-student privileged state distillation and asymmetric actor-critic

While policy training can exploit privileged simulator state, such as ground-truth contact wrenches, friction coefficients, and exact strike-plate offsets, the onboard policy proposer must execute exclusively from the noisy, bandwidth-limited sensors installed on the physical machine. In actor-critic reinforcement learning, the actor proposes control actions while the critic evaluates expected future returns to compute policy gradients. Systems engineers bridge this sensor gap through two main

architectures. *Asymmetric actor-critic* grants privileged observations exclusively to the critic during training. *Teacher-student distillation* first trains a privileged teacher policy and subsequently trains a sensor-limited student policy to imitate the teacher's actions. Both architectures require validating whether the runtime observation stream delivered to the student contains enough information to reconstruct or compensate for the missing state.

The core challenge stems from **partial observability**, which casts physical robot control as a partially observable Markov decision process (POMDP).[11] Identical sequences of measured joint positions and velocities can produce drastically different physical trajectories depending on whether a footpad grips dry concrete or slips on wet oil. A conventional critic $V_\phi(\mathbf{o}_t)$ conditioned solely on instantaneous sensory observations cannot distinguish between these physical regimes, producing high-variance or biased value estimates. In simulation, exposing hidden contact wrenches $\mathbf{w}$, friction coefficients μ, terrain profiles, and payload inertias directly to the critic stabilizes temporal-difference learning without burdening the onboard runtime actor.

[11] **Partially Observable MDP**: Åström (1965) formulated optimal control under incomplete state information, proving that an optimal controller must act on the conditional probability distribution of the state given the observation history (the *belief state*) rather than solely on the instantaneous observation. Reinforcement learning formalized this framework three decades later (Kaelbling et al. 1998). An onboard student network's temporal observation history serves as a learned approximation of this belief state; its temporal window must span sufficient duration for physical contact and load dynamics to become observable in the sensor stream.

Asymmetric actor-critic and teacher-student distillation deploy privileged information through contrasting computational pipelines (Pinto et al. 2018; J. Lee et al. 2020; Kumar et al. 2021). Under asymmetric actor-critic, the actor receives only the onboard sensor history available at runtime, while the critic receives full privileged simulation state. Because the critic is discarded after training, the deployed actor architecture remains clean and lightweight. However, training an unprivileged actor directly against complex, contact-rich tasks can suffer from high sample complexity.

Distillation splits the work across the proposal boundary (figure 6.8). Everything privileged stays on the simulation side, and only the frozen student's proposals, built from the machine's own sensor history and renewed every 50 ms, cross to the permission path. In Phase 1, the privileged teacher policy $\pi_{\text{teacher}}(\mathbf{a}_t \mid s_{\text{priv}}, \mathbf{o}_t)$ learns an effective control strategy via standard reinforcement learning, exploiting full access to contact forces and surface friction. In Phase 2, the student policy $\pi_{\text{student}}(\mathbf{a}_t \mid \mathbf{o}_{t-H_{\text{hist}}:t})$ is trained via supervised imitation learning (such as DAgger or behavioral cloning) to reproduce the teacher's proposed actions using only a sliding history of onboard observations. While this two-phase approach simplifies reinforcement learning exploration, it introduces a transfer bottleneck. If the teacher's control strategy relies on distinctions that cannot be reconstructed from the onboard observation history $\mathbf{o}_{t-H_{\text{hist}}:t}$, the student cannot replicate the teacher's behavior. Privileged information accelerates training convergence, but it cannot make physically unobservable states identifiable on hardware.

Consider the cage-door latch mechanism. A student network equipped with a temporal history can compare commanded motor efforts against observed joint accelerations over recent timesteps, inferring changes in contact stiffness or friction through the resulting mechanical resistance. However, identical joint kinematics can arise from multiple distinct physical causes, and an unobserved geometric offset in the strike plate cannot be inferred simply because the simulation teacher possessed that knowledge. A temporal convolutional network or transformer encoder can output a learned latent embedding of the environment, but its accuracy must be audited against physical ground truth. Adding auxiliary loss functions to predict privileged parameters during distillation regularizes the representation, but an auxiliary loss cannot create physical information that is absent from the underlying sensor stream.

Selecting the observation history length H_{hist} (distinct from the chunk horizon H) involves a trade-off in real-time estimator design. A window that is too short cannot filter high-frequency sensor noise or integrate enough kinematic evidence to distinguish sudden payload changes from transient disturbances. Conversely, an excessively long window increases onboard memory footprint, inflates neural inference latency, and risks diluting transient signals, such as the exact moment of initial mechanical contact, under an accumulation of pre-contact free-space observations. System qualification for the cage-door latch policy must verify contact-onset braking dynamics under the chosen history length while accounting for real hardware sensing delays. Buffering a longer temporal history in memory does not inherently add latency to incoming sensor frames, but the temporal encoder must be structured so that the newest observation immediately influences the output action.

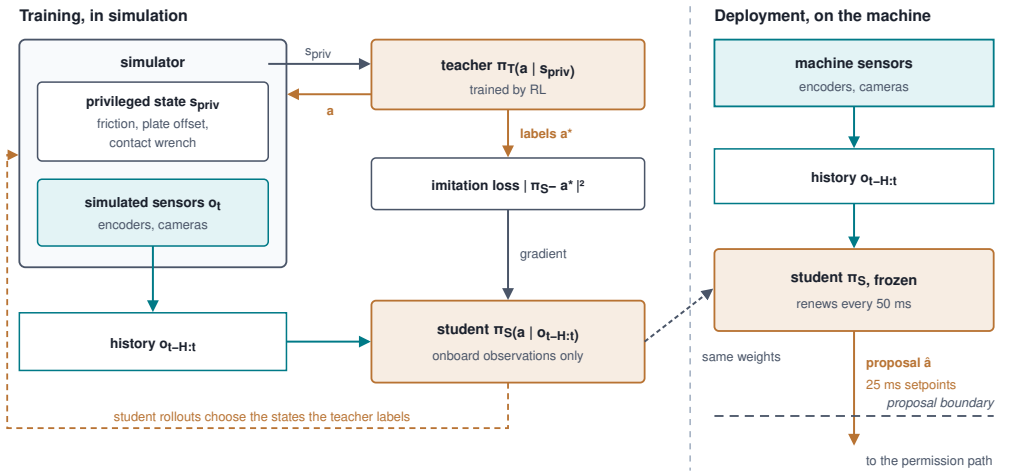

Figure 6.8: Teacher-student privileged state distillation: A schematic two-phase transfer pipeline. The teacher uses simulator state during training, and the student learns from onboard observations and their history. The training advantage does not establish that every privileged quantity is identifiable from those observations. On the machine, the frozen student renews a proposal every 50 ms and crosses the proposal boundary to the independent permission path; it still requires physical validation.

Checkpoint 6.2: Simulator fidelity and transfer

A simulator supplies cheap experience only for the mechanisms it models, and the evidence that it models them comes from the machine.

Sizing the gap

- ☐ **Parameter error vs. omitted mechanism**: Can you classify the rotor-inertia error, unmodeled backlash, and a missing transport lag of this chapter, say which of them domain randomization can cover, and explain why the latch's penalty stiffness, a parameter error, still sits in the omission log until a paired probe calibrates it?
- ☐ **Compliance estimate**: Suppose the push test returned exactly the break-even robot-side stiffness of notebook 6.3. How long after touch would a drive that keeps pushing at the fast approach reach the latch limit, and how does that compare with the plate-only contact yield deadline and the contact loop's response?

Crediting the result

- ☐ **Randomization range**: Can you explain why a range widened by a success threshold never enlarges the declared ODD, while a range set from a measured mechanism can be checked against the plant?
- ☐ **Privileged information**: Can you say which of the latch teacher's privileged quantities the student can recover from its observation history, and why it cannot infer an unobserved plate offset merely because the teacher knew it?

Even after system identification, domain randomization, and privileged state distillation, residual discrepancies persist in high-precision, contact-rich operational regimes. For the latch, both omission-log entries remain open. Engineers can resolve certain localized kinematic and friction mismatches through fine-tuning directly on the physical fixture. Physical training, however, consumes hardware operational life through mechanical wear and reopens qualification claims that depend on changed proposer behavior, timing, interfaces, or physical conditions. Every updated policy checkpoint produced by on-robot training demands fresh qualification evidence before it can be cleared for autonomous operation.

6.6 Real-Robot Fine-Tuning and Residual Control

Fine-tuning a simulation-trained policy directly on a physical robot to absorb a small fixture offset can fix the local contact error while overheating the motor windings, spending gearbox fatigue life on exploratory impacts, and silently corrupting the free-space approach trajectories that had already passed qualification. Mechanical assemblies rarely match their models exactly: on a warehouse cage door, for example, the physical strike plate may sit at a small mounting offset relative to its nominal position in the simulation model. By computing gradient updates directly from physical rollouts, on-robot fine-tuning adapts policy parameters to the true structural compliance, contact dynamics, and bus latencies of the hardware. However, because end-to-end policy gradients optimize cumulative task return rather than identifying individual system parameters, they do not isolate or quantify specific physical mechanisms. Unmodeled simulation discrepancies, such as an idealized contact spring or an omitted communication transport lag, therefore remain open in the engineering omission log until dedicated system-identification probes characterize them.

Furthermore, physical adaptation exacts a concrete hardware toll. In simulation, sampling aggressive state transitions near the boundaries of stability costs only compute cycles. On physical hardware, the exploratory actions and gradient updates that correct a contact error consume mechanical fatigue life and generate substantial heat in the motor windings. Every exploratory rollout risks driving the mechanism into an unrecoverable contact jam or an over-current trip, and unconstrained parameter updates can silently degrade nominal, previously certified behaviors.

Consider adapting the baseline policy `latch-sim-02` into `latch-res-03`, a residual candidate that adds a gated learned correction to the frozen `latch-sim-02` setpoints. This adaptation is motivated by the physical reality of the hardware fixture: the physical strike plate sits 1.5 mm away from its modeled location in simulation. The physical mechanism must guide a spring-loaded latch past this plate, where non-smooth Coulomb friction, cam surface geometry, and spring preloads produce sharp stick-slip transitions. The policy outputs setpoints every 25 ms (40 Hz). To adapt its control commands to the strike plate's contact dynamics, an on-robot fine-tuning routine collects 20,000 interaction steps, totaling 500 s of active contact and near-contact operation.

During exploration, stochastic perturbations can inject force transients faster than the low-level controller can reject them. If 1.5 percent of the sampled steps breach the 15 N contact tripwire, the fine-tuning run records 300 above-threshold samples. However, engineers must not mistake these raw sample counts for independent mechanical collisions. Consecutive over-threshold steps typically belong to a single sustained contact episode rather than multiple distinct impacts. Accurately counting mechanical shocks and evaluating their damage potential requires temporal event segmentation alongside continuous force-time telemetry.

Every mechanical impact transmits impulsive loads directly into the drivetrain. Translating that cumulative stress into an estimated expenditure of actuator service life requires an empirical, drive-specific load spectrum and fatigue life model. Actuator thermal dynamics impose a second, equally rigid operational boundary. Stochastic exploration dither elevates the root-mean-square current passing through the motor coils. Without explicit cooling intervals scheduled between training episodes, this continuous Joule heating can push motor windings to their thermal derating threshold within minutes.

Demonstrating improved performance on a specific contact fixture does not prove that the overall manipulation task remains sound. An optimization step yielding a parameter update $\Delta\theta$ produces an entirely distinct model checkpoint. Empirical evaluations gathered on the prior policy θ_0 remain historical observations of θ_0 alone; they do not substantiate safety claims for the updated weights. Gradient updates that successfully minimize contact forces on the strike plate can inadvertently distort free-space approach trajectories or degrade emergency stopping profiles in operational regions absent from the fine-tuning rollouts. Because physical trials consume valuable robot runtime and cause mechanical wear, requalification protocols must be strictly prioritized to verify both the targeted contact improvement and the baseline capabilities the update could destabilize.

Each updated checkpoint must carry its own explicit configuration manifest and regression evidence before deployment. Moreover, while optimization progresses on physical hardware, the safety permission path must actively evaluate every candidate action proposed by intermediate policies. Restricting where learned corrections may act keeps unconstrained weight updates from corrupting verified behaviors.

6.6.1 Residual policy architectures and bounded authority

To let `latch-res-03` adapt to the strike plate without perturbing its free-space approach, residual architectures freeze the base policy weights and multiply the learned additive correction by an independently enforced binary gate:

$$\mathbf{u}_{\text{nom}}(s) = \pi_{\text{base}}(s) + g(s)\,\Delta\pi_\theta(s), \tag{6.11}$$

where π_{base} is the frozen base controller, $\Delta\pi_\theta$ is a learned contact correction trained via reinforcement learning on the physical machine against the latch reward of equation 6.1, and $g(s) \in \{0, 1\}$ is an independently evaluated deterministic gate that equals one only within the certified contact envelope.

Both the base policy and the composite controller require explicit verification, because freezing an unverified base policy such as `latch-sim-02` does not make it qualified for deployment. Instead, the role of the gate $g(s)$ is structural: it forces the residual correction to evaluate *identically to zero* in free space and across all non-contact states. There, an absence of reward gradients during training would still allow a function approximator to output nonzero values on out-of-distribution inputs. Before any command reaches physical actuators, the permission path verifies the validity of the current state estimate (the machine's fused estimate of its own configuration, developed in chapter 9) and audits the proposed composite action.

Relying on a soft training loss, such as an action-norm penalty $\|\Delta\pi_\theta(s)\|^2$, merely biases the optimizer toward modest corrections during nominal rollouts; it offers no deterministic runtime guarantee. In contrast, the independent gate explicitly revokes residual authority whenever the robot operates outside designated regimes. Even with an architectural gate, the verification suite must evaluate transient switching behaviors at gate boundaries, state-estimation latency, execution timing jitter, and joint torque limits under the combined controller.

Imposing an output magnitude ceiling, $\|g(s)\Delta\pi_\theta(s)\| \le \Delta_{\max}$, restricts only one dimension of authority. A production permission path must also enforce slew-rate limits on the correction delta, prevent joint limit violations, verify multi-axis dynamic feasibility, and invoke the qualified fallback when active execution loses valid state, evidence, or lease. A late replacement proposal does not revoke a still-valid active prefix; that prefix may continue only within its own validity conditions. Furthermore, the authorized residual envelope must lie strictly within the verified stability margin of the *combined* closed-loop system across its intended operating envelope; checking an isolated torque limit against an idealized, single-axis specification is never sufficient. For the latch fixture, for instance, the architecture activates residual corrections exclusively during confirmed physical contact, enforces a hard zero via the gate throughout the free-space approach, and clamps joint torque slew rates. Following each optimization step on hardware, an automated regression suite must re-verify free-space trajectory tracking, contact engagement forces, emergency stopping, thermal duty cycles, and drivetrain shock profiles before granting operational authority to the new checkpoint. An improperly verified residual, even when clipped in magnitude, can still induce limit-cycle oscillations or drive the actuator gearboxes into saturation. Freezing the base policy and gating an additive residual is the most localized way to refine a policy with rewards; other post-training regimes modify the decoder's input noise or update every weight in the network, widening the regression scope accordingly.

6.6.2 Reinforcement learning after pretraining

The gated residual is one member of a broader family of post-training regimes. Every method that refines a pretrained policy using environmental rewards must specify which parameters are allowed to change, because updating shared weights to double throughput on one fixture can silently degrade baseline behaviors elsewhere. That choice determines how much regression evidence is required to re-qualify the resulting checkpoint. Modern robotic systems use four primary post-training strategies (table 6.3):

- **Residual control** freezes the base policy weights and learns an additive correction term, exactly as demonstrated by `latch-res-03`. This strategy has been successfully deployed to refine frozen chunked imitation policies for high-precision assembly, training the residual policy via PPO in simulation (Ankile et al. 2025). Residual architectures are straightforward to bound because independent hardware permission logic can directly gate, saturate, and rate-limit the additive output.

- **Noise-space steering** freezes every parameter of an underlying diffusion or flow-matching policy, training an auxiliary policy only to predict the initial latent noise vector supplied to the reverse diffusion trajectory. Every proposed trajectory still passes through the frozen generative decoder, so steering is restricted to outputs that decoder can generate. This restriction does not establish that those outputs lie within demonstrated support or satisfy physical limits. Furthermore, the optimizer requires only black-box sampling access to the base policy (Wagenmaker et al. 2025). Here, the support of the base distribution constrains the proposed behaviors; the independent permission path must still determine whether those proposals may execute.
- **Advantage-conditioned post-training** updates all network weights using supervised learning conditioned on advantage estimates. A learned critic evaluates the advantage of candidate actions across human demonstrations, autonomous rollouts, and real-time human interventions; the policy is then trained on this mixed corpus conditioned on target advantage and queried for high-advantage actions at run time. Rather than weighting gradients by the advantage or discarding failed trials, this formulation supplies an advantage indicator token as an additional conditioning input during supervised training so the network learns to associate suboptimal trajectories with negative advantage and successful recoveries with positive advantage, allowing runtime inference to prompt the policy with the positive-advantage indicator. Applied to generalist robot manipulation models, this approach more than doubled throughput and halved failure rates on the reported physical manipulation tasks (Physical Intelligence et al. 2025). However, because gradient updates modify every weight in the network, all nominal behaviors remain subject to drift.
- **Policy-gradient fine-tuning in simulation** applies reinforcement learning techniques (section 6.4.1) to update the weights of a pretrained vision-language-action policy using sparse or binary success rewards in parallel simulation (H. Li et al. 2025). Like advantage conditioning, this paradigm modifies all network parameters; in addition, it inherits every physical approximation and contact-solver idealization present in the underlying simulation environment.

Regression scope follows where the composite output can change and which execution assumptions the update affects. An independently enforced residual gate localizes the changed output, but regression still covers its active region, boundary transitions, combined closed-loop behavior, and timing and resource effects. Noise-space steering can change sampling throughout the base domain despite frozen decoder weights, so every affected operating mode requires regression unless a separate gate establishes a narrower scope. Full-weight updates can also alter behaviors across the entire operational envelope. A newly fine-tuned full-weight model demands complete end-to-end regression testing across all previously validated operational modes, and the system's `adaptation_wear_log` must document every modified parameter group. Whether adaptation rollouts accumulate physical machine wear on hardware or incur modeling dependencies in simulation, each rollout must be recorded in the policy manifest. No model can legitimately claim expanded operational authority without concrete validation data recorded in the system audit log.

Table 6.3: State of practice in robot policy training, as of 2026: Named systems that instantiate the mechanisms this chapter teaches, dated by their cited publications. The systems will be superseded; the mechanism and manifest columns are the durable part of the table.

Regime	Named Systems	Mechanism Taught in This Chapter	What the Policy Manifest Must Record
Pretrain, then post-train	Octo (Octo Model Team et al. 2024); OpenVLA (Kim et al. 2024); π_0 (Black et al. 2024); $\pi_{0.5}$ (Black, Brown, et al. 2025); GR00T N1 (Bjorck et al. 2025)	Pretraining on pooled multi-robot data, then supervised post-training on the task	Base weight digest; pretraining mixture as a known unknown; action-space mapping
Post-training recipe	OpenVLA-OFT (Kim et al. 2025)	Action chunking with parallel decoding and an ℓ_1 regression head	Decoder latency of the new head against the proposal deadline

Regime	Named Systems	Mechanism Taught in This Chapter	What the Policy Manifest Must Record
RL post-training on the machine	$\pi^*_{0.6}$ with RECAP (Physical Intelligence et al. 2025)	Advantage-conditioned updates from autonomous experience and corrections	Full-weight change; corrections as authority-record entries; regression over base domain
RL post-training in simulation	SimpleVLA-RL (H. Li et al. 2025)	Policy gradient with a binary success reward in a parallel simulator	Simulator provenance and omission log
Frozen-policy steering	DSRL (Wagenmaker et al. 2025)	Reinforcement learning over the decoder's input noise, base weights unchanged	Base digest unchanged; steering policy digest
Residual RL	ResiP (Ankile et al. 2025)	Residual trained by PPO on a frozen chunked imitation policy	Gate, magnitude, and slew limits; regression where the residual acts
Real-world RL from demonstrations	HIL-SERL (Luo et al. 2025)	Demonstrations, interventions, and a learned success reward with off-policy reuse	Success classifier as a learned sensor; interventions as authority-record entries
GPU-parallel simulation	Isaac Lab (NVIDIA, Mittal, et al. 2025); MuJoCo Playground (Zakka et al. 2025)	Batched, accelerator-resident physics feeding on-policy learning	Solver build and contact settings; throughput stated with its scene
World models	DreamerV3 (Hafner et al. 2025); V-JEPA 2 (Assran et al. 2025); Cosmos (NVIDIA, Agarwal, et al. 2025)	Learned dynamics for imagined rollouts, planning, synthetic data, and evaluation	Model weight digest and training data; generated experience unqualified

Bounded residual authority restricts the influence of an exploratory policy during execution, but it cannot alone prevent mechanical damage or eliminate latent vulnerabilities introduced during earlier training phases. Every stage of policy synthesis, from demonstration ingestion and simulation contact mechanics to residual adaptation, leaves a distinct behavioral signature on closed-loop execution. When an embodied machine develops high-frequency chattering, thermal derating, or semantic drift, systems engineers can trace that failure behavior directly back to the training assumptions, solver compromises, and architectural trade-offs that created it.

6.7 Training Failure Modes and Permission-Path Interceptors

A physical failure in a learned policy is rarely arbitrary. When an end-effector collides with a strike plate, that command reflects optimization over a specific dataset, loss formulation, and simulator dynamics, and the two failures that opened the chapter can now be traced back to theirs. The assumptions baked into that optimization leave a structural footprint on policy behavior, one that engineers can trace and mitigate before hardware ever runs. The **policy vulnerability inference chain** makes this causal trace explicit across five links: (Exposure → Dependency → Violated Assumption → Observable Signature → Permission-Path Interceptor). Training exposure establishes a learned dependency. An unmodeled deployment condition violates that dependency. The violation produces a measurable signature in the commands or physical plant telemetry. That signature names the specific runtime interceptor that the execution permission path requires. Reading the three latch checkpoints back through this chain shows how distinct optimization regimes produce different failure modes.

For `latch-bc-01`, behavioral cloning relies on the teleoperated openings. These demonstrations only support nominal plate alignment during the guarded approach; the data-collection campaign never demonstrated a displaced or misaligned plate. A sagging door frame directly violates that geometric dependency. The resulting failure signature is compounding covariate shift. Because behavioral cloning optimizes an open-loop supervised objective over expert trajectories, small drift errors compound at each control step. Individual motion proposals often remain physically plausible right up until the gripper mechanically binds against the frame. To prevent mechanical damage, a support monitor must evaluate runtime observations against the empirically supported demonstration cells and revoke policy authority outside them. Predeployment qualification follows directly from the known coverage gap that the scenario table of section 5.7.1 recorded: bench trials

with deliberately displaced plates must confirm that the support monitor trips reliably before the mechanism binds.

For `latch-sim-02`, training inside a physics simulator instills strong dependencies on idealized contact dynamics and negligible actuation lag. A physical steel plate violates both assumptions, generating sharp contact forces and unmodeled transport delays that produce the overforce transients quantified in section 6.4.2. Paired contact probes expose this dynamical mismatch before hardware deployment. If the physical contact deadline leaves insufficient time for closed-loop deceleration, a reactive force tripwire arrives too late. Detecting a force excursion confirms that an impact occurred, but actuator inertia and mechanical compliance will continue driving the mechanism into the plate before the brakes can arrest motion. The interceptor is therefore the pre-contact stopping envelope of section 6.4.2, which guarantees a full stop at the standoff before the plate and hands engagement beyond it to the separately qualified guarded contact mode.

For `latch-res-03`, adaptation concentrates real-robot experience on the contact states of a single hardware rig. Localized fine-tuning targets tight-tolerance contact dynamics on that specific fixture, but it does not qualify the frozen base across the rest of the operational state space. Unlike full-weight fine-tuning, which can introduce catastrophic forgetting, this gated residual retains the base weights and holds corrections at zero in free space; its primary regression risks arise from contact corrections and gate-boundary transitions. Before updated weights receive operational authority, they must clear a frozen regression suite that evaluates both nominal latch engagement and free-space flight. In addition, an architectural residual gate must hold corrections at zero outside the designated contact phase, preventing fine-tuned offsets from destabilizing the free-space approach. Physical exploration during real-machine tuning (section 6.6) also imposes mechanical shock and motor winding heat. The runtime supervisor must monitor these thermal and structural thresholds continuously to ensure that task reward improvements do not mask hardware degradation.

Subsequent training stages do not automatically heal the unresolved dependencies of earlier stages. In the simulation-and-residual lineage (`latch-sim-02` through `latch-res-03`), simulation artifacts persist until physical hardware evidence explicitly closes them. Conversely, the recovery-imitation branch adopts an alternative architectural path. The checkpoint `latch-bc-recovery-02` incorporates targeted, human-guided recovery demonstrations for a named displaced-plate condition, expanding the operational envelope without relying on an uncalibrated simulator. Its remaining engineering uncertainties, chiefly closed-loop trajectory stability and potential regression on nominal openings, are made explicit through targeted qualification requests.

Ultimately, each inference chain connects a specific training assumption to an empirical test and an active execution limit. The policy manifest preserves these connections alongside the checkpoint's source data, simulator configuration, optimization objective, and architectural constraints. By maintaining this end-to-end traceability, verification suites can systematically evaluate candidate policies against the exact physical vulnerabilities created by their training history.

6.8 The Policy Manifest

Handing a candidate checkpoint to an evaluation team with only its weight file and a training curve hides whether its behavior on a displaced plate comes from human recovery demonstrations, uncalibrated simulator rollouts, or pure network extrapolation. The candidate selection must distinguish nominal behavior supported by demonstrations, newly taught recovery, and contact behavior that still depends on unverified simulation. The failure chains of section 6.7 make that distinction concrete for each checkpoint; the record accompanying the candidate into evaluation preserves the reasoning, including the assumptions that remain open.

The **policy manifest** records how a checkpoint was produced (table 6.4). It lists the training stages and the data support the checkpoint inherits from the provenance records. It also lists the simulator versions, together with the **omission log** of mechanisms they leave out and mismatches paired probes have not closed. Finally, it records the wear incurred during adaptation and the operating domain the checkpoint declares. These fields state what evaluation must test and what runtime enforcement must accommodate. The runtime safety supervisor can check the manifest against its validated configuration before enabling a checkpoint. A declared boundary does not automatically generate a reliable detector or a safe clamp; those mechanisms require their own engineering and evidence.

The manifest separates optimization results from the conditions the policy may be asked to operate in. The **declared ODD** is the part of the ODD from section 5.7 that the policy manifest claims: the supported cells of the data join, minus every state the omission log excludes. High training reward or low offline loss does not show that the policy is safe outside it. The declared ODD is therefore computed from the join and the log, never from the training curve, and a convergent metric cannot stand in for clearance over regimes nobody characterized.

The separate `latch-bc-recovery-02` manifest consumes the original provenance and the stipulated `latch-recovery-02` archive, adding the positively displaced-plate cell at the guarded approach to the candidate domain with the expert recovery labels and held-out sessions identified by digest. Its qualification request asks whether the updated policy completes that recovery and preserves nominal service under the same physical limits. The original archive remains unchanged, and negative displacement and the fast approach remain excluded. Current provenance bounds the evidence already available, whereas collecting and qualifying new experience expands the machine's useful competence.

Table 6.4: Policy manifest schema: Fields the policy manifest adds to the provenance records it consumes, recording policy synthesis stages, any pretrained base checkpoint, inference execution parameters, data support by digest, physics engine specifications and their omission log, hardware fine-tuning wear, and the declared ODD.

Record Schema Field	Recorded Quantities and Artifacts	Provenance & Immutability Guarantee	Downstream Verifier & Usage
`regime_sequence`	Array of optimization stages (BC $\rightarrow$ SimRL $\rightarrow$ Distill $\rightarrow$ Residual), loss formulas, teacher privileged state dimensions $(\mathbf{w}, \xi)$, student observation history length H_{hist}, reward weights, and stopping criteria hashes	Git commit SHA, PyTorch/JAX checkpoint UUIDs, parameter hash $\text{hash}(\theta_k)$	Tracing which regime introduced latent failure modes or high-gain chatter
`base_checkpoint`	Weight digest of any pretrained checkpoint the policy started from, its source, the action-space mapping applied, and the layers post-training changed; the pretraining mixture recorded as a known unknown when it cannot be cited by digest	Base weight digest; never counted as data support	Scopes forgetting regression tests; confirms that no supported cell is attributed to pretraining
`policy_inference_contract`	Model architecture class, parameter count, checkpoint weights hash $\text{hash}(\theta)$, chunk prediction horizon H, execution horizon H_{exec}, decoder evaluations N_{eval}, inference deadline T_{chunk}, and chunk lease T_{lease}	Cryptographic checkpoint hash $\text{hash}(\theta)$, compiled engine digest	Parameterizes the runtime proposal buffer (section 3.5.1) and real-time lease monitor (section 4.4)

Record Schema Field	Recorded Quantities and Artifacts	Provenance & Immutability Guarantee	Downstream Verifier & Usage
`data_support`	Digests of the consumed provenance records and of the scenario table they were measured against; the `supported_cells` and `known_absences` of their occupancy join	Cites each provenance record by digest; no dataset field is copied	Upper bound on the declared ODD; parameterizes out-of-distribution support monitors
`negative_event_registry`	Authority-record entries (section 5.8) from training and adaptation rollouts	Cites each authority-record entry by digest; its pre-trigger trace is not copied	Isolating physical failure boundaries and preventing corrupted drift rollouts from training
`simulation_provenance`	Physics engine build, integrator method, timestep Δt, contact solver penalty parameters, and domain randomization ranges $\mathcal{P}(\Xi)$ with their source (measurement or curriculum); for a learned world model, its weight digest and training data	Physics engine binary hash, robot model asset tree hash (URDF/MJCF)	Reproducing the training physics and auditing paired-trace budgets
`omission_log`	Mechanisms each simulator leaves out (backlash, compliance, transport lag) and the residual mismatches paired probes did not close, with the states each one affects	Bound to the simulator build it describes; an entry closes only on paired-trace evidence	Removes the states it affects from the declared ODD; carried into evaluation's coverage gaps and the fault list
`adaptation_wear_log`	Serialized hardware IDs, contact shock counts, motor current RMS thermal logs, modified layer indices, and regression suite hash	Calibration certificate hashes, hardware lifetime fatigue logs	Re-opening formal qualification cases and preventing silent regression of nominal capabilities
`declared_odd_boundary`	Declared ODD: the supported cells minus the states the omission log excludes (for the latch policy, the nominal strike plate at the guarded approach speed)	Never exceeds the supported cells of `data_support`	Bounds the target ODD that evaluation may sample and the region in which the permission path admits policy proposals

For the original latch campaign and its simulation-residual lineage, a compact manifest links the fields into one decision:

- `regime_sequence`: demonstration checkpoint `latch-bc-01` → `latch-sim-02`, a student initialized from `latch-bc-01` and distilled from a simulator teacher trained by reinforcement learning on privileged state (privileged contact wrenches $\mathbf{w}$ distilled into an 8-step observation-history buffer) → gated residual candidate `latch-res-03`. Retain each checkpoint hash, loss or reward specification, and stop rule.

- `base_checkpoint`: no pretrained robot policy underlies the latch checkpoints, which descend from `latch-bc-01` as `regime_sequence` records; any pretrained image encoder they use belongs here by digest. A candidate post-trained from the machine's intent model would record that model's weight digest, its pretraining mixture as a known unknown, and its action-space mapping, and would inherit the same declared ODD (section 6.2.8).
- `policy_inference_contract`: specify checkpoint weights hash hash(θ), the machine's 80M-parameter ACT architecture with one decoder pass per chunk, chunk prediction horizon $H = 16$ setpoints at 25 ms, and the 40 ms p99 inference target. Record the selected execution prefix separately from the 50 ms proposal-renewal deadline and the selected chunk lease. Each renewed prefix requires valid evidence and a feasible continuation or fallback; the prediction horizon is not the active lease.
- `data_support`: cite the latch campaign's provenance records and its scenario table by digest; their join supports the nominal strike plate at the guarded approach, and lists the displaced plate and the faster approach, whose cells hold no demonstrations, as known absences with no recovery label.
- `simulation_provenance`: record the actual solver build and contact parameters.
- `omission_log`: the example simulator models strike-plate contact with a penalty spring far softer than the plate and omits actuator transport lag, so the contact states those two departures govern are unverified for the checkpoints trained in simulation.
- `negative_event_registry`: cite by digest the authority-record entry, with its pre-trigger ring-buffer trace, for every fixture-shoulder strike, operator veto, or permission-path clamp with its event classification, without treating rejected learner commands as expert targets. Mark episodes an operator truncated, so that an update does not score an aborted command as a success.
- `adaptation_wear_log`: associate `latch-res-03` with the specific rig, above-threshold samples and separately identified contact events, motor-current history, modified residual weights, and free-space regression result.
- `declared_odd_boundary`: the supported cells minus the states the omission log excludes, here the nominal plate at the guarded approach of 0.03 m/s. The contact states governed by the two omissions stay outside the declared ODD for every simulation-refined checkpoint, `latch-sim-02` and `latch-res-03` alike, until paired probes close them. The displaced plate and the 0.10 m/s approach lie outside it, and the fast approach would stay outside even with demonstrations, because its contact deadline (section 6.4.2) leaves almost nothing beyond the contact-loop response. There the permission path must impose the guarded approach or refuse policy authority.

A qualification review would withhold operational authority from `latch-res-03` until paired contact probes quantify the contact-stiffness error and the omitted lag, and the combined controller passes contact, free-space, stopping, and wear-budget tests. With only the original campaign, the same rule leaves `latch-bc-01` as the checkpoint evaluation may sample, provided the support monitor of its chain refuses policy authority off the nominal plate (section 6.7). Trained without a simulator, it carries no omission-log exclusions, so its declared ODD keeps the door's contact states at the nominal plate and the guarded approach. The manifest records that decision and its evidence rather than converting a training score into permission.

The manifest references the collector, plant, calibration, and action taps through the provenance record of section 5.11. The cited digests preserve which data and scenario table produced the checkpoint; later changes require a new record rather than silently updating its lineage. Simulator provenance similarly fixes the solver and timestep[12] used during optimization. Its separate omission log carries unresolved discrepancies from section 6.5 into evaluation's coverage gaps and fault-injection tests.

Downstream engineering teams consume the manifest throughout the design, evaluation, and release lifecycle. The evaluation record of section 7.8 consumes it directly. Its target ODD is sampled from inside the declared ODD, and its catalog of coverage gaps inherits the known absences and the omission log, so evaluation suites probe the specific failure modes each training regime predicts. Targeted exploratory tests outside the candidate domain can also identify gaps, but they do not

12 **Penalty-Contact Timestep**: The contact timescale scales as $\sqrt{m_{\text{eff}}/k_{\text{eff}}}$. For the latch's 9 kg moving mass it is about 24 ms against the soft penalty spring and 4.7 ms against the real plate, so a timestep sized to resolve the simulated contact is about 5× too coarse once the spring is stiffened to match the plate. The integrator, damping, and solver tolerances set the final step, which is refined until contact onset, peak force, and impulse converge.

establish an operational claim there without new support and qualification. The permission path takes the declared ODD as the outer limit of the region in which it admits policy proposals, and uses the recorded support to parameterize out-of-distribution detectors. Verification and the safety case draw on the manifest to establish the provenance of every parameter update and to confirm that each omission is bounded by an independent physical interlock.

↪ The omission log becomes one of the upstream records from which fault records are compiled for release, developed in section 15.11.

> **Checkpoint 6.3: Policy manifests and declared ODDs**
>
> Before releasing a trained policy checkpoint to physical verification, confirm the following relationships between the policy manifest, its omission log, and the declared ODD:
>
> - ☐ **Complete the latch record**: A fixture-shoulder strike appears after `latch-res-03` was trained with a soft penalty contact and no actuator lag. Which omitted mechanism belongs in `omission_log`, and which paired probe and admission decision must the manifest record?
> - ☐ **Confining the declared ODD**: Suppose demonstrations were collected at the fast approach and every omission-log entry were closed by paired probes. Why would the latch policy's declared ODD still exclude the fast approach, which timing comparison decides it, and what must the permission path impose on a proposal that arrives at that speed?
> - ☐ **Negative event logging**: Why does the manifest keep the pre-trigger trace of an operator veto or fixture strike as labeled failure evidence rather than as an imitation target?
> - ☐ **Declared operational boundaries**: `latch-bc-01` proposes to open the door while the strike plate sits displaced from its nominal mount. How does the permission path use the `data_support` field to classify that state as ungrounded extrapolation rather than demonstrated competence, and why does a confident policy output not change the classification?

The manifest turns a training history into a claim with stated limits. The original record sends `latch-bc-01` to evaluation and keeps `latch-res-03` out of service until paired probes and regression tests close its gaps. The stipulated recovery record sends `latch-bc-recovery-02` with a wider, explicitly testable candidate claim. The common ways that decision goes wrong all let a training score stand in for that evidence.

6.9 Fallacies and Pitfalls

Minimizing loss on an offline demonstration split or maximizing cumulative return in simulation measures compliance with training assumptions rather than physical competence on hardware. When an objective rewards behavior that exploits a curated demonstration distribution or a simulator approximation, the ranking of candidates established in training can invert on deployment. The candidate that scored highest in simulation finishes lowest on hardware, through unsupported state drift, contact-force spikes past the structural limit, or torque oscillations that grow into resonant chatter (figure 6.9). Virtual environments forgive maneuvers that physical hardware penalizes with tripwires, resonance, or thermal overload, so the causal assumptions connecting a training metric to physical execution have to be tested before a policy receives actuator authority.

Pitfall: *Sanitizing recovery episodes to achieve lower offline validation loss.*

Suppose an archive of latch manipulation demonstrations includes human recovery maneuvers, and two separate policies train on competing subsets of this corpus. One policy trains on the full archive, including episodes where a human teleoperator backed off the gripper and re-aligned the jaws after the latch cam caught on the strike plate. The second policy trains on a sanitized subset stripped of all hesitation and retries, achieving a markedly lower loss on its held-out validation split. When deployed on the physical cell, both policies eventually encounter a misaligned cam. The first policy recognizes the contact anomaly, backs off, and seats the latch successfully. The second policy relentlessly drives along the nominal path, building contact force until the safety supervisor's force tripwire halts the cell. Because the sanitized dataset excluded off-nominal recoveries, the lower validation loss proves only that predicting smooth nominal trajectories is easier to fit than handling

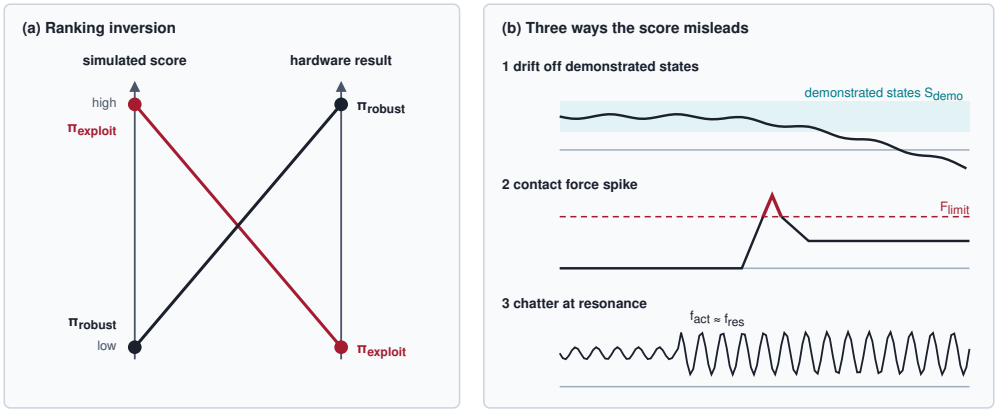

Figure 6.9: Illustrative policy ranking inversion: (a) A constructed slope graph shows how a candidate favored by a simulated score can lose its advantage under physical evaluation. (b) Possible causes include unsupported recovery states, contact mismatch, and actuator chatter. The rankings are a teaching example, not measured results for the latch checkpoints.

physical disturbances. Pruning corrective demonstrations simplifies the loss score at the exact price of removing the feedback behaviors the physical controller needs off the nominal path. **Filtering out recovery trajectories to drive down offline prediction loss strips the policy of the corrective demonstrations required to escape compounding physical errors.**

Architect's countermeasure: Retain all authority-record entries during dataset ingestion and admit, as training targets, only the stabilized, human-reviewed segments of attributable expert recoveries. Never prune demonstration corpora to minimize offline validation loss, and mandate closed-loop physical perturbation benchmarks to verify recovery competence before signing off on deployment candidate checkpoints.

Fallacy: *Transitioning from human demonstrations to simulation reinforcement learning removes the failures training left in the policy.*

An assembly team switches from behavioral cloning to simulation reinforcement learning to eliminate lateral drift during automated gasket seating. The resulting policy cures the drift in the virtual environment but commands joint torque oscillations at 65 Hz. The physics simulator permits this aggressive chatter because its rigid-body solver assumes massless motor rotors and instantaneous torque reversal. On the physical machine, this high-frequency command excites drivetrain mechanical resonance and rapidly heats the motor windings toward their thermal trip point via $i_q^2 R$ Joule losses. The drive electronics throttle current to prevent permanent motor damage, causing the assembly stroke to stall before seating completes. Shifting training regimes solved an imitation drift problem by introducing a high-frequency chatter exploit that the simulator did not penalize. Qualification must therefore evaluate the full physical task under sustained cyclic operation, verifying simulator dynamics assumptions against physical hardware telemetry. **Switching to simulation reinforcement learning substitutes numerical solver shortcuts and unmodeled mechanical dynamics for human demonstration deficits.**

Architect's countermeasure: Require paired-trace validation across all four reality gap channels before deploying simulation-trained policies. Enforce low-level hardware rate limiters and digital low-pass action filters ($f_{\text{cutoff}} \leq 20$ Hz) within the embedded motor drives to suppress high-frequency chatter originating from unmodeled rotor inertia.

Fallacy: *Assuming online gradient updates preserve predeployment safety envelopes.*

When a simulation-trained policy shows steady-state positioning error on a physical assembly fixture, an engineer might enable online policy-gradient fine-tuning directly on the robot. After 5,000 gradient steps, the arm successfully eliminates contact positioning error at the fixture, prompting the team to declare the updated model production-ready. Applying parameter updates $\Delta\theta$ directly to the policy network, however, produces an entirely new checkpoint with changed weights.

The behavioral trials accumulated during predeployment qualification remain observations of the original checkpoint and do not establish performance of the updated one. Independent permission and fallback properties may remain applicable only while their plant, timing, authority, isolation, and realization premises hold; integration must check those premises after the update. While local contact accuracy improves, unconstrained backpropagation into shared representations triggers catastrophic forgetting in rarely visited state-space regions. As a result, the fine-tuned policy may lose stability during high-speed free-space slews or corrupt its emergency deceleration profiles. Because physical robot time and mechanical wear preclude repeating full-scale testing suites on hardware, regression suites must isolate and verify every operational envelope that gradient updates might perturb. **Online gradient updates require fresh behavioral qualification and reopen every assurance claim that depends on the changed checkpoint or execution conditions.**

Architect's countermeasure: When a bounded correction suffices, use gated residual policy architectures ($\mathbf{u}_{\text{nom}} = \pi_{\text{base}} + g(s)\,\Delta\pi_\theta$) with an externally enforced binary gate ($g(s) \equiv 0$ in free space) to localize real-world adaptation. Mandate automated, frozen non-regression suites that verify trajectory tracking and stopping profiles before granting execution authority to updated parameters.

Fallacy: *Believing that widening parameter distributions can substitute for missing physical mechanisms.*

When an assembly policy repeatedly fails on physical hardware, an engineering team might attempt to brute-force sim-to-real transfer by radically widening the simulator's domain randomization bounds. They randomize link masses by ±50 percent and vary surface friction coefficients across the extreme interval from 0.05 to 1.5. On the physical test bench, however, the trained policy behaves poorly: it moves sluggishly through free space and hesitates indefinitely upon initial contact. Randomization perturbs coefficients exclusively within the governing differential equations already hardcoded in the physics engine. It cannot synthesize missing physical phenomena such as gearbox backlash, joint cable compliance, Stribeck friction, or sensor transport jitter. When dynamically incompatible virtual plants produce indistinguishable observations, a memoryless policy cannot choose separately for each plant; average-return optimization may favor a slow compromise or may sacrifice low-probability cases. While recurrent or history-conditioned architectures can adapt to wide parametric variations by estimating system properties online, even an adaptive policy cannot identify or compensate for physical mechanisms that never existed in its training simulator. **Expanding parameter randomization bounds merely shifts the probability distribution across existing simulator equations; it cannot synthesize unmodeled physical dynamics.**

Architect's countermeasure: Calibrate baseline physics engine parameters against real hardware test fixtures before introducing domain randomization. Explicitly document whether parameter distributions derive from empirical instrument measurements or heuristic curricula such as automatic domain randomization. Enumerate known physical omissions, including transmission elasticity and actuator deadbands, in the policy manifest's omission log, ensuring that hardware-level safety watchdogs bound operations within verified modeling assumptions.

Fallacy: *Assuming multi-step generative decoders can execute synchronously within inner actuator control loops.*

Aiming to capture multimodal trajectory distributions observed in offline demonstration logs, an engineer replaces the single-pass ACT feedforward decoder in `latch-bc-01` with an iterative 16-step diffusion denoising head. The team deploys the new architecture synchronously into the robot's real-time inner control loop, scheduling a complete iterative sampling cycle for every 25 ms actuator setpoint. Under the hardware inference budget evaluated in section 6.2.6, executing all denoising steps consumes 48 ms, exceeding the allowable control step deadline. Because the synchronous dispatch pipeline stalls awaiting model convergence, the system routinely misses setpoint deadlines. The low-level controller must either freeze on stale command setpoints or trip safety watchdogs on every iteration overrun. The weight-streaming floor of section 3.4.1 bounds each evaluation from below, and section 3.5.1 shows that re-reading the action head on every evaluation can dominate the decoder's cost. Each of the 16 dependent evaluations pays that floor, so the sum misses the setpoint deadline before scheduling jitter is even counted. **Deploying multi-step generative policies into high-rate actuator loops requires decoupling iterative trajectory generation from real-time setpoint tracking through asynchronous execution contracts.**

Architect's countermeasure: Decouple iterative policy inference from high-frequency actuator control loops whenever measured inference latency approaches the control period. Formally partition the pipeline into an asynchronous planner generating trajectory chunks and an inner controller tracking them under qualified execution leases. Explicitly track prediction horizons, executed setpoint prefixes, and proposal renewal deadlines. Buffering trajectory chunks never grants permanent operational authority: the execution engine continuously validates physical safety invariants and triggers safe stopping profiles whenever a lease expires without a fresh proposal.

6.10 Summary

A policy's weights keep what its training experience rewarded and forget which experience that was, so each regime is best remembered by the dependency it leaves behind. Demonstrations leave a dependency on coverage: a point-regression head averages valid modes into an action no one chose, and even a multimodal head drifts into states the demonstrations never recovered from. A reward-labeled log leaves a dependency on the support of the logged actions, and a pretrained base on someone else's embodiment. Trial on the machine pays for its experience in calendar time, winding heat, and drivetrain life. Simulation pays almost nothing per trial but inherits every approximation in its contact solver and every mechanism it omits. Fine-tuning on the machine creates a new checkpoint that needs its own behavioral evidence and review of affected assurance premises. None of these dependencies shows in a validation loss or a simulated return.

Orthogonal to the source of experience, every policy must deliver its proposal inside the machine's deadline T_{deadline}. The decoder that represents several modes buys that representation with dependent evaluations, and what decides whether it can run is renewal slack against the jitter allowance, not mean latency. When slack runs out, the chunk lease, not the decoder, bounds how long an admitted prefix keeps moving the arm.

The policy manifest gathers these dependencies into one claim with stated limits. Its declared ODD is the supported cells of the data join minus every state the omission log excludes, never a region read off a training curve. For the latch, that rule sends `latch-bc-01` to evaluation at the nominal plate and the guarded approach. It holds the simulation-refined checkpoints until paired probes bound the contact and timing omissions. It also lets `latch-bc-recovery-02` carry a wider claim that new recovery experience has to earn. An admitted action crossing the causal boundary carries no guarantee beyond the evidence that qualifies it, and the load-bearing relations behind that evidence are collected in table 6.5.

Table 6.5: Key equations of policy training: Each load-bearing equation of the chapter, the limit it bounds or the decision it settles, and the equation where it is derived.

Equation	What it bounds or decides	Derived in
$\pi^*(\mathbf{o}) = \mathbb{E}[\mathbf{a} \mid \mathbf{o}]$	The squared-error optimum of a point-regression policy, which lies between demonstrated modes	equation 6.3
$Q^\pi(s,\mathbf{a}) = r(s,\mathbf{a}) + \gamma\,\mathbb{E}[Q^\pi(s',\mathbf{a}')]$	The value recursion that offline and policy-gradient learning estimate from samples	equation 6.2
$t_{\text{infer}} = t_{\text{enc}} + \sum_{k=1}^{N_{\text{eval}}} t_{\text{pass}} \le T_{\text{deadline}}$	Whether a decoder fits the setpoint step synchronously or the renewal period asynchronously	equation 6.4
$T_{\text{wall}} = N\,(t_{\text{rollout}} + t_{\text{reset}})/N_{\text{rig}}$	The calendar of a physical training campaign, which rigs divide but wear does not follow	equation 6.5
$F_{\text{unbraked}} = v\sqrt{k_{\text{contact}}\,m}$	The peak force of a mass coasting into a contact, which a soft penalty spring understates	equation 6.7
$k_{\text{eff}} = (1/k_{\text{latch}} + 1/k_{\text{robot}})^{-1}$	The robot-side stiffness above which a coasting approach exceeds the latch limit	equation 6.8
$t_{\text{yield}} = F_{\text{lim}}/(k_{\text{contact}}v)$	The time from touch to the force limit under constant drive, which confines the declared ODD to the guarded approach	equation 6.9
$J_{\text{DR}}(\theta) = \mathbb{E}_{\xi\sim p(\xi)}[J(\theta;\xi)]$	Return averaged over the parameters a simulator models, never over mechanisms it omits	equation 6.10

Equation	What it bounds or decides	Derived in
$\mathbf{u}_{\text{nom}} = \pi_{\text{base}} + g(s)\,\Delta\pi_\theta$	Where a learned residual may act, and so what the regression evidence must cover	equation 6.11

Key Takeaways: Policy synthesis and sim-to-real transfer

- **Every regime leaves a dependency no training score shows:** Offline loss and simulated return reward compliance with training data and numerical solvers rather than real-world physics. Candidate model rankings frequently invert when transferred to hardware. When an operating condition violates an unmodeled dependency, it produces a predictable failure signature that identifies exactly which runtime monitor the permission path must enforce.
- **Mode choice and recovery are separate problems:** Point regression can average valid, mutually exclusive demonstrations into an unviable intermediate action, whereas compounding execution drift pushes the system into states that the demonstrations never sampled. Multimodal decoders resolve action ambiguity; targeted recovery experience and closed-loop data resolve distributional drift. Independent runtime limits remain mandatory for both.
- **Decoder latency must fit the proposal contract:** Iterative denoising and deep autoregressive evaluations substantially increase compute latency and memory bandwidth pressure. When a policy cannot generate actions within the synchronous deadline, asynchronous action-chunk playback requires a validated hardware lease and deterministic fallback behavior. An expressive action distribution earns no extra execution time at the actuator.
- **Training information must survive the sensor boundary:** Privileged simulation states, such as ground-truth contact wrenches or global object poses, accelerate training, but the deployed student policy observes only noisy onboard sensor streams. Observation histories disambiguate physical variations only when those conditions leave distinct temporal signatures. Model distillation never removes the necessity for hardware calibration and empirical transfer testing.
- **Randomization covers parameters, not missing mechanisms:** Domain randomization widens policy robustness across modeled simulator parameters, but it cannot bridge physical effects that the numerical solver neglects. Backlash, unmodeled compliance, and sensor transport delays remain absent regardless of parameter range, requiring explicit entries in the omission log and channel-by-channel probe characterization on hardware.
- **Fine-tuning spends wear and reopens qualification:** On-robot trials consume component life, introduce thermal stress, and generate wear that cannot be parallelized across separate test rigs. Behavioral evidence gathered for an earlier checkpoint does not qualify an updated model, and independent permission properties require an integration check of their unchanged premises. A gated residual architecture strictly confines where learned adaptations take effect, but the integrated controller still demands thorough regression testing and hardware-level execution limits.
- **A wider declared ODD needs new support:** The policy manifest records dataset digests, training hyperparameters, and unmodeled simulator phenomena, explicitly excluding operational domains affected by unverified gaps. Scaling simulator throughput or pretraining a foundation model adds no supported cell to the declared ODD. Broadening the deployment boundary requires attributable physical recovery data and rigorous closed-loop hardware qualification.

The declared ODD is where the second law, endogenous data (principle 2), becomes a field in a record. A policy chooses its next observations by acting, so the states it meets in service are not the states its training visited, and no regime in this chapter escapes that. Cloning meets it as drift out of the demonstrated tube, learning by trial on the machine meets it as calendar time and wear

spent visiting the policy's own states, and simulation meets it as states whose dynamics the solver invented. The manifest does not remove the dependency. It writes down where the policy's own evidence ends, so that everything beyond that line is treated as a claim still to be earned rather than as competence the weights happen to display.

When a candidate looks better than its evidence, the useful question is which of its states were visited on this machine and which were only scored. A wider declared ODD is bought with experience that joins to new cells, and choosing a training regime is choosing what that experience costs: an operator's hours, a drivetrain's life, or a probe campaign that closes a simulator's omissions.

6.11 Historical Perspective and Further Reading

The mathematical foundations of modern policy optimization originate in classical dynamic programming. Bellman (1957) introduced the principle of optimality and the recursive decomposition that defines value functions, while Howard (1960) formulated policy iteration to solve discrete Markov decision processes. Parallel to dynamic programming, learning from demonstration developed along an empirical path in robotics. Pomerleau's ALVINN demonstrated early autonomous road following by training a shallow artificial neural network to map camera images directly to steering angles (Pomerleau 1989). ALVINN quickly exposed the vulnerability of pure behavioral cloning to covariate shift and compounding error. The network trained exclusively on demonstrations from an attentive human driver, so it never encountered the off-center heading angles produced by its own steering mistakes, which led to catastrophic departures from the roadway (Pomerleau 1991). Ross et al. (2011) formalized this failure mode through the Dataset Aggregation (DAgger) algorithm, proving no-regret reduction bounds by querying an expert supervisor on the actual state distribution induced by the learner's policy. When demonstrations encompass multiple valid strategies, naive regression averages distinct modes into invalid intermediate actions. Mixture density networks (Bishop 1994) resolved this multimodality for low-dimensional outputs, and diffusion policies (Chi et al. 2025) generalized the approach to high-dimensional action trajectories, executing action chunks with receding horizons on physical manipulators.

Algorithmic reinforcement learning split into two primary branches: policy-gradient methods originating with REINFORCE (Williams 1992) and value-based temporal-difference learning formalizing around Q-learning (Watkins and Dayan 1992). Both paradigms measure sample complexity in abstract environmental transitions, ignoring the physical costs of real-time execution. On a real robot, every trial consumes calendar time, strains mechanical linkages, overheats actuators, and demands human intervention for environment resets. Large-scale physical grasping campaigns (Levine et al. 2018; Kalashnikov et al. 2018) demonstrated that collecting hundreds of thousands of real-world interactions requires dedicated robot farms running continuously for months under heavy maintenance. To bypass this physical bottleneck, robotic learning shifted sample generation into simulation. Proximal Policy Optimization (Schulman et al. 2017) established itself as the standard policy learner by clipping the update objective to discourage excessive policy drift. Simultaneously, physics engines co-located directly on hardware accelerators eliminated host-to-device communication bottlenecks, enabling thousands of parallel rollouts on a single workstation and delivering billions of simulated timesteps per day (Makoviychuk et al. 2021; Rudin et al. 2022).

Simulated rollouts solved the sample-throughput bottleneck, but they elevated the reality gap into the central engineering challenge. Policies trained inside idealized physics often fail catastrophically when deployed against the unmodeled friction, latency, and compliance of physical hardware. Domain randomization addressed this discrepancy by treating the real world as an unobserved draw from a randomized distribution of simulated environments, perturbing visual features (Tobin et al. 2017) and inertial dynamics (Peng et al. 2018). The OpenAI Dactyl project (Andrychowicz et al. 2020) showed that broad dynamics randomization paired with a recurrent policy could reorient a block in a dexterous hand trained entirely in simulation, while reporting the unsimulated failures of the physical hand, chiefly hardware breakage under load. Its successor extended the approach to solving a Rubik's cube with automatic domain randomization (OpenAI et al. 2019). Classical system identification (Ljung 1999) found new life inside neural pipelines through learned actuator networks that capture non-ideal actuator dynamics and drive compliance (Hwangbo et al. 2019). More recently, generalist foundation policies trained across diverse robotic platforms (Kim et al. 2024; Black et al. 2024) use pooled fleet demonstrations to cross-train visual and motor representations.

However, borrowing cross-embodiment data introduces unverified physical assumptions and subtle distributional shifts. The policy manifest introduced in this chapter provides the rigorous systems contract required to track these lineage dependencies, documenting simulation distributions, sensor bounds, and training assumptions so that hardware deployment can be audited and verified.

Six foundational works trace the trajectory from classical dynamic programming to modern sim-to-real policy deployment:

- Sutton and Barto (2018) provides the definitive derivation of Markov decision processes, value functions, and policy-gradient theorems from first principles, serving as the core reference for the reinforcement learning formulations in section 6.2.1.
- Ross et al. (2011) establishes the theoretical bound on compounding error in sequential prediction, introduces the DAgger reduction algorithm, and outlines the recoverability assumptions that section 6.2.4 evaluates on physical robot hardware.
- Chi et al. (2025) introduces score-based diffusion models for action sequence generation on physical manipulators, establishing the receding-horizon chunk execution and iterative denoising computational budgets analyzed in section 6.2.6.
- Peng et al. (2018) focuses domain randomization on unmodeled physical dynamics rather than visual textures, demonstrating that recurrent policies implicitly identify system dynamics across randomized friction, mass, and damping distributions to achieve robust sim-to-real transfer.
- Andrychowicz et al. (2020) offers one of the most comprehensive engineering case studies of an end-to-end sim-to-real deployment, detailing the distributed training pipeline, dynamics randomization ablations, and physical maintenance challenges encountered while reorienting a block with an anthropomorphic hand.
- Ljung (1999) provides the definitive treatise on classical system identification, detailing the input-output parameter estimation techniques, excitation design, and validation metrics that ground modern actuator modeling and paired physical probing.

What's Next: From policy manifests to evidence

Twenty successful consecutive trials provide limited statistical confidence for a demonstration checkpoint whose manifest declares a single nominal cell and inherits none of the simulator's omissions. Chapter 7 takes the formal policy manifest as its contractual input. It opens with an illustrative campaign of twenty nominal door trials of `latch-bc-01`, the single cell its manifest declares, and evaluates the bound so small a physical sample can establish. It then evaluates `latch-bc-recovery-02` through nominal regression and displaced-plate trials to decide whether the new recovery experience earns the wider claim its manifest requests within the guarded approach.

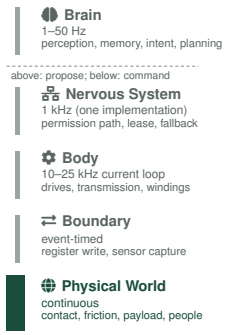
Purpose

Why can a robot pass every trial and still lack the evidence needed for deployment?

A robot that repeatedly opens one door has supplied evidence about that door, its own hardware, and the conditions of those trials. It has not established how it will behave at a displaced latch, with a different payload, or after its sensors drift, and a flawless record from a short campaign remains consistent with a policy that fails a substantial fraction of its attempts. Its admitted actions also change the observations it receives, so agreement with recorded demonstrations cannot substitute for testing the resulting motion. Physical trials expose that feedback, but each consumes time and mechanical life, every further factor of ten in demonstrated reliability costs roughly ten times the trials, and protective interventions stop some trajectories before their consequences unfold. A team that reads a clean record as readiness releases the machine into conditions no trial visited and credits the learned policy with protection its supervisors supplied. Evaluation exists to prevent that error. It ties each task outcome to the conditions sampled, keeps every intervention in the record, states the uncertainty that remains, and names the uncovered conditions the rest of the machine must guard. Because actions cross an irreversible causal boundary, evidence of policy competence must remain distinct from permission to move.



Learning Objectives

- Interpret physical success rates as conditional evidence about a specified machine, environment, and trial protocol
- Interpret completion and intervention metrics without crediting the policy for protection supplied by its supervision
- Compare open-loop prediction accuracy with closed-loop behavior shaped by the policy's own actions
- Select the evidence regime (replay, simulation, shadow operation, or constrained physical testing) that can answer a given evaluation question
- Design a predeclared trial protocol with fixed outcome rules and full-denominator accounting of interventions and aborts
- Calculate confidence bounds, trial counts, and test time for a zero-failure campaign under stated sampling assumptions
- Construct an evaluation record that bounds its operational claim and identifies coverage gaps and required protections
- Evaluate which rare failures remain unsupported by feasible testing and the available statistical assumptions
- Apply sequential stopping rules and two-policy comparisons without inflating the error rate a campaign declares

7.1 From Clean Runs to Bounded Claims

The checkpoint `latch-bc-01` arrives from offline imitation learning with a policy manifest that declares exactly one supported condition, the nominal strike plate at the guarded approach. The manifest marks where the policy's training evidence ends, and evaluation asks what physical trials can establish inside that line. The recovery candidate `latch-bc-recovery-02`, whose wider claim new experience still has to earn, receives its own campaign later in the chapter (section 7.8.1). `latch-bc-01` is flashed onto the warehouse mobile manipulator for a nominal validation campaign. In each trial, the mobile base begins 2 m (illustrative; see the Reader Guide) from the spring-latched cage door, drives forward, and comes to a complete halt. With the base at rest, the manipulator executes a guarded approach at 0.03 m/s, unlatches the mechanism, and opens the door without crossing the 15 N contact tripwire or drawing a human intervention. Suppose the robot completes twenty consecutive runs this way, an empirical success rate of $\hat{p} = 1.00$ (100 percent). On a static vision or language benchmark, an unblemished score might suggest that the model is ready for production. On physical hardware, twenty clean runs leave the deployment decision open. They establish only a wide lower confidence bound, one that a policy failing a substantial fraction of its attempts can still satisfy, and they reveal nothing about failure modes too rare to appear in twenty draws.

↩ The policy manifest, which records how a checkpoint was produced and the operating domain it declares, is established in section 6.8.

The gap between that perfect score and a deployable claim comes from three ways in which physical evaluation departs from the static protocol of machine learning. In that protocol, engineers draw a held-out dataset once from a stationary distribution, score each example independently, and treat the aggregate as a faithful descriptor of model quality. First, a physical policy selects its own test distribution. Every admitted action alters the environment and determines the observations that follow, so no pre-recorded dataset can stand in for the states the policy will visit. This is the second law, endogenous data (principle 2), acting on evaluation. The same feedback that pushes a cloned policy off its demonstrations also decides which states a test campaign samples. Second, every trial consumes test-cell time, battery charge, and mechanical life, which keeps sample counts small and each sample expensive. Third, a physical trial delivers kinetic energy across the causal boundary, and that energy cannot be recalled. When an interlock, a contact tripwire, or a safety operator aborts an errant motion before damage occurs, the trial ends early and leaves a censored observation that is neither an unequivocal success nor an unmitigated crash. Aerospace, automotive, and industrial automation engineers combine physical tests with model-based arguments about controller stability

and protection. The learned proposer in this campaign arrives without such a certificate, so its task reliability must be bounded by finite empirical sampling under the declared conditions.

Closed-loop evaluation therefore asks what a finite campaign of physical trials can establish about a learned proposer, and what it must leave for the rest of the machine to handle. Four obligations answer that question, and they order this chapter. A success rate is meaningful only when bound to a declared population of hardware states, environmental conditions, and trial procedures, with every protective intervention kept out of the policy's credit (section 7.2). The evidence must come from a regime that can expose the failure in question, which for most physical failures means routing proposals through the real permission path rather than scoring them against logs (section 7.3 and section 7.4). A finite record becomes a defensible bound only under a protocol fixed before the first run, and each additional "nine" of demonstrated reliability costs roughly ten times the trials (section 7.5 through section 7.7). Finally, the evaluation record, the link in the record chain after the policy manifest, must state which conditions were tested and which were not. It must also turn every untested condition, together with every hazard too rare for any campaign to sample, into an obligation for the runtime permission path (section 7.8 and section 7.9).

The first obligation begins with the twenty runs themselves. Before that perfect fraction can mean anything, the campaign must fix its outcome rules, define the operational population it sampled, and separate what the policy achieved from what supervision supplied. A defensible evaluation record never credits the learned proposer with successes that hardware interlocks or supervisory overrides actually purchased.

7.2 What a Physical Success Rate Measures

A latch-manipulation policy that reliably opens a door during morning bench tests can jam repeatedly when confronted with a strike plate displaced by only three millimeters. Its measured success rate does not belong to the neural network weights in isolation; it characterizes the coupled dynamical system formed by the policy, the mechanical plant, the onboard compute platform, the physical environment, and the trial protocol itself. While a reproducible offline benchmark score indicates how well a model fits a frozen dataset, a physical success rate measures how the embodied closed-loop system behaves across a distribution of physical executions.

Evaluating a policy requires executing a sequence of discrete physical runs. A single trial is fully determined only when every physical parameter capable of altering the state trajectory is either explicitly controlled or systematically sampled. Formally, a single trial condition is the tuple $c = (\mathbf{x}_0, e, m, \pi_\theta, \kappa)$, drawn from an operational testing distribution $\mathcal{D}$:

- The initial state vector $\mathbf{x}_0$ specifies the machine's starting condition, including its spatial pose (position and orientation), linear and angular velocities, and joint encoder positions.
- The environment vector e captures external physical variables, such as the tire-floor friction coefficient (μ), ambient illuminance, obstacle geometry, and ambient air temperature.
- The machine state m captures physical and hardware properties sampled from the fleet manufacturing and wear distribution $\mathcal{M}$. This encompasses unit-to-unit mechanical tolerances, battery state of charge, payload mass, tire wear, lost motion and compliance in the arm's transmissions, and sensor calibration matrices.
- The computational configuration π_θ represents the frozen policy weights θ, numerical quantization formats (such as FP16 or INT8), real-time thread scheduling deadlines, and software driver versions.
- The termination protocol $\kappa = (T_{\text{deadline}}, \mathcal{G}_{\text{goal}}, \phi)$ defines the execution deadline T_{deadline}, the spatial goal region $\mathcal{G}_{\text{goal}}$, and the binary evaluation predicate ϕ that maps the realized trajectory to a terminal outcome $Y \in \{0, 1\}$.

In static machine learning benchmarks, inputs (x_i, y_i) are sampled independently from a static data distribution $p_{\text{data}}(x, y)$. In Physical AI, the continuous trajectory $\text{Traj}(c) = (\mathbf{x}_0, \mathbf{u}_0, \mathbf{x}_1, \mathbf{u}_1, \dots, \mathbf{x}_T)$ is generated sequentially by the closed-loop physical state transition kernel:

$$\mathbf{x}_{t+1} \sim \mathcal{T}(\mathbf{x}_t, \mathbf{u}_t; m, e), \quad \mathbf{a}_t = \pi_\theta(\mathbf{x}_t), \quad \mathbf{u}_t = \text{Gate}(\mathbf{a}_t, \mathbf{x}_t)$$

Here Gate stands for the permission path, which admits, clips, or replaces each proposal $\mathbf{a}_t$ before it becomes the applied command $\mathbf{u}_t$. Its permission and controller parameters remain fixed and

are archived with the evaluated configuration; changing them changes the evaluated closed loop. The true success probability under this evaluation protocol is the expected value of the binary task outcome averaged over the joint distribution of trial conditions:

$$p(\mathcal{D}) = \mathbb{E}_{c\sim\mathcal{D}}[\phi(\text{Traj}(c))] \tag{7.1}$$

where $\text{Traj}(c)$ is the physical trajectory generated under condition c. Altering floor friction, ambient temperature, or battery voltage modifies the physical transition kernel $\mathcal{T}$ even when the neural network weights θ remain untouched. The operational testing distribution $\mathcal{D}$ is therefore an inseparable component of the quantity being estimated.

↪ The formal integral over the closed-loop trajectory distribution, including the plant transition kernel and the permission map, is developed in section A.5.5.

In test engineering, the abstract distribution $\mathcal{D}$ is realized through a **stratified test matrix**[1] across controllable parameters, systematically varying payload mass, approach speed, illumination, and initial spatial standoff, while logging uncontrollable environmental parameters such as ambient temperature and floor friction. Unstratified random sampling across the parameter space oversamples benign nominal states and leaves critical boundary regions unvisited. Each stratum of the matrix (one payload, one approach speed, one plate position) is then its own population for the statistical bounds that follow, with its own $\mathcal{D}$ and its own success probability. A claim about the whole matrix needs explicit weights across strata, which the evaluation record of section 7.8 declares before the first run.

[1] **Design of Experiments**: Fisher's agricultural field trials introduced randomization and blocking so that variation in the soil could not masquerade as a treatment effect (Fisher 1935). A stratified test matrix blocks on payload, approach speed, and lighting for the same reason, and randomizing the run order keeps winding heat and spring relaxation from entering the comparison as if they were properties of the policy (section 7.7.4).

Definition 7.1: Closed-loop evaluation estimand

Closed-loop evaluation estimand is the expected physical task outcome $p(\mathcal{D}) = \mathbb{E}_{c\sim\mathcal{D}}[\phi(\text{Traj}(c))]$ defined over the joint distribution of initial states, mechanical plant wear, environmental physics, frozen policy weights, and evaluation predicates:

$$c = (\mathbf{x}_0, e, m, \pi_\theta, \kappa) \sim \mathcal{D}$$

rather than an intrinsic property of the neural policy weights evaluated in isolation.

1. **Significance**: In static machine learning, held-out accuracy is treated as a property of the model π_θ. In physical AI, substituting a worn tire, letting battery voltage sag, or shifting ambient illuminance alters the physical state transition function without changing a single weight. The sampling distribution of operational conditions $\mathcal{D}$ is an inseparable part of the quantity being estimated.
2. **Distinction**: Unlike open-loop validation metrics (such as validation loss, cosine similarity, or mean squared trajectory error) that score predictions against frozen recorded states, the closed-loop estimand integrates over the endogenous feedback loop. In that loop, past actions physically move the machine and directly change the future sensor observations it receives.
3. **Common pitfall**: Reporting a single success rate percentage without predeclaring the support, density, and environmental bounds of the test distribution $\mathcal{D}$. Any physical policy can be made arbitrarily successful by testing exclusively in benign, unperturbed states.

7.2.1 Hardware instance variance and environmental unobservables

Freezing the neural network weights π_θ and the termination protocol κ fixes only two of the five entries in the trial condition c; the plant parameters m and environmental parameters e still vary from machine to machine and from morning to afternoon. On a mobile manipulator, this dispersion comes from two sources: **hardware instance variance** across individual builds and **environmental unobservables** in the operating workspace.

First, robotic production lines do not manufacture identical copies. Nominally identical units diverge in lost motion, thermal behavior, and controller response (section 5.10.3). The tolerances that matter for evaluation also include drivetrain compliance and hysteresis that grow with wear (Harmonic Drive LLC 2006), link deflection that shifts the tool center point, and camera-mount offsets between the sensor frame $\mathcal{F}_{\text{cam}}$ and the base frame $\mathcal{F}_B$. They further include torque constants

K_t that vary across windings and drive voltage that loses headroom against back-electromotive force (back-EMF) as the battery discharges. Each of these changes the trial condition without changing a weight, so qualification campaigns characterize every unit's lost motion, joint stiffness, and camera extrinsics on an inspection bench rather than assuming nominal catalog values.

Second, environmental unobservables alter physical interaction dynamics without changing camera pixels in ways that a neural network can easily recognize. Ambient daylight shifting across a warehouse alters illuminance, causing camera auto-exposure routines to lengthen shutter times and inducing motion blur during base turns. Direct solar glare at dawn or dusk saturates complementary metal-oxide-semiconductor (CMOS) sensor arrays, washing out optical contrast around the latch interface. On the floor, dust accumulation and ambient humidity alter the tire-floor friction coefficient (μ), lengthening braking distances and corrupting wheel odometry. Within the manipulator arm, repeated door openings generate Joule heating (I^2R) in motor windings and warm harmonic drive lubricants, decreasing viscous damping and causing thermal expansion across structural links. Consequently, the tool center point meets the latch with a millimeter-scale spatial offset on a hot afternoon compared to a cold morning.

Trial reset procedures introduce another major source of unintended drift in c. When human operators reposition the mobile base after a difficult or aborted run, subconscious bias often leads them to favor forgiving, nominal configurations, systematically excising difficult boundary states from the sample. Conversely, an automated reset routine that drives the identical recovery path repeatedly heats actuator windings cyclically, introducing progressive thermal degradation across runs. Worst of all, an operator who catches a stumbling robot mid-fall and discards the run as an invalid trial erases the most informative corner-case failures from the evaluation record.

Statistical evaluation must therefore maintain a strict distinction between sampling variation and shifts in the underlying estimand. When N independent trials are drawn from a stationary distribution $\mathcal{D}$, the sample proportion $\hat{p} = \frac{1}{N}\sum_{i=1}^{N} Y_i$ fluctuates around the true expectation $p(\mathcal{D})$ due to ordinary binomial noise, which standard statistical estimators bound. However, loading a payload onto the tote rack or moving the door's strike plate transitions the experiment to an entirely different distribution $\mathcal{D}'$ with its own success probability $p(\mathcal{D}')$. Pooling runs across these two conditions without declaring their sampling weights conflates distinct physical configurations into an uninterpretable average. Independent draws from a predeclared mixture support a claim about that mixture; a quota-based stratified matrix instead requires separate inference within each cell and explicit weighting for an aggregate claim. Fixing the condition tuple c settles which population a campaign samples, but a single binary outcome $Y \in \{0, 1\}$ still hides whether the learned proposer succeeded on its own or was rescued by the permission path.

7.2.2 Intervention-based physical metrics

Even when the trial condition c is fixed, a single binary pass rate cannot distinguish a policy that operated the door latch on its own from one that was rescued on every attempt by permission-path clips or remote teleoperators. Consider four divergent operational outcomes during a door-opening task:

- A policy proposes an excessive contact force, but the permission path clips the command, allowing the door to open smoothly while remaining within mechanical limits.
- The permission path detects an impending joint limit and halts the manipulator entirely, preserving hardware safety while leaving the task incomplete.
- A human safety operator intervenes via remote teleoperation to clear a jammed latch pin, after which the robot resumes autonomous execution and completes the run.
- The raw policy executes the entire trajectory unassisted, completing the manipulation task within nominal limits without intervention.

Every protective actor in these four scenarios other than the human operator is the permission path, acting by clipping a proposal, replacing it, or stopping the machine. The first scenario shows a well-functioning integrated machine where permission-path clips compensate for raw proposer imperfections, whereas the second protects the hardware at the expense of task completion. The third achieves the objective only by drawing on costly human labor, leaving only the fourth as genuine proposer autonomy.

Evaluating physical AI systems therefore requires decomposing performance into three independent channels: whole-machine task completion within operational limits, raw proposer autonomy, and supervisory intervention frequency. The task-completion rate, the fraction of trials whose outcome Y_i (defined in the first item below) equals 1, measures the first channel. The autonomous completion rate measures the second, and mean time between interventions and intervention density measure the third. Reset latency belongs to no channel; it prices what each outcome costs the test cell. Runtime safety adjustments are an intended feature of the architecture, so a small corrective clip by the permission path should not brand a completed run as a system failure. Nevertheless, tracking proposer autonomy separately reveals how often the learned model attempts to violate physical boundaries. Telemetry pipelines must log adjustments, command rejections, protective stops, and human overrides using predeclared event-counting rules, ensuring that a sustained safety clamp over several seconds is recorded as a single event rather than hundreds of spurious high-frequency faults.

1. **Autonomous completion rate (ACR)**: Let $n_{\text{int}_i} \in \{0, 1, 2, \dots\}$ be the total count of supervisory interventions during trial i, whether initiated by human safety operators, the permission path's clips and stops, or emergency tripwires, and let $Y_i \in \{0, 1\}$ denote goal achievement within the execution deadline T_{deadline}. The unassisted autonomous success indicator is:

$$A_i = \mathbb{I}(Y_i = 1 \wedge n_{\text{int}_i} = 0)$$

   ACR is the sample proportion of trials completed entirely without supervisory intervention:

$$\text{ACR} = \frac{1}{N} \sum_{i=1}^{N} A_i = \frac{N_{\text{unassisted}}}{N}$$

   ACR measures strict raw proposer autonomy: a single recorded intervention forces $A_i = 0$. In contrast, the whole-machine outcome Y_i can remain 1 when the permission path clips the proposer's commands and the task still completes within service bounds.

2. **Mean time between interventions (MTBI)**: For any declared intervention class, MTBI quantifies the mean active operating duration between supervisory events:

$$T_{\text{MTBI}} = \frac{T_{\text{active}}}{N_{\text{int}}} = \frac{\sum_{i=1}^{N} t_{\text{run}_i}}{\sum_{i=1}^{N} n_{\text{int}_i}}$$

   where t_{run_i} is the active operating duration of trial i and $N_{\text{int}} = \sum_{i=1}^{N} n_{\text{int}_i}$ is the total count of recorded interventions within that class. MTBI reflects the operational burden imposed by supervisory systems. Frequent automated filter adjustments signal aggressive policy proposals or model distribution shift, whereas frequent manual recoveries directly drive up staffing costs. Neither a favorable MTBI nor an absence of physical damage proves that a policy is ready for unattended deployment.

3. **Intervention density (D_{int})**: In spatial navigation and continuous trajectory tracking, interventions must be normalized against physical travel distance or discrete execution steps:

$$D_{\text{int}} = \frac{N_{\text{int}}}{\sum_{i=1}^{N} d_i} \quad \text{[interventions per kilometer]} \quad \text{or} \quad D_{\text{int}} = 1{,}000 \times \frac{N_{\text{int}}}{\sum_{i=1}^{N} N_{\text{steps},i}} \quad \text{[interventions per 1,000 st}$$

   where d_i is the physical path distance traversed during trial i, and $N_{\text{steps},i}$ is the number of control cycles executed. Normalizing by exposure makes intervention rates comparable across routes or operating conditions. Locating concentrated degradation also requires retaining each event's location and condition and comparing these rates across strata, such as narrow doorways or tight mechanical latches.

4. **Reset latency (T_{reset})**: In physical qualification campaigns, the primary bottleneck in testing throughput is governed by the time required to restore the robot and workspace after a trial completes or aborts:

$$T_{\text{reset}} = t_{\text{physical_restore}} + t_{\text{calibration}} + t_{\text{telemetry_flush}}$$

The standard door-opening run requires 25 s of active execution. While its nominal reset cycle is brief (section 7.7.2), a run that jams the latch pin requires an operator intervention of approximately 60 s (illustrative) to clear the jammed pin, recalibrate joint encoders, and return the mobile base to its initial standoff pose. For jammed runs, this manual reset consumes 70.6 percent of total test-cell occupancy. High reset latencies create organizational pressure to cut corners, for instance by skipping motor thermal cooldowns or manually nudging the robot into easier initial poses, and each shortcut breaks the statistical stationarity of the campaign.

Engineers must not conflate MTBI with mean time between failures (MTBF). While an MTBF metric tracks functional breakdowns or mechanical failures, MTBI, ACR, and D_{int} capture supervisory burden and proposer autonomy within an operating envelope. A robot fleet can maintain an unblemished record of zero hardware damage simply because vigilant human safety drivers or a conservative permission path intervene whenever an unsafe state nears. Recording a run that was truncated or guided by external supervision as an unassisted operational success masks policy shortcomings behind the protective capability of the safety system. Section 7.4 shows why such runs are censored observations and names this error the censored trial fallacy.

Evaluation protocols keep these metrics separate so that engineers can observe the trade-offs between safety filtering, autonomous capability, and operational throughput. These outcome channels fix which quantities must be recorded across experimental trials. The next challenge is to design a closed-loop evaluation harness that exposes these behaviors systematically under dynamic feedback.

7.3 Closed-Loop Dynamics

A policy checkpoint that achieves the lowest validation loss on held-out teleoperation logs can drive the mobile base into a warehouse rack or jam the door latch on its first physical trial. Offline scoring resets the robot's state to the demonstrator's recording at every step, erasing the cumulative consequences of the policy's own actions. In standard deep learning workflows, model evaluation centers on empirical risk minimization over a static, held-out validation dataset $\mathcal{D}_{\text{val}} = \{(x_i, y_i)\}_{i=1}^{N}$:

$$\mathcal{L}_{\text{val}}(\theta) = \frac{1}{N} \sum_{i=1}^{N} \mathcal{L}(f_\theta(x_i), y_i)$$

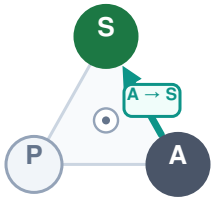
Whether the target metric is Top-1 classification accuracy, next-token perplexity, an F1 score, or coordinate regression loss, the evaluation pipeline remains passive and decoupled. The underlying data-generating process is feedforward and memoryless with respect to the model's outputs: mispredicting sample i exerts zero causal influence on sample $i+1$ ($\partial x_{i+1} / \partial \hat{y}_i = 0$).

Transporting this static paradigm to physical control creates the **offline evaluation illusion**, the unfounded assumption that lower validation loss, higher action cosine similarity, or smaller Mean Squared Error (MSE) on logged data guarantees superior physical execution. Offline loss metrics of the form $\mathcal{L}_{\text{val}}(\theta) = \frac{1}{N} \sum_{i=1}^{N} \|\mathbf{a}_i^* - \pi_\theta(\mathbf{x}_i^*)\|^2$ evaluate candidate predictions exclusively along frozen demonstrator trajectories. Controlled benchmarks across simulated and physical manipulation tasks demonstrate this failure directly: the training checkpoint with the lowest validation loss performed substantially worse during closed-loop rollouts than alternative checkpoints, with task success frequently rising even as validation loss climbed (Mandlekar et al. 2021).

The decoupling that justifies offline scoring vanishes in physical AI. Admitted policy actions cross the causal boundary into mass, momentum, and non-smooth contact mechanics. Instead of assigning categorical labels, the policy outputs forces, torques, and velocity setpoints that physically perturb the plant, endogenously generating future sensory observations through the system dynamics ($\mathbf{x}_{t+1} = f(\mathbf{x}_t, \mathbf{u}_t)$). These commands interact continuously with inertia, friction, and mechanical backlash. Consequently, a navigation policy can track recorded demonstrator trajectories with negligible regression error during offline playback, yet exhaust the vehicle's entire lateral clearance against a warehouse rack before traversing a third of the aisle. The failure stems directly from what each evaluation regime feeds back to the policy.

In an **open-loop evaluation**, a candidate policy π_θ is scored across a static dataset of recorded demonstrations $\mathcal{D}_{\text{demo}} = \{(\mathbf{x}_t^*, \mathbf{a}_t^*)\}_{t=1}^{S}$. At each discrete timestep t, the policy receives an expert state $\mathbf{x}_t^*$ and predicts an action $\hat{\mathbf{a}}_t = \pi_\theta(\mathbf{x}_t^*)$, which a standard loss function such as mean squared error or

cross-entropy compares against the recorded expert action $\mathbf{a}_t^*$. Because the harness then feeds the next recorded state $\mathbf{x}_{t+1}^*$ directly from storage and discards $\hat{\mathbf{a}}_t$ without ever executing it on hardware, the incoming state sequence remains strictly independent of prior predictions ($\partial \mathbf{x}_{t+1}^* / \partial \hat{\mathbf{a}}_t = \mathbf{0}$). In a **closed-loop evaluation**, by contrast, the policy proposes an action $\mathbf{a}_t = \pi_\theta(\mathbf{x}_t)$ from live sensory feedback. The deterministic permission path then validates that proposal against current plant state and safety invariants before dispatching an approved command $\mathbf{u}_t$ (or an intervention fallback) to the actuators. The plant then advances according to physical dynamics ($\mathbf{x}_{t+1} = f(\mathbf{x}_t, \mathbf{u}_t)$), so every admitted command alters the physical state and shapes all subsequent sensory inputs across the causal boundary.



Admitted actions choose the next observation.

7.3.1 Compounding error and kinematic integration

That feedback path turns small one-step tracking residuals into growing state deviations, following the worst-case structure derived in section 5.3. If a policy deviates from expert actions with probability at most ϵ per step on recorded expert states, open-loop evaluation across a horizon of S steps accumulates an expected cost bounded by $S\epsilon$. In closed loop, however, an early deviation can steer the robot into unvisited regions of the state space for the remainder of the trajectory, driving the cumulative imitation cost to scale as $S^2\epsilon$ (equation 5.1). An open-loop benchmark can therefore understate closed-loop task divergence by a factor proportional to the operating horizon. This bound governs zero-one decision divergence rather than unbounded quantities such as contact force or structural yield. Classical kinematics supplies the physical mechanism. Uncorrected heading and steering biases integrate forward into lateral displacements that exhaust the robot's clearance envelope.

A policy whose own actions displace it from its training distribution is the second law at work on a test bench, and evaluation must quantify what that displacement costs on physical hardware. Because the mobile manipulator's base remains stationary during door manipulation trials, the platform's warehouse navigation stack supplies the clearest illustration of kinematic accumulation. Consider the base traversing a 30 m aisle at its 1.5 m/s drive limit, where the nominal expert trajectory tracks the centerline with heading $\theta_{\text{head}}^* = 0$ rad and lateral offset $y_{\text{base}}^* = 0$ m. Suppose the candidate navigation policy possesses a systematic heading bias of $\Delta\theta_{\text{head}} = 1.0^\circ$ (0.01745 rad) at every control step. The deterministic permission path admits each individual velocity command because, in isolation, a one-degree heading adjustment remains dynamically feasible while lateral clearance persists.

In an open-loop evaluation, the policy receives the demonstrator state $\mathbf{x}_t^* = ({x_{\text{base}}}_t^*, 0, 0)$ at each step and predicts forward velocity with a 1.0° steering offset. The offline scoring pipeline records a mean absolute angular error of 1.0° (0.01745 rad) and a mean squared error of $\text{MSE}_{\theta_{\text{head}}} = (0.01745)^2 \approx 3.05 \times 10^{-4}$ rad^2.[2] The number is small because it is measured in radians squared. More important, the replay score stays at that same per-step value however long the aisle is, because each next input returns to the centerline and the error never accumulates. During closed-loop execution, however, the robot's physical movement reflects previously admitted commands, allowing uncorrected heading errors to integrate continuously. Under planar unicycle kinematics[3] ($\dot{y} = v \sin\theta_{\text{head}} \approx v\Delta\theta_{\text{head}}$), a persistent angular offset integrates directly into a lateral displacement that grows linearly with the time t_{drift} since the base left the centerline:

$$y_{\text{base}}(t_{\text{drift}}) = \int_0^{t_{\text{drift}}} v \sin\Delta\theta_{\text{head}}\, dt' \approx v\Delta\theta_{\text{head}} t_{\text{drift}}$$

If the policy carries a persistent yaw-rate bias ω_{bias} (steering drift) rather than a fixed angular offset, the heading angle itself grows linearly over time ($\theta_{\text{head}}(t_{\text{drift}}) = \int_0^{t_{\text{drift}}} \omega_{\text{bias}}\, dt' = \omega_{\text{bias}} t_{\text{drift}}$). Integrating forward velocity v then yields a cumulative lateral deviation that compounds quadratically in time:

$$y_{\text{base}}(t_{\text{drift}}) = \int_0^{t_{\text{drift}}} v \sin(\omega_{\text{bias}} t')\, dt' \approx \frac{1}{2} v \omega_{\text{bias}} t_{\text{drift}}^2$$

This quadratic growth resembles the $S^2\epsilon$ imitation bound, but the two characterize distinct phenomena. The kinematic derivation integrates a systematic yaw-rate bias through continuous dynamics,

↩ How a policy's own actions shift the states it visits away from the demonstrator's occupancy is established in section 5.2.

2 | **Mean Masking of Steering Spikes**: Averaging squared steering error over thousands of straight-aisle frames also hides a brief, large prediction spike, which barely moves the mean. Whether such a spike matters depends on whether its integrated motion spends the clearance before the permission path responds, a question only a plant and timing model can answer.

3 | **Unicycle Model**: The simplest planar vehicle model, in which pose $(x_{\text{base}}, y_{\text{base}}, \theta_{\text{head}})$ evolves as $\dot{x} = v\cos\theta_{\text{head}}$, $\dot{y} = v\sin\theta_{\text{head}}$, $\dot{\theta}_{\text{head}} = \omega_z$. This formulation captures the essential nonholonomic constraint of the aisle: because a wheeled base cannot translate instantaneously sideways, any heading discrepancy directly translates forward velocity toward the rack.

whereas the imitation bound accounts for accumulated discrete decision costs under distribution shift. Both show small, bounded errors accumulating polynomially over an operational horizon. Neither excludes the worse case that section 5.3 described, in which a smooth imitator of a stable expert can compound its errors exponentially with horizon; the aisle example simply does not need that mechanism to fail.

For the constant 1.0° heading bias, the mobile base spans 100 cm within a 130 cm aisle. This geometry leaves $W_{\text{clear}} = 15$ cm of lateral clearance to the storage racks on either side. At full drive velocity, the kinematic drift consumes this safety buffer at:

$$t_{\text{impact}} = \frac{W_{\text{clear}}}{v \sin \Delta\theta_{\text{head}}}, \tag{7.2}$$

which evaluates to 5.7 s, after just 8.6 m of forward travel, less than a third of the way through the aisle. The same heading offset that replay scores at an angular mean squared error of 3.05×10^{-4} rad^2, because each next input returns to the recorded centerline, spends the entire 0.15 m side clearance in the physical loop (figure 7.1). The computed point is the unmitigated collision horizon. To halt before impact, the runtime permission path must intervene earlier, allowing for qualified detection, command and actuation response, and stopping motion. A protective stop makes strict proposer autonomy fail while preserving protection; an unprotected rack strike fails protection as well. Both expose a limitation of the policy that offline evaluation rated as near-flawless.

This warehouse scenario highlights the two structural mechanisms that cause open-loop validation metrics to decouple from physical performance:

1. **State integration across time**: Static evaluation cannot integrate persistent control errors into physical displacements. By resetting the robot's input state to an expert demonstration at every clock cycle, offline scoring obscures error accumulation. In closed-loop deployment, however, the state at timestep t represents the unrolled composition of all prior control actions:

   $$\mathbf{x}_t = f(f(\dots f(\mathbf{x}_0, \mathbf{u}_0) \dots, \mathbf{u}_{t-2}), \mathbf{u}_{t-1})$$

   A persistent heading bias does not require an algorithmic flaw. Physical phenomena like asymmetric tire wear, mast vibration, uneven payload distribution, or floor camber routinely introduce systematic offsets that accumulate across steps.
2. **Covariate shift into unmodeled states**: Static benchmarks cannot evaluate how a policy behaves once early errors steer the plant away from nominal trajectories. The very first uncorrected action shifts the base from the expert state $\mathbf{x}_1^*$ to an unvisited state $\mathbf{x}_1$. Once the base drifts even a few centimeters off the centerline, it enters operating states absent from $\mathcal{D}_{\text{demo}}$. Because offline metrics are evaluated exclusively along demonstrator states where $y_{\text{base}} = 0$ m, they provide no evidence about policy behavior when $y_{\text{base}} \neq 0$ m. Lacking training on corrective maneuvers, the policy often generates larger prediction errors in these off-nominal regimes, precipitating rapid divergence.

7.3.2 Contact discontinuities and metric masking

↩ Compounding covariate shift, and the recovery experience a fixed demonstration archive lacks, are established in section 6.2.4.

In the warehouse aisle, a two-millimeter tracking residual spends a tiny fraction of lateral clearance; at the door latch, that same two-millimeter residual commands the gripper into rigid steel. The moment an end-effector touches a latch, unconstrained free-space kinematics give way to constrained contact mechanics governed by impact, stick, and slip. In classical rigid-body mechanics, collision produces discontinuous velocity jumps ($v_n^+ \neq v_n^-$), while Coulomb friction creates set-valued reaction forces ($F_{\text{friction}} \in [-\mu f_{k,\perp}, \mu f_{k,\perp}]$). Because these transitions violate Lipschitz continuity (a bound on how much the dynamics can change per unit change in state), infinitesimally small variations in spatial state produce disproportionately large, discontinuous changes in physical dynamics. Although mechanical compliance and structural damping distribute impact forces across small time windows in real hardware, aggregate offline loss metrics obscure the critical physical consequences of crossing contact boundaries:

1. **Action cosine similarity ignores operational magnitude**: In representation learning and behavior modeling, action cosine similarity:

   $$\text{Cosine}(\hat{\mathbf{a}}, \mathbf{a}^*) = \frac{\hat{\mathbf{a}}^\top \mathbf{a}^*}{\|\hat{\mathbf{a}}\| \|\mathbf{a}^*\|}$$

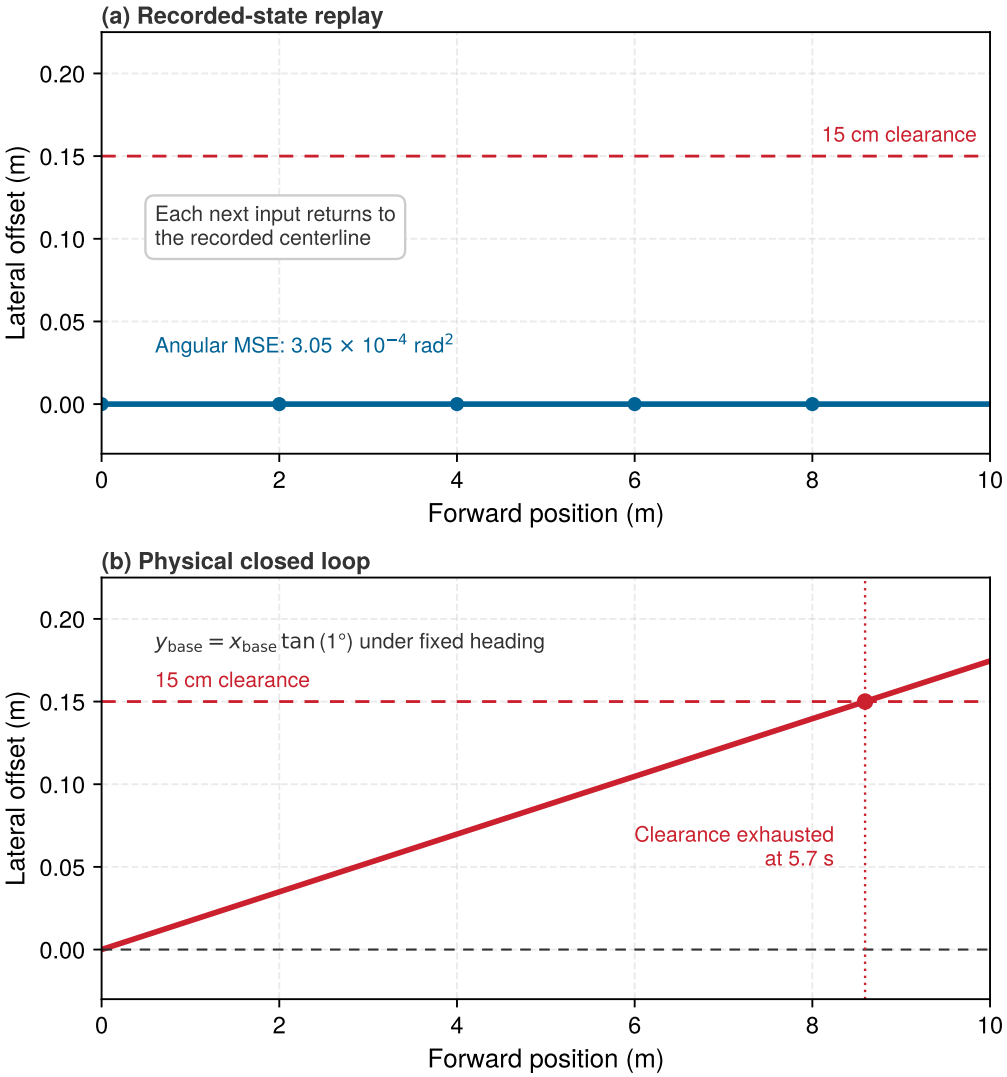


Figure 7.1: Open vs. closed loop divergence: A persistent 1.0° heading offset gives 3.05×10^{-4} rad^2 angular mean squared error on recorded centerline states. On the mobile manipulator's aisle, the navigation stack's admitted motion with that fixed heading drifts linearly and reaches the 0.15 m side clearance after 5.7 s at the 1.5 m/s drive limit. The example concerns the navigation stack, not the latch policy under evaluation.

evaluates directional alignment between predicted and expert commands. At a physical contact interface, however, directional alignment alone is insufficient because cosine metrics discard vector magnitude entirely. A policy proposal achieving 0.999 cosine similarity that commands 25 percent insufficient force fails to overcome the latch's mechanical preload and static friction, stalling against the mechanism and halting the task. Conversely, a command with identical 0.999 similarity that commands 150 percent of the required force overloads the contact interface, risking an immediate trigger of the 15 N protective tripwire. Whether hardware damage occurs depends on structural compliance, pre-contact kinetic energy, and joint impedance response. A trip invokes the protective response, whose ability to prevent damage requires qualification under those conditions. A stopped, incomplete run fails the task despite the favorable cosine score.

2. **Action mean squared error equates disparate physical regimes**: In offline supervised regression, Mean Squared Error:

$$\text{MSE} = \frac{1}{d_a}\sum_{j=1}^{d_a}(\hat{a}_j - a_j^*)^2$$

penalizes every millimeter of tracking residual identically, regardless of physical context. During free-space transit, an end-effector tracking discrepancy of 2 mm represents a benign perturbation that downstream control easily accommodates. Consider, by contrast, a stiff environmental interface modeled with contact stiffness $k_{\text{contact}} \approx 5 \times 10^5$ N/m. When an unmitigated position controller commands an apparent surface penetration δ, the resulting normal reaction force scales as:

$$\Delta f_{k,\perp} = k_{\text{contact}}\delta$$

For an uncorrected 2 mm penetration residual, this linear relationship demands a reaction force of 1,000 N. Realized loads depend on structural compliance, link elasticity, and active torque limits rather than bare stiffness alone. Even so, the calculation shows the dimensional mismatch. Offline MSE treats a benign 2 mm tracking error in free space identically to a contact error capable of tripping joint protection or damaging gearboxes.

3. **Hardware instance variance amplifies contact bifurcations**: Non-smooth contact mechanics compound the unit-to-unit manufacturing variance analyzed in section 7.2. Subtle physical discrepancies across production robots, such as transmission backlash, harmonic drive compliance, and millimeter-level camera-mounting tolerances, shift the physical boundary of the contact interface in Cartesian space. A policy trained on demonstrations recorded on Unit 01 will encounter the latch surface slightly earlier or later when deployed on Unit 02. Because contact transitions are discontinuous, this millimeter-scale spatial displacement triggers immediate operational bifurcations. The manipulator either halts prematurely in free space or collides aggressively with the mechanism frame, causing mechanical jamming that static evaluation over historical logs cannot detect.

The door manipulation benchmark illustrates this failure mechanism directly. An end-effector positioning error of a fraction of a millimeter per step registers as negligible Cartesian deviation on static logs. Against the rigid latch mechanism, however, that small offset acts as a mechanical wedge. The same stiffness relation, $\Delta f_{k,\perp} = k_{\text{contact}}\delta$, now acting sideways, transforms this lateral displacement into a steep reaction force that quickly crosses the 15 N contact tripwire, triggering an immediate safety abort before the door unlatches.

Conversely, offline benchmarks can also fail through false pessimism when tasks support multimodal solution paths. If a human demonstrator avoided an obstacle by steering left, an open-loop regression metric penalizes an autonomous policy that navigates safely to the right (the multimodal distribution dilemma), even though both trajectories satisfy the closed-loop objective. Static action loss measures divergence from a single historical recording, not functional task completion.

These asymmetries frequently produce rank inversions across candidate models. A policy whose small residual errors concentrate precisely at critical contact boundaries will score lower validation loss than a competitor with larger, yet harmless, errors distributed across free space. When deployed, however, their operational reliability reverses:

↩ Mode averaging over multimodal demonstrations is established in section 6.2.3.

$$\mathcal{L}_{\text{val}}(\pi_A) < \mathcal{L}_{\text{val}}(\pi_B) \quad \text{yet} \quad \text{ACR}(\pi_A) \ll \text{ACR}(\pi_B)$$

Evaluation campaigns must therefore measure autonomous completion rates, force profiles, and contact stability on physical hardware rather than ranking models by average offline loss. Each standard offline metric conceals a specific physical failure mode, and table 7.1 maps each metric to its implicit open-loop assumption, its physical failure mechanism, and the corresponding closed-loop metric required to expose it. Most of the closed-loop measures in its last column are physical quantities the record already logs. The one new measure is time to intervention (T_{TTI}), the elapsed duration from the granting of policy authority to the first permission-path override or safety operator takeover, which measures how long a drifting policy runs before something must stop it. Alongside ACR, MTBI, and D_{int}, these execution measures characterize real-world autonomy in ways that static loss calculations cannot.

Table 7.1: Offline metrics and the closed-loop failures they hide: Each open-loop metric assumes the demonstrator's state distribution is unaffected by policy error; on the machine, biases integrate into drift, valid alternatives are penalized, and shifted states produce boundary violations.

Offline metric	Open-loop assumption	Why it breaks in closed loop	Failure on the machine	Closed-loop measure
Action mean squared error	Small residuals give small path deviations	A persistent bias integrates into drift and carries the machine off the demonstrated states	The base spends its rack clearance (stop or strike)	Peak deviation from the reference path; time to intervention (T_{TTI})
Discrete action accuracy	Correct labels on logged states give identical execution	Benign alternatives and boundary excursions cost the same; errors correlated in time are invisible	Command chatter and joint over-torque	Peak jerk; adherence to actuator torque limits
Cosine similarity	Collinear proposals give stable paths	Magnitude is ignored, so under-actuation stalls against static friction and over-actuation slips	The base stalls or slips its wheels; the arm stalls short of the latch	Slip ratio (section B.7.4) and damping (section B.2.3)
Negative log-likelihood	Likelihood at the expert action captures the action distribution	A unimodal likelihood head averages valid alternatives, such as passing an obstacle on either side, into an invalid mean action	Valid policies rejected; demonstrator noise imitated as jitter	Closed-loop task success over randomized starts
Reconstruction or Chamfer loss	Accurate scene prediction gives safe plans	Background pixels outweigh thin obstacles and contact geometry	Phantom braking; clipping a cable or a glass partition	Measured clearance and its minimum margin

Systems Perspective 7.1: The offline evaluation illusion

Offline validation loss, Mean Squared Error (MSE), and action cosine similarity score predictions exclusively along frozen demonstrator trajectories where errors are artificially erased at every clock cycle. Physical closed-loop evaluation exposes accumulated trajectory drift, state distribution shift, and dynamic contact transitions absent from recorded logs. While the worst-case imitation bound ($\mathcal{O}(S^2\epsilon)$) models decision divergence under distribution shift, kinematic integration and contact mechanics ($f_{k,\perp} = k_{\text{contact}}\delta$) govern physical clearance and reaction forces. A score computed against recorded states cannot see a feedback loop that recording removed.

7.3.3 The proposal boundary in two-processor architectures

Drift and contact are failures of the plant. A third class of failure lives in the machine's own hardware, and replay misses it for a different reason, because the replay harness runs on the wrong processor. In the running machine, the proposal boundary of section 1.7 is also a processor boundary. The learned proposers run on an application processor, the permission path runs on a separate safety microcontroller, and every candidate proposal crosses the inter-processor bus before it can move the arm. Replaying sensory traces on the host application processor therefore verifies only whether neural inference completes within allocated memory bandwidth and latency budgets.

Evaluating an unverified neural policy strictly offline, without the physical plant, real-time bus transport, and safety monitors active in the loop, benchmarks isolated tensor computation rather than operational survivability. What replay on the host cannot see is everything the bus and the microcontroller add: transport delay, a late proposal arriving after its chunk lease has lapsed, a clip that changes the motion the policy expected, and a fallback that takes over mid-task. Shadow operation exposes the first two on real buses without letting the candidate move the machine, and constrained physical testing exposes all four.

Because open-loop metrics cannot certify closed-loop reliability, the proposer must be evaluated in settings that restore parts of the loop. Each setting alters a different element of the sensorimotor loop (the plant dynamics, the fidelity of the sensor stream, or the actuator authority), so each exposes a different set of failures.

↩ The two-processor split, stated as a hypothesis that placement must later test on silicon, is established in section 4.2.

↪ How the permission path admits a proposal, corrects it, or transfers authority to a resident fallback is developed in section 12.6.

7.4 Evidence Regimes

Before undertaking twenty physical door runs, an engineering team evaluating a robotic latch policy could score candidate predictions against logged human demonstrations, execute them inside a simulated physics environment, run them in shadow mode while a validated controller retains physical authority over the arm, or deploy them directly on the real mechanism with contact tripwires armed. These four configurations constitute the primary **evidence regimes** of embodied evaluation. Figure 7.2 and table 7.2 map them across two structural axes: physical realism on the vertical axis (from logged and synthetic feeds up to live hardware) and causal feedback on the horizontal axis (from open loop to closed loop). Each regime establishes a distinct coupling between the policy, its sensory observations, and the underlying physical machine states, so each regime supports only a bounded empirical claim. None of these four settings alone reveals how an unassisted policy behaves during open-ended physical deployment, because each environment either breaks the control loop's causal feedback or alters the distribution of states the robot encounters.

7.4.1 The four evaluation evidence regimes

The first axis, causal feedback, governs whether a candidate's emitted actions alter future states and subsequent sensor observations ($\partial \mathbf{x}_{t+1} / \partial \mathbf{a}_t \neq \mathbf{0}$), or whether the policy merely reads a prerecorded, invariant sensory stream. In an open-loop configuration, execution errors cannot compound because mistakes never propagate into future inputs. In a closed loop, small policy errors perturb subsequent machine states and accumulate into compounding drift at a rate dictated by system dynamics and closed-loop feedback gains. The second axis, physical realism, governs whether sensory observations originate from physical transducers interacting with unmodeled contact dynamics, gear backlash, tire slip, and variable illumination (f_{real}), or instead emerge from a synthetic numerical simulator or static buffer (f_{sim}). No single testing configuration can maximize both axes simultaneously without exposing expensive hardware, or nearby operators, to an unproven and potentially destructive policy. Each quadrant of figure 7.2 therefore provides evidence for specific claims and carries its own structural blind spot.

In recorded replay, the candidate policy executes strictly as a feedforward computation over static sensor buffers. Because the physical environment cannot respond to emitted actions, the state sequence remains fixed to the exact trajectory recorded during prior data collection. This regime provides solid empirical evidence for computational efficiency, dynamic memory allocation, and loss metrics against a reference benchmark. It can verify, for example, whether neural network inference fits within its target execution budget on an edge accelerator, and whether output distributions align numerically with logged human demonstrations. However, recorded replay cannot substantiate any claim regarding closed-loop stability or control authority. Because predicted actions never feed back into subsequent sensor frames, errors never induce consequences. If the policy commands an aggressive steering angle, the subsequent logged frame still shows the mobile base tracking straight down the corridor.

Closed-loop simulation restores the causal feedback path by substituting an explicit mathematical or numerical model, f_{sim}, for the physical robot and its operating environment. When the policy emits an action and the modeled safety permission path selects the control command $\mathbf{u}_t$, the physics engine numerically integrates the equations of motion, advances the scene geometry, and renders synthetic sensor observations for timestep $t+1$. This regime supports extensive testing of closed-loop dynamics, kinematic reachability, and recovery maneuvers. It can demonstrate, for example, whether a mobile base recovers gracefully from an initial tracking offset, or whether an articulated arm avoids self-collision throughout its reachable workspace across thousands of parallelized instances. However, the resulting evidence applies exclusively to the synthetic operator f_{sim}. Unmodeled transmission backlash, tire deformation, dynamic contact friction transitions, and optical sensor artifacts are omitted by construction. Demonstrating stability within f_{sim} therefore establishes that the policy stabilizes the model, not that it will stabilize physical hardware.

Shadow operation deploys the candidate policy directly onto an active physical machine while a validated baseline controller, or a human operator, retains exclusive authority over the physical actuators. The candidate policy ingests live streaming sensor data, executes onboard inference amid real mechanical vibrations and fieldbus contention, and computes candidate actions $\mathbf{a}_t^{\text{cand}}$.[4] These proposed actions are logged to high-speed storage but never dispatched to the motor drives.

[4] **Bus Jitter in Shadow Mode**: Inference that is steady on a bench stretches on the machine when direct memory access (DMA) transfers, shared memory, and fieldbus arbitration compete for the same paths. Shadow operation logs that jitter on the real buses, under real thermal load, without letting the late proposals move the chassis.

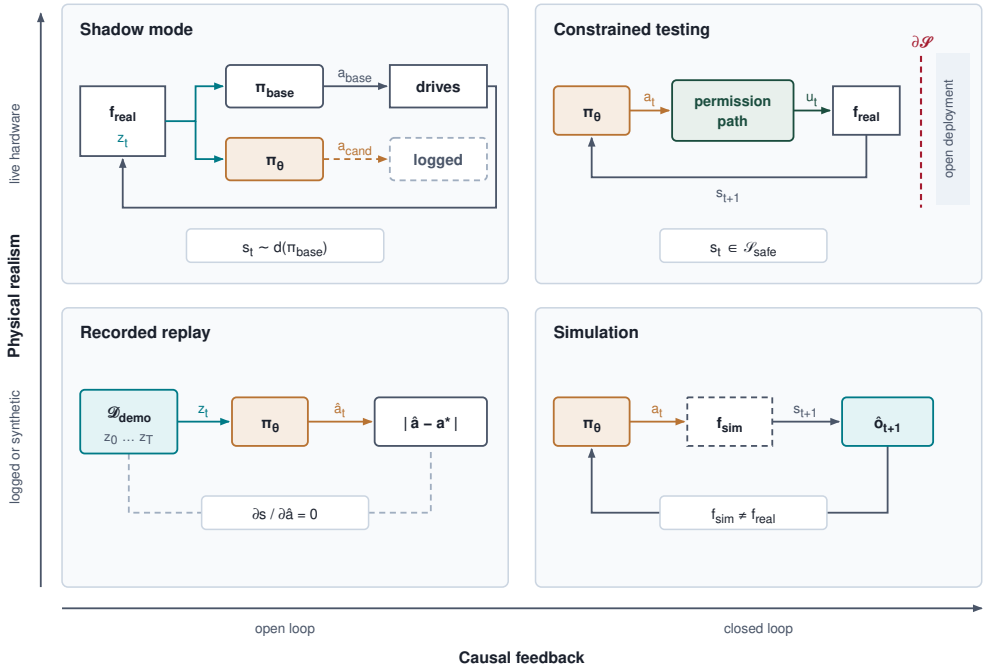

Figure 7.2: Evaluation evidence regimes: The regimes vary along causal feedback (open vs. closed loop) and physical realism (logged or synthetic vs. live hardware). Replay cannot observe compounding drift, simulation leaves the reality gap open, shadow operation locks the trajectory to the baseline controller, and constrained testing truncates failures at the constraint boundary $\partial\mathcal{S}$. No single regime tests deployment beyond that boundary.

Shadow operation yields direct evidence about real-time system performance. It can confirm, for instance, whether the latch policy maintains its target 20 Hz chunk rate under sustained thermal throttling, and quantify how frequently $\mathbf{a}_t^{\text{cand}}$ deviates from the baseline control action $\mathbf{a}_t^{\text{base}}$ beyond an acceptable safety threshold.

Shadow operation is limited, however, by the **trajectory confinement problem**. Because the baseline controller exercises exclusive control over the actuators, the physical robot traces trajectories governed strictly by the baseline state distribution $d^{\pi_{\text{base}}}$. If the candidate policy generates an action that would cause the arm to jam the latch, veer off course, or strike a support strut, the physical plant never executes the command. The candidate's sensory stream remains confined to the safe states visited by the baseline supervisor. As a result, shadow testing cannot reveal whether the candidate could recover from an unvisited off-nominal state, nor can it expose whether its divergent actions would have caused mechanical damage.

Constrained physical testing closes the causal feedback loop on actual hardware by routing candidate policy proposals through the permission path to the actuators, strictly within an enforced safety envelope. These operational boundaries are enforced via hardware tethers, software velocity clamps, geofenced test enclosures, or a dedicated real-time permission path that intercepts and overrides unsafe setpoints with deterministic latency. Constrained testing delivers authentic empirical evidence regarding real-world contact mechanics, friction transitions, structural compliance, and sensor noise under actual operating loads, which is why the experimental door-latch trials belong in this regime.

When the safety system triggers an intervention, it alters or truncates the raw policy trajectory ($n_{\text{int}_i} \geq 1, A_i = 0$), leaving the candidate's unmitigated behavior permanently unobserved. Such a run answers two different questions, and the record must keep them apart. For the autonomy outcome it is an unambiguous failure, $A_i = 0$, because the candidate policy could not finish without external override. Even if the supervisor guides the robot to successful task completion, the trial cannot be scored as an autonomous success. For the separate event of an unassisted crash, the

question of whether the policy would have damaged something had nobody stepped in, the run is right-censored.[5] The intervention terminated the trial before that terminal state could manifest, so the observation confirms neither unassisted success nor an inevitable crash. Any rigorous evaluation must report completion rates, intervention frequencies, and post-intervention recoveries strictly inside the verified operating envelope. Conflating safety-supervised task completion with unassisted policy survival commits the **censored trial fallacy**, which attributes to the machine learning policy a level of robustness that the permission path or the safety operator provided.

Certain software properties transfer cleanly across regime boundaries when inputs and execution semantics match. Deterministic numerical calculations, floating-point arithmetic invariants, and tensor shape contracts can be checked under the same precision, rounding, and overflow rules. An activation overflow transfers only when the simulator and target implement the same arithmetic behavior. In contrast, runtime execution latency, bus contention, and memory bandwidth utilization cannot transfer purely across regimes. They require re-measurement under the actual scheduling, fieldbus, and thermal environments of the deployment hardware. Above all, the operating state distribution never transfers directly. The instant the environmental operator transitions from synthetic simulation f_{sim} to live physical dynamics f_{real}, or when the arbitration parameters of the runtime permission path change, the state trajectory $\mathbf{x}_0, \mathbf{x}_1, \ldots, \mathbf{x}_t$ rapidly diverges.

Treating these four regimes as a monotonic ladder of fidelity is a mistake. Transitioning across replay, simulation, shadow execution, and constrained testing does not simply increase fidelity; every step exchanges one systemic distortion for another. Simulation secures closed-loop causality at the expense of authentic contact physics and sensory noise. Shadow execution reclaims real physical sensing and bus timing but surrenders candidate closed-loop causality. Constrained physical testing restores both causality and physical grounding, yet it systematically censors the state space beyond its safety boundary. Observing zero supervisor interventions across one hundred constrained trials proves that the policy maintained states within the un-triggered safety envelope; it offers no statistical guarantee about how the policy behaves once it breaches that boundary.

System verification therefore demands assigning each engineering question to the specific regime equipped to answer it (table 7.2). For the latch manipulation policy, verifying whether chunk inference executes reliably within its allocated cycle time belongs first in recorded replay and subsequently in hardware shadow mode. Testing whether the manipulator can recover from a wide range of positional offsets belongs in high-throughput simulation, where thousands of permutations inflict zero hardware wear. Evaluating whether passive gripper compliance and contact friction remain within structural force limits belongs strictly in constrained physical trials. Each regime remains blind to the failure modes of the others.

[5] **Right Censoring**: In clinical survival analysis, a patient who departs a study before the terminal endpoint has an unknown time of death rather than an established long life. Kaplan and Meier (1958) formalized an estimator that tracks such subjects within the population at risk only while they remain actively observed. An intercepted robotic trial is right-censored under identical logic: the intervention proves that the policy required supervisor takeover, not that the robot would have stabilized itself had the supervisor remained passive.

Table 7.2: Evaluation evidence regimes compared: Trade-offs between causal feedback coupling, environmental realism, supported empirical claims, and experimental boundary distortions across the four testing regimes. No single environment evaluates open deployment; rigorous certification requires combining complementary regimes rather than assuming a linear fidelity ladder.

Evaluation Evidence Regime	Causal Feedback Coupling	Physical Realism	Supported Empirical Evidence	Masked Failure Mode / Boundary Distortion
Recorded Replay	Open Loop ($\partial \mathbf{x}_{t+1} / \partial \hat{\mathbf{a}}_t = \mathbf{0}$)	Static Demonstration Buffers $\mathcal{D}_{\text{demo}}$	Latency budget, DRAM footprint, numerical accuracy	Covariate shift; errors never alter subsequent observations
Closed-Loop Simulation	Closed Loop ($\mathbf{x}_{t+1} = f_{\text{sim}}(\mathbf{x}_t, \mathbf{u}_t)$)	Synthetic Physics Operator f_{sim}	Kinematic reachability, large parallel test suites	Sim-to-real gap; unmodeled contact non-linearities and tire slip
Shadow Mode Operation	Open Loop for candidate (actions muted)	Physical machine f_{real}	Bus contention, thermal throttling, real sensor noise	Trajectory confinement; states locked to baseline controller $d^{\pi_{\text{base}}}$
Constrained Physical Testing	Closed Loop with permission-path override ($\mathbf{u}_{\text{safe}}$)	Physical machine f_{real} within envelope	Contact dynamics, compliance, friction, actuator limits	State censorship; permission-path overrides and tethers truncate failure tails

7.4.2 Simulation as a conditional proxy

A simulator can screen candidate latch policies before expensive hardware is committed to physical trials, but its screening validity depends on how accurately it models the physical mechanisms governing the decision. Paired probing, developed in section 6.4.2, drives the simulated and physical strike plates with identical commands and measures their discrepancies in newtons and milliseconds. The evaluation protocol incorporates those measured discrepancies directly into its test plan. A favorable simulated recovery qualifies a checkpoint for physical verification, but that result cannot resolve unmodeled discrepancies in the contact physics or data transport pipeline. Visual rendering artifacts, numerical friction regularization, and absent force-torque feedback can each alter candidate policy rankings.

Whether a simulator ranks candidate policies correctly is an empirical, measurable property. Proxy fidelity is measured with a paired benchmark across both regimes. The benchmark evaluates the same set of candidate policies (such as the latch training checkpoints) on both the simulated door mechanism and the physical hardware under tightly matched initial conditions, then compares the resulting performance orderings. While a standard Pearson or Spearman correlation coefficient between simulated and physical success rates summarizes overall monotonic agreement, correlation alone can hide the failure that matters most. A high correlation coefficient can coexist with a rank inversion, in which the simulator promotes a checkpoint that fails on the physical door. To address this risk, X. Li et al. (2024) measure rank agreement with the mean maximum rank violation (MMRV), computed across approximately 1,500 paired simulated and physical episodes. For each policy, MMRV finds its worst inversion against any other policy, weighting each pair the simulator orders wrongly by the two policies' real-world performance gap. MMRV then averages those worst cases across policies, so a simulator scores badly exactly when it swaps policies whose physical performance differs most.

This evaluation principle applies directly to the latch manipulation task. A simulator whose relative rankings across historical checkpoints correlate reliably with physical trials earns the operational authority to screen incoming models. Conversely, a simulation environment that has never been calibrated against paired physical benchmarks possesses no screening credibility, regardless of how photorealistic its graphics engine appears. The identical constraint governs learned neural world models deployed as simulated environments: predicted candidate success serves as a justification for scheduling physical tests, not as verifiable evidence of physical capability, until paired real-world trials validate model calibration. Furthermore, even a validated ranking proxy only authorizes candidate filtering. Physical trials remain the ground truth for safety and performance claims, because knowing that policy A outperforms policy B reveals nothing about whether policy A satisfies the machine's absolute failure-rate limits.

↩ Learned world models used as simulators, whose simplifications cannot be enumerated, are established in section 6.4.3.

Two additional systems factors dictate the generalization bounds of any simulation-based evaluation: parameter domain coverage and execution timing fidelity. The first factor is the physical parameter variation spanned during simulation trials. A simulation calibrated against telemetry logs from a single robotic arm provides evidence strictly for that physical unit under those specific ambient conditions. Similarly, domain randomization evaluates policy resilience only across the bounded support of the randomized parameter distributions; it cannot account for dynamic phenomena entirely absent from the simulator's underlying differential equations. Formal sim-to-real gap analysis identifies unmodeled dynamics and compiles them into the omission log that the policy manifest carries. The closed-loop evaluation protocol must incorporate that log directly, cataloging the operating regimes and edge conditions about which simulation can make no empirical claims.

↩ Formal sim-to-real gap analysis, which yields a supported region and a residual mismatch list, is established in section 6.5.

The second factor is whether the evaluation regime reflects true hardware execution dynamics. Standard software-in-the-loop simulations pause virtual simulation time while the policy executes neural inference, masking real-world computational bottlenecks. A simulator that pauses virtual time during inference cannot expose the consequences of a late inference chunk, a rejected stale proposal, or an executing chunk that continues under its 60 ms chunk lease while awaiting updated sensor verification. Explicit delay models can exercise those transitions, but establishing their actual timing requires the neural policy and runtime permission arbiter on target embedded compute hardware interconnected via the physical buses.

↩ The chunk lease, sized between the renewal floor and the stopping budget, is established in section 4.4.

Closed-loop simulation, whether executed purely in software or integrated with hardware in the loop, serves as a filter for screening candidate models. Only physical trials, however, measure

embodied competence, and engineers must formalize the safety envelopes and evaluation protocols long before the first trial begins.

↪ The qualification ladder, which stages software-, processor-, and hardware-in-the-loop benches before physical fault rigs, is developed in section 15.7.

Checkpoint 7.1: Trade-offs across evidence regimes

Before fixing a physical trial protocol, review evidence regimes and fidelity trade-offs:

- ☐ **Regime causality trade-offs**: Contrast the causal feedback properties of recorded trace replay against closed-loop simulation.
- ☐ **Shadow-mode trajectory confinement**: Explain why shadow-mode evaluation on the running machine cannot test the candidate policy's recovery maneuvers.
- ☐ **Transfer across regimes**: Describe which properties transfer reliably across regimes and which one stays behind.

7.5 Fixing the Trial Protocol

If an engineering team executes fifty ad hoc physical runs across arbitrary trajectories in a constrained test cell and reports a 90 percent success rate, that statistic lacks an interpretable denominator. Empirical success probabilities and intervention rates are meaningful only with respect to a specific joint distribution $\mathcal{D}$ over initial system states, environmental parameters, and task goals, so the intended operating region must be formalized before executing a single physical trial. The **target ODD** is the concrete subset of the declared ODD recorded by the policy manifest of section 6.8 that the evaluation campaign samples. Its sampling weights define $\mathcal{D}$, and no rigorous empirical claim reaches beyond its support. A measured success rate supports a target-distribution claim only when the support and sampling weights of $\mathcal{D}$ are specified in advance, setting explicit bounds on scene illuminance, payload mass and inertia, surface friction coefficients, allowable initial state offsets, and the specific hardware serial numbers under test.

Extracting valid confidence bounds from empirical trials requires three operational conditions:

1. *Independent and identically distributed (iid) sampling:* Trials must be independent realizations drawn from $\mathcal{D}$. In embodied physical systems, standard offline dataset intuition often fails; randomly shuffling log records cannot eliminate physical coupling. On real robotic hardware, thermal accumulation in motor windings from resistive heating (I^2R), battery voltage sag under discharge, and progressive mechanical backlash introduce temporal autocorrelation across sequential trials. Correlated trials, like the serially correlated telemetry of section 5.4, carry fewer independent observations than their count suggests. Run 20 is not drawn from the same physical distribution as Run 1 unless operators strictly enforce thermal cooldown intervals and battery recharging cycles between runs. Furthermore, repeated trials executed on a single physical unit (such as Unit 01) cannot serve as iid draws from the broader fleet distribution $\mathcal{M}$, because unit-level manufacturing tolerances and sensor calibrations bias the sample.
2. *Fixed outcome predicates:* The binary evaluation function ϕ and termination criteria κ must remain frozen throughout the entire campaign. Modifying the execution deadline T_{deadline}, adjusting collision thresholds, or widening the spatial tolerance of goal region $\mathcal{G}_{\text{goal}}$ midway through testing alters the definition of success. Doing so commits post-hoc metric drift and invalidates statistical comparisons against baseline models.
3. *Full-denominator accounting:* Every initiated run must remain in the trial log, including hardware communication faults, sensor timeouts, emergency protective stops, and operator interventions. Culling inconvenient or anomalous runs corrupts the statistical denominator. A hardware abort that halts execution prior to goal completion yields a task failure ($Y = 0$). Under a strict autonomy metric, any human intervention forces $A = 0$. An operator nudge that guides the robot around an obstacle followed by on-time completion records $Y = 1$ and $A = 0$. Safety monitoring systems must record kinematic limit violations and physical damage separately from task completion. When a safety tripwire or human supervisor intercepts an impending collision, the counterfactual unmitigated trajectory remains unknown. Consequently, zero recorded damage cannot be credited as evidence of unassisted survival. Discarding aborted

or intercepted runs changes the underlying question and inflates perceived reliability by measuring an idealized survivor population.

When these conditions hold, the sample mean provides an unbiased point estimate of the policy's closed-loop performance under $\mathcal{D}$. The remaining engineering challenge is determining how much statistical uncertainty a finite sample leaves, particularly when high-reliability targets yield zero observed failures across the test budget.

7.6 Confidence from a Finite Campaign

With the operational outcome, target population, evaluation regime, and trial denominator fixed, the twenty clean nominal runs pose an immediate statistical problem: determining what degree of reliability the campaign has actually demonstrated. A confidence bound quantifies the uncertainty that remains under the declared sampling model. Systems engineers must treat this bound as a measure of statistical evidence rather than an assessment of physical failure severity or an automatic deployment permit.

The standard textbook interval for a proportion, the Wald normal approximation $\hat{p} \pm 1.96\sqrt{\hat{p}(1-\hat{p})/N}$, collapses to zero width when the observed success fraction $\hat{p}$ reaches 1.0 because its sample variance term vanishes. This collapse exposes the breakdown of the asymptotic normal assumption near the boundary rather than empirical certainty. Evaluating the statistical assurance of a zero-failure record requires only the product rule for independent events.

Suppose the true per-run success probability of the latch policy is p. If individual trials are independent, twenty consecutive runs all succeed with joint probability p^{20}. Consider a flawed policy that fails one run in eight ($p = 0.875$). That policy still produces an unbroken twenty-run success streak in 6.9 percent of evaluation campaigns. An empirical run of twenty successes cannot rule it out. As the candidate success rate p decreases, a clean record becomes increasingly improbable. When p drops to 0.861, the probability of observing twenty consecutive successes falls to exactly $\alpha_{\text{sig}} = 0.05$, which corresponds to the significance level for a 95 percent confidence requirement $(1 - 0.95)$. Any underlying success probability lower than 0.861 would make the observed twenty-run clean record rarer than a 1-in-20 chance ($p^{20} < 0.05$). The one-sided lower confidence bound therefore identifies the threshold below which candidate policies become statistically inconsistent with the experimental data. In standard frequentist qualification, "95 percent confidence" describes the long-run coverage of the testing protocol. Across repeated qualification campaigns, the procedure traps the true parameter p above the calculated bound at least 95 percent of the time. The bound represents a conservative floor under the declared sampling model rather than a point estimate of p or a Bayesian posterior belief about this specific policy.

Reading the inversion as a curve makes the logic visible. Plotting p^{20} against every candidate p (figure 7.3) shows the clean record ruling out only the candidates whose curve lies below the α_{sig} line, the region left of $p = 0.861$. The one-in-eight policy sits just above that line, which is why twenty flawless runs cannot reject it.

For a predeclared zero-failure campaign of n trials, this inversion yields the exact one-sided Clopper-Pearson lower bound[6] (Clopper and Pearson 1934). Setting $p^n = \alpha_{\text{sig}}$ gives

$$p_{\text{lower}} = \alpha_{\text{sig}}^{1/n} \tag{7.3}$$

with the corresponding upper confidence limit on the per-run failure probability given by:

$$p_{\text{fail, upper}} = 1 - \alpha_{\text{sig}}^{1/n}$$

Section 7.6.1 extends this inversion principle to evaluation campaigns that record failures.

For rare failures ($p_{\text{fail}} \ll 1$), a first-order Taylor series expansion linearizes this bound into the **rule of three** (Hanley and Lippman-Hand 1983). Expanding $\ln(1 - p_{\text{fail}}) = -p_{\text{fail}} - p_{\text{fail}}^2/2 - \cdots \approx -p_{\text{fail}}$ and setting the clean-run probability $(1 - p_{\text{fail}})^n$ equal to $\alpha_{\text{sig}} = 0.05$ yields $-n\,p_{\text{fail}} \approx \ln(0.05) \approx -2.996 \approx -3.0$. When n independent trials pass without a single failure, the upper 95 percent confidence limit on the per-trial failure probability simplifies to:

$$p_{\text{fail, upper}}^{95\%} \approx \frac{3}{n}. \tag{7.4}$$

[6] **Exact Binomial Bound**: Clopper and Pearson (1934) inverted the binomial tail directly instead of approximating it with a normal distribution. Here "exact" denotes that algebraic inversion rather than exact coverage probability; because binomial counts are discrete, the true coverage equals or exceeds the nominal confidence level for all values of p. Under the declared binomial sampling model, the procedure places the lower bound at or below the true reliability in at least the nominal fraction of repeated campaigns; an individual campaign can still overstate it.

↪ The discrete and continuous-time derivations of the zero-failure bound, and why the normal approximation fails at zero failures, are developed in section A.8.

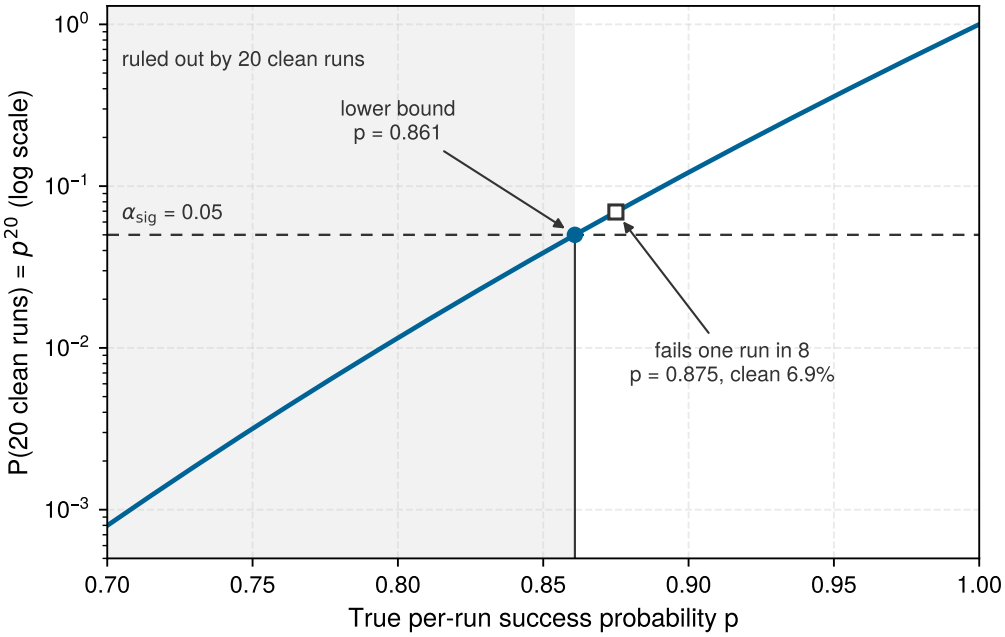

Figure 7.3: Inverting a clean record into a bound: The probability that 20 independent runs all succeed, p^{20}, against the true per-run success probability p. Candidates left of the crossing with $\alpha_{sig} = 0.05$ would make the observed record rarer than one campaign in twenty, so the record rules them out; the crossing at $p = 0.861$ is the lower bound. The one-in-eight policy still logs a clean record in 6.9 percent of campaigns.

DRAFT

Inverted to size test campaigns, the rule establishes the empirical burden for any target reliability: $n \approx 3/(1-p_{\text{target}})$. Each additional "nine" of target reliability multiplies the required trial volume tenfold. For the twenty door-opening trials, equation 7.4 yields an approximate upper failure bound of $3/20 = 0.15$, whereas the exact Clopper-Pearson computation in notebook 7.1 establishes 13.9 percent. A policy with a true failure probability as high as 13.9 percent remains entirely compatible with twenty consecutive successes at 95 percent confidence. The campaign cannot substantiate an industrial claim of 99 percent reliability. Formally certifying a 99 percent lower confidence limit ($p_{\text{target}} = 0.99$) at 95 percent confidence demands:

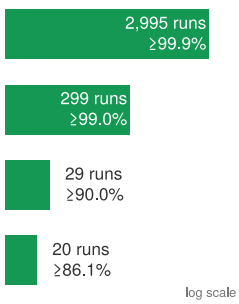
$$n = \left\lceil \frac{\ln(\alpha_{\text{sig}})}{\ln(p_{\text{target}})} \right\rceil = \left\lceil \frac{\ln(0.05)}{\ln(0.99)} \right\rceil \tag{7.5}$$

which equals 299 consecutive clean trials, an order of magnitude beyond the twenty trials conducted in the initial campaign.[7]

The bound inherits the iid condition of section 7.5. Twenty runs on Unit 01 therefore bound Unit 01's success probability under the sampled conditions and nothing more. The unit-to-unit variance of section 7.2 puts Unit 02 in a different population, whose bound needs its own trials or a sample drawn across the fleet.

> Napkin Math 7.1: The clean-record bound
>
> **Problem**: The mobile manipulator completes $n = 20$ door-opening runs with no contact-tripwire crossing and no intervention. What one-sided 95 percent lower limit on its per-run success probability p does that record support, and what does it cost to claim 99.9 percent instead?
>
> **Variables**:

7 | **Rule of Three**: The heuristic originates in biostatistics, where Hanley and Lippman-Hand (1983) evaluated the risk to future patients following a clinical trial with zero adverse events across n participants. An embodied evaluation campaign asks an identical question of the next robot trial, and the same $3/n$ ratio governs the bound.



Each added nine of reliability costs ten times the clean runs.

- $n = 20$ clean runs (Illustrative; the chapter's opening campaign, independent and identically distributed draws from the target operational design domain).
- $\alpha_{\text{sig}} = 0.05$ (Chosen; one minus the 95 percent confidence level).

Math: Setting $p^n = \alpha_{\text{sig}}$ (equation 7.3) and taking logarithms, $\ln(1/\alpha_{\text{sig}}) = 2.996$, divided by n gives the exponent 0.1498, and p_{lower} is e raised to minus that exponent, 0.861. The failure upper limit is $1 - p_{\text{lower}}$, or 13.9 percent, which the rule of three (equation 7.4) approximates as $3/20 = 0.15$.

Result: 86.1 percent success lower limit at 95 percent confidence; a 99.9 percent limit needs 2,995 clean runs (notebook 7.2).

Systems insight: Twenty clean runs leave a failure probability as high as one run in seven statistically consistent with the empirical data. The evaluation campaign establishes a formal lower confidence bound under its specific sampling assumptions. It should never be conflated with a steady-state failure rate, an MTBF, or an unconditional deployment authorization. Improving the bound requires scaling n, because the numerator $\ln(1/\alpha_{\text{sig}}) \approx 3$ remains anchored by the chosen confidence level. This structural property explains why the rule of three matches the exact Clopper-Pearson bound whenever failure probabilities are small.

7.6.1 Bounds when failures occur

If the mobile manipulator jams on the twentieth door run after nineteen clean openings, the zero-failure rule of three no longer applies, yet discarding the campaign would waste nineteen valid observations. Encountering an operational failure during testing does not invalidate statistical evaluation. Instead, it shifts the calculation from the zero-failure boundary to the full binomial distribution. Given k successful trials out of N total runs, the one-sided lower confidence limit is the parameter value p for which the probability of observing k or more successes equals α_{sig}:

$$\Pr(X \geq k \mid N, p) = \sum_{j=k}^{N} \binom{N}{j} p^j (1-p)^{N-j} = \alpha_{\text{sig}}, \tag{7.6}$$

where the random variable X denotes the success count. A hypothesis test rules out a low candidate reliability p by asking how likely a policy that poor would be to produce an outcome at least as favorable as the observed k successes, so summing from $j = k$ up to N captures the full upper tail of outcomes that meet or exceed the observed record. When $k = N$, the summation collapses to a single term, $p^N = \alpha_{\text{sig}}$, recovering the zero-failure Clopper-Pearson bound of equation 7.3. With that single failure across twenty runs ($k = 19$), the relationship expands to $p^{20} + 20p^{19}(1-p) = \alpha_{\text{sig}}$. Although this polynomial lacks a closed-form algebraic root, numerical root-finding yields a 95 percent lower confidence limit of 78.4 percent. Even though the empirical success fraction is 95 percent, a single observed failure drops the certified lower bound from 86.1 percent to 78.4 percent. In production evaluation pipelines, libraries compute this limit directly using quantiles of the incomplete beta function, which follows from the exact identity between binomial tails and Beta distributions.

Two engineering cautions govern this method. First, any observed failure must remain permanently logged in the audit trail. Halting a test campaign upon observing an anomaly and restarting a clean run counter introduces optional-stopping bias. Engineers cannot subsequently claim a zero-failure bound on the post-restart run sequence (section 7.7.1). Second, the Clopper-Pearson method is conservative by construction because its coverage probability equals or exceeds the nominal confidence level for every value of p. For standard exploratory data analysis, Brown et al. (2001) recommend the Wilson score interval[8] or Jeffreys prior intervals, which maintain average coverage closer to nominal while producing tighter intervals. For physical qualification and safety certification, however, overestimating autonomous reliability is the costly error. The conservative Clopper-Pearson bound therefore serves as the defensible systems default, and engineering test records must explicitly state the inference method applied.

The twenty nominal door-opening runs now have a concrete statistical interpretation under nonasymptotic sampling theory. Elevating the certified lower bound requires expanding the trial budget,

[8] **Wilson Interval**: Wilson (1927) inverted the score test around the parameter p rather than substituting the empirical estimator $\hat{p}$, allowing the interval to maintain a nonzero width even when $\hat{p} = 1.0$. This formulation resolves the boundary collapse of the Wald normal approximation. However, because its coverage guarantees hold on average across the parameter space rather than strictly at every point p, physical qualification protocols default to the exact Clopper-Pearson bound.

which directly compounds the physical testing hours, mechanical wear, and facility costs needed to qualify embodied machine learning policies.

7.7 Trial Budgets, Stopping Rules, and Comparisons

While a million software unit tests consume only processor cycles, each closed-loop trial of a physical robot consumes test-cell time, exhausts bearing and linkage fatigue life, burns thermal headroom in motor windings, and risks costly hardware damage. Statistical theory dictates how many trials a reliability claim demands, but on a physical machine the plant, not the compute budget, determines what each trial costs. Sizing a qualification campaign therefore means reconciling the trial count required by statistical confidence with the operational time and fatigue life of the testbed that must supply it. That reconciliation separates a rigorous qualification argument from an anecdotal demonstration. The same budget pressure then motivates the two refinements that close the section: stopping a campaign early without inflating its error rates, and deciding whether a retrained checkpoint is better than the one it would replace.

7.7.1 Sample size requirements per empirical claim

Reconciling confidence with testbed capacity starts by fixing the statistical claim before scheduling the cell, because the reliability target, not the length of an afternoon shift, dictates the required sample size. For a zero-failure campaign the count is equation 7.5, with the rule of three as its rare-failure approximation. Figure 7.4 plots it across confidence levels, and table 7.3 tabulates it. The claim (target and confidence) is fixed first, the count follows from it, and if a testing facility cannot afford that count, the engineering team must narrow its claim rather than present an underpowered test as formal qualification. If a campaign records any failure, it must apply the general binomial bound of section 7.6.1. An engineering team cannot salvage a zero-failure claim by appending clean runs after inspecting intermediate data.

7.7.2 Test-cell time and wear per trial

↪ The same bound, counted in operating hours rather than trials, and the population such a statistic describes are developed in section 15.10.1.

The door-opening campaign illustrates how the physical cost of a single trial accumulates. During a nominal execution run, the mobile base navigates inward from its 2 m standoff position and stops. The manipulator arm then executes a guarded unlatching sequence at 0.03 m/s and swings the door open. These physical motions occupy 25 s of active test-cell time. Preparing the testbed for the next statistically independent draw requires an automated reset: re-latching the door mechanism, navigating the base back to its standoff position, and flushing onboard telemetry buffers. This reset sequence adds 15 s, bringing the total wall-clock budget for each trial to 40 s. At this cycle duration, the initial twenty clean runs take 13.3 min. Qualifying a 99.9 percent success lower limit (notebook 7.2) demands a far larger campaign, even before accounting for the thermal cooldown intervals required by the actuator windings.

↩ The recovery time a periodic duty cycle forces between loaded bursts, before the windings reach their temperature ceiling, is established in section 2.5.2.

Napkin Math 7.2: The nines tax

Problem: An evaluation target calls for a one-sided success lower limit of $p_{\text{target}} = 0.999$ at 95 percent confidence. How many zero-failure door runs does it need, and how long does the latch cell take to supply them?

Variables:

- $p_{\text{target}} = 0.999$ and $\alpha_{\text{sig}} = 0.05$ (Chosen; the claim).
- $t_{\text{run}} = 25$ s and $T_{\text{reset}} = 15$ s (Illustrative; drive-in, guarded unlatch, swing, then re-latch and return), so $T_{\text{trial}} = 40$ s.
- two safety operators per run (Illustrative).

Math: From equation 7.5, $n = \lceil \ln(1/\alpha_{\text{sig}}) / \ln(1/p_{\text{target}}) \rceil = \lceil$ 2.996 / 0.0010005 $\rceil$ = 2,995, close to the rule of three's $3/(1-p_{\text{target}})$. The cell time is 2,995 × 40 s = 119,800 s, or 33.3 h (1.4 days) of continuous testing, and 66.6 h of operator time, over eight eight-hour shifts.

Result: 2,995 clean runs and 33.3 h of cell occupancy, against 13.3 min for the opening twenty.

Systems insight: The denominator $\ln(1/p_{\text{target}}) \approx 1 - p_{\text{target}}$ shrinks tenfold with each added nine, so each nine multiplies the runs, the cell hours, and the wear by ten. A longer cycle scales the hours in proportion. A campaign this long also outlives the stationarity it assumes, and a component replaced midway may require a new population definition rather than pooling incompatible runs.

The two panels of figure 7.4 separate two lessons. Early clean runs buy confidence cheaply, and the 95 percent lower limit already reaches 86.1 percent after twenty runs. Past that point the curves crowd under the 99.9 percent target, and the confidence level matters far less than the target itself. On log axes the failure upper limit falls only one decade per decade of trials, so the last nine is the expensive one: 2,995 runs, or 33.3 h of test-cell time at the door cycle.

Table 7.3: One-sided binomial confidence limits after zero failures: Success lower limits are $\alpha_{\text{sig}}^{1/n}$ and the corresponding failure upper limit is $1 - 0.05^{1/n}$. Test times use the 40 s door cycle.

Zero-failure trials n	90% lower success limit	95% lower success limit	99% lower success limit	95% upper failure limit	Test time at door cycle	Interpretation under iid test draws
10	79.43%	74.11%	63.10%	25.89%	0.1 h	Wide uncertainty; no observed failures
20	89.13%	86.09%	79.43%	13.91%	0.2 h	Bound applies only to the sampled distribution
50	95.50%	94.18%	91.20%	5.82%	0.6 h	More evidence; untested conditions remain
100	97.72%	97.05%	95.50%	2.95%	1.1 h	No deployment permission follows from the interval
250	99.08%	98.81%	98.17%	1.19%	2.8 h	Check hardware and sampling stationarity
500	99.54%	99.40%	99.08%	0.60%	5.6 h	Bound remains tied to declared conditions
1,000	99.77%	99.70%	99.54%	0.30%	11.1 h	Below a 99.9% lower-limit target
2,995	99.92%	99.90%	99.85%	0.10%	33.3 h	Meets that statistical target if assumptions hold

The physical plant also degrades as trials accumulate. Statistical confidence bounds assume iid draws from a stationary process, but physical wear breaks stationarity. Transmission backlash (lost motion), effective wheel radius, tire surface friction, and joint damping all drift at rates that engineers must monitor directly on the test hardware. Pooling a thousand trials without that monitoring treats an evolving, degrading machine as an unchanging platform. A failure on trial 950 may reflect testbed wear, a policy limitation, or their interaction; configuration and condition logs are needed to distinguish these causes. The wear itself is budgeted as it is for demonstration collection, by charging each trial's cycles against the rated life of the drivetrain components.

Trials this expensive make stopping early attractive. A fixed-sample, zero-failure protocol already permits safe early rejection: testing halts immediately upon the first observed failure, avoiding pointless exposure to a hazardous policy. Early acceptance, however, presents a different statistical challenge. Halting testing prematurely simply because intermediate results appear favorable inflates the false-positive rate unless the stopping threshold was calibrated in advance. To balance test efficiency with rigorous error guarantees, section 7.7.3 develops sequential boundaries for both acceptance and rejection.

↩ Sizing a physical campaign against operational yield and the fatigue life of drivetrain components is established in section 5.6.3.

7.7.3 Sequential probability ratio testing

Wald's sequential probability ratio test (SPRT)[9] (Wald 1945) provides those pre-calibrated stopping boundaries by evaluating the cumulative log-likelihood ratio after each successive trial, comparing an unacceptable failure rate against an acceptable one. For a strict autonomy campaign, the Bernoulli

[9] **Sequential Testing in Wartime**: The test grew out of work at Columbia University's Statistical Research Group during the Second World War, as a way to accept or reject production lots after inspecting fewer items, and it carried a restricted classification until Wald (1945) set it out in the open literature. The robot campaign faces the same economics, because every trial consumes hardware, and stopping as soon as the evidence is decisive saves trials at the declared error rates.

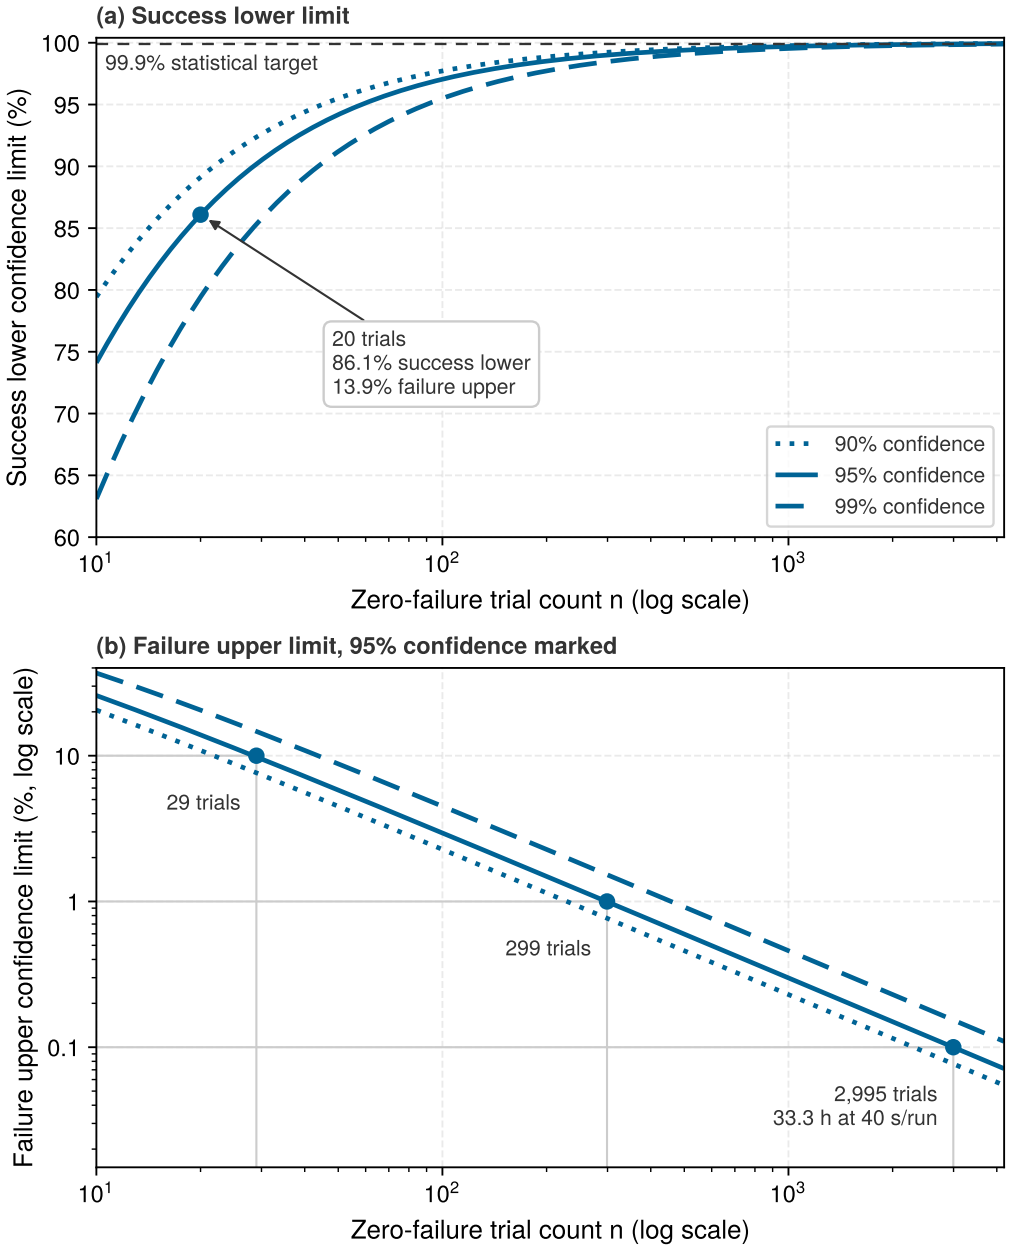


Figure 7.4: Confidence bounds and testing budgets: (a) One-sided Clopper-Pearson success lower limits after zero failures at 90, 95, and 99 percent confidence; at 95 percent, 20 iid runs give 86.1 percent, and the curves then crowd under the target. (b) The same limits read as failure upper limits on log axes fall one decade per decade of runs, so each further nine costs ten times the trials: 99.9 percent needs 2,995 runs, or 33.3 h at the 40 s door cycle.

outcome records unassisted task completion; for a full-system service evaluation, it records the separately specified operational outcome. While the mathematical formulation accommodates either metric, the outcome definition must remain strictly frozen throughout data collection.

Following the convention of section A.9, this subsection states its hypotheses in failure probability. Within it, p_{fail} denotes the per-trial failure probability (the p_{fail} of section 7.6), not the success probability of the preceding sections, and p_0 and p_1 are failure rates. The comparison of two policies

↪ The full SPRT derivation for Bernoulli trials, including Wald's boundary approximations and their overshoot calibration, is developed in section A.9.

that follows returns to success rates. For hypotheses $H_0 : p_{\text{fail}} = p_0$ (unacceptable failure rate) and $H_1 : p_{\text{fail}} = p_1 < p_0$ (acceptable reliability), observing k failures across m independent trials yields the log-likelihood ratio:

$$\Lambda_m = k \ln\left(\frac{p_1}{p_0}\right) + (m-k)\ln\left(\frac{1-p_1}{1-p_0}\right) \tag{7.7}$$

Each success increments the ratio toward acceptance, while each failure drives it sharply toward rejection. With the illustrative hypotheses $p_0 = 0.10$ and $p_1 = 0.01$, a success adds 0.0953 while a failure subtracts 2.303. This metric tracks cumulative evidence for the declared outcome; it never grants permission to continue an unsafe physical run when a safety tripwire is breached.

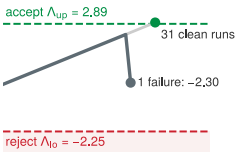
Wald's approximate boundaries on the log-likelihood ratio are:

$$\Lambda_{\text{up}} \approx \ln\left(\frac{1-\beta}{\alpha_{\text{sig}}}\right), \quad \Lambda_{\text{lo}} \approx \ln\left(\frac{\beta}{1-\alpha_{\text{sig}}}\right) \tag{7.8}$$

where α_{sig} represents the allowed probability of accepting H_1 when H_0 holds, and β represents the allowed probability of rejecting H_1 when it holds. For nominal targets of $\alpha_{\text{sig}} = 0.05$ and $\beta = 0.10$, the boundaries evaluate to $\Lambda_{\text{up}} \approx$ 2.890 and $\Lambda_{\text{lo}} \approx$ -2.251. Following each physical rollout m, the evaluation supervisor executes one of three rules:

1. If $\Lambda_m \geq \Lambda_{\text{up}}$: Halt testing and accept H_1 under the declared test (documenting certified evidence within the target ODD).
2. If $\Lambda_m \leq \Lambda_{\text{lo}}$: Halt testing and reject H_1 (policy rejected; abort the campaign immediately to prevent hardware damage).
3. If $\Lambda_{\text{lo}} < \Lambda_m < \Lambda_{\text{up}}$: Continue sampling; execute rollout $m+1$.

Tracing an evaluation run reveals the operational efficiency of this sequential framework. Starting from a neutral score of zero, a failure on the first run crosses boundary Λ_{lo} immediately, halting testing. Conversely, reaching acceptance from zero requires 31 consecutive clean runs, found by dividing threshold Λ_{up} by the per-success increment and rounding up. Unlike a rigid zero-failure protocol, a failure mid-campaign does not force immediate termination. After 25 clean runs and one failure, the score settles at 0.08, remaining between the thresholds, so testing continues. Compare this with a fixed-sample zero-failure test for a 90 percent success lower limit, which requires 29 clean runs and rejects upon any failure. While both designs demand comparable trials on a spotless record, the fixed test rejects an acceptable policy with $p_{\text{fail}} = p_1$ in 25.3 percent of campaigns, whereas the sequential test explicitly bounds that Type II error. The sequential design earns its place on the testbed by controlling both error modes, not simply by promising fewer trials.



Each clean run adds 0.0953; one failure subtracts 2.303.

The error guarantees follow directly from the likelihood ratio itself. Under H_0, the likelihood ratio e^{Λ_m} forms a nonnegative martingale with unit mean, a sequence whose expected next value, given everything observed so far, equals its current value. Because no run is expected to raise it, no rule for choosing when to stop can raise its expected size either. By Ville's inequality,[10] the probability that it ever reaches $e^{\Lambda_{\text{up}}}$ is bounded by $e^{-\Lambda_{\text{up}}}$ (Ville 1939). Under Wald's boundary, that bound evaluates to $\alpha_{\text{sig}}/(1-\beta) = 0.056$, slightly above nominal α_{sig} because the chosen Wald threshold is an approximation. An analogous argument under H_1 bounds false rejection by $\beta/(1-\alpha_{\text{sig}}) =$ 0.105. These are upper bounds, not the realized error probabilities of this discrete test (Wald 1945). Establishing its actual operating characteristics requires calibration that accounts for score-step overshoot. A campaign that must guarantee false acceptance at or below α_{sig} adopts the conservative threshold $\Lambda_{\text{up}} = \ln(1/\alpha_{\text{sig}})$, requiring only a few additional clean runs. A complete qualification record archives the hypotheses, outcome definitions, stopping thresholds, the full trial trace, and the final decision. Even when those stopping rules hold, a sequential design only reduces expected testing time for a single policy against fixed thresholds. It cannot compensate for an ill-defined operational domain, a filtered evaluation denominator, or unverified policy transfer to another physical unit. Deciding between two candidate checkpoints requires a comparative test design.

10 **Ville's Inequality**: Ville's thesis was a critique of von Mises's frequency definition of a random sequence, the "collective" of its title, and it brought martingales into probability through a gambling argument (Ville 1939). The same argument now underwrites anytime-valid tests, whose error bound holds however often the evaluator reads the running score, the freedom a campaign needs when it is watched run by run.

7.7.4 Comparing two policies

Most robot-learning evaluations do not qualify a single policy against a static regulatory target; they compare competing models. An engineering team retrains the door-latching policy and asks

whether the new checkpoint outperforms `latch-bc-01`. Such comparisons inherit every constraint of single-policy evaluation while adding three distinct systems requirements: experimental trial design, exact non-parametric testing, and statistical power analysis.

The first requirement is experimental trial design. Physical testbeds drift while a comparison proceeds: actuator windings warm, latch springs relax, ambient lighting shifts across the day, and tire surfaces wear. If all runs of one checkpoint precede all runs of the other, that physical drift corrupts the comparison, masquerading as a policy effect. The two policies must therefore execute in an interleaved, randomized sequence on the same physical unit and fixture, initialized from matched states sampled from the target ODD. Furthermore, the human operator who resets the cell and annotates borderline outcomes must remain blinded to which checkpoint executed. Kress-Gazit et al. (2024) established these practices as a reporting standard for physical robot evaluation, requiring explicit run counts, stated initial conditions, unambiguous success criteria, and qualitative failure analyses. Toyota Research Institute adopted this discipline when evaluating large behavior models, executing physical comparisons as blind A/B trials (TRI LBM Team et al. 2025).

The second requirement is selecting an appropriate hypothesis test. Each policy arm yields a count of binary outcomes, and the analysis asks whether the two observed totals could plausibly arise from a single shared success rate. Fisher's exact test[11] resolves this for small physical samples by calculating the hypergeometric probability of every contingency table matching the observed margins (Fisher 1922). Suppose, for illustration, that `latch-bc-01` completes all 20 interleaved nominal runs and a candidate completes 16. Evaluating significance requires only combinatorial counting. Under the null hypothesis that both checkpoints share the same success probability, the 40 total runs produced 4 failures. Assigning policy labels under the null is an arbitrary partition of the 40 runs into two arms of 20, making every configuration of 4 failures equally probable. The probability that all 4 failures land exclusively in the candidate's arm is $\binom{20}{4}/\binom{40}{4} = 0.053$. Accounting for an equally extreme split in the opposite direction yields a two-sided p-value (a probability computed under the null hypothesis, not a success rate) of 0.106. Because a disparity this large occurs by chance more than 10 percent of the time at this sample size, the campaign cannot declare either checkpoint superior at $\alpha_{\text{sig}} = 0.05$. Robot-learning evaluations frequently rest on samples this small, where genuine performance gaps remain statistically undetectable (Snyder et al. 2025).

The third requirement is statistical power, which fixes the sample size before executing the first run. Cohen's power analysis determines the necessary trials per arm. The analyst specifies the significance level α_{sig}, the Type II error rate β (or power $1-\beta$), and the minimum effect size worth detecting (Cohen 1988).[12] For two binomial success rates, p_{high} for the better policy and p_{low} for the worse, the effect size is Cohen's $h = 2\arcsin\sqrt{p_{\text{high}}} - 2\arcsin\sqrt{p_{\text{low}}}$. Because the raw binomial variance of an arm's sample proportion, such as $p_{\text{high}}(1-p_{\text{high}})/n_{\text{arm}}$, depends on the underlying success rate and shrinks near 100 percent, a fixed percentage-point gap carries a different sampling variance near the top of the probability scale than near the middle, and the arcsine transformation stabilizes that variance. The sample transform $2\arcsin\sqrt{\hat{p}}$, computed from the success fraction $\hat{p}$ across n_{arm} runs, has asymptotic variance approximately equal to $1/n_{\text{arm}}$ regardless of the underlying rate. Consequently, the difference between two arms has variance $2/n_{\text{arm}}$. Requiring the expected difference h to span the two-sided critical value $z_{1-\alpha_{\text{sig}}/2} = 1.96$ plus the power buffer $z_{1-\beta} = 0.84$, both expressed in units of standard error $\sqrt{2/n_{\text{arm}}}$, gives $n_{\text{arm}} = 2\left((z_{1-\alpha_{\text{sig}}/2} + z_{1-\beta})/h\right)^2$ runs per arm. Distinguishing a 90 percent policy from a 80 percent one ($h = 0.28$) at $\alpha_{\text{sig}} = 0.05$ with 80 percent power requires about 195 runs per arm. The Toyota team reached this same conclusion in real-world policy comparisons: measuring subtle performance differences required substantial sample sizes and rigorous hypothesis testing rather than informal demonstrations (TRI LBM Team et al. 2025).

Physical comparisons also invite the pitfall of optional stopping, because engineers monitoring live rollouts face strong temptations to halt testing as soon as a favored checkpoint pulls ahead. Sequential tests designed specifically for policy comparisons, such as STEP, allow an evaluator to stop as soon as evidence is decisive while holding the Type I error strictly at its declared level (Snyder et al. 2025). They are the comparative counterpart to the single-policy test of section 7.7.3. In parallel, simulators can rank candidates before committing to physical rollouts only after paired

11 **Lady Tasting Tea**: Fisher's best-known illustration of the test concerns a lady who claimed she could tell whether the milk or the tea had been poured into the cup first (Fisher 1935). With eight cups, four of each kind, there are 70 ways to choose which four had milk first, so a perfect score by guessing has probability 1/70, a figure that only exact counting of the arrangements gives. Twenty runs per arm sit in the same small-sample regime, where a normal approximation misstates the p-value.

12 **Statistical Power in Physical Trials**: The probability $1-\beta$ that a test detects a difference that is really there, here the chance that a campaign separates two checkpoints whose success rates truly differ by the stated effect.

sim-and-real trials have validated their rank correlation (section 7.4.2). Table 7.4 summarizes modern implementations of these evaluation mechanisms across the field.

Table 7.4: State of practice in policy evaluation, as of 2026: Each row is a dated instance of a mechanism taught in this chapter; the mechanisms outlast the instances.

Practice	What it measures or controls	Instance (as of 2026)
Reporting standard for robot trials	Conditions, run counts, success criteria, statistics, and failure narratives	Kress-Gazit et al. 2024 (Kress-Gazit et al. 2024)
Paired sim-and-real ranking check	Whether a simulator orders policies as the physical cell does	SIMPLER, Li et al. 2024 (X. Li et al. 2024)
Blind randomized A/B trials	Policy differences with drift and evaluator bias controlled	TRI large-behavior-model study 2025 (TRI LBM Team et al. 2025)
Sequential two-policy test	Early decisions with the Type I error held at its declared level	STEP, Snyder et al. 2025 (Snyder et al. 2025)
Exposure-matched rate comparison	Crash-rate ratios against human benchmarks aligned by road, vehicle, city	Waymo rider-only study, Kusano et al. 2025 (Kusano et al. 2025)

Checkpoint 7.2: Bounds, budgets, and stopping rules

A clean record buys a confidence limit, and the claim, not the facility's schedule, fixes what that limit costs.

Reading the bound

- ☐ **One-sided lower limit**: Explain why the 86.1 percent lower limit from twenty clean runs is a property of the procedure rather than a 95 percent probability that this policy's success rate exceeds it.
- ☐ **Failures in the record**: Formulate equation 7.6 for a twenty-run campaign with two failures and state which way its limit moves relative to one failure.

Pricing the claim

- ☐ **Trial-budget estimate**: Using the rule of three and the 40 s door cycle, estimate the clean runs and test-cell hours that a 99.5 percent success lower limit at 95 percent confidence needs, then compare the count with equation 7.5.
- ☐ **Sequential vs. fixed sample**: Contrast the guarantees that the sequential test's 31 clean runs provide against the fixed test's 29.
- ☐ **Policy comparison**: Explain why 20 of 20 against 16 of 20 does not separate two checkpoints, and what must be fixed before the first comparison run.

Whether an evaluation campaign qualifies a single policy against a target specification or compares two competing models, the findings become reviewable only when the trial count, stopping rule, and reset-adjusted time budget are established in advance. That empirical outcome must remain explicitly bound to the tested configuration and carried forward as an evaluation record.

7.8 The Evaluation Record

When a twenty-run door campaign finishes with twenty clean latches, the pass count alone cannot tell an auditor which strike-plate cell was tested, whether aborted runs were dropped from the denominator, or which network weights were loaded on the robot. The **evaluation record**, the fifth link in the record chain, preserves the formal reasoning that connects empirical observations to a bounded operational claim. It consumes the policy manifest, citing it by cryptographic digest, and incorporates the known absences listed in the provenance record of section 5.11. Across the seven fields of table 7.5, it then documents precisely which operational conditions were tested, how physical outcomes were counted, which statistical assumptions justify the conclusions, and where that

empirical support ends. Its `runtime_monitor_specs` field establishes explicit detection requirements for runtime safety engineering. These specifications require an independent implementation whose sensing latencies, execution timing, and fallback transitions undergo separate validation. By binding measured physical outcomes to declared operational boundaries and isolating human supervisory observations with their source, the record enables review of the learned proposer without granting its weights direct authority over hardware actuators.[13]

[13] **Safety of the Intended Functionality (SOTIF)**: ISO 21448 covers hazards that arise without an electrical or mechanical fault, originating instead from functional insufficiencies or reasonably foreseeable misuse (International Organization for Standardization 2022). That is precisely the failure class of a learned proposer: its neural network weights can remain perfectly intact while still proposing an unsafe trajectory. Consequently, the evaluation record catalogs unsupported operational conditions rather than faulted components. The record serves as an engineering evidence artifact rather than a format mandated by the standard itself.

↪ The sixteen-record chain (fifteen records from Parts I to IV plus the residual-claims register), in which the evaluation record is Record 5, is developed in section C.14.2.

DRAFT

Record Schema Field	Physical / Statistical Modality	Cryptographic & Provenance Guarantee	Downstream Verifier & Usage

Table 7.5: Physical policy predeployment evaluation record schema: Fields the evaluation record adds to the policy manifest it consumes, recording the target ODD, configuration digests, the sampling protocol, the complete-denominator trial log, non-asymptotic confidence bounds, the unsupported coverage gaps, and the runtime monitor specifications.

Record Schema Field	Physical / Statistical Modality	Cryptographic & Provenance Guarantee	Downstream Verifier & Usage
`target_odd_boundary`	Target ODD: the sampled cells of the declared ODD, here the nominal strike plate at the 0.03 m/s guarded approach under the door's own latch load, base stopped	Signed ODD specification; must lie inside the policy manifest's `declared_odd_boundary`	Defining tested conditions and calibrated out-of-distribution alerts; physical gating remains independent
`component_hashes`	Policy manifest digest, frozen neural network weights (hash(θ)), inference engine binary, chassis serial number, unit hardware tolerances (transmission lost motion and stiffness, structural link compliance), tire batch, sensor calibration matrices, and firmware build	SHA-256 binary digests, hardware UUID, ISO 9001 calibration certificate references	Supporting configuration traceability; preventing unrecorded hardware substitutions or unit-specific overfitting
`sampling_protocol`	Target-distribution draw weights or per-stratum quotas, PRNG seed, reset procedure, and independence audit	Automated test harness configuration script hash, telemetry sequence log	Auditing against optional stopping and testing against hidden autocorrelation across trials
`complete_outcome_log`	Full-denominator task, autonomy, and protection outcomes; raw counts (N, $N_{\text{unassisted}}$, N_{int}, n_{estop}, n_{timeout}) and physical metrics (ACR, MTBI, D_{int}, and T_{reset} time-series)	Monotonic microsecond hardware timestamps, uninterrupted ring-buffer telemetry	Preventing censored trial fallacy; calculating uncorrupted empirical reliability and supervisory burden
`statistical_evidence`	Exact non-asymptotic Clopper-Pearson binomial lower bound, rule-of-three limit, or a predeclared sequential decision record with its error calibration; for hazards, a Poisson rate bound from exposure hours (section 7.9)	Cryptographic verification signature, reproducible Python evaluation script	Passing bounded evidence and explicit assumptions to section 15.11

Record Schema Field	Physical / Statistical Modality	Cryptographic & Provenance Guarantee	Downstream Verifier & Usage
`unsupported_gap_catalog`	Explicit catalog of unvisited state spaces and omitted dynamics (surface water, dynamic crowds); contains the provenance record's known absences and the manifest's omission log	Declared non-support manifest, signed safety engineering sign-off	Parameterizing runtime permission-path checks, formal safety constraint sets, and fallback policies
`runtime_monitor_specs`	For each monitorable boundary of the claim: signal, threshold, and tested response, across the five monitoring channels that section 7.9 sets out	Measured detection coverage and false-negative rate per channel	Implemented by the permission path and the observation contract's health field; read by the enforcement record

Engineering claims and acceptance predicates in table 7.5 must be established prior to data collection. For the door's strict autonomy claim, success requires opening the latch mechanism without triggering the 15 N contact tripwire or invoking a permission-path override. The target ODD is restricted to a declared subset of the manifest domain, explicitly separating the tested fixture from doors with alternative strike plates, latch frictions, or return spring rates. Fixing these boundaries before testing prevents post-hoc rationalization, ensuring an evaluation team cannot alter success criteria after observing an anomalous run.

Rigorous configuration tracking ensures that subsequent performance comparisons remain physically interpretable. Cryptographic software hashes pin the evaluated policy weights and inference engine binaries, while chassis serial numbers, measured mechanical tolerances, and calibration logs bind the physical plant. When a camera lens is swapped, motor firmware is updated, or transmission backlash develops in an actuator, the physical plant changes. Recording these modifications allows engineers to assess whether historical evaluation evidence remains valid for the current hardware assembly. A shared component identifier establishes audit traceability, but it cannot guarantee physical equivalence when mechanical wear or manufacturing tolerances alter dynamic response.

The evaluation record preserves the trial protocol, which must be fixed before the first physical run begins to eliminate the optional-stopping hazard of section 7.7.1 and section 7.7.3. The protocol predeclares the required sample size n derived from the claim's target reliability and confidence level, the discrete outcome classifications, and the explicit stopping rule. Under a zero-failure protocol, the campaign halts immediately upon encountering its first failure, formally rejecting the target acceptance condition rather than retroactively adjusting sample sizes. If the campaign completes all n trials without failure, it reports the exact non-asymptotic bound $\alpha_{\text{sig}}^{1/n}$. A pooled binomial bound requires each trial condition to be drawn independently and identically distributed from the target operational distribution. A stratified quota grid instead demands separate inference within each stratum and explicit weighting before any aggregated claim can span the target ODD. The record documents how runs were sampled across the cells of the target ODD, the pseudorandom seed sequence governing mobile base placement, and the automated reset sequence executed between consecutive attempts to re-latch the mechanism and return the base to its 2 m standoff. When the mobile base navigates back to this standoff autonomously, real-world physical side effects accumulate. Each drive cycle warms the motor windings and draws down the battery, and wheel slip creates odometry drift, the dead-reckoning error that grows when wheel-encoder and inertial measurements are integrated. These physical couplings introduce statistical dependence between adjacent attempts. The record therefore specifies whether trials were conducted with independent physical resets or chained in series, cataloging every manual intervention, hardware abort, and protocol deviation.

The outcome log gives every run four distinct classifications: task completion, strict proposer autonomy, safety intervention history, and physical protection status. Decoupling these dimensions prevents optimistic misclassification. For example, a trial in which the permission path clamps motor torques to prevent an impact can satisfy task completion ($Y_i = 1$) while failing strict proposer autonomy ($A_i = 0$). Conversely, an emergency protective stop that halts the manipulator before collision safely mitigates the physical hazard, yet it leaves the latch closed, yielding a task failure ($Y_i = 0$). Omitting censored trials is strictly forbidden: timeouts, communication dropouts, and hardware aborts must remain in the trial denominator. The log reports ACR, MTBI, spatial intervention density, and recovery reset durations, stratified by intervention class. Alongside these reliability statistics, the log archives raw physical telemetry: cycle durations, peak contact forces, actuator temperatures, operational clearances, and limit crossings. Preserving these fields ensures that downstream reviewers understand both useful task delivery and the physical wear or supervisory burden required to sustain it.

The statistical specification formally defines the point estimator, confidence method, nominal confidence level, assumed sampling distribution, and underlying mathematical validity conditions. For fixed-sample campaigns, the record mandates exact non-asymptotic formulations, such as the Clopper-Pearson binomial lower bound ($p_{\text{lower}} = \alpha_{\text{sig}}^{1/n}$) and, for hazard rates, the exposure bound that section 7.9 develops next, rejecting degenerate normal approximations that fail near boundary probabilities. If the campaign employs sequential testing, the record preserves the competing operational hypotheses, decision thresholds, complete outcome sequence, terminal boundary decision, and calibrated error rates. As detailed in section 7.7.3, sequential testing allows valid early stopping without inflating Type I or Type II error rates, provided the stopping boundaries are enforced rigorously. Alongside the supported claim, the record documents unsupported claims and known coverage gaps. This catalog incorporates known absence regions from the demonstration datasets and unmodeled simulator dynamics from the policy manifest, appending any operational conditions left unvisited during physical testing. For coverage gaps amenable to onboard perception, the runtime monitor specifications define the monitoring signal, detection threshold, and validated fallback action across the five monitoring channels that section 7.9 sets out once it has shown which gaps testing cannot close. Any coverage gap that cannot be sensed at runtime remains in the catalog as a hard operational constraint, restricting where and how the physical machine may be deployed.

Consider the twenty-run door campaign that opened this chapter. The learned latch policy engaged and opened the cage door twenty times from the 2 m standoff at the 0.03 m/s guarded approach speed, with the mobile base stationary and zero overrides from the runtime permission path. An auditor inspecting the evaluation record interprets this evidence through the exact non-asymptotic Clopper-Pearson bound of section 7.6. At a 95 percent confidence level, twenty clean runs establish a lower confidence limit of 86.1 percent. This result rejects the degenerate interval $[1.0, 1.0]$ that the Wald normal approximation reports for a spotless record.

The completed record exposes the structural limits of the claim, showing how far evidence narrows on its path from offline data curation through policy training. The scenario table of section 5.7.1 crossed three strike-plate positions with two approach speeds, yielding six cells in total, yet the retained demonstrations supported only one: the nominal strike plate at the guarded approach. The policy manifest designated that single cell as the declared ODD of `latch-bc-01`, and the target ODD encompassed the entire cell. Twenty clean physical trials were drawn from it. They bound the failure probability there at 13.9 percent, the one-sided upper confidence limit under the tested iid distribution (table 7.3). Every condition excluded by this narrowing enters the coverage gap catalog as an inherited deficit rather than an empirically closed claim. The five operational cells that contained zero demonstrations received zero physical trials, leaving every displaced-plate condition unvalidated. The policy manifest's omission log does hold two unclosed simulator omissions (soft penalty contact dynamics and missing network transport lag). Section 6.8, however, scoped them to the simulation-refined checkpoints, the distilled student `latch-sim-02` (initialized from `latch-bc-01`, then distilled from a simulator teacher) and the residual candidate `latch-res-03` built on it. Because `latch-bc-01` was trained directly on hardware demonstrations without a simulator, its gap catalog does not inherit those omissions. The record names them only to state that its bound does not transfer. The simulation-refined checkpoints require their own empirical campaigns, and the evaluation record of `latch-bc-01` can neither resolve their simulation discrepancies nor lend its

statistics to their modified weights. Physical testing introduces an additional operational gap. The mobile base carried zero payload in its 50 kg tote rack during these trials, so the record provides no empirical evidence for machine dynamics under loaded conditions. Finally, the record makes plain why twenty clean runs cannot justify high-reliability deployment. Establishing a 99 percent lower confidence limit on task success at 95 percent confidence requires at least 299 consecutive zero-failure trials. The evaluation record thus gives a reviewer a quantitative basis for rejecting the assertion that the policy is ready for unmonitored production deployment.

7.8.1 Qualifying a recovery update

Retraining a policy to recover from a displaced strike plate modifies every layer of its neural network weights, so the twenty clean nominal trials logged for `latch-bc-01` no longer certify the updated model even on the centered strike plate. A separate, explicitly stipulated teaching branch therefore evaluates `latch-bc-recovery-02`, the candidate policy trained on the curated `latch-recovery-02` archive of displaced-plate recovery demonstrations, while keeping the original nominal campaign unchanged. This added experience covers one displaced-plate cell, the positive-offset plate in the scenario table of section 5.7.1, at the same 0.03 m/s guarded approach speed. The negative-offset plate and all three cells at the faster approach remain known absences. It provides a concrete engineering justification to test expanded competence, though training convergence alone does not qualify the policy for operational deployment.

↩ The curated recovery archive from which `latch-bc-recovery-02` is trained is established in section 5.8.

The evaluation engineer freezes the new network weights and reserves fresh physical runs for both the nominal cell and the recovery cell. The nominal campaign verifies that the policy has not regressed against the original service baseline, while the displaced-plate campaign evaluates the proposed capability expansion. Each campaign maintains its own full denominator, declared within-cell sampling distribution, fixed execution time limit, strict autonomy predicate, and contact force thresholds. Exploratory rollouts and the earlier checkpoint's twenty trials cannot be credited toward either candidate's denominator.

Suppose, solely for this worked evidence branch, that each cell supplies 2,995 independent zero-failure trials under the predeclared protocol, with on-time door completion, zero counted overrides, and no contact-limit violations. Each cell individually satisfies the 99.9 percent one-sided lower success target at 95 percent confidence. These represent separate marginal bounds; establishing a simultaneous claim across both cells requires an explicit confidence allocation because when two cells are tested separately at that confidence level, each cell carries up to a α_{sig} chance of a false pass and the union bound allows up to $2\alpha_{\text{sig}}$ total risk that at least one of the two claims is false. Splitting the significance level α_{sig} equally between the two cells using a Bonferroni allocation assigns each cell $\alpha'_{\text{sig}} = 0.025$, raising the per-cell requirement to 3,688 clean runs. At the illustrative 40 s cycle duration, each 2,995-run marginal campaign consumes 33.3 h of testing, and the Bonferroni count lengthens it in proportion, before accounting for recovery-specific resets, thermal cooldowns, or scheduled maintenance. Variations in the physical cycle time alter the total testing duration, but they do not alter the underlying statistical sample size required to certify the claim.

Under these stipulated premises, with 2,995 clean runs per cell, the evaluation record supports two marginal 99.9 percent claims for the updated policy candidate, one on the nominal cell and one on the displaced-plate cell of the tested robot. It does not support the simultaneous claim that both hold at once. That claim would need 3,688 clean runs per cell. The original policy candidate retains its narrower operational boundary. Strike plates at other lateral offsets, higher approach velocities, loaded chassis dynamics, and uncalibrated robot units remain outside this certified envelope. If the runtime permission path executes protective adjustments while tasks still complete, the evaluator records successful whole-machine service alongside reduced strict proposer autonomy, recomputing statistical bounds directly from those distinct outcome classes. System operators must not conceal permission-path interventions to artificially inflate autonomous completion rates, nor should they conflate a safe intervention with an unmitigated service failure.

This teaching branch completes the policy improvement cycle without claiming that an unperformed physical experiment took place. Incorporating recovery demonstrations alters the policy candidate; conducting independent regression and expansion trials alters what can be formally claimed about that candidate. The numerical results presented above follow from stipulated trial counts rather than empirical measurements of the physical machine described in this book.

Rather than serving as a blanket safety certification for the autonomous machine, an evaluation record establishes the formal empirical boundaries and statistical uncertainty of an individual learned component operating under controlled conditions. In section 15.11, the fault-record set ingests these evaluation records as structured evidence, combining empirical policy bounds with fault-injection results and permission-path latency bounds for the safety case that decides whether the integrated machine may operate.

↪ The distinction between a demonstration and calibrated evidence in a release safety case is developed in section 16.3.1.

Systems Perspective 7.2: Evaluating a machine that falls

An evaluation record must account for physical damage when every failure in an unsupported cell is a fall that damages the test article.

A failed guarded latch engagement can leave the wheeled mobile manipulator and mechanism intact for subsequent trials when qualified precontact limits, passive protection, and intervention response make the engagement recoverable. A reactive contact tripwire alone cannot prevent every initial impact. When a bipedal humanoid loses balance, however, a single failure can strike the floor, destroying actuators, structural links, and onboard sensor payloads.

- **Fall frequency constitutes an independent estimand**: Because a catastrophic fall damages the physical test article, the evaluation record must track fall events using a dedicated denominator and an independent statistical confidence bound, rather than burying structural collapse inside a blended task completion metric.
- **Disturbance strata must be fixed prior to testing**: Environmental perturbations (low-friction spills, compliant turf, curb thresholds, and horizontal impact impulses) along with their respective sampling weights must be declared in the sampling protocol before commencing physical evaluation. Testing exclusively on polished concrete provides no support for unvisited disturbance regimes.
- **Human demonstrator stability does not transfer to robot dynamics**: Retargeted human motion reflects the human demonstrator's balance and vestibular feedback, whereas teleoperation and kinesthetic demonstrations collected on the robot involve the robot's physical plant. Either modality can omit balance and recovery states under relevant disturbances, including dynamic reaches under heavy external loads. Those omissions belong in the coverage gap catalog. Investigating them requires appropriate containment rather than exposing an unqualified test article to destructive trials.

By keeping these cell boundaries explicit, the evaluation record separates the nominal and recovery behaviors it validated from the operating regimes it did not. Rare physical hazards and unobserved dynamic mechanisms remain distinct evidence obligations that an autonomous task campaign cannot dismiss, even when every monitored trial completes successfully.

7.9 Verification Ceilings and the Exposure Wall

A clean record on a bounded manipulation task, such as cycling a warehouse door latch, supports a task-success claim under the sampled nominal operating conditions. It does not, however, establish that the system is safe against rare hazards or catastrophic structural overloads. Extending task success claims to rare physical hazards demands an explicit operating exposure budget, while bounding peak mechanical loads requires an explicit physical contact model.

7.9.1 Rare-event exposure

Failing to pull a warehouse door latch open wastes a cycle, whereas crushing an obstacle or shearing a structural pin creates a physical hazard whose rate must be bounded across every hour the robot stays energized. Evaluating task success and evaluating system safety therefore require different statistical currencies. Repetitive manipulation tasks measure success across discrete trials, whereas physical hazard bounds measure event rates per unit of operating exposure, typically operating hours or travel distance. Engineers cannot conflate a task failure with a hazardous outcome, nor can they infer physical hazard severity from a trial success percentage alone.

Under the assumption of a constant hazard rate λ, an empirical test that logs an uninterrupted operational exposure T without observing a hazardous event yields a record whose likelihood is $e^{-\lambda T}$, the continuous-time analog of the Bernoulli trial probability p^n. Setting this observation probability equal to the significance threshold α_{sig}, exactly as equation 7.3 established for discrete trials, yields the minimum failure-free exposure time required to bound the hazard rate from above:

$$T \geq \frac{\ln(1/\alpha_{\text{sig}})}{\lambda} \approx \frac{3.0}{\lambda} \tag{7.9}$$

evaluated at a 95 percent confidence level ($\alpha_{\text{sig}} = 0.05$). This relationship is the continuous-time formulation of the rule of three, substituting continuous operating hours for discrete test cycles. In life-critical cyber-physical systems, mandated rate targets routinely reach 10^{-9} dangerous failures per operating hour.[14]

Definition 7.2: Exposure wall

Exposure wall is the failure-free operating exposure, $T \geq \ln(1/\alpha_{\text{sig}})/\lambda$, that a zero-event test must accumulate before it can bound a hazard rate λ at a stated confidence, a requirement that grows tenfold with each tenfold reduction in the target rate.

1. **Significance**: At 95 percent confidence the wall sits near $3/\lambda$, so a claim of 10^{-9} per hour needs 3.0×10^9 failure-free hours, against the 33.3 h that the door's 99.9 percent trial claim occupies. Past the wall, evidence for a hazard rate must come from the permission path and physical safeguards rather than from testing the learned proposer.
2. **Distinction**: The exposure wall bounds a rate from event-free hours, and the zero-failure trial bound (equation 7.3) bounds a per-trial probability from clean trials. Both invert a clean record; neither estimates a mean time between failures from observed failures.
3. **Common pitfall**: A frequent misconception is that fleet hours carry a claim past the wall. Under the constant-rate model, parallel rigs do add exposure hours, which is why the notebook below divides the wall across a fleet. What they fail to add is diversity. Hours pooled across machines that share a facility, a production batch, and an operating protocol bound the rate only for the conditions those machines share, and simulated hours add no physical exposure at all.

Napkin Math 7.3: Rig-years against the wall

Problem: How much failure-free exposure does equation 7.9 demand to bound a hazard rate of 10^{-6} and of 10^{-9} per hour at 95 percent confidence, and what rate can one test rig bound in a year of continuous running?

Variables:

- $\ln(1/\alpha_{\text{sig}}) = 2.996$ (Chosen; 95 percent confidence).
- $\lambda = 10^{-6}$ and 10^{-9} per hour (Chosen; analytical targets at the magnitudes of aviation and IEC 61508 bands).
- One rig-year = 8,766 hours (Derived; continuous operation) and 100 rigs (Illustrative).

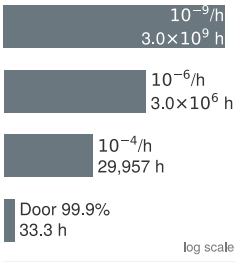
Math: \$T= \$ 2.996 $/10^{-6} = 3.0 \times 10^6$ hours, or 342 machine-years; at 10^{-9}, $T = 3.0 \times 10^9$ hours, which 100 rigs running continuously would need about 3,420 calendar years to supply. Inverting for one rig-year gives an upper confidence limit of 2.996 / 8,766 $= 3.4 \times 10^{-4}$ per hour.

Result: A rig-year of clean running bounds the rate only to 3.4×10^{-4} per hour, about 340 times short of 10^{-6} and 340,000 times short of 10^{-9}.

Systems insight: A rig-year of testing reaches the order of a site's mission-reliability target, such as the 10^{-4} per hour campaign sized below. Each further decade of rate costs a decade of

[14] **Ultra-Reliability Targets**: The figure comes from civil aviation, where a catastrophic failure condition must be "extremely improbable," on the order of 10^{-9} per flight hour (Federal Aviation Administration 1988). IEC 61508 sets a comparable band for its highest safety integrity level, SIL 4, of 10^{-9} to 10^{-8} dangerous failures per hour in continuous operation (International Electrotechnical Commission 2010a). The exposure-wall examples borrow these magnitudes as analytical targets and are not claims of compliance with either document.

machine-years. Claims at 10^{-6} and beyond must therefore rest on the permission path and physical safeguards, whose own faults can be injected and tested at the component level.



Failure-free hours climb from 33.3 h for the door to 3.0×10^9 hours at 10^{-9} per hour.

Systems Perspective 7.3: Limits of testing for ultra-reliability

The exposure wall is not a shortage of test budget that a larger program could cure. Butler and Finelli made this argument for fly-by-wire flight control software, whose catastrophic failure rate must satisfy $\lambda \leq 10^{-9}$ per hour. The failure-free exposure such a requirement demands exceeds any feasible test program by orders of magnitude, so operational testing alone cannot validate it (Butler and Finelli 1993). The evidence for a requirement past the wall must therefore come from the architecture, from what the design makes impossible, rather than from what testing failed to observe.

Butler and Finelli's conclusion (perspective 7.3) carries over to physical AI unchanged. Notebook 7.3 priced the wall in rig-years, and the definition's pitfall explains why a fleet of parallel rigs buys hours but not the diversity of conditions a deployment claim needs. Autonomous road vehicles confront the same wall at scale. Placing one real fleet's exposure against RAND's mileage requirements (figure 7.5) shows that 56.7 million rider-only miles clear the zero-failure bars for injuries and crashes and the crash precision bar. The same exposure falls short of every fatality requirement, by more than two orders of magnitude for the precision and better-than-human rows. High-assurance physical AI systems must therefore establish safety through deterministic runtime constraints and structured hardware fault injection. While rare-event simulation and importance sampling can reduce the required sample count by orders of magnitude, their mathematical validity extends only as far as the simulator's physical fidelity in those extreme tail regimes.

↪ Rare-event importance sampling, and the proposal-coverage assumption its estimates rest on, are developed in section 15.10.2.

Empirical road testing demonstrates concretely what fleet-scale operational exposure can and cannot substantiate. The first benchmark evaluated in the RAND study represents the exposure wall translated into driving mileage. Given an average human driver fatality rate of 1.09 per 100 million miles, an autonomous vehicle fleet must log 275 million failure-free miles to establish an upper bound matching the human baseline at 95 percent confidence. That single demonstration requires approximately 4.9 times the total rider-only commercial mileage accumulated by Waymo through January 2025 (56.7 million miles). Producing an empirical estimate of the fatality rate within a 20 percent margin of error requires 8.8 billion miles.

Nevertheless, tens of millions of operational miles can validate claims regarding higher-frequency events. Kusano et al. (2025) evaluated crashed-vehicle rates across 56.7 million rider-only miles against human driving benchmarks matched for vehicle class, road type, and operating jurisdiction. They demonstrated a 79 percent reduction in police-reported injury crashes and an 81 percent reduction in airbag-deployment collisions, both with confidence intervals that exclude zero. A finite operational exposure bounds only those event classes whose expected counts within that window are large enough to measure. Any rigorous comparative safety claim requires an exposure-matched baseline and confidence intervals over the incident rate ratio. The rarest and most severe failure modes remain untestable through on-road fleet mileage alone, and simulated driving mileage adds no true physical exposure to these empirical totals.

The exposure wall restricts verification even for target failure rates orders of magnitude less stringent than aerospace standards. Consider an industrial requirement for the warehouse mobile manipulator. The platform must certify a critical failure rate $\lambda \leq 1.0 \times 10^{-4}$ failures/hour, corresponding to a Mean Time Between Critical Failures of MTBF $\geq 10{,}000$ hours[15] at a 95 percent statistical confidence level ($\alpha_{\text{sig}} = 0.05$). In this operational scenario, each warehouse retrieval mission takes $T_{\text{mission}} = 360$ s (0.10 h) and covers 540 m at the platform's 1.5 m/s maximum drive velocity. Automated docking, battery replenishment, and telemetry offloading introduce an overhead of $T_{\text{reset}} = 120$ s, resulting in a total cycle duration of 480 s per trial. Each drive wheel uses a direct-drive hub motor with an outer diameter $D_{\text{wheel}} = 266$ mm, eliminating mechanical gearbox reduction between the motor and the wheel rim.

15 **MTBF and a Constant Rate**: The constant-rate model used here describes the flat middle of the bathtub curve after burn-in; it makes the reciprocal rate an MTBF and supports the zero-event bound $T \geq 3/\lambda$. Wear-out mechanisms such as bearing fatigue raise the rate as revolutions accumulate, so a rate bounded this way says nothing about wear-out life, which the L_{10} rating below addresses separately.

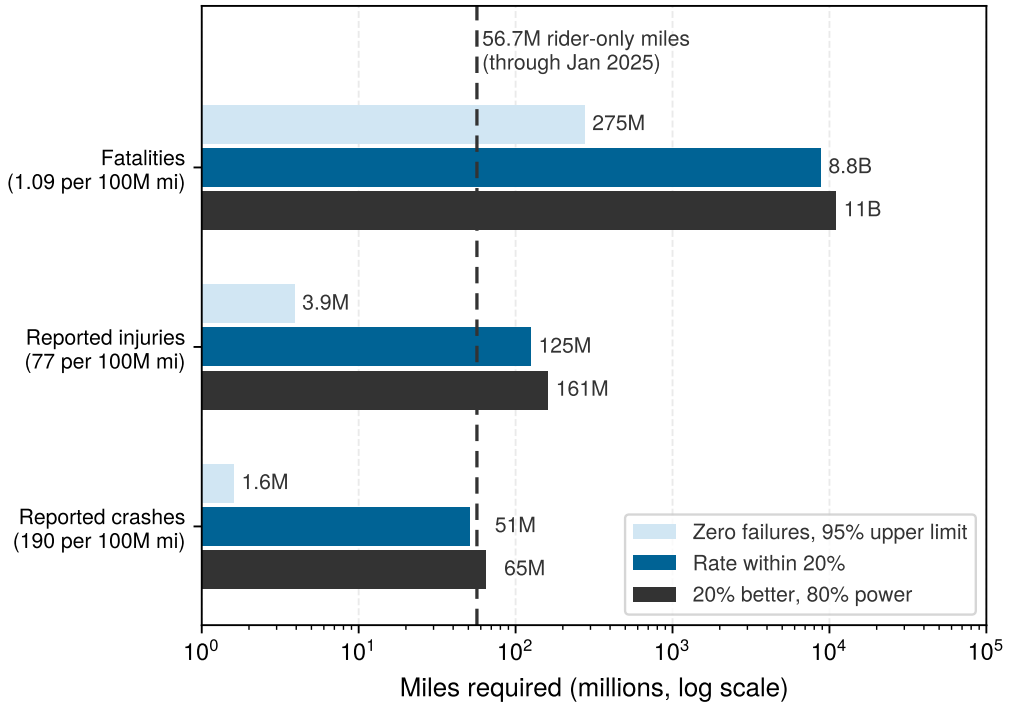


Figure 7.5: Miles needed to demonstrate road-vehicle reliability: RAND's Table 1 requirements at three human-driver benchmark rates (Kalra and Paddock 2016b), for three statistical questions: a zero-failure 95 percent upper limit at the benchmark, a rate estimate within 20 percent, and a demonstration that the rate is 20 percent better than human at 80 percent power. The dashed line marks 56.7 million rider-only miles, Waymo's total through January 2025 (Kusano et al. 2025). That exposure clears the zero-failure rows for injuries and crashes and the crash-precision row, and falls short of every fatality requirement.

Applying equation 7.9 reveals that establishing this 10^{-4} failures/hour ceiling without observing a single failure requires 29,957 hours (3.42 years) of continuous, uninterrupted operation. Discretized across operational sorties, each mission has an allocated failure probability budget of $p_{\text{fail}} \leq \lambda \cdot T_{\text{mission}} = 1.0 \times 10^{-5}$. Inverting the zero-failure binomial model from section 7.6 yields $n = \ln(\alpha_{\text{sig}})/\ln(1-p_{\text{fail}})$, demanding 299,572 consecutive clean missions. This total dwarfs typical empirical validation budgets, which rarely exceed hundreds or thousands of runs. Conducting these trials sequentially on a single physical machine at 480 s per cycle requires 39,943 elapsed hours (4.56 calendar years). It also subjects each direct-drive wheel to $N_{\text{rev}} = (n \cdot v \cdot T_{\text{mission}})/(\pi D_{\text{wheel}}) \approx 1.94 \times 10^8$ continuous revolutions.

Because the hub motor drives the wheel without an intermediate gearbox, every wheel revolution directly rotates the internal hub bearings. Their endurance is rated by the L_{10} convention of section 5.6.3, here the revolutions that 90 percent of an identical bearing cohort completes before fatigue flaking at a stated load, a population statistic that falls steeply as the carried load increases. Determining whether this test campaign exhausts the mechanical endurance of the running gear requires comparing N_{rev} against the manufacturer's internal bearing load rating and measuring the actual static and dynamic wheel reactions with corner-scale load cells. This is the stationarity problem of section 7.7.2 at the scale of a reliability campaign. The revolution count states how much wear the campaign itself inflicts, and only an L_{10} rating at the measured load can say whether that wear reaches the fatigue regime. Because hub-motor datasheets rarely disclose that internal load rating, a campaign of this duration cannot be shown to stay clear of wear-out until the load is measured. Systems teams must therefore schedule, log, and isolate component refurbishments and sensor recalibrations before pooling runs across extended operating intervals.

The distinction drawn in section 7.2 between MTBF and the intervention-based metrics matters most in a supervised campaign. When operating with real-time safety guardrails, permission-path filters, software limits, emergency stops, and human supervisor overrides can intercept hazardous trajectories before physical damage occurs when their sensing, response, and physical margins are qualified for those conditions. Such interventions censor the unassisted physical outcome while remaining recorded autonomy failures. The campaign measures an empirical intervention rate, $\lambda_{\text{int}} = N_{\text{int}}/T_{\text{active}}$, whose inverse is the MTBI.

Consider an evaluation run in which the permission path or human supervisors intervene 38 times during 100 retrieval missions configured identically to the scenario above. With each sortie lasting 360 s and covering 540 m, the campaign aggregates 10 h of active physical movement across 54 km. These trials yield an MTBI of approximately 15.8 min and an intervention spatial density of 0.70 per kilometer. Because interventions occur frequently throughout the campaign, the resulting rate parameter supports rigorous statistical inference. If interventions are modeled as a Poisson arrival process, the exact 95 percent Garwood confidence interval for λ_{int} spans 2.7 to 5.2 interventions per active operating hour around the empirical mean of 3.8 (Garwood 1936).

A system can achieve zero hardware damage while simultaneously imposing an intolerable intervention overhead. Aggregate intervention counts do not reveal ACR, because multiple interventions can cluster within a single difficult run, while other missions might abort without triggering a formal intervention. Determining autonomous completion requires inspecting the cycle-by-cycle mission log. Furthermore, observing zero hardware damage across 10 h of supervised testing provides no statistical evidence that the unassisted policy possesses an MTBF of 10 h. From the standpoint of unassisted physical reliability, every intervened mission represents a right-censored observation. The safety layer terminated the trial before its unconstrained physical trajectory could unfold. The log captures neither a confirmed physical disaster nor an autonomous success. Interpreting these censored runs as demonstrations of unassisted task survival commits the censored trial fallacy detailed in section 7.4. In deployment budgets, the reset and recalibration latency following each intervention represents an unavoidable operational penalty.

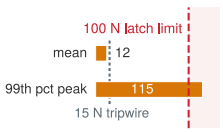
7.9.2 Peak loads and unvisited conditions

Operating exposure represents only one dimension of the verification ceiling. A second boundary arises because safety-constrained testing censors the physical regimes that pose the greatest operational risk (section 7.4). Because a destructive physical failure cannot be undone (the first law, irreversibility), supervisory safety interlocks must truncate trajectories before structural damage occurs. The empirical record terminates exactly where the intervention fires.

↩ The first law, irreversibility, which holds that work delivered to the plant cannot be rolled back, is established in section 1.10.

The corner cases an engineering team most needs to characterize, such as loss of traction on slick surfaces at maximum transit speed, dynamic wheel slip, or imminent collisions in tight aisles, are the physical regimes the system cannot be permitted to explore. Allowing an automated mobile manipulator to skid into structural shelving damages the drive chassis, knocks calibrated lidar and camera constellations out of alignment, and sidelines the entire test cell for mechanical repair. Physical cages, virtual geofences, and human operators with emergency stops truncate trials at a conservative safety boundary. The test log records an intervention event and counts it in the denominator, but the physical consequences of the policy's unconstrained commands remain unobserved.

When evaluating physical hardware survival, average metrics can mask structural overloads. Consider a learned mobile manipulation policy whose average latch contact force across one hundred nominal trials is only $\bar{F} = 12$ N, below the 15 N contact tripwire threshold. However, if the gripper strikes the strike plate at a slight angular offset, the tail of the empirical peak-force distribution reaches a 99th-percentile impact of 115 N. This transient peak breaches the structural latch limit of 100 N despite the benign average. A peak of that size in a campaign guarded by a 15 N tripwire is not a contradiction. The first impact peak arrives faster than the tripwire can act, so these trials record the overshoot first and are ended by the tripwire afterward, as failures. The rise-time argument below shows why no reactive monitor can prevent it. While a single force peak does not directly equate to total impulse or plastic deformation (which depend on the full force-time profile, structural load paths, and material yield criteria), it reveals how central tendencies conceal destructive tail behavior.



A 12 N mean hides a 115 N peak past the 100 N limit.

The undamped spring-mass model of equation 6.7, which in section 6.4.2 exposed how a soft simulated spring understated the latch force, bounds this initial impact. Written for evaluation, its moving mass becomes the reduced mass of the colliding bodies, $m_{\text{red}} = (1/m_{\text{eff}} + 1/m_{\text{obj}})^{-1}$, which reduces to the arm's effective inertia against an immovable frame. Its spring becomes the local contact stiffness k_{contact}. The peak force is then $v_{\text{approach}}\sqrt{m_{\text{red}}\,k_{\text{contact}}}$, and it arrives a quarter of the natural oscillation period after touch, a rise time of $\Delta t_{\text{rise}} \approx (\pi/2)\sqrt{m_{\text{red}}/k_{\text{contact}}}$. Inverting the peak for a structural threshold F_{lim} gives the quantity an evaluation campaign can actually enforce, a precontact speed limit:

$$v_{\text{approach}} \leq \frac{F_{\text{lim}}}{\sqrt{m_{\text{red}}\,k_{\text{contact}}}}, \tag{7.10}$$

This physical relationship governs the transient contact velocity limits in ISO/TS 15066 Annex A for power- and force-limited collaborative robots (International Organization for Standardization 2016). The collaborative application requirements of ISO/TS 15066 have since been incorporated into ISO 10218-2:2025, and ISO/TS 15066:2016 remains published while it is revised into the international standard ISO 15066-1 (International Organization for Standardization 2025b).

Evaluating this bound on a physical door latch requires measuring both the effective mass of the arm at the end-effector and the local contact stiffness of the latch mechanism. These parameters depend heavily on joint posture and kinematics, and they are never found in high-level hardware datasheets. The systems takeaway, however, is structural rather than numerical. If a software monitor's sensing, compute, and actuation latency exceeds the mechanical rise time Δt_{rise}, no reactive software policy can attenuate the initial force spike, regardless of model inference speed. Software intervention comes too late. Physical protection against initial impact must therefore rely on two pre-contact mechanisms: passive mechanical compliance, which lowers effective stiffness k_{contact} and extends rise time Δt_{rise}, and strict pre-contact kinematic velocity caps, such as the platform's 0.03 m/s guarded approach limit.

Extreme value theory (EVT), developed in section 15.10.3, models such tail extremes by fitting a limiting distribution family to many independent block maxima, yet the physical mechanics of contact do not prescribe which family applies.[16] In the absence of thousands of destructive physical trials, table 7.6 pairs measurable physical disturbance channels with concrete architectural safeguards rather than relying on unverified tail extrapolations.

[16] **Extreme Value Theory**: Fisher and Tippett (1928) found the three limiting forms that the largest member of a large sample can take, Gnedenko (1943) proved that under general conditions no other limits exist, and Gumbel (1958) made the theory an engineering tool for floods and material fatigue. Each of those applications fitted many block maxima.

Table 7.6: Peak-disturbance evidence and protection: Mechanisms identify measurements and safeguards, not an EVT family or event rate. Any quantitative tail claim needs a defined population, fitted model, goodness-of-fit checks, and uncertainty.

Disturbance channel	Peak quantity and sampling record	Physical consequence to test	Candidate protection to validate
Compute and bus latency	Per-cycle end-to-end age and deadline misses	Stale proposals erode braking margin	Chunk lease and independently timed fallback
Contact shock	Force-time trace, impulse, and peak at the load path	Yield or overload before a reactive command takes effect	Passive compliance and precontact speed limit; reactive limits address later load
Low traction	Local friction estimate and stopping response	Slip extends stopping distance	Conservative speed ceiling and tested fallback on low-grip surfaces
Optical glare	Saturation duration and perception misses	False clearance or lost state estimate	Redundant sensing and independent physical constraints

The door latch campaign shows why the contact shock entry in table 7.6 pairs a measurement with an architectural safeguard rather than with a fitted tail. Each trial yields only one block maximum, its peak latch contact force, and twenty maxima cannot fit a generalized extreme value tail that would predict the probability of exceeding 100 N. The safeguard therefore comes from the rise-time argument above. The guarded 0.03 m/s approach is a candidate precontact limit whose adequacy depends on the measured effective mass, contact stiffness, and structural threshold. Reactive force monitoring addresses the sustained load that follows.

Figure 7.6: Standardized robotic evaluation facility: NIST response-robot test bays photographed in 2013 (Linda Joy/NIST); their test methods are standardized by ASTM subcommittee E54.09 on response robots. A zero-failure run across standardized bays establishes competence inside the arena and says nothing about glare, surface contaminants, or obstacles outside it.

Deploying parallel robots across a test fleet does not establish statistical independence, as the pitfall in definition 7.2 warns. Ten identical machines operating concurrently in a single warehouse share the same manufacturing batch, firmware revision, concrete sealant finish, heating and ventilation airflow, and operator handling protocols. Environmental disturbances absent from that facility, such as low-angle winter solar glare, surface water pooling, or floor polishing glazing, affect none of the machines. Standardized physical test fixtures, such as the response-robot test bays captured in figure 7.6, ensure repeatable benchmark comparisons by strictly constraining the test environment to known, fixed obstacle geometries.

The standardized obstacle courses documented in figure 7.6 enable repeatable comparisons across robotic platforms under ASTM E54.09 test methods. However, their controlled geometry, uniform surface traction, and regulated indoor lighting also define the perimeter of empirical evidence.

Validating system performance against factory chemical spills, erratic pedestrian crossings, or blinding solar glare requires intentionally introducing those environmental distributions into the test matrix.

These physical and statistical verification ceilings lead to an architectural conclusion. Safety in physical AI cannot rest on statistical confidence derived from testing learned weights. The exposure that failure rates between 10^{-6} and 10^{-9} per hour demand, from 3.0×10^6 to 3.0×10^9 failure-free hours, shows that empirical test volume cannot serve as the primary safety argument. Deterministic runtime constraints must supply their own independent verification evidence, including explicit physical assumptions under which hazardous transitions are prevented and rigorous bounds on worst-case execution time. Empirical policy trials measure task competence and quantify intervention rates inside a nominal operational envelope; they do not prove that the system can contain arbitrary out-of-distribution failures. The burden of safety certification therefore shifts from the learned proposer to the deterministic permission path and verified physical safeguards, each of which must be evaluated through independent verification pathways.

A model-based stability certificate, such as the Lyapunov argument developed in section B.3.1, provides structural guarantees that empirical finite trials cannot establish. When the learned proposer lacks a validated certificate for the declared plant and observation model, the embodied computing platform must provide architectural containment and targeted fault injection:

1. **Runtime Containment**: The system enforces hard physical bounds on the learned policy by delegating collaborative force thresholds, kinematic acceleration boundaries, and emergency stop triggers to an independent, deterministic permission path situated beneath the proposal boundary. The system's safety claims then rest on the permission path and its associated fallback strategies. These controllers rely on validated state estimation, conservative plant and actuator dynamics models, worst-case execution timing, and guaranteed stopping margins, all verified independently of the neural network proposer.
2. **Physical Fault Injection**: Rather than passively waiting for rare environmental disturbances or hardware faults to manifest during operational testing, systems engineers deliberately inject them on instrumented test benches. Because fault injection artificially alters the operational failure rate, these trials must be recorded in a separate, explicitly labeled log rather than pooled with nominal operational draws.

↪ The derivation of a fault list, by inverting design records and working forward from physical hazards, is developed in section 15.6.

Checkpoint 7.3: Sample size and MTBF evidence target

Before moving on, review sample size scaling and physical test limits:

- ☐ **Exposure-wall estimate**: Under a stationary Poisson failure model, estimate the failure-free hours a relaxed 1,000 h MTBF target needs at 95 percent confidence, and determine whether one rig running continuously for a year could supply them.
- ☐ **Mechanical fatigue exhaustion**: Explain why a campaign's wheel revolutions cannot be compared with a bearing L_{10} rating without knowing the load the bearing carries.
- ☐ **Architectural containment vs. statistical sampling**: Explain why a task campaign needs separate evidence for runtime constraints and physical safeguards.

Even under automated test cells and rigorous qualification protocols, statistical sampling of learned policies cannot demonstrate ultra-reliable autonomy. The integrity of an operational release decision depends on identifying precisely what remains unvisited by a finite test campaign and deploying verified runtime monitors to supervise those uncharacterized boundaries.

7.9.3 Turning coverage gaps into runtime obligations

Those uncharacterized boundaries come from every stage of the pipeline: offline datasets omit recovery states, physics simulators omit real-world contact and stator phase lag, and finite hardware campaigns sample only a handful of cells in the condition matrix. Because the physical states a machine traverses depend on the specific sequence of actuator commands admitted by the permission path (section 7.3), small discrepancies between modeled and real-world dynamics compound over

closed-loop horizons. They drive the platform into state regimes that never appeared during training or simulation. Neither a static dataset nor a simulator can match the physical plant's closed-loop state distribution, and an empirical hardware test bounds nothing beyond the specific operating conditions it directly sampled.

The operational conclusion of the door campaign is correspondingly narrow. The physical trial records establish that a single software build deployed on a specific hardware platform (Unit 01) bounded its per-cycle failure probability below 13.9 percent at 95 percent confidence. That bound was evaluated from the sampled initial poses under the specific ambient illumination and temperature present during testing. This record provides no assurance about system behavior on a cold morning that thickens gearbox lubricant or derates actuator drive current. It provides none on an aging transmission whose compliance and backlash have increased through gear tooth wear, or against a door whose strike plate has shifted several millimeters out of true. Testing across multiple physical units broadens the declared operating population, whereas executing additional runs solely on Unit 01 with a nominal strike plate merely tightens the binomial confidence interval (table 7.3). Logging two thousand additional nominal cycles measures that single hardware unit with high statistical precision while leaving displaced strike plates, payload variations, unit-to-unit manufacturing variations, and real-time bus jitter unsupported by empirical evidence.

Because finite evaluation cannot characterize behavior outside the sampled operational distribution, every unverified boundary of an empirical safety claim must be translated into an explicit runtime monitoring obligation. Each boundary requires an identifiable sensor signal, a calibrated detection threshold, a validated mitigation response, and deterministic enforcement by the permission path. Because operational distribution support is only partially observable and software out-of-distribution (OOD) detectors have nonzero false-negative rates, environmental conditions that cannot be sensed with high confidence require hard ODD constraints, passive mechanical guards, or independent physical barriers.

The evaluation record captures these obligations in its `runtime_monitor_specs` field (section 7.8), across five mandatory monitoring channels whose detection coverage, latency, and mitigation responses must be independently validated:

1. **Input Support and Out-of-Distribution (OOD) Monitor:** Quantifies whether incoming sensor observations remain within the support of the training and verification distributions using a calibrated score, with measured false-negative rates on held-out OOD test sets.
2. **Execution Latency and Freshness Monitor:** Tracks sensor observation age and neural inference execution time against separate hard deadlines. It verifies proposal renewal against nominal controller cadence (for example, verifying that the latch policy meets its 40 ms p99 inference target inside its 50 ms chunk period at 20 Hz), logs deadline misses, and ensures that an expired chunk lease immediately engages a validated fallback. A p99 latency is an empirical percentile; it does not replace a hard real-time execution bound.
3. **Constraint Margin Monitor:** Continuously tracks the distance between the current physical state and hardware protection boundaries, monitoring joint torque limits, motor winding Joule heating, and physical obstacle clearances against calibrated stopping-distance models.
4. **Intervention Rate Monitor:** Computes the running frequency of permission-path interventions and trajectory overrides as a warning of growing supervisory burden or behavioral drift. Preventive detection of a specified instability requires a declared window and threshold, with qualified detection-plus-response lead time. This warning does not replace instantaneous clearance and constraint checks or a feasible fallback.
5. **Environmental Assumption Monitor:** Verifies whether current physical conditions comply with operating design assumptions, tracking surface traction through wheel slip ratios and ambient illumination via calibrated photometric sensors.

A runtime monitor that merely records an anomaly to a diagnostic log provides zero physical protection. Under active control, if a newly generated policy proposal fails validation, the permission path rejects the replacement command without revoking the currently executing chunk, whose chunk lease is still valid. If the active command expires, encounters a safety violation, or lacks sufficient clearance, the permission path overrides the proposer and commands a validated fallback, such as a conservative speed restriction or a controlled deceleration to rest. The fallback is valid

only if current state estimates, actuator torque headroom, and braking distances render it physically feasible. Even when a neural policy produces timely, high-confidence proposals, every candidate control action $\mathbf{u}_{\text{nom}_t}$ must pass independent geometric clearance and actuator dynamic limits before the low-level hardware bridge applies torque to the plant.

Certain catastrophic failure modes cannot be detected by any software runtime monitor. A software out-of-distribution monitor operates exclusively on digitized sensor telemetry and latent neural representations. When a physical transduction failure occurs, such as a clean glass wall, a blinding specular laser reflection, or a camera occluded by uniform mud, the sensory telemetry itself is corrupted or absent. The perception pipeline may extract seemingly normal visual features from the reflection, reporting benign obstacle clearance while the physical chassis is on a collision course with the glass. Software cannot detect physical reality that hardware transduction failed to capture. In such failure modes, the proposal can satisfy every execution deadline, respect all motor torque envelopes, and produce familiar latent embedding vectors, yet drive the platform directly into an invisible obstacle. Physical safety against transduction failures cannot come from statistical evaluation or software-based OOD monitors. It requires architectural physical zoning, hardware current limiters, sensitive tactile bumpers, and physical safety barriers validated under explicit mechanical assumptions independently of the learned policy.

↪ The barrier condition that keeps braking feasible within the remaining clearance is developed in section B.4.

These verification ceilings bind every evaluation campaign, no matter how rigorously executed. The empirical evidence preserved in an evaluation record is only as trustworthy as the measurement protocols that produced it. Procedural flaws, silent sensor drift, and statistical fallacies can corrupt an evaluation campaign long before its summary metrics reach the evaluation record.

↪ Observational indistinguishability, in which a hazardous state yields the same telemetry as a safe one until the response deadline, is developed in section 18.3.4.1.

7.10 Evaluation Pitfalls and Metric Masking

A physical qualification report can present a spotless pass rate and an exact confidence bound while still misrepresenting what the machine can safely do, if the test procedure quietly narrowed the operating domain, tuned weights on the test unit, or discarded inconvenient runs before the bound was computed. Systematic errors undermining policy evaluation rarely stem from deliberate fraud; they arise when an evaluation protocol answers an easier question than the claim asks, creating statistical or procedural mirages that mask physical vulnerability.

7.10.1 Six evaluation pitfalls in practice

An audit of an evaluation record checks six links between the headline metric and the physical trials that produced it, because breaking any one of them leaves the reported pass rate intact while invalidating the claim.

The first link breaks through environment selection, whenever the test bench is narrower than the claim. The twenty door runs all met the nominal strike plate at the 0.03 m/s guarded approach with the base stopped and the tote rack empty. If the report states their success rate as the machine's ability to open the site's cage doors, the claim silently expands to the five unsampled cells of the scenario table and the loaded machine (section 7.9). Environment selection is detected by comparing a condition log, which records the measured strike-plate position, approach speed, payload, and floor condition of every trial, against the boundaries of the claimed domain. A log that covers one cell establishes nothing about the others.

Even when the workspace matches the claim, metric drift can substitute an offline surrogate for physical closed-loop task completion, scoring candidates by action agreement, validation loss, action Mean Squared Error (MSE), or action cosine similarity against recorded expert buffers. Offline scoring is cheap, so the substitution happens gradually, and it inherits the ranking inversions of section 7.3. Metric drift is prevented by keeping the primary evaluation metrics closed-loop physical observables, namely task-completion rate, ACR, MTBI, and D_{int}. Protection violations, including unmitigated tripwire crossings, remain a separate recorded outcome and an explicit acceptance condition; they never justify dropping runs.

Keeping the metric physical still fails if repeated tuning against a fixed evaluation setup introduces unit-specific test set contamination. Adjusting the checkpoint or observation filtering after each batch on Unit 01 makes that robot and door part of development, not an independent holdout. The resulting improvement may depend on their particular backlash, calibration, and lighting. The countermeasure is to audit the history of policy versions, tuning decisions, and chassis identities,

and to reserve fresh units and conditions for any claim that requires generalization beyond the development setup.

During execution on a clean holdout unit, optional stopping and multi-look inflation can still corrupt the stopping rule: an engineer who watches a sequence of physical runs and halts as soon as the tally crosses a target reports a confidence the procedure does not have. Each look at the accumulating result is another chance for a false positive. Five independent 5 percent looks would have a 22.6 percent chance of at least one false positive. Repeated looks at one accumulating run are dependent, so the inflation for a real stopping rule must be computed for that rule. Optional stopping cannot be detected from summary tables or final pass rates. It is detected only by auditing the pre-registered trial protocol, verifying that sample sizes, stopping conditions, and evaluation milestones were fixed before the first physical run began. The calibrated alternative is a sequential rule declared in advance (section 7.7.3).

After the runs finish, a fifth distortion occurs when the denominator is quietly filtered, breaking the full-denominator condition of section 7.5. A team that discards runs ending on timeouts, emergency stops, sensor communication drops, or permission-path overrides as invalid test artifacts reports success over the surviving trials only. Every metric of section 7.2 then moves in the flattering direction: ACR rises, MTBI grows, intervention density falls toward zero, and the reset time spent clearing a jammed gripper disappears from the budget. If the arm opens the door on nine of ten attempts and the tenth needs an operator takeover to stop the gripper wedging against the latch, removing that attempt raises the apparent success rate from 90 percent to 100 percent. The batch then reports an infinite MTBI. Infrastructure aborts, such as dropped wireless packets, stalled kernel threads, or bus brownouts, also stay in the denominator. A base that stalls in the aisle because an operating system thread locked has failed its mission, whichever subsystem caused it, and removing such aborts evaluates an abstraction rather than the deployed machine. When physical constraints or safety limits truncate a run before its deadline T_{deadline} expires, the trial stays in the trial log as not unassisted ($A_i = 0, n_{\text{int}_i} \geq 1$), and for the unassisted-failure event it is right-censored rather than omitted. Reading survival on truncated trajectories as operational competence is the censored trial fallacy of section 7.4. Denominator filtering is detected by cross-referencing low-level actuator telemetry and permission-path logs against the trial log, confirming that every power-on cycle, autonomy engagement, and physical reset corresponds to a recorded outcome.

War Story 7.1: The 2017 NHTSA Autopilot crash rate mirage

Context: In January 2017, the National Highway Traffic Safety Administration (NHTSA) closed Preliminary Evaluation PE 16-007, which it had opened after a fatal Florida crash of a Model S operating in Autopilot mode (National Highway Traffic Safety Administration (NHTSA) 2017). The closing report compared airbag-deployment crash rates in the subject Tesla vehicles before and after Autosteer was installed and stated that "the Tesla vehicles crash rate dropped by almost 40 percent after Autosteer installation," from 1.3 to 0.8 crashes per million miles.

Mechanism: The rate divided airbag deployments by miles driven before and after installation, and the report's own footnote noted that the rates "are for all miles travelled before and after Autopilot installation and are not limited to actual Autopilot use." The denominator therefore never measured exposure to Autosteer itself, and it was incomplete as well. A replication by Quality Control Systems Corporation found that the odometer reading at installation appears to have been reported for fewer than half of the vehicles, and that exact exposure before and after installation could be computed for only 13 percent of them (Quality Control Systems Corp. 2019). The mileage NHTSA left uncounted, because it could be assigned to neither period, was concentrated among the vehicles with the least exposure before installation.

Impact: In the one cohort with complete exposure in both periods, the airbag-deployment crash rate rose 59 percent after installation, from 0.76 to 1.21 per million miles, a result the replication qualified with "if these data are to be believed." Its authors concluded that the overall 40 percent reduction was "an artifact of the Agency's treatment of mileage information that is actually missing in the underlying dataset." The replication does not measure Autosteer's effect either. It shows that the published denominator could not support the reported reduction.

Response: The correction came from outside the agency and two years after the closing report, because the per-vehicle mileage records that exposed the denominator were released only after a Freedom of Information Act lawsuit against the Department of Transportation (Quality Control Systems Corp. 2019).

Systems lesson: In physical AI evaluation, an unverified denominator produces a statistical mirage. Aggregating open-world mileage without engagement telemetry, operational design domain boundaries, and complete exposure records turns missing data into a safety claim. An evaluation audits the integrity of its denominator with the same rigor it applies to the failure events in its numerator.

At the extreme of denominator filtering, teams sometimes substitute visual demonstrations for statistical measurements altogether. A successful video shows that the machine reached the goal under one sequence of conditions; without a sampling record, it does not establish how often that outcome recurs. Smooth $SE(3)$ kinematics (rigid-body motions in three dimensions) can conceal small physical margins. A representative campaign needs predeclared sampling from the target ODD or separate per-stratum analysis, full-denominator accounting, and a sample size tied to its stated claim.

None of these pathologies is visible in the final pass rate. Each is caught only by auditing the record against the protocol that was declared before the first run, which is why the evaluation record keeps the protocol, the condition log, and the complete outcome sequence rather than the summary alone.

7.11 Fallacies and Pitfalls

An empirical evaluation supports engineering claims only within the precise physical boundaries and statistical assumptions of its test protocol. In embodied machine learning systems, severe evaluation errors arise when teams extrapolate localized results across untested operational envelopes or attribute system-level safety guarantees to a learned policy when deterministic enforcement mechanisms actually did the work.

Fallacy: *Repeated success in a single nominal condition proves broad operational readiness.*

Consider a door-opening evaluation campaign that repeats a single nominal configuration twenty times: a standard strike plate, an unencumbered approach vector, a stationary mobile base, and an empty payload rack. Under the binomial model, twenty flawless runs yield the 86.1 percent lower confidence bound derived in notebook 7.1 for that specific setup. However, they provide no statistical evidence for the remaining operating conditions, such as misaligned latch hardware, floor irregularities, or a loaded tote rack that shifts the manipulator's center of mass and reduces actuator torque margins. Repeating identical trials merely sharpens precision on a single nominal operating point while leaving deployment-critical boundary conditions unprobed. An engineering claim of operational readiness must explicitly define the target ODD, distribute test budgets across the physical parameters governing that domain, and bound uncertainty within each stratified cell. **Nominal repetition sharpens precision on a single cell; it provides zero evidence for the rest of the operational design domain.**

Architect's countermeasure: Explicitly partition the declared operational design domain into a structured condition matrix, allocate trial quotas across all operational strata, and report confidence intervals per cell rather than pooling unstratified runs.

Fallacy: *Zero failures in 1,000 trials proves compliance with a 99.9 percent reliability specification.*

Suppose a latch manipulation policy opens a door 1,000 consecutive times without a single safety trip, evaluated against a specification requiring 99.9 percent success at 95 percent confidence. The observed sample success proportion is perfect ($\hat{p} = 1.00$). Standard Wald intervals based on the asymptotic Central Limit Theorem collapse into the degenerate point $[1.0, 1.0]$ because the estimated variance $\hat{p}(1-\hat{p})/n$ vanishes identically at the boundary. However, an exact non-asymptotic Clopper-Pearson inversion ($p_{\text{lower}} = 0.05^{1/n}$) demonstrates that the true one-sided lower confidence bound reaches only 0.9970, falling decisively short of the 99.9 percent target (table 7.3). Certifying compliance with that target requires 2,995 consecutive clean runs. A parallel fallacy recurs in early-stage pilot

testing. Observing zero failures across 20 trials ($p_{\text{lower}} = 86.1$ percent) cannot demonstrate even a modest 90 percent success bound (29 clean runs required), much less an industrial 99 percent standard (299 clean runs required). Test budgets must be derived directly from the required confidence level and reliability target before execution begins, and validation reports must document exact non-asymptotic bounds rather than empirical success ratios. **Zero failures across an insufficient sample size represent an evidence deficit, not empirical proof of compliance.**

Architect's countermeasure: Reject asymptotic Wald intervals near parameter boundaries. Precalculate the minimum sample budget using the exact non-asymptotic Clopper-Pearson formulation ($n = \lceil \ln \alpha_{\text{sig}} / \ln p_{\text{target}} \rceil$) or its continuous-time counterpart for exposure hours ($T \geq 3.0/\lambda$), and report exact one-sided lower confidence bounds in all compliance audits.

Fallacy: *High offline action agreement on static logs guarantees closed-loop physical stability.*

An evaluation report citing close agreement with expert actions on recorded teleoperation logs, whether framed as negligible action mean squared error (MSE), high discrete token prediction accuracy, low validation perplexity, or high action cosine similarity, measures dataset imitation on static buffers and nothing more. As demonstrated by the mobile aisle policy in section 7.3, a policy can match its offline demonstrations with near-zero error and still exhaust its lateral clearance through the kinematic integration of a minute, persistent heading bias. Compounding this error, covariate shift drives the system into unmodeled state spaces once trajectory drift departs from the demonstration support.

Physical contact introduces even sharper failure modes. At non-Lipschitz mechanical interfaces, sub-millimeter positional deviations that barely register in aggregate MSE trigger destructive reaction forces ($F = k_{\text{contact}} \Delta x$) and mechanical wedging. This produces dramatic ranking inversions where policies with lower offline MSE fail completely while policies with higher MSE succeed. Directional metrics such as cosine similarity fail for complementary reasons: they ignore command magnitude entirely. A policy commanding the correct directional vector with 25 percent too little force stalls below a latch's breakout threshold, whereas commanding 150 percent of the required force can trip protective torque boundaries. Offline metrics serve well as initial screening filters to discard defective training checkpoints. Empirical closed-loop capability, however, must be evaluated using physical observables, namely task-completion rate, ACR, MTBI, and D_{int}, tracked against the complete execution denominator, with protection outcomes recorded separately. Even then, these finite-sample empirical metrics do not constitute a formal proof of closed-loop stability. **Offline validation loss, MSE, and cosine similarity measure dataset mimicry; closed-loop physical dynamics decide survival.**

Architect's countermeasure: Treat offline loss, action MSE, and cosine similarity strictly as preliminary triage filters. Require closed-loop physical rollouts with full-denominator accounting to support behavioral claims, and require separate model-based Lyapunov or invariant set analyses for any formal stability guarantee.

Pitfall: *Peeking at accumulating rollouts and terminating testing early inflates false safety certification.*

When an engineering team halts an evaluation campaign after 30 consecutive clean runs because intermediate results look favorable, and then reports the confidence bounds of a fixed-sample protocol, they commit sequential peeking. Halting on a winning streak distorts the underlying statistical distribution. An adaptive stopping rule inflates the false-positive rate, rendering standard fixed-sample confidence calculations invalid. While a predeclared zero-failure test can terminate upon the first observed failure to reject an inadequate policy, terminating early to accept a candidate requires an explicit sequential design. Sequential probability ratio testing provides a mathematically sound alternative. Ville's martingale inequality bounds the probability of false acceptance by $e^{-\Lambda_{\text{up}}}$ for any declared acceptance threshold Λ_{up}, which resolves to $\alpha_{\text{sig}}/(1-\beta)$ under classic Wald boundaries (section 7.7.3). **Choose the stopping rule before collecting outcomes, and report the error guarantee for that rule.**

Architect's countermeasure: Pre-register sequential decision boundaries ($\Lambda_{\text{up}} \approx \ln((1-\beta)/\alpha_{\text{sig}})$, $\Lambda_{\text{lo}} \approx \ln(\beta/(1-\alpha_{\text{sig}}))$) before running trials. Update the cumulative log-likelihood ratio Λ_m after each physical rollout, and award the declared SPRT acceptance or rejection decision only when the statistic crosses its corresponding threshold. A physical hazard or invalidating protocol evidence

can terminate the campaign independently. Keep the complete trial log and the termination reason, and claim no favorable result that the declared statistical rule does not support.

Pitfall: *Crediting the learned policy with surviving transport stalls that the enforcement architecture handled.*

Suppose a mobile manipulator completes 50 nominal aisle navigation trials, leading the engineering team to credit the learned transformer policy with inherent robustness against serializer/deserializer (SerDes) bus jitter. Later, a qualification trial injects a synthetic mailbox stall that exceeds the 60 ms chunk lease. The lease expires, and the deterministic permission path detects the deadline miss and commands an immediate controlled dynamic stop. This stop is analogous to an industrial Category 1 stop (a controlled deceleration under drive power, with torque removed once the machine stands still), as classified in section 12.9.2. This safe recovery is executed entirely by the enforcement architecture, not the learned model. Nominal task completion does not prove that the neural network weights can detect, absorb, or recover from communication dropouts. Rigorous fault injection must evaluate the permission path's detection latency and stopping distance margins under stress, and the final evaluation report must attribute safety enforcement directly to the hardware and runtime mechanisms that actually executed the stop. **Do not credit unverified neural weights with safety guarantees provided by the deterministic permission path.**

Architect's countermeasure: Conduct systematic fault injection, including synthetic communication stalls and sensor frame drops, to independently benchmark the permission path's braking envelope, and attribute safety mechanisms strictly to the hardware and software layers that executed them.

Fallacy: *Zero physical collisions or hardware damage in testing proves high autonomous policy reliability.*

When an autonomous vehicle or mobile manipulator completes an extended test campaign without collisions, teams frequently declare that the policy demonstrated exceptional reliability (for example, claiming an MTBF equal to the total logged run time). However, if human safety operators disengaged the autonomy system or the permission path intervened repeatedly to avert impending collisions, the zero-damage outcome ($N_{\text{damage}} = 0$) occurred only because the protective safety envelope actively censored catastrophic trajectories. What the testbed truly recorded was a sequence of intervention events. True autonomous capability must be evaluated through ACR and MTBI. Frequent human takeovers render commercial deployments economically unviable, whereas small automatic clips by the permission path may represent routine boundary regulation. An evaluation report must classify and audit these intervention tiers separately. Censoring interventions or tallying assisted rollouts as unassisted policy successes confuses the protective competence of the supervisory envelope with the autonomous competence of the learned policy. **Zero collisions under active safety supervision must be interpreted alongside interventions; they do not by themselves establish policy reliability or complete protection coverage.**

Architect's countermeasure: Enforce strict full-denominator accounting. Record every human takeover, permission-path clamping action, and virtual tripwire breach as an autonomy disengagement ($A_i = 0, n_{\text{int}_i} \geq 1$). Report these unassisted autonomy metrics alongside overall task completion rates, mission cycle times, and protective safety statistics.

Pitfall: *Qualifying a policy on a single reference robot assumes zero unit-to-unit hardware variance across the fleet.*

Consider an engineering team that logs 300 failure-free trials on a single laboratory robot (Unit 01) and certifies the policy for fleet deployment. When deployed onto Unit 02 on the manufacturing floor, the identical policy repeatedly jams against fixtures or develops severe actuator chatter. As detailed in section 7.2, physical unit-to-unit variations (transmission lost motion, harmonic drive compliance and stiffness, structural link flexure under load, camera mounting misalignments, and motor winding tolerances) substantially alter the plant transfer function across robot builds. Qualifying a policy on a single "golden unit" merely calibrates the model to that individual chassis's electromechanical profile rather than establishing fleet-wide reliability. Furthermore, running evaluations during a single shift overlooks non-stationary environmental factors: diurnal sunlight glare sweeping across vision sensors, floor traction changes driven by ambient humidity, or thermal drift from motor winding resistance heating (I^2R) that alter plant dynamics without altering a single neural network parameter. **Evaluating a single robot chassis characterizes that specific unit's mechanical quirks; fleet release requires stratifying trials across the manufacturing distribution.**

Architect's countermeasure: Stratify physical qualification protocols across multiple chassis serial numbers sampled from the fleet manufacturing distribution $\mathcal{M}$. Audit unit-specific lost motion and kinematic link offsets prior to evaluation, and reserve final acceptance testing for untouched production units that were never used during policy development or hyperparameter tuning.

7.12 Summary

Closed-loop evaluation characterizes the fully coupled execution system: the proposer policy, the permission path, the physical plant, the surrounding environment, and the experimental protocol. Consequently, an empirical success rate never describes a static weight checkpoint in isolation; it characterizes a declared population of operational trajectories. Because the machine's admitted actions dictate the future states it encounters, which is the second law, endogenous data, applied to testing, only closed-loop execution through the active permission path reveals how the proposer truly behaves. Open-loop evaluations on pre-recorded datasets remain blind to the compounding errors that real-world interaction induces.

A zero-failure confidence bound quantifies performance over this sampled population under explicit sampling assumptions. When safety tripwires intervene to prevent physical damage, they censor trials right at the operational safety boundary, keeping empirical testing confined to the envelope the experimental campaign can safely explore. Gathering additional trials narrows statistical uncertainty within that sampled distribution, but it cannot expand the boundaries of the characterized population. The exposure wall adds a further ceiling, because validating ultra-rare hazard rates requires far more continuous operating hours than any single physical platform can feasibly run.

The robotic door-opening campaign illustrates the precise scope of an empirical engineering claim. Twenty incident-free trials establish a statistical lower bound on success at the nominal strike plate and the guarded approach speed, with the base stopped and the tote rack empty. That evidence justifies no claims about displaced strike plates omitted from the demonstration dataset, nor does it guarantee performance when carrying heavy payloads. To handle these uncharacterized regimes safely, the engineering team maintains a coverage gap catalog that explicitly documents every unvisited condition. Rather than trusting an unverified proposer policy or relying on an out-of-distribution detector that can fail when encountering novel inputs, the system delegates safety in these unvisited regions to independent physical constraints and verified fallback behaviors in the permission path.

The stipulated recovery branch demonstrates how engineers systematically expand this operational boundary over time. When developers gather targeted experience to train an updated candidate policy, they must validate it through independent regression testing on nominal regimes alongside rigorous qualification on displaced plates. An initial evaluation archive never represents a permanent barrier to capability; rather, it establishes an empirical baseline from which verified competence can methodically advance.

The ultimate output of a closed-loop testing campaign is the evaluation record. Four core artifacts from this record govern downstream deployment and system safety:

1. *Bounded operational claim:* The target ODD, established within the broader declared ODD of the policy manifest, specifying the precise environmental and kinematic envelope where closed-loop performance has been empirically characterized.
2. *Reproducible configuration and trial log:* Cryptographic digests of neural network weights, controller firmware, and sensor calibrations, paired with measured hardware tolerances and an unedited trial log. Retaining every attempted, aborted, and overridden trial in the denominator is essential to compute honest task-completion, autonomy, intervention, and reset metrics (ACR, MTBI, D_{int}, T_{reset}), with protection outcomes recorded separately.
3. *Coverage gap catalog:* A systematic audit detailing known data omissions from training demonstrations, operational regimes unvisited during testing, and specific hardware units that remain uncharacterized.
4. *Runtime monitor specifications:* Explicit signal definitions, trigger thresholds, and tested fallback maneuvers that the permission path must execute whenever an observable safety boundary is reached.

Table 7.7 summarizes the foundational mathematical relationships that support these operational decisions, linking each formal bound to its engineering consequence. Each row connects the governing expression to the specific test quantity a campaign must declare or report before deployment.

Table 7.7: Key equations of closed-loop evaluation: Each equation fixes one quantity a campaign must declare or report. The statistical bounds assume independent, identically distributed draws from the declared population; the kinematic and contact relations are first-order models whose inputs must be measured on the machine.

Equation	What it bounds or decides	Derived in
$p(\mathcal{D}) = \mathbb{E}_{c\sim\mathcal{D}}[\phi(\mathrm{Traj}(c))]$	The estimand: a success rate belongs to the declared population $\mathcal{D}$, not to the weights	equation 7.1
$t_{\mathrm{impact}} = W_{\mathrm{clear}}/(v \sin \Delta\theta_{\mathrm{head}})$	How soon a persistent heading bias spends clearance that open-loop scoring never sees	equation 7.2
$p_{\mathrm{lower}} = \alpha_{\mathrm{sig}}^{1/n}$	Success lower limit after n clean trials	equation 7.3
$p_{\mathrm{fail,\ upper}} \approx 3/n$	Rule of three: failure upper limit at 95% confidence, and $n \approx 3/(1-p_{\mathrm{target}})$	equation 7.4
$n = \lceil \ln \alpha_{\mathrm{sig}} / \ln p_{\mathrm{target}} \rceil$	Clean trials a claim needs; each added nine costs ten times the trials	equation 7.5
$\Pr(X \geq k \mid N, p) = \alpha_{\mathrm{sig}}$	Success lower limit when the record contains failures	equation 7.6
Λ_m against $\Lambda_{\mathrm{up}} \approx \ln((1-\beta)/\alpha_{\mathrm{sig}})$, $\Lambda_{\mathrm{lo}} \approx \ln(\beta/(1-\alpha_{\mathrm{sig}}))$	Sequential acceptance or rejection with both error rates declared before the first run	equation 7.7 and equation 7.8
$T \geq \ln(1/\alpha_{\mathrm{sig}})/\lambda$	Exposure wall: failure-free hours before a hazard rate can be bounded	equation 7.9
$v_{\mathrm{approach}} \leq F_{\mathrm{lim}}/\sqrt{m_{\mathrm{red}}\, k_{\mathrm{contact}}}$	Precontact speed that keeps the first impact peak under a force limit	equation 7.10

DRAFT

Key Takeaways: Closed-loop evaluation and reliability

- **A success rate belongs to a population**: Any empirical success metric reflects the coupled proposer policy, permission path, physical plant, environment, and trial protocol. Additional trials narrow uncertainty within sampled conditions, but evaluating new hardware units or altered operating regimes requires fresh empirical evidence.
- **Select evaluation regimes to match engineering questions**: Offline replay validates predictive accuracy and compute budgets, simulation tests closed-loop feedback under modeled dynamics, shadow deployment tests runtime execution against live sensor streams, and constrained physical trials expose real unmodeled contact. Each evaluation modality leaves distinct coverage gaps; their results cannot be pooled as interchangeable evidence.
- **Separate task completion from protective interventions**: Autonomous completion rate (ACR) quantifies unassisted task success, whereas mean time between interventions (MTBI) and intervention density characterize the operational burden of specific safety tripwires. Physical task success and protective safety outcomes must be tracked independently. In addition, reset latency (T_{reset}) captures the operational overhead of recovering after a safety disengagement. Recording every attempted run prevents safety supervision from artificially inflating policy performance.
- **Failure-free trials leave residual statistical uncertainty**: Twenty consecutive successful trials yield a one-sided 95 percent success lower bound of 86.1 percent under independent and identically distributed sampling. Reliability targets and statistical confidence levels dictate the required trial budget. Predeclared, calibrated sequential testing rules allow early stopping decisions without introducing post hoc selection bias.
- **Rare hazards demand independent physical safeguards**: Physical testing campaigns cannot feasibly supply the millions of failure-free operating hours required to bound

catastrophic risk. Runtime monitors, mechanical interlocks, and physical safety boundaries require independent validation of their sensing fidelity, actuation latency, and fallback dynamics. A high policy success rate can never substitute for verified protective mechanisms.

- **The evaluation record binds capability to operational limits**: The record documents what the proposer achieved within its target ODD, preserves an unedited trial log, and highlights unsupported operational conditions. Its monitor specifications guide runtime safety design, while unmonitorable coverage gaps impose firm operational restrictions on deployment claims.

The second law, endogenous data, closes Part II by leaving every evaluation record conditional on the closed loop that produced it. A sequence of incident-free trials samples only the trajectory distribution generated by admitted actions; it neither explores every physically reachable state nor certifies the absence of hazards outside the tested envelope. Systems engineers must carry both the characterized competence and the uncharacterized uncertainty forward into runtime system design. The evaluation record formalizes this transition through its target operational design domain, coverage gap catalog, and monitoring requirements. With the evaluation record, the first of the record chain's two strands is complete, pairing the plant limits of the limit record with the bounded competence recorded here. Part III builds the second strand, the live observations and proposals that meet the first at the permission decision on every control tick.

7.13 Historical Perspective and Further Reading

The statistical foundations of closed-loop evaluation were established long before autonomous systems encountered physical hardware. Standard textbook treatments of binomial confidence intervals rely on asymptotic normality, yet normal approximations fail near the extreme boundaries ($p \approx 0$ or $p \approx 1$) where robot qualification and safety certification operate. Wilson (1927) resolved the degeneracy of the textbook interval at zero failures by inverting the score test, ensuring that confidence intervals would not collapse to zero width on a spotless empirical record. Clopper and Pearson (1934) went further by directly inverting the cumulative binomial distribution to produce the exact, conservative confidence bounds that modern physical qualification audits require. In clinical trials evaluating rare adverse medical events, Hanley and Lippman-Hand (1983) popularized the "rule of three" as an accessible analytical shorthand for zero-failure campaigns. They established that when zero incidents occur across n independent trials, an upper 95 percent confidence bound on the true event probability is approximately $3/n$. Decades later, Brown et al. (2001) demonstrated the persistent systematic flaws and erratic coverage probability of standard Wald intervals. That result shows why rigorous evaluation campaigns for embodied agents must rely on exact binomial methods or inverted score statistics rather than asymptotic Gaussian assumptions.

The formal methodology for designing controlled evaluation campaigns emerged from agricultural experimentation and industrial manufacturing. Fisher (1935) formulated the core principles of randomized design, Latin squares, and blocking to prevent uncontrolled environmental factors, such as thermal drift, surface wear, and ambient lighting shifts, from being mistaken for genuine differences in algorithmic performance. Fisher's exact test for contingency tables (Fisher 1922) remains the standard baseline when comparing categorical success rates between discrete policy checkpoints under small sample sizes. During the Second World War, the Statistical Research Group at Columbia University introduced sequential hypothesis testing to inspect manufacturing lots efficiently without sacrificing statistical rigor. Wald (1945) published this Sequential Probability Ratio Test (SPRT) once military classification was lifted. The underlying mathematical machinery that guarantees valid stopping times and bounds Type I and Type II errors traces back to the martingale formulation of Ville (1939). In contemporary robot learning, these martingale arguments directly underwrite sequential testing protocols and anytime-valid confidence sequences, enabling practitioners to evaluate candidate policies adaptively and terminate underperforming runs early without invalidating target significance guarantees (Snyder et al. 2025).

The physical impossibility of validating safety-critical systems purely through black-box testing, the exposure wall, became evident during the development of fly-by-wire avionics. Butler and Finelli

(1993) demonstrated that verifying catastrophic failure rates on the order of 10^{-9} per flight hour requires operational test durations spanning hundreds of thousands of years. This result proves that ultra-high reliability cannot be certified through black-box testing alone and must instead rely on formal architecture, modular containment, and provable safety envelopes. Kalra and Paddock (2016b) applied this statistical reality to autonomous road vehicles, demonstrating that establishing statistical proof of safety parity with human drivers requires driving hundreds of millions or billions of physical miles across complex operational domains. Within machine learning, the gap between offline accuracy and online execution stems from the fundamental dynamics of closed loops. When Pomerleau (1989) demonstrated autonomous steering via artificial neural networks, small prediction errors caused the vehicle to drift into unfamiliar road configurations that were absent from the human demonstration dataset. Ross and Bagnell (2010) and Ross et al. (2011) formalized this breakdown by showing that distribution shift in sequential decision problems causes one-step prediction errors to compound quadratically over the planning horizon, producing a rigorous bound on the gap between open-loop validation and closed-loop rollouts. A defensible evaluation campaign brings these disciplines together: it delineates the operational design domain, accounts for human interventions as primary events within the statistical denominator, and confines the policy to verified envelopes when environmental conditions exceed tested bounds.

For further reading, six foundational works trace the trajectory from small-sample statistical theory to modern closed-loop robot evaluation:

- Brown et al. (2001) provides a definitive comparative analysis of binomial confidence intervals, exposing the systematic under-coverage of asymptotic approximations and motivating the exact bounds detailed in section 7.6.1.
- Wald (1945) formulates the Sequential Probability Ratio Test, establishing the mathematical boundaries and error guarantees applied to checkpoint screening in section 7.7.3.
- Butler and Finelli (1993) delivers a foundational proof that operational testing alone cannot certify ultra-high reliability in critical software systems, explaining why physical certification must lean on architectural safety design.
- Kalra and Paddock (2016b) quantifies the exposure wall for autonomous driving, providing accessible mathematical models and tables that show the hundreds of millions to billions of miles needed to measure catastrophic failure rates empirically.
- Ross et al. (2011) provides the theoretical analysis of compounding error under policy-induced distribution shift and introduces Dataset Aggregation (DAgger), formalizing why offline validation metrics fail to predict closed-loop performance.
- Kress-Gazit et al. (2024) establishes concrete reporting standards and metrology guidelines for physical robot evaluation, offering operational checklists covering trial counts, initial state distributions, blind evaluations, and failure mode accounting.

What's Next: From evaluation records to perception

Part II ends with a record that confines trust in the learned proposer to its target ODD and names the runtime monitors the rest of the machine must supply. Part III builds the runtime that meets those obligations. The first of them falls on perception, because an input-support monitor or a latency monitor can act only on observations that carry their capture time, their coordinate frame, and their uncertainty. Chapter 8 opens on a detection that is correct and already late, because the base keeps moving while the camera exposes, reads out, and infers, and it follows that measurement from the sensor to a spatial claim that the permission path can date, place, and bound before it permits motion.

Running the Machine

Part II ended with an evaluation record that bounds what the learned proposer has shown it can do inside its target operational design domain and names the runtime monitors the machine must supply. Now, as the warehouse mobile manipulator drives down an aisle, its navigation camera catches a person stepping out from the rack end ahead. The chunk policy's next proposal still carries the base forward, and the permission path must decide whether the observation behind it is still fresh and whether the remaining clearance permits that motion or only a stop. The decision has a deadline, and no better proposal helps once the machine has crossed its braking margin. Running a physical AI machine means reconciling the timescales of sensing, planning, and actuation with that physical deadline. Human goals may change over seconds and trajectories over tens of milliseconds, while the permission loop, in one implementation, runs every millisecond. The required rates and response times come from the plant and its measured delays, not from the names of the levels.

Principle 3: Proposal is not permission

Invariant: A learned model may propose motion; only an independent permission path may admit it. The path decides each action on state whose age is known, within a deadline set by observation age, computation, transport, actuator response, and the clearance the delay leaves. It owns a fallback that is feasible from the current state without the proposer.

Implication: Every runtime stage serves one decision, whether this proposal can cross the causal boundary before the margin runs out. Stages ahead of the permission path deliver evidence with its age and uncertainty attached. The permission path runs on resources that learned workloads cannot delay. Any guarantee the path offers, such as a barrier filter's (section 12.5), holds only while its model, state estimate, actuator authority, and deadline hold.

Part III develops the runtime that uses the proposer's evaluated capability without assuming it is correct on every occasion, and that supplies the runtime monitors the evaluation record names. It builds the record chain's second strand, the live observations and proposals that meet the first at the permission decision. Perception qualifies each measurement, stating when it was captured, where it was measured from, and how far it can be trusted. Memory develops the state estimator that fuses those measurements into the current scene and decides how long that estimate may stand. Intent bounds the requested task, and planning constructs candidate motion. Enforcement admits feasible motion, makes a least-change correction when possible, or initiates a qualified response when continued motion cannot be supported. Placement supplies the resources needed to make those decisions on time. These are dependencies in the engineering argument, not a claim that the running machine executes every stage serially. The base's run to the rack end and the arm's reach for the mug share one whole-body proposal stream and its time-limited permission. By tracing that stream, the reader learns which stage owns each physical constraint and how a failure upstream changes the action permitted downstream.

- **Sensor Perception (chapter 8):** Decides whether a measurement is current and calibrated enough to use, and produces the observation contract, which dates each measurement in a clock the permission path can convert to its own. It stops at the qualified measurement.
- **Spatial Memory (chapter 9):** Teaches state estimation, fusing dated measurements into a tracked state whose covariance is tested against its actual error. It then decides how long that

estimate may stand without fresh evidence and produces the belief record, which keeps the age of the evidence separate from the age of the estimate.

- **Grounded Intent (chapter 10):** Decides how a human goal becomes a bounded, expiring request, and produces the intent lease, which grants a target and effort ceilings but never a path.
- **Trajectory Planning (chapter 11):** Decides when a trajectory may commit, and produces the trajectory record, which carries its deadlines and a matched stop suffix.
- **Safety Enforcement (chapter 12):** Decides on every tick whether a proposal is admitted, projected, or refused. The first projection on the machine slows the arm's fast latch approach to the guarded speed that Part II's target ODD covers. The chapter produces the enforcement record, where the two strands of records meet.
- **Workload Placement (chapter 13):** Decides where the permission path runs so that learned workloads cannot delay it. It treats the two-processor split that section 4.2 states as a hypothesis to put to a loaded test, and produces the placement record, which names the test that would support it.

Across this six-stage chain, the first four records remain on the application processor, only the enforcement record sits across the proposal boundary on the safety microcontroller where the proposal is evaluated against its physical lease, and the placement record tests whether the hardware provides the isolation that boundary assumes (figure 7.7).

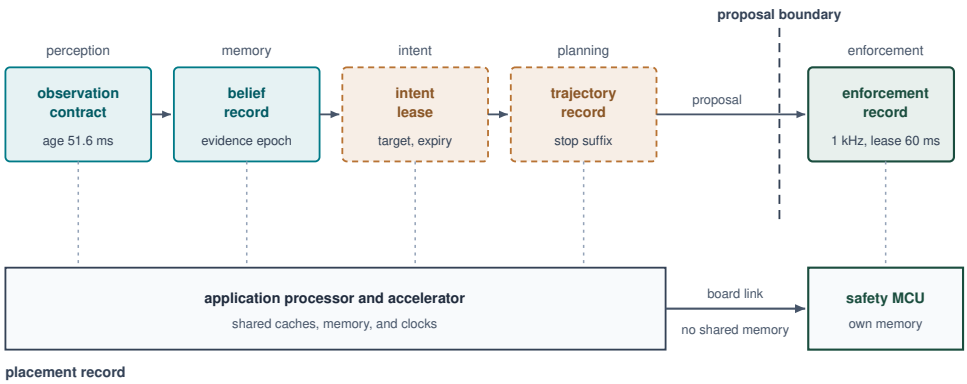

Figure 7.7: The Part III record chain and its placement: Each stage hands the next a record with its age or expiry attached, and only the enforcement record sits across the proposal boundary. The placement record assigns the four proposal-side stages to the application processor, where they share caches, memory, and clocks with learned workloads, and the permission path to a separate safety MCU reached over a board-level link. That split is a hypothesis until the loaded test of hardware separation supports it.

Part III hands forward the runtime evidence that Part IV must judge. Observation contracts date every measurement, belief records expire, intent leases and trajectory records name their parents and their deadlines, and the enforcement record states the stopping envelope and the premises of each guarantee. Its worked stopping budget selects a candidate aisle speed under declared timing and physical assumptions (section 12.3). Remaining clearance is conditional on those assumptions, including the still-unqualified dispatch-to-admission interval. A dispatch timestamp does not stop evidence from aging, and the chunk lease (section 4.4) begins at admission. The placement record names the loaded test that would show learned workloads cannot delay the permission path (section 13.7), and on this machine its loaded field is still empty. Each record is a claim with conditions, and none is yet a license to operate. Part IV must assess both useful service and containment, preserving the distinction between a permitted correction and failure to complete the task.

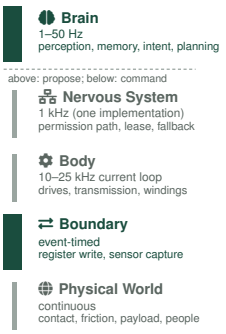
Purpose

Why can an accurate detection still be too late to guide a robot?

A camera can recognize an obstacle correctly and still report where it stood before the robot moved. Exposure, readout, transport, and inference all take time, the machine keeps moving through every millisecond of it, and a shifted mount or a misread clock then places the obstacle somewhere it never stood. None of these errors lowers a detection score. The worst of them, a frame stamped with the wrong time, narrows the estimate's uncertainty around the wrong position, so the machine grows more confident as it grows more wrong. A machine that treats a recognized object as a current position spends its stopping clearance on errors nobody measured. Perception serves a moving machine only when each observation states when it was captured, where it was measured from, and how far it can be trusted, because at the causal boundary a stale or misplaced observation becomes motion that cannot be taken back, and the permission path can refuse only evidence whose age and limits it can check.



Learning Objectives

- Select sensing modalities by the physical quantity, coverage, and failure limits required for a spatial decision
- Diagnose exposure, rolling-shutter, and calibration errors before measurements enter a geometric estimate
- Calculate capture-to-dispatch age and account for continued aging through downstream consumption without double charging delay
- Evaluate whether stopping margins fit the available clearance once the clearance inset and clock bound rest on measured error, not reported covariance
- Distinguish qualified metric evidence from learned depth estimates and semantic confidence
- Diagnose silent sensor failures, including a misdated frame, that pass transport checks while misrepresenting the scene
- Design an observation contract whose timing, calibration, error qualification, and health checks support downstream use

8.1 Choosing Evidence for a Spatial Decision

A vision model on the warehouse mobile manipulator can detect a worker stepping past a rack upright with near-perfect benchmark accuracy and still hand the trajectory planner an obsolete position. The world keeps moving while the navigation camera integrates charge, serializes pixel rows across the bus, and runs inference through the vision pipeline. On this machine, 51.6 ms elapses between the midpoint of optical exposure and the dispatch of the processed observation (derived in the latency waterfall of section 8.4.1). Driving at its 1.5 m/s drive limit, the base covers 77.4 mm over that single interval. Benchmark accuracy reveals nothing about whether an observation is still fresh enough to support safe clearance. On a moving machine, every observation carries an expiration date.

Every motion a physical AI system executes rests on a claim about the world derived from earlier sensor readings. Perception converts raw energy incident on a detector (photons on a CMOS sensor array, laser pulses reflected to an avalanche photodiode, or elastomer deformation at a fingertip) into spatial claims: the volume a coworker occupies, the metric range to a rack upright, or the incipient slip of a grasped object. Machine perception has historically been scored by static recognition accuracy on fixed benchmarks, which rewards a correct label regardless of when the exposure occurred or how the camera was moving. For an embodied machine that abstraction collapses. A spatial claim can support motion only if it states three properties: the instant its energy was captured, the coordinate frame in which it was measured, and a bound on its spatial uncertainty. Set against the machine's current velocity, that qualified uncertainty must fit inside the clearance that remains.

The evaluation record that closed Part II (section 7.8) hands the runtime a list of obligations rather than a verdict of trust. It limits the learned proposer to its target operational design domain (ODD) and leaves the rest of the machine to supply the runtime monitors that hold it there (section 7.9). Two of those monitors, the input-support monitor and the latency and freshness monitor, can act only on observations that carry their capture time, frame, and uncertainty, so their first obligation falls on perception. Perception delivers this runtime evidence as dated spatial claims across the proposal boundary. It executes within the non-deterministic Brain above that boundary and holds no actuator authority. The deterministic permission path below the boundary evaluates each proposed action against the capture timestamps, coordinate frames, and error qualifications of the perceptual claims behind it. Part III's governing law, proposal is not permission (principle 3), applies to perception in a specific way. A confident detection does not license motion. It is evidence behind a proposal, and the permission path can refuse that proposal only when the evidence carries an age, a frame, and an error bound it can check.

↩ The proposal boundary and permission path are established in section 1.7.

Checking a claim against physical margin means following the evidence from capture to qualification. Each sensor type must first match the physical quantity an action requires. Calibration and detector physics then ground the measurement in space and time, the capture-to-dispatch age

must be budgeted, and the spatial error, including the silent corruption no driver reports, must be bounded before any downstream check permits motion. The chapter closes by packaging those properties into an observation contract, so that a consumer can check a measurement's age, frame, and error before reading a single payload byte. The contract is the first record of the runtime strand, which meets the limit record and the evaluation record at the permission decision. Perception ends once it yields a qualified measurement. Fusing such measurements across time into persistent spatial state is the work of state estimation and spatial memory in chapter 9.

Whether an architecture employs an end-to-end vision-language-action (VLA) policy (Brohan, Brown, Carbajal, Chebotar, Chen, et al. 2023; Kim et al. 2024), an end-to-end visuomotor model without a language backbone (Zhao et al. 2023), or a modular estimator, it must reconcile the physical scene captured at a past instant with the kinematic state of the robot at execution. Architectural choices alter processing latency and representation formats, but no network topology can bypass photon integration, sensor readout, or bus transport delay. Explicit timestamps and spatial transforms keep this relationship inspectable; a latent representation holds it only implicitly, so checking it requires external instrumentation. Neither approach converts ambiguous sensor signals into ground truth. A specular reflection on a polished warehouse floor remains an optical hazard regardless of model capacity.

Navigating past a blind rack corner requires establishing a bounded occupied volume in the robot's base coordinate frame before available stopping distance runs out. RGB appearance helps classify an object as a person, but monocular bearing alone cannot supply metric range. The navigation camera therefore requires corroborated depth measurements before its detections can justify motion clearance, and on the running machine the spinning LiDAR introduced below supplies them. At the end-effector, sensing requirements change completely. While external optical cameras guide the initial reaching approach, detecting contact mechanics, shear forces, and incipient slip requires tactile sensing directly at the fingertips. Sensor selection begins by identifying the physical quantity governing each action, followed by analyzing sensor coverage, update rates, and environmental failure modes.

Table 8.1 compares the physical evidence each sensing mechanism provides alongside the primary failure modes and safety checks required before fusing claims across an embodied sensor suite. Adding a secondary sensor mitigates a shared failure mode only when its independent spatial coverage, timing guarantees, extrinsic calibration, and correlated failure risks are established.

Table 8.1: Spatial sensor modality comparison: Sensor mechanisms provide complementary but fallible claims across physical operating regimes. Numeric range, accuracy, refresh, and link budgets require a named device and mode. For example, Prophesee EVT2 encodes an event in 32 bits, so an event camera's link load scales with its event rate before transport overhead.

Modality	Direct physical information	Main limitation	Permission-relevant check
RGB camera	Bearing, appearance, and image motion	Monocular depth scale is ambiguous; glare, darkness, and occlusion can hide objects	Fresh capture time and validated metric corroboration
Active stereo	Disparity-derived range with infrared texture projection	Sunlight washes out projected pattern; range error grows quadratically with distance (z^2)	Range-dependent residual and bias validation
Structured light	High-density triangulated depth from projected coded patterns	Ambient solar infrared flooding; multi-robot pattern crosstalk; short range ($< 3\,\mathrm{m}$)	Lighting lux limits and pattern decoding integrity
Time-of-flight	Metric depth via phase delay (iToF) or photon arrival timing (dToF)	iToF phase wrapping; multipath reflections in corners; flying pixels on moving edges	Ambiguity distance and corner multipath flags
Pulsed LiDAR	Metric time-of-flight range at sampled laser beam directions	Near-field aerosol backscatter in fog/rain; retroreflector blooming; specular puddle dropouts	Qualified range, return quality, and scan timing
FMCW radar	Metric range and instantaneous radial Doppler velocity of targets	Multipath ghost returns off ground; lower angular resolution; antenna sidelobe clutter	Track association and coverage of crossing targets
Event camera	Asynchronous per-pixel log-intensity contrast events ($\geq C_{\mathrm{th}}$)	Unchanging scenes supply little event evidence; noise and flicker can still generate events	Event-rate health and independent metric depth source

Modality	Direct physical information	Main limitation	Permission-relevant check
Optical tactile	Contact micro-depth, surface normals, and shear force vectors	Zero sensing before physical contact; strictly localized to gripper elastomeric pad	Contact threshold, slip flags, and marker tracking

On an operational robot, this division of responsibility is explicit and follows established industrial safety standards. Neither the vision model nor the spinning LiDAR owns the certified safety claim regarding an obstacle at the rack end. ISO 3691-4 mandates that an autonomous industrial truck detect persons in its path at Performance Level d (PL d) (International Organization for Standardization 2023b; TÜV Rheinland 2021), the second highest of the five reliability grades (a through e) defined in ISO 13849-1 (International Organization for Standardization 2023a). Mobile bases satisfy this mandate using an industrial safety laser scanner, a dual-channel planar time-of-flight sensor certified as an active opto-electronic protective device under IEC 61496-3 (International Electrotechnical Commission 2025; Keyence Corporation 2026). By design and certification standards, the safety scanner performs no semantic classification; it reports solely whether an opaque object has entered its protective optical field, directly triggering the certified emergency stop circuit.

The mobile base's spinning LiDAR (an Ouster OS1-64) carries no functional safety rating; its datasheet certifies only electrical, laser, and electromagnetic compatibility (Ouster, Inc. 2025). Instead, it provides the dense 3D metric range field that the permission path evaluates against spatial clearance limits. The permission path runs on its own safety microcontroller (MCU), as chapter 4 placed it, but the clearance evaluation it performs there is an unrated admission check, a software layer above the certified safety scanner. Two components therefore guard the rack end, the permission path's unrated clearance check and the certified scanner beneath it. The permission path's role is to keep learned proposals smooth and proactive, adjusting trajectories well before the robot approaches the scanner's protective boundary and causes an abrupt hardware stop.

↪ The certified drive, scanner, and arm safety functions beneath the permission path, and the one rated watchdog on it, are developed in section 12.9.3.

Meanwhile, the navigation camera enriches the learned proposer with semantic context: distinguishing a coworker from a stationary tote and predicting velocity headings. Because the proposer constructs its trajectory predictions relative to the camera frame, that image frame's capture timestamp defines the evidence epoch carried by the resulting motion proposal. Section 8.4.2 details how the high-rate LiDAR stream is synchronized and cross-dated against this camera epoch. When operational conditions shift, other sensors fill the gaps: active illumination resolves textureless surfaces, event cameras preserve high-speed edge transitions across wide dynamic ranges, and tactile arrays capture localized contact dynamics that remote cameras cannot see. Before any of these sensors can anchor downstream motion, however, the system must account for how physical capture and mounting geometry distort the raw signal.

8.2 Capture Physics and Calibration

When photons from a warehouse rack upright strike the navigation camera's silicon detector, they do not become an instantaneous feature tensor in host memory. Before a neural backbone or state observer ever reads the frame, the photodiode array must accumulate charge over a finite exposure window, serialize rows off the sensor die, and move bytes across the interconnect, while the robot keeps moving through every millisecond of that process. In CMOS active-pixel sensors, incident photons generate electron-hole pairs through the photoelectric effect according to a wavelength-dependent quantum efficiency $\eta_{\mathrm{QE}}(\lambda_{\mathrm{wl}})$. Silicon photodiodes accumulate this photocharge across a finite exposure interval t_{exp}, collecting total charge:

$$Q = \int_0^{t_{\mathrm{exp}}} \frac{q\eta_{\mathrm{QE}}(\lambda_{\mathrm{wl}})}{h\nu} P_{\mathrm{opt}}(t)\, dt$$

where q is the elementary charge, h is Planck's constant, ν is optical frequency, and $P_{\mathrm{opt}}(t)$ is incident optical power. Exposure integration, readout serialization, bus transport across PCIe or MIPI CSI, memory staging, preprocessing kernels, and neural backbone inference each consume a slice of the end-to-end latency budget.

Because the photodiode accumulates charge over the finite exposure duration t_{exp}, the captured frame integrates scene radiance over time while both the robot and the surrounding environment

are in motion. Assuming approximately constant linear velocity $\mathbf{v}$ and angular velocity ω, with the optical center displaced from the vehicle's center of rotation by lever arm $\mathbf{r}_{P/O}$, a conservative bound on the physical displacement of the camera center during exposure is:

$$\Delta x_{\text{motion}} = \|\mathbf{v}\| t_{\text{exp}} + \|\omega \times \mathbf{r}_{P/O}\| t_{\text{exp}}$$

This distance measures the physical displacement of the camera center, not the pixel footprint of the blur on the detector plane. Projecting this displacement into image pixels requires scene depth, focal length, viewing direction, and relative attitude changes. Pure rotational motion can smear the image severely even when the camera center remains completely stationary. The resulting **motion blur** acts as a low-pass spatial filter, attenuating image gradients and destroying high-frequency edge information before neural feature extraction or corner detection can run. Downstream estimators can use accurate timestamps and extrinsic calibrations to position the blurred observation at its capture epoch, but no coordinate transformation can synthesize geometric detail lost during optical integration.

The finite integration window also determines which physical instant the resulting image represents. Under an idealized linear sensor response, the pixel value reflects incoming scene radiance $I(t)$ integrated across the exposure window:

$$I_{\text{pixel}} = \int_0^{t_{\text{exp}}} I(t)\, dt$$

The exposure midpoint is the reference epoch assigned to the integrated image, exactly $t_{\text{exp}}/2$ after the shutter opens and $t_{\text{exp}}/2$ before it closes. This convention dates the measurement without making its blurred content an instantaneous sample; changes in illumination or motion within the window still require qualification. For the mobile base running at its 1.5 m/s drive limit with the navigation camera configured to a 16 ms exposure, the frame represents the scene where the robot was 8 ms earlier, while the robot traverses 24 mm of translation during the exposure itself. Exposure time is a configured software parameter rather than an immutable hardware constant. The warehouse mobile manipulator configures this relatively long exposure to operate reliably in dim aisle lighting; higher ambient illumination permits shorter integration times, scaling down both motion blur and midpoint latency proportionally.

8.2.1 Rolling shutter distortion and motion compensation

Assigning a single exposure midpoint to an entire image assumes that every pixel row integrates light over that same window. In a **global shutter** sensor, every photodiode integrates charge during the exact same time window and transfers accumulated electrons to shielded in-pixel storage nodes simultaneously. In contrast, cost and silicon die area constraints often dictate the use of a **rolling shutter** sensor, where rows are reset, exposed, and read out sequentially from top to bottom ($y = 0$ to $y = H - 1$). Each successive scanline begins its exposure after an incremental row readout period t_{row}, introducing a progressive time skew across the vertical axis:

$$t_{\text{scan}}(y) = t_{\text{start}} + y \cdot t_{\text{row}}$$

where t_{start} denotes the exposure start time of the initial row ($y = 0$). When the vehicle translates at linear velocity $\mathbf{v}$ perpendicular to a vertical object, scanline y samples that object at an along-track spatial offset:

$$\Delta \mathbf{x}(y) = \mathbf{v} \cdot y \cdot t_{\text{row}} \tag{8.1}$$

Section 5.5.2.2 met this row timing as a skew that corrupts the pairing of a logged frame with an action. On a moving base the same skew becomes the spatial offset of equation 8.1, and it is charged against clearance.

Under angular motion, rolling shutter distortion becomes non-linear. If the camera rotates with angular velocity vector $\omega = [\omega_x, \omega_y, \omega_z]^\top$ (for example, rapid yaw or pitch during aggressive vehicle maneuvers), the camera attitude drifts continuously throughout the readout phase. The optical axis points in a slightly different direction for every single scanline. For a row at vertical coordinate y, the incremental rotation relative to the start of the frame is approximately $\Delta\theta_{\text{att}}(y) \approx \omega \cdot y \cdot t_{\text{row}}$. This

line-dependent rotation bends straight structural lines into curves, stretches or compresses vertical scale during pitching motions, and shears vertical surfaces into inclined planes, as photographed on the rotating propeller blades in figure 8.2.

Consider the warehouse mobile manipulator navigating past a vertical rack upright at its 1.5 m/s drive limit. A vertical post that spans the full frame height does not appear vertical in the raw pixel array, because the sensor reads the bottom scanline ($y = 3{,}039$) an entire readout cycle after the top scanline ($y = 0$). This delay induces two distinct geometric errors that consume separate safety margins: along-track translation shears the upright along the direction of travel, while base yaw during a turn shifts the feature laterally. Notebook 8.1 quantifies both effects.

Napkin Math 8.1: The readout shear

Problem: The base passes a rack upright at its drive limit while turning into the aisle. How far apart does the navigation camera record the upright's top and bottom rows, and what share of the corresponding clearance allowance does each error consume?

Variables:

- Rows $H = 3{,}040$ and readout $t_{\text{readout}} = 16.6$ ms (Datasheet, full-resolution mode).
- Drive limit $v_{\text{base}} = 1.5$ m/s (Illustrative).
- Yaw rate $\omega_z = 0.5$ rad/s while turning into the aisle, at the rack-end range $z = 1.10$ m (Illustrative).
- Localization allowance $\delta_{\text{loc}} = 50$ mm, the along-travel term of the stopping budget (section 2.3.1), and side clearance 0.15 m, the gap the base keeps between its flank and the rack faces while it drives the aisle (both Illustrative; section C.14.1).

Math:

Row interval.

$$t_{\text{row}} = \frac{t_{\text{readout}}}{H} = \frac{16.6 \text{ ms}}{3040} = 5.46 \ \mu\text{s}$$

Along-track skew. At the last row, equation 8.1 gives

$$\Delta x = v\, t_{\text{readout}} = 1.5 \text{ m/s} \times 16.6 \text{ ms} = 24.9 \text{ mm}, \quad \frac{\Delta x}{\delta_{\text{loc}}} = \frac{24.9 \text{ mm}}{50 \text{ mm}} = 0.50$$

Lateral skew. The bearing rotates by $\omega_z\, t_{\text{readout}}$ during readout, which moves the upright sideways at range z by

$$\Delta y = z\omega\, t_{\text{readout}} = 1.10 \text{ m} \times 0.5 \text{ rad/s} \times 16.6 \text{ ms} = 9.1 \text{ mm}, \quad \frac{9.1 \text{ mm}}{150 \text{ mm}} = 0.061$$

Sensitivity. At the aisle's chosen 1.3 m/s, the along-track skew is still 21.6 mm, 43.2 percent of δ_{loc}.

Result: The bottom rows see the upright from a camera position 24.9 mm farther down the aisle than the top rows did, half of δ_{loc}. Yaw adds 9.1 mm sideways, about 6.1 percent of the side clearance.

Systems insight: Uncorrected, one readout would spend half of the localization allowance that the stopping budget holds for the whole state estimate, and slowing to aisle speed barely helps. The budget's δ_{loc} is therefore valid only if the skew is removed before the estimator sees the frame. The lateral term is small at the rack end, but it grows with range and turn rate, so it belongs in the calibration and timing checks rather than in a budget row.

The along-track error charges directly against the localization allowance δ_{loc} established in section 2.3.1. Treating the image as an instantaneous rigid perspective projection mistakenly models the bottom of the upright as closer along the corridor than the top, directly consuming the along-travel stopping allowance. Both error components scale linearly with total readout time. A global-shutter

sensor, such as the wrist camera on the arm, eliminates scanline skew at the expense of larger pixel pitch and higher silicon cost. Selecting a shutter architecture is therefore a primary systems decision whenever a sensor's measurements inform clearance boundaries. The running machine deliberately carries a rolling-shutter navigation camera on its base, so its perception pipeline must handle this constraint rather than avoid it.

Resolving this spatial artifact requires **rolling-shutter motion compensation**: unwarping image coordinates geometrically using an interpolated camera pose for every scanline. The onboard IMU supplies high-rate (1,000 Hz) angular velocity and specific-force[1] samples rather than direct velocity measurements. A fused state estimator integrates these inertial readings with bias estimates, gravity tracking, and wheel odometry to compute continuous body poses. Transforming these poses through calibrated body-to-camera extrinsics yields an estimated optical pose for each scanline, allowing the perception pipeline to rectify the image before running stereo matching or landmark triangulation. Plotted against row index, the uncompensated skew is a straight line, because each row is read a fixed interval after the one above it (figure 8.1). The line ends halfway to the 50 mm allowance, which is why compensation, not a budget row, must absorb it.

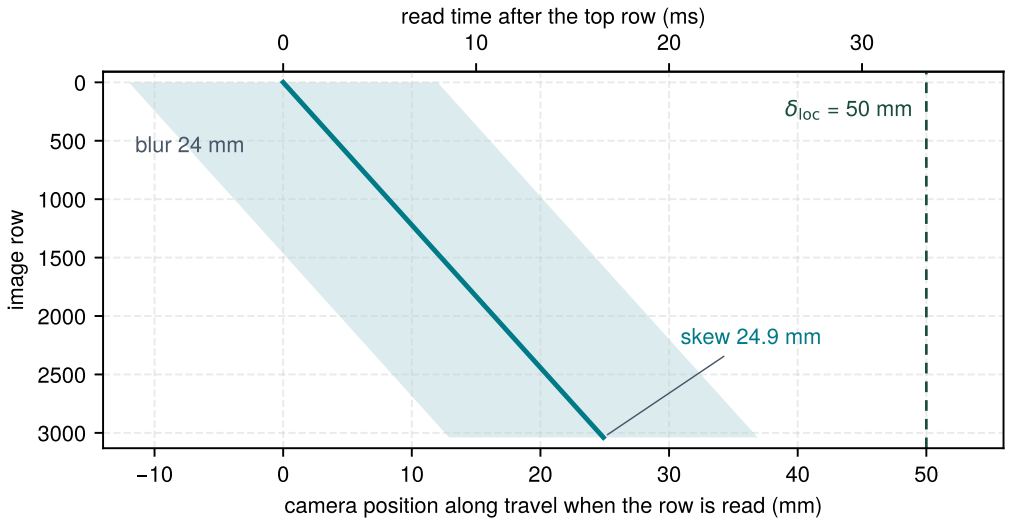


Figure 8.1: Row-by-row sampling on the navigation camera: At the 1.5 m/s drive limit, each of the 3,040 rows is read 5.46 µs after the one above it, so the bottom row sees the rack upright from a camera position 24.9 mm farther down the aisle than the top row (solid line; upper axis gives the read time). The shaded band is each row's own motion blur, 24 mm over the 16 ms exposure. Uncorrected, the skew alone spends about half of the 50 mm localization allowance (dashed line).

[1] **Specific Force**: An accelerometer measures non-gravitational acceleration, $\mathbf{a} - \mathbf{g}_0$, so a unit resting on the floor reads one g upward and one in free fall reads zero. Dead reckoning must therefore rotate specific force into the navigation frame and restore the gravity vector, and an attitude error θ_{att} leaks $g \sin \theta_{att}$ into horizontal acceleration, which integrates twice into the per-row poses that de-skewing relies on.

Figure 8.2: Rolling shutter distortion geometry: A phone camera's rolling shutter photographs a turning aircraft propeller. Because scanlines are exposed and read sequentially from top to bottom rather than simultaneously, blades that move appreciably during the frame's readout are recorded as curved, disconnected arcs; each row samples the blade at a later instant. On a moving robot the same row-by-row sampling shears straight structures and biases the geometry downstream estimators triangulate. (Credit: Dick Lyon, Wikimedia Commons, CC BY-SA 4.0.)

Geometric unwarping must precede spatial interpretation, as the detached propeller blades of figure 8.2 show. Because scanlines are exposed and read in sequence rather than simultaneously, rapid motion shears radial structures across rows. Learned feature backbones can misinterpret row-by-row shear as intrinsic physical geometry, while classical stereo matchers fail when scanline displacement shifts correspondences off the calibrated epipolar line.[2] Scaling up model capacity cannot compensate for uncorrected physical sampling distortion; the network learns biased geometric representations instead.

[2] **Epipolar Line**: For a calibrated camera pair, a point seen in one image can appear in the other only along one line, the projection of the ray from the first camera's center through that point (section 8.6 derives it). Stereo matchers search that line alone, so a rolling-shutter shear that moves a correspondence even one row off it produces a mismatch rather than a slightly worse match.

8.2.2 Camera calibration

Unwarping a rolling-shutter image still leaves a pixel without a physical direction or position if the camera's internal lens parameters or chassis mount have shifted. Under the **pinhole camera model** (Hartley and Zisserman 2003), the intrinsic matrix $\mathbf{K}$ maps a point $\mathbf{p}_c = [X_c, Y_c, Z_c]^\top$ in the camera's optical frame to the pixel $[u, v]^\top$:

$$\tilde{\mathbf{m}} \sim \frac{1}{Z_c}\mathbf{K}\mathbf{p}_c = \frac{1}{Z_c}\begin{bmatrix} f_x & 0 & c_x \\ 0 & f_y & c_y \\ 0 & 0 & 1 \end{bmatrix}\begin{bmatrix} X_c \\ Y_c \\ Z_c \end{bmatrix} \tag{8.2}$$

where f_x, f_y are focal lengths in pixels and (c_x, c_y) is the principal point. Inverting the map recovers only a bearing ray, along which every depth is consistent with the pixel:

$$\mathbf{r}(\tilde{\mathbf{m}}) = \mathbf{K}^{-1}\tilde{\mathbf{m}} = \begin{bmatrix} \frac{u-c_x}{f_x} \\ \frac{v-c_y}{f_y} \\ 1 \end{bmatrix} \tag{8.3}$$

This bearing ray emanates from the camera's optical center at the precise instant of photon capture t_{capture_0}. If downstream motion planning unprojects $\mathbf{r}(\tilde{\mathbf{m}})$ using the robot's *current* pose instead of its historical capture pose, the current evidence age at that downstream use, $t_{\text{now,mono}} - t_{\text{capture}_0}$, translates the ray origin by $\Delta\mathbf{p} = \int_{t_{\text{capture}_0}}^{t_{\text{now,mono}}} \mathbf{v}(t)\,dt$. These timing and angular errors scale along entirely different physical axes. At the 1.5 m/s drive limit, each millisecond of unmodeled latency shifts the ray origin by 1.5 mm, making the dispatch-age contribution of 51.6 ms displace the origin by 77.4 mm. Attitude errors, by contrast, scale with range. A single degree of orientation misalignment shifts a target at the 1.10 m rack-end distance by 19.2 mm laterally, expanding proportionally with distance. Unchecked, either discrepancy can push a physical rack upright entirely outside the bounding volume evaluated by the permission path. A single monocular camera cannot recover metric range along its bearing rays; scale must be supplied by stereo disparity, an active ranging sensor, or a learned geometric prior, and each introduces uncertainty that section 8.6 audits against the operating clearance budget. Optical lens distortion is rectified inside the hardware image signal processor (ISP) stage detailed in table 8.3. Section C.12 develops the full projection equations, radial distortion models, and Zhang's planar calibration method (Zhang 2000).

Spatial extrinsics and temporal synchronization between the camera and the IMU must be calibrated jointly (Furgale et al. 2013). An extrinsic orientation error θ_{ext} misplaces an observed feature at depth z by approximately $z\theta_{\text{ext}}$, while spatial translation between the camera center and the IMU introduces the centripetal and tangential lever-arm accelerations given in section B.6.4. Similarly, an uncalibrated temporal offset Δt_{imu} between image exposure and inertial sampling causes an effective orientation error of $\omega_z \Delta t_{\text{imu}}$ while turning at angular velocity ω_z. This timing skew displaces the reconstructed feature by approximately $z\omega_z \Delta t_{\text{imu}}$, growing with both vehicle yaw rate and target distance. Hardware-latching exposure triggers and IMU clock signals to a shared real-time counter bounds this synchronization offset to sub-microsecond regimes, leaving small residual latencies for online filtering. Because mechanical shocks and thermal expansion degrade calibration over time, every observation packet must record its calibration identifier alongside its empirical operating envelope.

8.2.3 Choosing metric depth for the aisle

Because a single bearing ray leaves range undetermined, robotic systems often pair passive cameras with active optical depth cameras to recover scale. In a warehouse aisle, however, ambient lighting, surface material properties, and multi-robot optical interference dictate which depth-sensing principle survives in practice. **Structured light** projects a known pseudo-random or coded infrared pattern onto the scene and triangulates surface deformation using an offset receiver camera. Although this active pattern injects distinct visual texture onto featureless cardboard cartons, direct sunlight from skylights or open loading docks easily washes out the projected infrared pattern, and overlapping projectors from adjacent mobile bases create optical interference that corrupts feature correspondence. Engineering qualification must therefore evaluate the operating environment under peak ambient lux and multi-robot contention rather than treating structured light as an unconditional depth source.

Rather than triangulating a spatial pattern, **indirect time-of-flight (iToF)** calculates distance by measuring the phase shift of continuous-wave amplitude-modulated infrared light. Phase differences yield dense range maps with compact hardware. Modulation periodicity, however, creates phase wrapping and distance ambiguity intervals. Multipath reflections in metallic warehouse corners and industrial shelving also send diffuse photons along several bounces, which bias the depth estimate. Motion between sequential phase exposures also introduces edge artifacts in dynamic scenes. **Direct time-of-flight (dToF)** avoids periodic phase wrapping by measuring the arrival times of discrete photon pulses using single-photon avalanche diodes (SPADs), yet it remains subject to timing jitter in the receiver discriminator, multipath contamination, and optical pile-up from high-reflectance foregrounds.

Active stereo combines structured infrared illumination with a calibrated stereo camera pair. Unlike structured light systems that must decode a proprietary pattern, active stereo uses projected speckle purely to synthesize artificial texture on smooth surfaces while computing standard epipolar stereo correspondence. If bright ambient light washes out the infrared pattern, the underlying stereo

pipeline continues operating over ambient visible texture; if a smooth surface lacks ambient texture, however, high illumination alone still cannot resolve depth. The range-dependent uncertainty analysis in section 8.6 determines whether active stereo depth uncertainty satisfies the robot's required stopping clearance.

For the rack end, the running machine carries none of these depth cameras. Each of these active principles has a failure mode the aisle supplies, whether daylight through open dock doors, a neighboring base's projector, or multipath off metal shelving. The machine's metric range comes instead from the OS1-64 LiDAR described later, and the navigation camera contributes bearing and class. Stereo returns in section 8.6 only as an illustrative rig that shows where a camera-only design meets a range wall.

8.2.4 Event cameras and asynchronous contrast

Conventional CMOS sensors integrate photons over a fixed exposure window, forcing a trade-off between motion blur on fast targets and photon starvation in dim aisles. **Neuromorphic event cameras** (Dynamic Vision Sensors, or DVS)[3] avoid frame-rate exposure trade-offs by abandoning discrete frames entirely (Lichtsteiner et al. 2008; Gallego et al. 2022). Each pixel on an event sensor array operates autonomously, containing a logarithmic photodiode, an analog amplifier, and two differential voltage comparators. The pixel continuously monitors incoming scene radiance $I(u, v, t)$. Whenever the temporal change in logarithmic intensity exceeds a configurable contrast threshold C_{th}, the pixel emits an asynchronous digital event packet e_k:

$$|\Delta \ln I(u,v,t)| = |\ln I(u,v,t) - \ln I(u,v,t_{\text{last}})| \geq C_{\text{th}}$$

$$e_k = \langle u_k, v_k, t_k, p_k \rangle$$

where (u_k, v_k) is the pixel address, t_k is the event timestamp latched with microsecond resolution (1–10 µs), and $p_k \in \{-1, +1\}$ is the polarity indicating whether radiance increased or decreased.

Event sensing preserves the temporal fidelity of high-speed edge transitions without waiting for a complete exposure cycle and serial scanline readout, providing high temporal resolution for rapid maneuvers. The systems trade-off lies in the nature of temporal contrast. Static obstacles produce zero events when the camera is stationary, so an unmoving obstacle is undetectable without ego-motion. Furthermore, high-frequency fluorescent lighting flicker and thermal noise generate spurious event bursts. The bandwidth demand across the physical sensor interface is therefore dynamic and scene-dependent rather than deterministic and fixed.

Downstream estimation algorithms must convert asynchronous coordinate streams in (u, v, t) space into representations suitable for neural networks or state observers. Accumulating events into fixed time slices allows the use of standard convolutional backbones but reintroduces latency; processing individual event timestamps maintains sub-millisecond temporal responsiveness at the cost of specialized asynchronous graph or spiking architectures. Neither representation provides absolute metric depth without stereo baseline pairing or active sensor fusion. For the rack-end decision, an event camera would add edge timing but no range, and it would lose a worker who stops at the corner, so the running machine does not carry one.

8.2.5 LiDAR and radar ranging

Passive cameras cannot measure metric distance along a single viewing ray, and short-range depth cameras fail when dock sunlight or metal shelving corrupts their patterns. Active ranging sensors, principally Light Detection and Ranging (**LiDAR**) and Radio Detection and Ranging (**radar**), overcome these limits by emitting structured electromagnetic energy and timing its return to measure metric range and radial velocity directly. Pulsed time-of-flight LiDAR calculates radial distance R by measuring the round-trip flight duration Δt of an emitted laser pulse traveling at the speed of light c:

$$R = \frac{c \cdot \Delta t}{2}$$

In three-dimensional space, optical scanners steer each pulse along azimuth θ_{az} and elevation ϕ, casting an emitted ray along unit direction vector $\mathbf{d}(\theta_{\text{az}}, \phi) = [\cos\phi\cos\theta_{\text{az}},\ \cos\phi\sin\theta_{\text{az}},\ \sin\phi]^\top$.

[3] **Neuromorphic**: Carver Mead coined the term at Caltech for analog circuits that compute the way neural tissue does (Mead 1990), and the silicon retina built in his group is the ancestor of the Dynamic Vision Sensor (Lichtsteiner et al. 2008). Like the retina, each pixel reports change rather than level, so an obstacle that stands still in front of a stationary sensor produces no events and is invisible to it.

When reflected energy trips the receiver threshold after flight time Δt, the sensor unprojects the return into a 3D point in the sensor frame $\mathcal{F}_{\text{lidar}}$ via ray casting (equation 8.4):

$$\mathbf{p}_{\text{lidar}} = R \cdot \mathbf{d}(\theta_{\text{az}}, \phi) = \frac{c \cdot \Delta t}{2} \begin{bmatrix} \cos\phi \cos\theta_{\text{az}} \\ \cos\phi \sin\theta_{\text{az}} \\ \sin\phi \end{bmatrix} \tag{8.4}$$

Spatial uncertainty in this unprojected 3D point decomposes into two distinct physical mechanisms:

1. **Radial uncertainty (σ_R)**: Governed by receiver discriminator timing jitter $\sigma_{\Delta t}$ and pulse rise time, $\sigma_R = \frac{c}{2}\sigma_{\Delta t}$ remains approximately constant across operating distances until return signal attenuation drops photon counts near the detection threshold. The manufacturer datasheet for the robot's OS1-64 specifies a one-standard-deviation precision between 5 mm and 30 mm beyond 1 m. It also specifies a systematic accuracy bias of 25 mm on diffuse targets in the specified 1024×10 Hz mode (Ouster, Inc. 2025). These are datasheet scales, not qualified bounds for the running machine's selected scan mode, surfaces, and motion. The accuracy figure describes the bias of the mean, a calibration offset that temporal averaging cannot remove.
2. **Transverse footprint**: Governed by optical beam divergence $\delta\theta_{\text{div}}$; internal angular encoder quantization contributes a separate bearing error. The laser pulse expands into a narrow cone rather than propagating along an infinitesimal line. Taking $\delta\theta_{\text{div}}$ as the full-angle divergence, the transverse spot diameter scales as range times divergence. At $R = 30$ m, the illustrative 2 mrad divergence gives a 60 mm spot diameter. This geometric footprint is not a standard deviation of position error. When it strikes a surface boundary, the detector receives mixed returns from foreground and background, blurring geometric edges; the resulting error distribution must be measured.

Most terrestrial systems operate either at near-infrared wavelengths below $1{,}000\,\text{nm}$, where silicon detectors respond, or at an eye-safe $1{,}550\,\text{nm}$ (permitting higher pulse energies under IEC 60825-1 Class 1 laser regulations).[4] The machine's OS1-64 is of the first kind; it emits at 865 nm as a Class 1 laser product (Ouster, Inc. 2025). Mechanical spinning LiDAR systems rotate an array of 16 to 128 laser diodes and avalanche photodiode (APD) detectors across an internal spindle at 10–20 Hz to sweep a 360° panoramic point cloud.

Much like rolling-shutter cameras expose scanlines in sequence, a spinning mechanical LiDAR does not record an instantaneous 3D snapshot. Completing a full 360° azimuth sweep requires $T_{\text{sweep}} = 1/f_{\text{scan}}$, corresponding to 50 ms on the machine's OS1-64 configured at 20 Hz. If the mobile base translates at velocity $\mathbf{v}$ and rotates at angular velocity ω while the sensor spins, pulses fired at the start of the sweep ($\theta_{\text{az}} = 0^\circ$) and near completion ($\theta_{\text{az}} = 360^\circ$) originate from physically distinct vehicle poses. At the 1.5 m/s drive limit and an illustrative 0.5 rad/s turn rate, the robot travels 75 mm and rotates 25 mrad (1.4°) during a single scan. Without motion correction, this sampling lag produces an apparent geometric tear where the end of the revolution meets the beginning, while shearing vertical structures across the corridor.

Restoring rigid geometric fidelity requires **continuous-time LiDAR de-skewing**. The sensor hardware latches each point return $\mathbf{p}_i$ with an exact firing timestamp $t_i \in [t_{\text{sweep}}, t_{\text{sweep}} + T_{\text{sweep}}]$. A rigid pose transformation $\mathbf{T} \in \text{SE}(3)$ encapsulates orientation and translation. In the two-subscript convention, the first subscript names the destination frame and the second names the source: `T_ab` maps coordinates from frame b to frame a, and its inverse maps back. A homogeneous point appends a final coordinate of 1 so that the matrix applies translation as well as rotation. Section B.6.4 develops this representation and composition; section 8.3.1 applies it to the machine's mounting chain. Combining high-frequency (1,000 Hz) inertial data with wheel odometry allows the state estimator to compute the continuous trajectory of the vehicle body frame, $\mathbf{T}_{wb}(t_i)$. Applying the calibrated mounting extrinsic $\mathbf{T}_{bl}$ transforms coordinates from the LiDAR frame to the body frame,

[4] **Laser Class 1**: The class of IEC 60825-1 whose emission is safe under all reasonably foreseeable viewing, including through optical instruments (International Electrotechnical Commission 2014). Below about $1{,}400\,\text{nm}$ the eye focuses the beam onto the retina, while at $1{,}550\,\text{nm}$ the cornea and lens absorb it first, so the permitted pulse energy is far higher. Those longer wavelengths need indium gallium arsenide detectors rather than silicon, which makes wavelength a range vs. cost choice made under a fixed safety ceiling.

yielding the world-frame sensor pose $\mathbf{T}_{wl}(t_i) = \mathbf{T}_{wb}(t_i)\mathbf{T}_{bl}$. Each individual homogeneous point return is then projected back into the LiDAR's coordinate frame at the frame reference epoch t_{sweep}:

$$\mathbf{p}_i(t_{\text{sweep}}) = \mathbf{T}_{wl}^{-1}(t_{\text{sweep}}) \cdot \mathbf{T}_{wl}(t_i) \cdot \mathbf{p}_i(t_i)$$

De-skewing is what makes an accumulated LiDAR map usable. The returns registered in figure 8.3, gathered over about 18 s of driving through a city intersection, keep crisp building facades, road striping, and parked vehicles only because each return was placed with the vehicle pose at its own firing epoch t_i. Independently moving obstacles in the environment require separate velocity estimation and clustering. Flash LiDAR architectures avoid sweep distortion altogether by illuminating the entire field of view with a single laser pulse to capture an instantaneous 3D range matrix. Distributing finite optical pulse energy across a wide solid angle, however, sharply limits maximum operational range compared to concentrated, steerable beams.

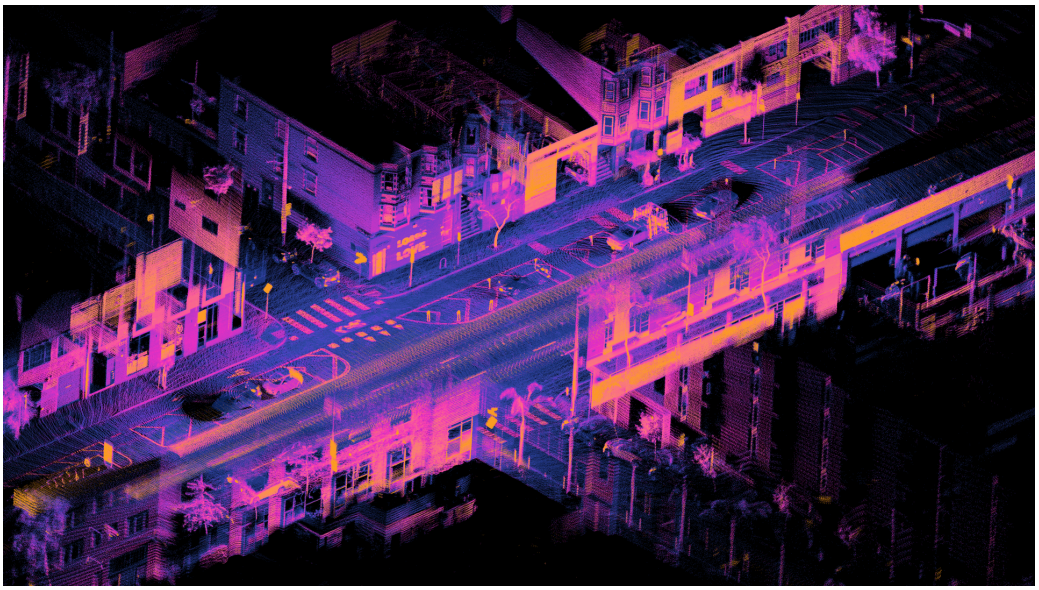

Figure 8.3: Registered LiDAR point cloud: Returns from a 64-beam spinning LiDAR on a moving car, registered into one map over about 18 s as a simultaneous localization and mapping (SLAM) estimator tracked the vehicle's trajectory, and shown in orthographic projection colored by return intensity times range. The sharp building edges and vehicles hold only because every return was placed with the pose at its own firing time; a single sweep is far sparser than this aggregate. (Credit: Daniel L. Lu, Wikimedia Commons, CC BY 4.0.)

Millimeter-wave radar offers an orthogonal active sensing channel, operating in the 76–81 GHz band ($\lambda \approx 3.9\,\text{mm}$). Rather than emitting short, high-energy pulses, **Frequency-Modulated Continuous-Wave (FMCW) radar** transmits linear frequency chirps whose instantaneous carrier frequency sweeps across bandwidth BW_{chirp} over chirp duration T_c with slope $S = \text{BW}_{\text{chirp}}/T_c$. When the emitted waveform reflects from an obstacle at range R, the echo returns delayed by round-trip flight time $t_{\text{rt}} = 2R/c$. Mixing the received echo with a replica of the transmitted signal generates an intermediate frequency (IF) beat tone at frequency f_b:

$$f_b = S \cdot t_{\text{rt}} = \frac{2R\,\text{BW}_{\text{chirp}}}{cT_c}$$

Computing a fast Fourier transform across the digitized fast-time samples of each chirp (the **Range-FFT**) extracts metric range R directly, without requiring optical contrast or ambient scene illumination. Physical range resolution depends strictly on total sweep bandwidth:

$$\Delta R = \frac{c}{2\,\text{BW}_{\text{chirp}}}$$

For a standard 4 GHz radar sweep (77–81 GHz), FMCW radar achieves a fine range resolution of $\Delta R \approx 3.75$ cm. The transmitted chirps simultaneously encode radial velocity and bearing. A moving target shifts the phase of successive chirp reflections proportionally to its Doppler velocity; evaluating a second Fourier transform across chirps (the Doppler-FFT) extracts this radial velocity within a single coherent processing interval, avoiding the latency and noise of multi-frame position differencing. Array processing across multiple receive antennas resolves target azimuth and elevation, albeit at substantially coarser angular resolution than optical LiDAR. The running machine does not mount radar, but millimeter-wave sensing is a primary modality on outdoor autonomous platforms. Its millimeter wavelength penetrates the dust, fog, and steam that scatter optical wavelengths (section 8.7). However, radar returns remain sensitive to specular scattering, surface orientation, and multi-path ghost targets, providing complementary evidence rather than an infallible, all-weather guarantee.

8.2.6 Tactile contact sensing

At the end-effector interface, external cameras and range finders cannot measure contact pressure or verify friction adhesion during physical manipulation; indeed, the gripper structure often occludes the contact patch entirely. An optical tactile sensor[5] addresses this perceptual blind spot by mounting a compliant, internally illuminated elastomer membrane on the fingertip and imaging its deformation with an internal camera. Photometric stereo algorithms translate surface shading into calibrated local contact topography, while tracking arrays of embedded fiducial markers yields direct measurements of tangential shear strain and incipient slip. Converting these raw optical deformations into a calibrated contact wrench requires a validated finite-element or empirical model that accounts for elastomer hysteresis, dynamic loading, and mechanical wear over time.

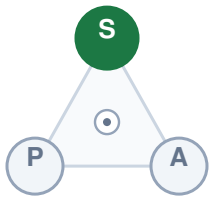
Tactile sensing thus governs the terminal contact phase of robotic grasping, whereas external cameras and range sensors guide the initial approach trajectory. Across both regimes, downstream estimators cannot treat sensor outputs as timeless, unframed tensors. Every tactile frame and spatial point cloud carries a finite physical age, a mounting transform, and a calibration uncertainty that must be attached to the measurement before any consumer can use it.

[5] **GelSight**: Adelson's group at MIT turned a reflective elastomer skin and an internal camera into a contact sensor that recovers surface geometry and, from painted markers, shear force (Yuan et al. 2017). The design makes touch one more image stream, so a tactile frame carries an exposure, a readout, and a calibration of its own and must be dated and qualified like the navigation camera's.

8.3 Dating and Placing the Measurement

A frame from the navigation camera lands in host memory as an array of pixel values. Nothing in that array says when the light was captured, where the camera was mounted, or how far a position read from it can be trusted, yet the planner that checks rack-end clearance needs all three. Every modality has the same gap. A trajectory optimizer cannot plan against unorganized time-of-flight returns, and a force controller cannot track a grid of raw intensities. Downstream estimation, planning, and spatial memory require structured measurements: metric positions, bounding volumes, and semantic classes, with directly measured velocity where the sensing modality supplies it. Translating raw streams into those measurements is the perception pipeline's responsibility. Whatever form its output takes, whether an explicit message packet or an observation token sequence, it must carry three mandatory properties before any consumer can use it: a capture timestamp, a reference frame, and a qualified uncertainty envelope.

The first mandatory property is the **capture timestamp** t_{capture_0}, which specifies the temporal midpoint of the energy integration window, the effective instant of a camera exposure or a laser firing. Physical sensors do not take instantaneous snapshots. An optical camera integrates photons across an exposure duration, and a mechanical lidar sweeps laser pulses over an azimuth arc across several milliseconds. Downstream state observers and vision-language-action policies require t_{capture_0} to ground observation tokens into the machine's dynamic equations of motion. By contrast, the arrival stamp t_{recv} marks the moment the operating system kernel completes the direct memory access (DMA) transfer. It is the software arrival timestamp that section 5.5.2.1 showed corrupting logged velocities; at runtime it corrupts the pose an observation is paired with. Half of the exposure duration, sensor readout, physical transport, and host DMA transfer all elapse before that interrupt fires. Consequently, the arrival offset $\Delta t_{\text{recv}} = t_{\text{recv}} - t_{\text{capture}_0}$ is never zero. Substituting arrival time for capture time directly corrupts downstream state estimation and action generation.



The Sense stage: photons become dated, framed claims.

At constant velocity v_{base}, the hidden travel is $\Delta x = v_{\text{base}}\,\Delta t_{\text{recv}}$. On the mobile manipulator, the navigation camera's frame completes its DMA transfer 26.6 ms after the exposure midpoint. An

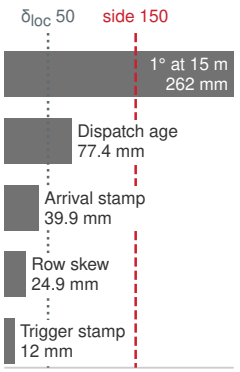
estimator that timestamps the frame upon arrival dates the measurement late by that full duration. At the base's 1.5 m/s drive limit, this temporal mismatch pairs the visual observation with an estimated pose 39.9 mm ahead of the physical position the camera occupied at capture.

Eliminating this arrival offset and bounding the camera-to-inertial offset Δt_{imu} of section 8.2 require stamping the capture event directly in hardware rather than recording when a software thread first handles the frame buffer. Software timestamps inherit operating system scheduling jitter, driver queue delays, and thread preemption. While the base rotates at 0.5 rad/s, each millisecond of scheduling jitter misorients the camera by 0.5 mrad, producing a lateral displacement of 0.55 mm at rack-end distance. Two hardware architectures avoid dating capture by software-handler scheduling. In the first architecture, a hardware GPIO strobe (such as FSYNC) from the IMU microcontroller simultaneously latches an inertial sample and triggers the camera exposure. Because this trigger edge marks only the start of exposure for the first sensor row rather than the optical midpoint, the driver must add $t_{\text{exp}}/2$ to reach the exposure midpoint. It must also add $y\,t_{\text{row}}$ for the specific image row y under consideration. Omitting this correction dates the navigation camera frame 8 ms early, translating to 12 mm of unmodeled travel at the drive limit. Furthermore, because automatic exposure control varies t_{exp} dynamically across frames, the driver must apply the specific exposure time reported in each frame's metadata. In the second architecture, used for networked sensors such as the lidar units and GigE Vision cameras, each peripheral timestamps samples against an onboard hardware clock. The Precision Time Protocol (PTP) (IEEE 2020a), or its time-sensitive networking profile gPTP (IEEE 2020b), disciplines these local clocks to a master reference across the Ethernet bus. Each free-running oscillator (the camera trigger counter, the LiDAR's internal clock, the application processor, the safety MCU) defines its own **clock domain**. A capture time stamped in one domain cannot be compared with a time read in another until it is converted. The largest error that conversion may carry is the **clock-conversion bound** ϵ_{sync}, which every dated observation must carry alongside its capture time; section 8.6.2 details how to measure it.

The second mandatory property is the **reference frame** identifier $\mathcal{F}_{\text{sensor}}$. Every spatial measurement is natively resolved in the local coordinate system of the physical transducer. A camera measures bearing angles relative to its optical center, whereas a radar measures range and Doppler velocity relative to its antenna array. Downstream trajectory planners and occupancy maps, by contrast, operate in a chassis body frame $\mathcal{F}_B$ or an inertial navigation frame $\mathcal{F}_W$. Transforming an observation from $\mathcal{F}_{\text{sensor}}$ to $\mathcal{F}_B$ requires applying a rigid-body spatial transformation consisting of a rotation matrix and a translation vector that define the sensor mounting extrinsics, the calibrated location and orientation at which the sensor is bolted to the machine. Coordinate frames nest hierarchically from the physical operating environment down to the transducer: $\mathcal{F}_{\text{earth}} \to \mathcal{F}_{\text{map}} \to \mathcal{F}_{\text{odom}} \to \mathcal{F}_B \to \mathcal{F}_{\text{sensor}}$, where every link in this tree introduces its own transform and uncertainty (figure 8.4).

When perception outputs omit the frame identifier or rely on nominal CAD dimensions rather than calibrated physical extrinsics, small angular offsets create large spatial errors that scale with distance. The same uncalibrated yaw error of $\theta_{\text{ext}} = 1°$ that costs 19.2 mm at the 1.10 m rack end grows linearly as the planner looks farther down the aisle. For an object at an illustrative range $z =$ 15 m down a long aisle, it induces a transverse position error $\Delta y \approx z \sin\theta_{\text{ext}}$ of 0.26 m. This lateral offset is approximately 1.7× the 0.15 m side clearance that the base maintains from the warehouse racks, causing the planner to either steer into the racking or falsely reject an open aisle as obstructed.

The third mandatory property is an **uncertainty representation**, such as a measurement covariance Σ_z paired with a validated tail bound or hard error envelope when physical clearance depends on it. Environmental degradations such as low illumination, atmospheric scattering, specular reflections, and out-of-distribution neural network errors distort the residual distribution far beyond Gaussian assumptions. While a covariance matrix characterizes second moments, it does not guarantee a conservative bounding volume for the true physical state. Downstream state estimators and policy heads rely on Σ_z to weight incoming sensory updates against dynamic motion predictions. If perception reports an artificially optimistic covariance, the estimator over-weights spurious measurements and commands aggressive, erratic actuator responses. Robust physical safety decisions must therefore account explicitly for systematic bias, missed detections, and sensor operational limits alongside the reported covariance.



Timing slips cost tens of millimeters; a 1° mount error at 15 m costs 0.26 m.

8.3.1 Calibrating the coordinate chain

Even when each sensor frame is named, an observation measured at the wrist camera still cannot guide the arm or base until the runtime chains every joint and mount transform back to the world at the exact capture instant t_{capture_0}. A coordinate frame transform maps a point expressed relative to one origin into the coordinate system of another: its rotational part reorients the coordinate axes, while its translational part accounts for the spatial offset between origins. Homogeneous matrix representations package both operations so that camera-to-wrist, wrist-to-base, and base-to-world transforms can be composed at t_{capture_0}. The notation below writes the destination as a lower index and the source as an upper index, expressing the same mapping direction as the two-subscript convention used for LiDAR de-skewing.

A robot's spatial coordinate system forms a **directed acyclic graph (DAG)** of transforms $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, where vertices $\mathcal{V} = \{\mathcal{F}_i\}$ represent physical coordinate frames and directed edges $\mathcal{E}$ represent time-varying rigid-body transforms $\mathbf{T}_{ij}(t) \in \mathrm{SE}(3)$. In practice, systems constrain this DAG to a directed tree where each non-root frame has exactly one parent, ensuring a unique path between any two frames. When unprojecting an optical observation $\mathbf{p}_c(t_{\text{capture}_0})$ into world coordinates, the runtime composes the transforms along that tree:

$$\mathbf{p}_{\text{world}}(t_{\text{capture}_0}) = \mathbf{T}^{\text{map}}_{\text{world}} \cdot \mathbf{T}^{\text{odom}}_{\text{map}}(t_{\text{capture}_0}) \cdot \mathbf{T}^{\text{base}}_{\text{odom}}(t_{\text{capture}_0}) \cdot \mathbf{T}^{\text{flange}}_{\text{base}}(t_{\text{capture}_0}) \cdot \mathbf{T}^{\text{cam}}_{\text{flange}} \cdot \mathbf{p}_c(t_{\text{capture}_0})$$

The physical mounting location of the sensor on the kinematic chain dictates whether those transforms stay fixed on the body or update with the arm's joints across this DAG. Two canonical mounting topologies govern how the extrinsic calibration is solved.

In an **eye-in-hand** configuration, the camera or depth sensor is bolted directly to the manipulator's moving tool flange ($\mathcal{F}_{\text{flange}}$). Moving any preceding joint alters the sensor's optical center relative to the world, requiring continuous forward kinematics updates. Solving for the rigid extrinsic transform $\mathbf{X} = \mathbf{T}^{\text{cam}}_{\text{flange}} \in \mathrm{SE}(3)$ requires executing robot motions across $N \geq 2$ non-parallel rotational axes while observing a stationary fiducial target, such as a ChArUco grid.[6] The running machine's wrist camera is mounted this way, which makes this the calibration its grasps depend on. Because the fiducial target stays fixed in the base frame across both poses, the composed base-to-target transform $\mathbf{T}^{\text{flange}}_{\text{base},k}\mathbf{X}\mathbf{T}^{\text{target}}_{\text{cam},k} = \mathbf{T}^{\text{flange}}_{\text{base},k+1}\mathbf{X}\mathbf{T}^{\text{target}}_{\text{cam},k+1}$ is identical at poses k and $k+1$, and left-multiplying by $(\mathbf{T}^{\text{flange}}_{\text{base},k})^{-1}$ while right-multiplying by $(\mathbf{T}^{\text{target}}_{\text{cam},k+1})^{-1}$ isolates the relative motions on opposite sides of the unknown mount so that the closed kinematic loop establishes the classic **hand-eye matrix equation**:[7]

$$\mathbf{AX} = \mathbf{XB}$$

where $\mathbf{A} = (\mathbf{T}^{\text{flange}}_{\text{base},k})^{-1}\mathbf{T}^{\text{flange}}_{\text{base},k+1} \in \mathrm{SE}(3)$ is the relative flange displacement reported by the forward kinematics chain, and $\mathbf{B} = \mathbf{T}^{\text{target}}_{\text{cam},k}(\mathbf{T}^{\text{target}}_{\text{cam},k+1})^{-1} \in \mathrm{SE}(3)$ is the relative camera displacement extracted from optical target unprojection.

In an **eye-to-hand** calibration rig, the camera overlooks the workspace from a body-mounted mast or a stationary overhead beam. When calibrating against an overhead camera, the mobile base must remain parked so that the camera-to-base transform remains constant ($\mathbf{X}' = \mathbf{T}^{\text{cam}}_{\text{base}} \in \mathrm{SE}(3)$), while the target is affixed to the robot's moving end-effector ($\mathbf{Z} = \mathbf{T}^{\text{target}}_{\text{flange}} \in \mathrm{SE}(3)$). At each joint configuration, let $\mathbf{A}' = (\mathbf{T}^{\text{flange}}_{\text{base}})^{-1}$ map base coordinates into the flange frame and $\mathbf{B}' = (\mathbf{T}^{\text{target}}_{\text{cam}})^{-1}$ map camera coordinates into the target frame. These are absolute pose transforms for this rig, rather than the relative motions used above. Both paths then map camera coordinates into the flange frame:

$$\mathbf{A}'\mathbf{X}' = \mathbf{Z}\mathbf{B}'$$

If the mobile base subsequently moves relative to the overhead camera, the runtime must update the camera-to-base transform accordingly. For a mast-mounted camera that rides with the chassis, $\mathbf{T}^{\text{cam}}_{\text{base}}$ remains fixed on the body while $\mathbf{T}^{\text{base}}_{\text{odom}}(t_{\text{capture}_0})$ carries the base motion into the world frame.

Treating the nominal rigid transform chain from CAD as an exact physical calibration ignores load and temperature effects. Physical manipulators deflect under payload mass, accumulate lost motion and torsional wind-up in the joints (strain wave gears have near-zero backlash, but their

6 **ChArUco Board**: A chessboard whose white squares carry uniquely coded ArUco markers. The chessboard corners give subpixel accuracy and the codes identify which corners are in view, so calibration works from partial views of the board, the usual case for a camera on a moving wrist.

7 **Hand-Eye Calibration**: The problem was posed as $\mathbf{AX} = \mathbf{XB}$ independently by Shiu and Ahmad (1989) and Tsai and Lenz (1989), for cameras bolted to robot wrists. The camera's pose relative to the flange is never measured directly, only inferred from paired motions, so any error in $\mathbf{X}$ enters every grasp the arm plans from that camera, and poorly spread calibration motions leave it weakly determined.

flexsplines still twist under load), and expand with temperature (structural aluminum expands at $\alpha \approx 23{\times}10^{-6}/\mathrm{K}$). For an illustrative 1 m aluminum link that warms uniformly by 10°C, the corresponding expansion is 0.23 mm. A motor temperature rise alone does not establish that link-temperature change, as localized thermal gradients across structural members and encoder mountings require direct measurement before updating calibration parameters.

Fusing joint kinematics with optical frames also requires temporal alignment across the transform DAG. Any uncalibrated timestamp skew $\Delta t_{\text{skew}} = t_{\text{cam}} - t_{\text{joint}}$ between the motor communication bus (such as EtherCAT or CANopen) and the camera exposure window evaluates the forward kinematics chain at stale joint angles $\mathbf{q}(t_{\text{joint}}) \neq \mathbf{q}(t_{\text{cam}})$, inducing spatial tracking error:

$$\Delta \mathbf{p}_{\text{skew}} = \mathbf{v}_{\text{wrist}}\, \Delta t_{\text{skew}} + (\omega_{\text{wrist}} \times \mathbf{r}_{P/O})\, \Delta t_{\text{skew}}$$

At an illustrative wrist linear velocity $v = 1$ m/s and angular velocity $\omega = 2$ rad/s with a camera lever arm $r = 0.15$ m, an unmodeled 10 ms skew displaces the observation by 10 mm plus 3 mm, or 13 mm. This error causes the arm to miss a grasp whose position tolerance is 5 mm. Holding that displacement within the tolerance gives the timing requirement $\Delta t_{\text{skew}} \leq r_{\text{tol}}/(v + \omega r)$, which evaluates to 3.8 ms. Millisecond-level alignment therefore suffices, whereas microsecond synchronization is unnecessary. Systems typically meet this requirement by timestamping both streams against a single shared clock (a fieldbus distributed clock or a PTP master) and interpolating the high-rate joint stream at the camera's exposure midpoint.

The REP 105 frame convention[8] names these frames and separates a locally continuous `odom` pose from a globally corrected `map` pose. On the mobile manipulator, $\mathcal{F}_B$ is the base's `base_link`, tracked through the odometric frame `odom`, and the arm's serial chain maps its mounting flange `tool0` through the joint angles back to `base_link`. Table 8.2 lists the frame roles and the behavioral rules each consumer follows. A local controller consumes a continuous estimate and rejects unexpected transform jumps, while runtime checks verify transform timestamps and estimator uncertainties before execution.

DRAFT

8 **ROS Enhancement Proposal (REP)**: The Robot Operating System records its community conventions as numbered REPs, a process copied from Python's enhancement proposals. REP 105 fixes the meaning of `map`, `odom`, and `base_link` and the continuity each must keep (Meeussen 2010), so a frame name written into a record denotes the same physical frame for every consumer that reads it.

Table 8.2: REP 105 frame roles for a mobile robot: A compact example of global, local, body, and sensor frames. REP 105 requires `odom`-relative pose to remain continuous but does not prescribe C^1 smoothness, a covariance growth rate, or fixed accuracy; these require estimator-specific evidence.

Frame	Parent in this example	Meaning	Consumer rule
`earth`	root	Optional geodetic datum	Verify datum before global routing
`map`	`earth` if present	Global localization; corrections may jump	Keep relocalization jumps out of local feedback
`odom`	`map`	Locally continuous pose estimate; may drift	Track motion locally; monitor uncertainty and discontinuities
`base_link`	`odom`	Body-fixed origin	Body pose still inherits odometry uncertainty
`sensor_link`	`base_link`	Calibrated sensor mounting frame	Apply time-valid extrinsics and their uncertainty

Splitting consumers across the tree keeps a relocalization jump out of the actuators (figure 8.4). Global planners absorb the discontinuous Σ_{map} corrections at relocalization, while high-rate local tracking loops consume only the continuous `odom` → `base_link` branch, so a global correction never reaches the actuators as an abrupt tracking step. Mounting uncertainty still compounds with dynamic pose uncertainty across every intermediate link. Under a first-order propagation model with independent error sources:

$$\Sigma_{\text{world}} = \mathbf{J}_{\text{map}} \Sigma_{\text{map}} \mathbf{J}_{\text{map}}^{\top} + \mathbf{J}_{\text{odom}} \Sigma_{\text{odom}} \mathbf{J}_{\text{odom}}^{\top} + \mathbf{J}_{\text{ext}} \Sigma_{\text{ext}} \mathbf{J}_{\text{ext}}^{\top}$$

where the Jacobians $\mathbf{J}$ project each frame's spatial covariance into world coordinates. When frame errors correlate, the propagation must include their cross-covariance terms. A downstream consumer requires the frame identifier, capture epoch, and compounded uncertainty envelope, rather than a transform selected merely by its latest publication timestamp.

↪ How these sensor-to-body transforms go stale as the joints and base move is developed in section 9.5.

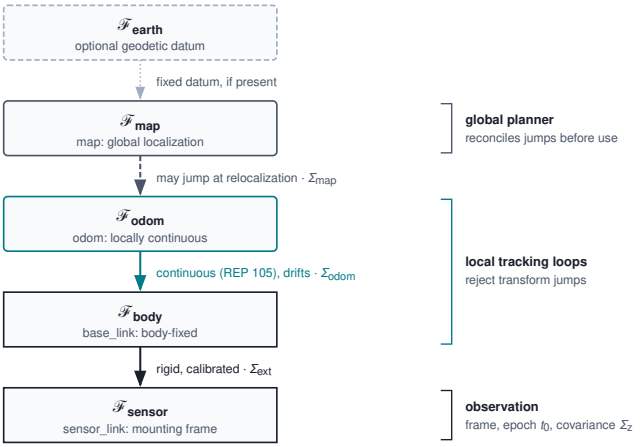


Figure 8.4: Coordinate frame tree and its consumers: Each edge states the property REP 105 or calibration gives it and the uncertainty it adds to the prose equation below. Only the odom to base_link edge is required to stay continuous; the map to odom correction may jump at relocalization, so local tracking loops consume the continuous branch while global planners reconcile the jump. A sensor observation reaches the consumers with its frame, capture epoch t_{capture_0}, and covariance Σ_z.

> **Systems Perspective 8.1: The three invariants of observation**
>
> Pass a perception claim with its capture time and clock domain, coordinate frame, and qualified uncertainty. Refuse a claim when any of those cannot be checked for the proposed motion.

8.4 Bounding Observation Age

Even when a rack-end observation is dated at capture and placed in a calibrated coordinate frame, the scene it describes belongs to the past. Delivering that measurement across an embodied runtime adds acquisition, bus transport, queueing, and neural inference delay while the robot continues to move. Any delivery deadline for perception must therefore track the full physical interval from energy integration at the detector through dispatch, bounding the observation's age before downstream actuators act.

> **Definition 8.1: Observation age**
>
> ***Observation age*** (t_{age}), also called spatial information age, is the physical time elapsed between the exposure midpoint at the transducer and the moment perception dispatches the resulting observation. It is the capture-to-dispatch part of the measurement age that section 2.2 counts from transduction. The observation keeps aging after dispatch, and the age a consumer computes on its own clock when it admits or reuses the observation is its **current evidence age**, which equals t_{age} plus the time elapsed since dispatch.
>
> 1. **Significance**: Because the robot continues moving while the compute pipeline runs, observation age converts directly into physical displacement (equation 8.5) and expands the stopping budget through the pre-brake delay τ_{delay}. On the warehouse mobile manipulator, the navigation-camera observation is already 51.6 ms old at dispatch, which is 77.4 mm of blind travel at the 1.5 m/s drive limit before any downstream consumer has inspected the frame.
> 2. **Distinction**: Conventional benchmark latency measures only the software execution time of a forward pass. In contrast, observation age spans the entire physical journey from photon arrival to dispatch: the exposure midpoint, sensor rolling readout, serialized bus transport, direct memory access (DMA) transfers, driver queueing, image signal

processor (ISP) conversions, model inference, and inter-process dispatch. Scheduling delay after dispatch belongs to the current evidence age, not to t_{age}.

3. **Common pitfall**: Systems engineers frequently confuse a frame's arrival timestamp in userspace memory (t_{recv}) with its actual physical observation time (t_{capture_0}). On the navigation camera, the arrival timestamp overlooks 26.6 ms of front-end exposure, readout, and transport. At the maximum drive limit, this unmeasured interval conceals 39.9 mm of physical travel, saddling downstream controllers with an unmodeled phase lag.

When evaluated along the machine's trajectory, observation age integrates directly into spatial displacement (equation 8.5):

$$\Delta \mathbf{p} = \int_{t_{\text{capture}_0}}^{t_{\text{capture}_0}+t_{\text{age}}} \mathbf{v}(t)\, dt \tag{8.5}$$

Travel is one of three error sources that perception must bound. Adding this motion-induced displacement to first-order stereo triangulation noise and small-angle extrinsic error gives a single error scale for the pipeline (equation 8.6):

$$\epsilon_{\text{scale}} = \underbrace{\int_{t_{\text{capture}_0}}^{t_{\text{capture}_0}+t_{\text{age}}} \|\mathbf{v}(t)\|\, dt}_{\text{path-length travel}} + \underbrace{\frac{z^2}{fb}\sigma_d}_{\text{stereo depth standard deviation}} + \underbrace{z|\theta_{\text{ext}}|}_{\text{small-angle mounting error scale}} \tag{8.6}$$

The first term integrates instantaneous speed to compute path length, providing an upper bound on net translation during the perception delay. The latency waterfall below sizes it for the navigation camera. The second term characterizes depth uncertainty for a calibrated stereo camera with baseline b, focal length f, operating range z, and disparity standard deviation σ_d. Section 8.6 derives it and evaluates it on an illustrative rig. It is a standard-deviation scale rather than an absolute bound. The third term models the lever-arm displacement produced by a small extrinsic angular misalignment θ_{ext} over target distance z, the error section 8.3 already sized at the rack end. The sum is therefore an order-of-magnitude scale, not a safety envelope. It adds magnitudes that point in different directions and leaves out calibration bias and the heavy tail of real residuals, which is why the clearance a consumer holds rests instead on a measured residual quantile (equation 8.9).

8.4.1 The latency waterfall

While the navigation camera integrates photons, clocks out pixel rows, transfers buffers across the bus, and runs neural inference kernels, the mobile base keeps moving at velocity v, turning every millisecond of pipeline delay into blind travel:

$$\Delta x_{\text{blind}} = v \cdot t_{\text{age}}$$

On the navigation camera, the observation age t_{age} accumulates stage by stage from the exposure midpoint to the moment perception publishes its processed measurement. When hardware stages execute sequentially, the total age expands as a **latency waterfall**; if adjacent stages overlap in hardware or stream through pipelined ring buffers, their combined duration replaces the naive sum of individual stage times:

$$t_{\text{age}} = \frac{t_{\text{exp}}}{2} + t_{\text{readout}} + t_{\text{transport}} + t_{\text{DMA}} + t_{\text{ISP}} + t_{\text{backbone}} + t_{\text{IPC}} \tag{8.7}$$

A complete stopping margin must also count the downstream response: expiry of the chunk lease sized in section 4.4, the control tick, fieldbus transmission, and brake onset. Summing these terms yields the partial pre-brake delay $\tau_{\text{delay}} = t_{\text{age}} + T_{\text{lease}} + T_{\text{tick}} + T_{\text{bus}} + T_{\text{act}}$, which governs the corresponding subtotal of blind travel:

$$d_{\text{blind}} = v \cdot \tau_{\text{delay}}$$

At constant operating velocity, every millisecond of unmodeled latency drains physical clearance linearly. Because the permission path runs concurrently on its own MCU, the safety calculation must reflect that dedicated architecture rather than assuming that every stalled neural forward pass postpones emergency braking. Notebook 8.2 steps through each hardware and software stage of this waterfall for the warehouse mobile manipulator, converting elapsed time into traveled distance.

Napkin Math 8.2: Travel before the frame is read

Problem: The mobile manipulator drives toward a rack end at its drive limit when a person steps out. How old is the navigation camera's observation of that person when perception dispatches it, and how far has the base traveled by then?

Variables:

- Exposure $t_{exp} = 16$ ms (Chosen low-light setting), so the midpoint lag is $t_{exp}/2 = 8$ ms; rolling readout $t_{readout} = 16.6$ ms (Datasheet).
- Residual MIPI CSI-2 transport $t_{transport} = 0.8$ ms (Illustrative). The Sony IMX477 flyer specifies a four-lane option up to 2.1 Gbps/lane; the budget assigns only the transport left after streaming readout, not frame size divided by peak lane rate.
- DMA and driver queue $t_{DMA} = 1.2$ ms, ISP debayering and rectification $t_{ISP} = 2.5$ ms, INT8 vision backbone $t_{backbone} = 22$ ms, and covariance packaging with zero-copy dispatch $t_{IPC} = 0.5$ ms (all Illustrative).
- Drive limit $v = 1.5$ m/s (Illustrative).

Math:

Age at dispatch. The serial stages of equation 8.7 sum to

$$t_{age} = 8ms + 16.6ms + 0.8ms + 1.2ms + 2.5ms + 22ms + 0.5ms = 51.6ms$$

Travel. Holding speed through the age window:

$$\Delta x = (1.5m/s) \times (0.0516s) = 0.0774m = 77.4mm$$

Sensitivity. Each further millisecond in any stage adds 1.5 mm of travel at the drive limit.

Result: The observation is 51.6 ms old at dispatch, and the base has covered 77.4 mm. The backbone is the largest single stage, but exposure and readout alone contribute 24.6 ms before any computation starts.

Systems insight: The base covers this distance before the perception record exists. Timestamped pose propagation can place the old observation correctly in the current frame, but no later stage returns the distance already traveled, so vt_{age} enters the stopping budget as a term of its own.

The seven stages of table 8.3 sum to the observation age at dispatch, $t_{age} = 51.6$ ms. Each stage value is a budgeted allocation, the most that stage may take under load, rather than a typical measurement. The sum is therefore the age the rest of the machine plans against, and the last column of the table names the measurement that must confirm it. The stopping budget then adds the active lease and response path of section 4.4:

$$\tau_{delay} = \underbrace{t_{age}}_{51.6ms} + \underbrace{T_{lease} + T_{tick} + T_{bus} + T_{act}}_{82ms} = 133.6ms$$

This is the pre-brake delay that section 1.4.3 and the event timing table of chapter 4 carried with t_{age} entered as a given; its first term is now derived rather than assumed.

This subtotal is a **partial delay budget** rather than an end-to-end capture-to-response bound. In the timing breakdown of table 4.1, perception governs the first interval from capture to dispatch, while actuator mechanics govern the third interval of physical braking. The observation continues to age across the intermediate second interval while the proposer completes inference, transmits the candidate trajectory, and awaits admission from the permission path. Let Δ_{da} denote this

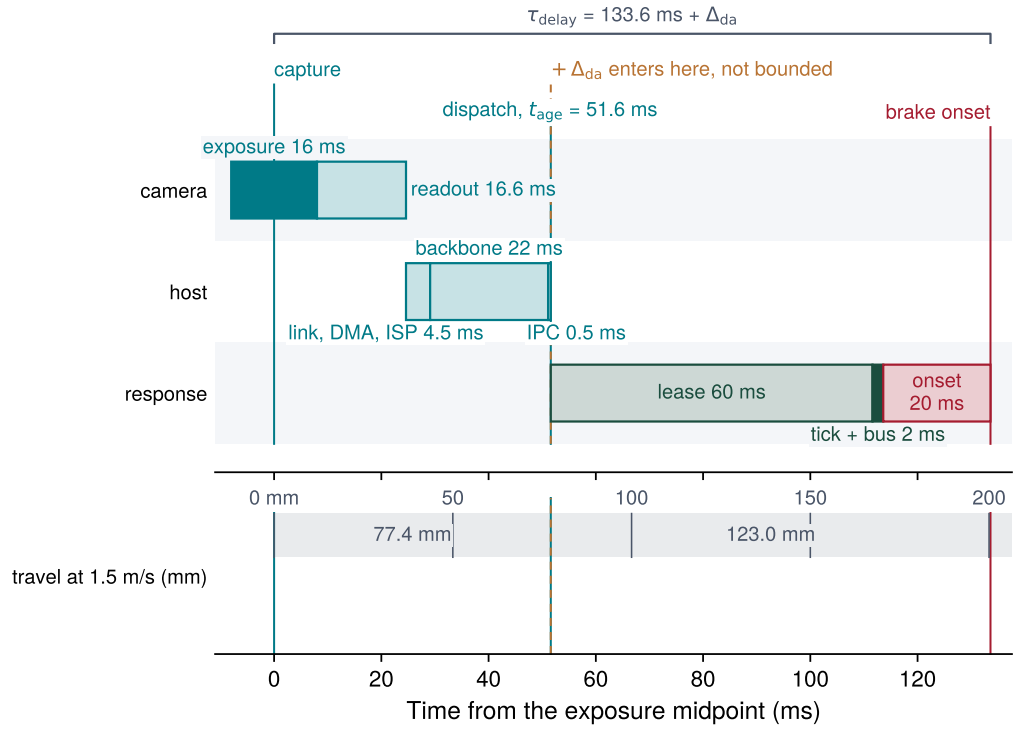

Figure 8.5: Capture-to-brake timing strip: Time runs from the exposure midpoint of the frame that first shows the hazard. The camera and host lanes carry the navigation camera's serial stages, with link, DMA, and ISP drawn as one segment, to dispatch at 51.6 ms; the response lane adds the lease, tick, bus, and actuator onset of a stalled proposer to reach 133.6 ms. The row beneath reads the same axis as base travel at the 1.5 m/s drive limit. The dashed line at dispatch marks where the dispatch-to-admission interval Δ_{da} enters; this chapter does not bound it, so every later event shifts right by its measured value.

dispatch-to-admission interval, encompassing model planning and inter-process communication overheads. Because an active lease takes effect only upon candidate admission, the total delay under a stalled-proposer fault equals the displayed subtotal plus Δ_{da}. The transport-budget calculation in section 13.6.2 allocates a budget for Δ_{da} that awaits empirical validation on hardware. That allocation includes a full inference after dispatch, and part of that inference overlaps the vision backbone already counted in t_{age}. Adding the two therefore counts the overlap twice and overstates the delay, which errs on the safe side; timestamping both intervals on the loaded machine removes the overlap.

Laid on one clock, the partial budget shows where the unbounded interval sits (figure 8.5). Everything before dispatch at 51.6 ms belongs to perception, while everything after it belongs to the response path that reaches brake onset at 133.6 ms. The dispatch-to-admission interval Δ_{da} enters at the dispatch line, so whatever value it takes on the loaded machine shifts every later event to the right.

Because the permission path validates geometric safety without reprocessing raw images, it cannot retroactively compress this perception pipeline delay; the age reaches it strictly through the proposal's stamped evidence epoch. At the 1.5 m/s drive limit, the observation-age term vt_{age} contributes 77.4 mm of blind displacement. That travel is the fifth row of the stopping budget. The first three rows are the Body's terms from equation 2.2, braking distance $v^2/2a_{brake}$, the overhead $\delta_{loc} + \delta_{margin}$, and brake-onset travel vT_{act}, written together below as d_{base}. The fourth row is the lease-path travel $d_{lease} = v(T_{lease} + T_{tick} + T_{bus})$ of section 4.4. Adding the fifth row gives

$$d_{stop} = \underbrace{d_{base} + d_{lease}}_{835.5mm} + \underbrace{v \cdot t_{age}}_{77.4mm} = 912.9mm$$

This additional term raises the partial stopping distance from 835.5 mm to 912.9 mm. Although 187.1 mm remains within the nominal 1.10 m rack-end clearance, that remainder cannot be claimed as safety buffer. It must still absorb the travel during the dispatch-to-admission interval Δ_{da}, the extra distance of a jerk-limited rather than instantaneous brake application (section 11.5.4), and the tracking inset of section 12.3. This analysis sizes the perception subsystem's contribution to the stopping budget and clarifies the empirical measurements required before an integrated motion claim can be certified; the final column of table 8.3 names that measurement stage by stage.

Table 8.3: Serial observation-age budget: The navigation camera's budgeted stage increments, assumed nonoverlapping, sum to its observation age at dispatch. A real pipeline can overlap readout, transfer, and processing, so capture-to-dispatch age requires an end-to-end measurement including queueing tails. Later consumers must add their elapsed post-dispatch interval.

Stage	Increment	Serial age after stage	What to verify
Exposure midpoint	8 ms	8 ms	Exposure and row timestamp convention
Rolling readout	16.6 ms	24.6 ms	Selected row and overlap with streaming
Residual transport	0.8 ms	25.4 ms	Selected sensor mode and host receiver
DMA and queue	1.2 ms	26.6 ms	Arbitration and queue tail
ISP	2.5 ms	29.1 ms	Mode and competing jobs
Vision backbone	22 ms	51.1 ms	Workload, clock, thermal state
Dispatch	0.5 ms	**51.6 ms**	Capture-to-dispatch age and queue tail

Checkpoint 8.1: Observation age and the stopping budget

Observation age is paid in travel before any consumer can react, and no later stage returns it.

- ☐ **Observation age**: Can you explain how the interval from the exposure midpoint to dispatch converts into travel that erodes the stopping clearance before a policy can react?
- ☐ **Exposure midpoint vs. arrival timestamp**: Can you explain why dating a frame at DMA completion rather than at its exposure midpoint pairs the observation with the wrong pose?
- ☐ **Pose propagation from capture time**: Can you explain how propagating the machine's pose forward from an observation's capture time places an old observation correctly in the current frame, and why that propagation cannot return the distance already traveled?
- ☐ **Observation age in the stopping budget**: Can you explain why the observation-age term vt_{age} adds to the stopping distance, and why the permission path, which never reads the image, cannot shorten it?
- ☐ **Dropped-frame estimate**: If a dropped frame leaves a proposal resting on the previous frame, one frame period (16.7 ms) older, how much travel does that add at the 1.5 m/s drive limit, and what share of the 187.1 mm remainder does it consume?

8.4.2 Dating the machine's LiDAR

The permission path's clearance check inspects range returns from the mobile base's Ouster OS1-64 LiDAR, whose timing structure differs from that of the optical camera. A rolling-shutter camera exposes and reads out a discrete frame grid. In contrast, a spinning mechanical LiDAR continuously fires laser diodes and timestamps each azimuth column at the firing instant, disciplined by the IEEE 1588 Precision Time Protocol (PTP). Because every point carries an individual capture epoch, the scan lacks a singular frame time. The age of the resulting rack-end spatial estimate is therefore governed by how long the software pipeline buffers returns before releasing the angular sector facing the hazard.

At the configured scan rate, one mechanical revolution requires 50 ms. At a clear distance of 1.10 m, the 1.30 m aisle subtends a forward azimuth sector of 61.2°, which the sensor sweeps in 8.5 ms. Table 8.4 compares two ingestion architectures for handling this point stream: streaming sector

packets to consumers immediately upon arrival vs. buffering the entire sweep before dispatching a complete 360° point cloud.

Table 8.4: LiDAR age at the rack end: The OS1-64's upper age before host processing under two consumption policies, at the configured scan rate. Data latency and clock accuracy are the datasheet's upper bounds; processing time must be measured on the machine under the synchronized camera and inference load.

Stage	Stream the forward sector	Wait for the full sweep	Source
Acquisition of the oldest relevant point	8.5 ms	50 ms	Scan rate and aisle geometry
Sensor data latency, upper bound	10 ms	10 ms	Datasheet
Clock-conversion bound (PTP)	1 ms	1 ms	Datasheet; measure on the machine
Upper age before processing	**19.5 ms**	**61 ms**	Computed
Travel at the drive limit	29.2 mm	91.5 mm	Computed
De-skew and occupancy extraction	Needs measured value	Needs measured value	Host measurement under camera load

Waiting for a full revolution consumes 61 ms before host computation begins, exceeding the camera's 51.6 ms acquisition/processing allocation. In contrast, streaming the forward azimuth sector immediately leaves 32.1 ms of processing headroom within that allocation for motion de-skew and occupancy extraction. This arithmetic compares pipeline allocations; different scan and frame phases, buffered reuse, and downstream waiting still determine which selected observation is older at consumption. The real-time latency budget therefore dictates the architecture. The robot streams and processes sector packets incrementally, propagating individual point timestamps rather than a single aggregated sweep time.

Two strands of evidence therefore meet at the rack end, and the oldest required capture sets the shared age charge. The proposal is anchored to the camera's frame epoch, while the admission check rests on LiDAR range. The permission path must date both on its own clock at the same admission or tick, including bounded clock uncertainty. Streaming fits the illustrated camera-sized acquisition/processing allocation only when de-skew, occupancy extraction, and any phase, reuse, or waiting allowance required by the selected consumption policy fit the 32.1 ms headroom. Sharing the camera's row-five charge further requires that the actual LiDAR capture be no older than the camera capture supporting the proposal at that common check. Otherwise the budget must charge the older required evidence, with each elapsed interval counted once. The dispatch-to-admission interval remains a separate downstream charge. Neither strand includes the internal latency of the certified safety scanner, because its worst-case response time is a factory-certified parameter accounted for separately in the scanner's own timing budget described in section 12.3.1.

Per-column timestamps also enable continuous motion de-skew. Over a single LiDAR revolution at full speed, the mobile base translates 75 mm, and the state estimator eliminates this distortion by interpolating robot odometry at each return's precise firing timestamp (section 8.2). While the optical camera avoids rotational sweeping delays, its serial latency budget has no spare stage to absorb arbitrary queueing, because row five charges exactly the budgeted age. In particular, collecting consecutive frames into multi-frame batches introduces substantial latency penalties before host memory contention is even considered.

8.4.3 Temporal batching

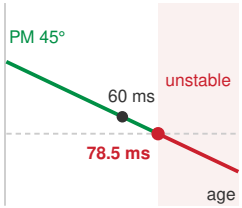
At the navigation camera's 60 Hz sampling rate ($T_{\text{sample}} \approx 16.7$ ms), forming a batch of four consecutive frames to amortize kernel launch overhead or raise systolic-array utilization requires holding the first frame for 50 ms, the second for 33.3 ms, and the third for 16.7 ms, while only the fourth enters immediately. Accumulating frames across successive capture times ages the earliest samples: appending that 50 ms queueing delay to the baseline 51.6 ms observation age roughly doubles total age to 101.6 ms. Because row five of the stopping budget charges only the single-frame age, the observation contract at the end of this chapter sets its dispatch threshold at that age plus a sub-millisecond clock bound (section 8.8). The batched frame is therefore refused before candidate

admission begins. When multi-camera systems synchronize exposure pulses in hardware, grouping frames from distinct sensors across spatial dimensions can improve throughput safely; however, temporal batching across successive timestamps directly erodes closed-loop timeliness.

8.4.4 Observation age and feedback stability

Beyond draining physical stopping distance, observation age also spends the phase margin of any feedback loop closed through perception, the extra lag that loop can absorb before its corrections reinforce the motion they were meant to damp. Section 4.3.1 establishes that a pure delay removes phase in proportion to frequency without changing loop gain. A loop with nominal phase margin $\mathrm{PM}_{\mathrm{nom}}$ at gain crossover frequency ω_c therefore has no margin left once $t_{\mathrm{age}} \geq \mathrm{PM}_{\mathrm{nom}}/\omega_c$. Perception draws on that same account. A visual-servoing tracking loop crosses over at 10 rad/s (approximately 1.6 Hz) with a nominal phase margin of 45° (0.785 rad). With no other delay charged, its nominal zero-margin ceiling for this perception contribution is $t_{\mathrm{age,max}} = \mathrm{PM}_{\mathrm{nom}}/\omega_c = 78.5$ ms. If sensor exposure, transport, and neural inference consume 60 ms, the perception pipeline spends 76.4 percent of the loop's stability allowance before motor commands are even computed. Whether the integrated loop remains adequately damped requires qualification of its complete dynamics and delays.

The perception contribution to both checks spends the same elapsed duration in different currencies. Phase lag erodes closed-loop stability, while displacement consumes forward clearance ($\Delta x_{\mathrm{blind}} = v \cdot t_{\mathrm{age}}$), so each consequence is checked on its own terms and the latency is never counted twice in the stopping budget. Rigorous capture timestamps, qualified reference frames, and explicit error bounds make these physical consequences observable throughout the software stack. Even when zero-copy DMA architectures eliminate intermediate buffer copies during host ingestion, memory controller arbitration and bus contention continue to introduce subtle waiting times.



Delay spends phase margin linearly; at 78.5 ms none remains.

8.5 Ingestion Overhead and Memory Bus Contention

A common architectural pitfall in early physical AI prototypes is connecting multiple high-resolution cameras through standard USB or Ethernet ports and ingesting frames using naive user-space libraries, such as OpenCV's `VideoCapture` or default ROS image transport nodes. In this unoptimized baseline, every incoming frame is copied from kernel USB request blocks into a driver ring buffer, copied a second time into user-space process memory, and copied a third time across the PCIe bus into GPU memory. For four 1080p cameras streaming 24-bit color at 60 Hz, each copy stage moves 1.5 GB/s, meaning the pipeline churns through about 4.5 GB/s of continuous memory copies. This overhead generates substantial memory traffic and CPU copying work, though the exact utilization depends on host core capabilities, memory architecture, and pixel format. That data rate alone does not establish CPU saturation or accelerator starvation, but it wastes memory bus bandwidth and cache capacity that concurrent real-time inference urgently requires.

Real-time physical systems avoid this collapse by treating pixel ingestion as a zero-copy DMA hardware pipeline. Raw pixel streams arriving over dedicated camera buses bypass CPU copying entirely, writing frames directly into shared physical DRAM before any software thread touches the data. On a shared application processor, however, these camera writes still contend for memory service before inference can read them, and unmanaged bursts can delay host reads or overrun a receiver FIFO and drop a frame.

8.5.1 MIPI CSI-2 DMA ingress and zero-copy buffers

Once analog-to-digital converters on the sensor die digitize the accumulated pixel charges, the frame must cross a physical link into host memory without stalling the CPU on byte-by-byte copies or dropping scanlines when a receiver buffer fills. Camera streams enter the application processor over the MIPI CSI-2 bus.[9] Across that link, dedicated receiver logic and scatter-gather DMA engines move serialized pixel packets from the physical lanes into kernel ring buffers in four stages.

[9] **MIPI CSI-2 (Mobile Industry Processor Interface, Camera Serial Interface 2)**: The MIPI Alliance's point-to-point camera link streams serialized pixels from the sensor straight to an application processor's receiver and DMA controller, over differential D-PHY lanes or three-wire C-PHY trios, with no network stack between them. That directness is why the camera's transport term in table 8.3 is set by sensor mode and lane rate rather than by protocol processing.

Systems Perspective 8.2: Silicon ingestion dataflow architecture

1. **D-PHY / C-PHY physical layer**: Physical lanes serialize pixel packets at the selected sensor and receiver's supported rate; packet headers carry error checks.
2. **System-on-chip (SoC) CSI-2 host controller**: Deserializes byte packets, strips headers, and validates CRC integrity.
3. **Scatter-gather DMA controller**: A dedicated DMA engine transfers pixel byte words directly into DRAM over the internal system interconnect (for example, an AXI crossbar).
4. **Kernel DMA ring buffers**: A Linux `v4l2` driver can map capture buffers into user space.

Once DMA write completion occurs, the kernel capture driver (V4L2, the Linux video-capture interface) issues an interrupt. To eliminate user-space copies, modern embedded Linux systems export DMA buffers directly through the Linux `dma_buf` subsystem. Compared with a staged three-copy variant (Kernel DMA buffer → User-space buffer → Pinned host memory → GPU VRAM), `dma_buf` allows the hardware Image Signal Processor (ISP), CPU, and GPU to import and share identical physical DRAM pages through system IOMMU[10] page tables. A zero-copy buffer handoff eliminates bulk CPU copying, but DMA arbitration, synchronization, queueing, and consumer scheduling still contribute to ingestion latency. Format conversion, layout changes, or device alignment constraints can still require a targeted transform, but the bulk pixel payload never traverses the CPU cache hierarchy. On a platform without hardware I/O cache coherency, the buffer handoff must explicitly synchronize ownership for the intended consumer. CPU access requires the platform's DMA-to-CPU cache maintenance primitives; accelerator access requires corresponding device mapping, completion ordering, and device-side cache invalidation. Flushing or invalidating the CPU cache alone does not guarantee that an independent neural accelerator will read current pixel values. These synchronization and cache maintenance operations belong directly in the measured ingestion budget.

[10] **IOMMU (Input-Output Memory Management Unit)**: The device-side counterpart of the CPU's MMU. It translates the addresses a DMA engine issues through page tables the kernel controls, so the ISP, CPU, and GPU can share one set of physical pages without copying while each device stays confined to its own mappings. A translation miss on that path is one more source of ingestion delay that the measured budget must include.

The copy path in figure 8.6 uses pinned host staging rather than the USB driver ring in the earlier baseline. The shared path separates physical storage from device mappings and marks the release that permits the capture engine to reuse that storage.

A frame identifier therefore cannot establish that all consumers read the same physical pages. A conversion preserves the observation's identity while changing its representation, and the capture driver must track the lifetime of the source pages independently of the converted output.

Interface selection balances cable reach and mechanical routing flexibility against transport, queueing, and copying overhead. MIPI CSI-2 supports direct sensor ingress to the SoC. Serializer/deserializer links extend that path across the machine over multi-meter automotive wiring. USB introduces a host protocol stack and driver buffering whose timing penalty must be measured empirically. The stage breakdown in table 8.3 locates those costs for the selected MIPI path. Any alternative interface requires its own measured stage budget, because an interface specification alone does not determine end-to-end latency. Sensor operating modes, inference workloads, and host memory contention must all mirror the intended deployment conditions.

8.5.2 Memory bus contention and observation age

Even when camera frames sit comfortably within peak DRAM bandwidth when averaged over a one-second window, synchronized camera DMA bursts can still stall neural accelerator reads for milliseconds and inflate the tail of observation age. The raw bandwidth requirements of the mobile manipulator's navigation and wrist cameras are sized in section 5.6.2. When the perception stack reads those frames, transforms intermediate buffers, and the accelerator fetches model weights and writes activations, the memory controller carries several times that ingress rate, yet average utilization hides the microbursts that stretch individual read transactions. On edge robotics SoCs such as the NVIDIA Jetson AGX Orin, the CPU cluster, deep learning accelerator (DLA), GPU, and CSI-2 DMA engines share a single physical DRAM bus in a Unified Memory Architecture (UMA). Synchronized cameras concentrate their DMA writes into sharp microbursts, saturating memory channels and triggering widespread DRAM bank conflicts. When multiple cameras dump

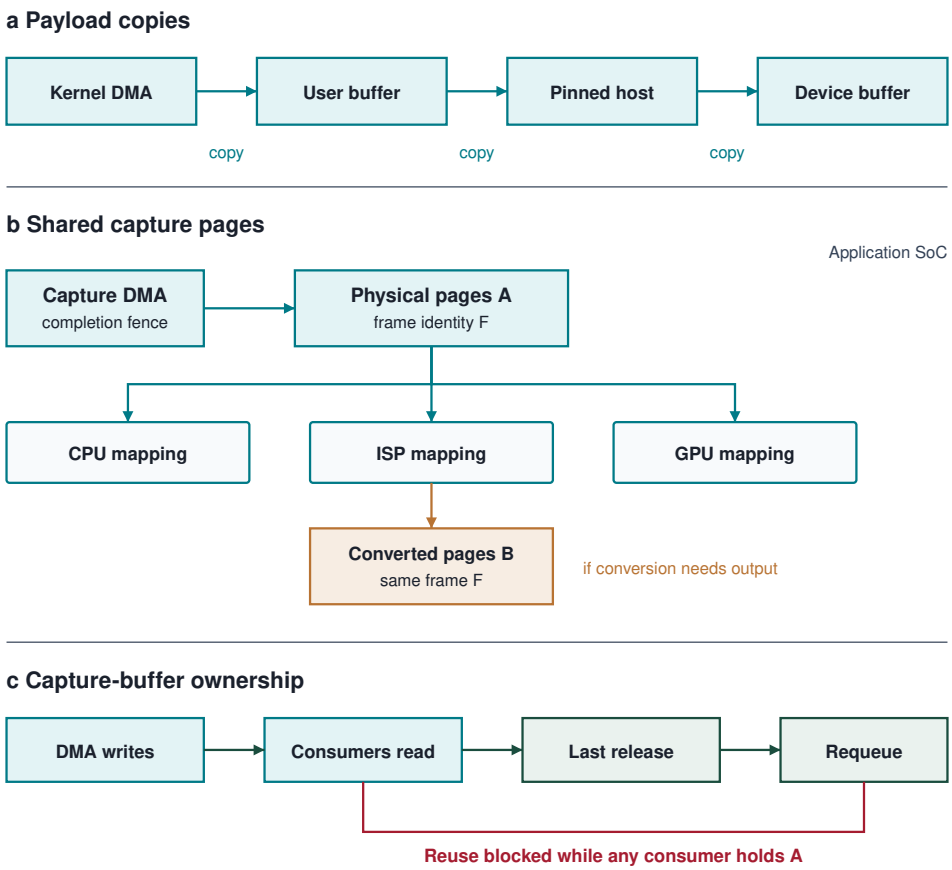


Figure 8.6: Shared Capture Buffers and Safe Reuse: The copy path allocates successive payload buffers. The shared path gives several devices mappings to capture pages A; an ISP conversion may instead write output pages B while preserving frame identity F. Capture pages become reusable only after DMA completion, the required ordering and cache maintenance, and release by their last consumer. The ownership strip shows a lifecycle, not measured durations or simultaneous device execution.

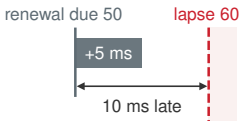
uncached raster lines across the system crossbar simultaneously, they repeatedly open and close DRAM page buffers across active banks. If the neural accelerator attempts to stream transformer model weights and intermediate activation tensors during this exact window, memory controller arbitration stalls accelerator read requests behind high-priority sensor DMA streams. These memory read stalls introduce pipeline bubbles into hardware tensor cores, stretching neural inference latency and inflating its tail (p99 jitter). The magnitude of this latency stretch depends on the platform, its interconnect arbitration policy, and the concurrent camera load. Rather than assuming nominal inference latency, engineers must measure tail stretch directly on physical hardware under the synchronized camera workload; the safety lease below constrains the loaded end-to-end renewal interval.

On the mobile manipulator, this burst lands only on the application processor. Because the permission path executes on its own microcontroller and reads its state from isolated SRAM, a memory burst cannot stretch its safety tick; rejecting a shared-die placement removed that hazard. Contention on the application processor reaches the permission path only through two observable timing channels: the age of the frame used to construct an action proposal, and the lateness of the renewal message sent by the chunk policy. These two paths have fundamentally different timing allowances. A frame that waits behind camera and accelerator traffic reaches dispatch older than

↪ Contention for the shared memory system, and how it would stall the permission tick on a shared-die placement, are developed in section 13.3.

the budgeted stages. The observation contract of section 8.8 sets the dispatch threshold at exactly the budgeted age, because a frame any older would spend travel that row five does not charge. The permission path therefore refuses every proposal built on that delayed frame.

A chunk policy whose inference stalls behind that same memory traffic renews the execution lease late. Under the coupled budget rule of section 4.9.1, the lease reserves 5 ms of renewal jitter above the 50 ms chunk period. The ratio to the chunk policy's 40 ms inference is 12.5 percent, a conditional sensitivity when incremental inference delay reaches admission one-for-one. The actual allowance constrains inter-admission jitter, so the inference stretch it tolerates depends on the renewal schedule and the scheduling, transmission, validation, and mailbox delays sharing that allowance. Qualification must measure the loaded end-to-end inter-admission interval. A renewal that arrives 10 ms late causes the lease to lapse, triggering a deterministic stop. When physical isolation, frame-age validation, and feasible fallback maneuvers remain intact, excess contention compromises availability rather than safety, because the permission path refuses any action delayed beyond the qualified budget. That guarantee holds only so long as those architectural premises and uncorrupted local sensor evidence remain intact.



A renewal may run 5 ms late; at 10 ms late the lease lapses.

The duration of a bus-saturating burst also threatens the camera interface itself. Ingest engines rely on direct memory access ring buffers with double or triple buffering to decouple hardware arrival interrupts from consumer reading threads. If host memory bus contention delays DMA completion beyond what the CSI-2 receiver hardware FIFO can buffer, the receiver suffers an overrun and silently drops the frame. A dropped frame immediately doubles the effective observation interval between samples. Downstream state estimators must treat the missing update as an age or sequence fault rather than assuming that fresh scene geometry will arrive on schedule.

The underlying microarchitectural mechanisms governing frame delivery (DMA rings, IOMMU mappings, and memory controller arbitration) are treated systematically by Hennessy and Patterson (2019) and Bryant and O'Hallaron (2015). For physical AI systems, the main design metric is capture-to-consumer age and its tail distribution under the intended camera workload. Delivering an on-time frame establishes only when the physical scene was sampled, however. Determining where objects reside within that frame, and bounding the uncertainty of that spatial estimate, introduces geometric and calibration errors that consume the remainder of the safety clearance envelope.

8.6 Spatial Error and Clearance Bounds

If perception places a warehouse rack upright just a few centimeters farther from the base's trajectory than it actually stands, the motion planner consumes those missing centimeters directly from its 0.15 m side clearance, although no stage of the pipeline decided to spend them. Once downstream control logic uses an estimated coordinate to authorize motion, every spatial error becomes a physical displacement drawn from the clearance that protects the robot from collision. Transforming a raw sensor observation into a trustworthy clearance claim requires **metric grounding**, which maps detector measurements into Euclidean space. This grounding relies on unprojecting two-dimensional sensor measurements into three dimensions, an inverse problem that assumes calibrated optics, rigid structural mountings, and predictable surface properties.

Classical projective geometry and triangulation (Hartley and Zisserman 2003; Szeliski 2022) govern how measurement noise converts into three-dimensional spatial displacement. In two-view streaming perception, two calibrated cameras with optical centers $\mathbf{o}_1, \mathbf{o}_2$ observe a physical scene point $\mathbf{p} \in \mathbb{R}^3$. The baseline vector $\mathbf{t} \in \mathbb{R}^3$ connecting $\mathbf{o}_1$ and $\mathbf{o}_2$, together with the target point $\mathbf{p}$, defines the **epipolar plane**. The intersection of this baseline with each image plane defines the two **epipoles** $\mathbf{e}_1, \mathbf{e}_2$.

For corresponding image coordinates $\tilde{\mathbf{m}}_1, \tilde{\mathbf{m}}_2$ expressed in homogeneous pixel coordinates, the rigid spatial transformation $(\mathbf{R}, \mathbf{t}) \in \mathrm{SE}(3)$ relating the camera frames establishes the fundamental **epipolar constraint**:

$$\tilde{\mathbf{m}}_2^\top \mathbf{F} \tilde{\mathbf{m}}_1 = 0$$

where $\mathbf{F} = \mathbf{K}_2^{-\top} \mathbf{E} \mathbf{K}_1^{-1} \in \mathbb{R}^{3\times3}$ is the **Fundamental matrix**, and $\mathbf{E} = [\mathbf{t}]_\times \mathbf{R} \in \mathbb{R}^{3\times3}$ is the **Essential matrix** (with $[\mathbf{t}]_\times$ denoting the skew-symmetric matrix of baseline translation). Geometrically, because the two unprojected bearing rays $\mathbf{K}_1^{-1}\tilde{\mathbf{m}}_1$ and $\mathbf{K}_2^{-1}\tilde{\mathbf{m}}_2$ meet at the same physical point, both rays and the baseline vector $\mathbf{t}$ lie in the epipolar plane, so expressing the first ray in the second camera's frame via $\mathbf{R}$ and taking its cross product with $\mathbf{t}$ (written as multiplication by $[\mathbf{t}]_\times$) produces the plane normal

that must be orthogonal to the second ray. The vector $\mathbf{l}_2 = \mathbf{F}\tilde{\mathbf{m}}_1$ defines the **epipolar line** in the second image; any valid physical correspondence $\tilde{\mathbf{m}}_2$ must lie strictly along $\mathbf{l}_2$.

In a calibrated **rectified stereo rig**, both images are digitally warped onto a shared virtual image plane parallel to the baseline ($\mathbf{R} = \mathbf{I}$, $\mathbf{t} = [b, 0, 0]^\top$). Rectification forces epipolar lines to be exactly parallel and collinear with horizontal pixel scanlines ($v_1 = v_2$). This geometric transformation collapses an expensive two-dimensional correspondence search, the kind dense optical-flow networks perform, into a one-dimensional search along the same horizontal scanline. Neural stereo networks such as RAFT-Stereo evaluate this correspondence as a 1D correlation cost volume (Lipson et al. 2021). Disparity is then the horizontal coordinate difference $d = u_1 - u_2$, recovering metric depth through $Z_c = \frac{fb}{d}$.

When mechanical vibration, chassis twist, or thermal expansion induces uncalibrated relative pitch or roll between cameras, or when rolling-shutter readout shears scanlines during sharp platform turns, the true physical correspondence shifts vertically off the horizontal epipolar line ($\Delta v \neq 0$). The 1D correlation cost volume fails or latches onto spurious texture matches across adjacent rows, injecting severe triangulation outliers into the reconstruction. Differentiating the unprojection $Z_c = \frac{fb}{d}$ with respect to disparity yields a negative signed derivative whose magnitude defines the small-error relation (equation 8.8):

$$|\delta Z_c| \approx \frac{Z_c^2}{fb}|\delta d| \tag{8.8}$$

where δd represents disparity error. If δd denotes a disparity standard deviation σ_d, first-order error propagation gives $\sigma_z \approx \frac{Z_c^2}{fb}\sigma_d$. Doubling range quadruples this modeled standard deviation at fixed focal length f, baseline b, and disparity precision σ_d. For distant landmarks, an estimator instead parameterizes depth as inverse depth[11] $\rho = 1/Z_c = d/(fb)$. Differentiating inverse depth with respect to disparity yields:

$$\frac{\partial \rho}{\partial d} = \frac{1}{fb} = \text{constant}$$

Because this derivative is independent of distance, measurement errors in disparity map linearly into inverse depth ($\delta\rho = \frac{1}{fb}\delta d$). This linear mapping provides **inverse-depth metric grounding**, preserving numerical conditioning for distant landmarks when the disparity-error model is appropriate. Inverse depth does not eliminate mismatch outliers or guarantee estimator stability. In contrast, a pulsed time-of-flight sensor estimates range directly from transit time, $R = \frac{c\Delta t}{2}$; its range error depends on its timing and detection electronics, remaining approximately flat across its rated operating region.

On the running machine, the rack-end range comes from the OS1-64 LiDAR, whose datasheet quotes one-standard-deviation precision of 5 mm to 30 mm beyond 1 m in the 1024×10 Hz mode. Applying that scale to the selected scan mode requires bias and residual-tail qualification under the intended surfaces and motion. A design that tried to range with cameras alone would have to triangulate, because the navigation camera by itself recovers only the bearing ray of equation 8.3. An illustrative stereo pair shows where such a design meets a range wall, by asking how far down the aisle its depth error stays inside the stopping budget's allowances. Notebook 8.3 evaluates equation 8.8 on that rig, and figure 8.7 plots the curve.

11 | **Inverse-Depth Parametrization**: Civera et al. (2008) introduced it for monocular SLAM, where a newly seen landmark may lie arbitrarily far away. Storing $\rho = 1/Z_c$ lets a point at infinity enter the estimate as $\rho = 0$ with finite variance, where a depth coordinate would need an infinite one, so near and distant landmarks share one well-conditioned representation. The full parameterization is given in section A.3.

Napkin Math 8.3: The stereo range wall

Problem: An illustrative stereo pair must place a rack upright for the base's clearance checks. How large is its one-standard-deviation depth scale at the rack end, and at what range does that scale alone consume the localization allowance and then the whole side clearance?

Variables:

- Baseline $b = 0.20$ m, focal length $f = 800$ px, and disparity standard deviation $\sigma_d = 0.5$ px over the tested range (Illustrative rig; the running machine carries no depth camera).
- Rack-end range $Z_c = 1.10$ m (Illustrative).

- Allowances C: localization $\delta_{\text{loc}} = 50$ mm and side clearance 0.15 m (Illustrative; section C.14.1).

Math:
Depth scale. At the rack end, and between the figure's two quoted ranges,

$$\sigma_z = \frac{z^2 \sigma_d}{fb} = \frac{(1.10\ \text{m})^2 \times 0.5\ \text{px}}{800\ \text{px} \times 0.20\ \text{m}} = 3.8\ \text{mm}, \quad \frac{\sigma_z(10\ \text{m})}{\sigma_z(2\ \text{m})} = \frac{312.5}{12.5} = 25$$

Crossover ranges. Setting σ_z equal to an allowance C and solving for range,

$$z^* = \sqrt{\frac{C\, fb}{\sigma_d}} : \quad \sqrt{\frac{0.05\ \text{m} \times 160\ \text{px} \cdot \text{m}}{0.5\ \text{px}}} = 4\ \text{m}, \quad \sqrt{\frac{0.15\ \text{m} \times 160\ \text{px} \cdot \text{m}}{0.5\ \text{px}}} = 6.9\ \text{m}$$

Sensitivity. Five times the range costs twenty-five times the depth scale, so the crossovers move only with the square root of fb/σ_d.

Result: At the rack end, one standard deviation is 3.8 mm. It equals δ_{loc} at 4 m and the whole side clearance at 6.9 m.

Systems insight: Stereo depth error is a range budget. This rig's nominal depth scale fits the rack-end allowance, but supporting that decision still requires the tail, bias, and timing qualification developed below. A claim about an obstacle several meters down the aisle spends the stopping budget's δ_{loc} on one standard deviation alone. Beyond a few meters, the clearance claim must therefore come from a range sensor whose error does not grow with Z_c^2, or the speed must fall.

The values in Notebook 8.3 are nominal **one-standard-deviation scales**, not clearance insets or certified 99th-percentile bounds. A usable safety inset requires an empirical tail quantile of the *full spatial residual*, calibrated on the intended sensor across realistic range, surface texture, platform motion, and ambient lighting conditions, with systematic bias and missed detections handled separately. A pervasive trap in visual estimation is assuming that measurement errors follow a nominal Gaussian distribution where a 3σ gate bounds 99.7 percent of all errors. In physical vision, disparity estimation relies on matching pixel appearance across views. When scenes contain repetitive textures (such as corrugated warehouse siding), specular reflections from polished concrete floors, or partial occlusions along object silhouettes, correspondence matching produces catastrophic multimodal outliers rather than Gaussian scatter. A fraction of stereo returns are then gross mismatch outliers lying many standard deviations from the true surface. Because that outlier fraction depends on scene texture, lighting, and the matching architecture, it must be measured directly on residuals from operational deployments rather than assumed. Relying on Gaussian 3σ bounds without robust loss formulations (such as Huber or Tukey loss) or heavy-tailed empirical quantile validation allows these gross outliers to distort the state estimate, directly compromising physical clearance. When validated range-error bounds exceed stopping margins, the vehicle must reduce speed or refuse the motion proposal entirely. Even when optical depth error is bounded in the camera's own frame, however, the obstacle's position must still be mapped across the robot's physical joints and mounts into the frame of the moving body.

8.6.1 Clearance insets and transform chain error

Before an estimated point can govern motion, it must propagate through kinematic coordinate transformations into the robot base frame and end effector. The mechanics of rigid body transformations and SE(3) kinematic frame composition follow classical treatments by Craig (Craig 2005) and Lynch and Park (2017). Each link in this transform chain contributes scale errors, mounting calibration drift, joint encoder quantization, and mechanical compliance under load. As demonstrated by the reference-frame principles of section 8.3, angular misalignment at the sensor mount amplifies linearly with range. If the navigation camera's mount shifts by $\theta_{\text{ext}} = 0.005$ rad against the chassis, the lateral error $\delta x \approx Z_c \theta_{\text{ext}}$ at $Z_c = 10$ m reaches 50 mm. The shift is lateral, so on the approach to

the rack end it is charged against the side clearance, as the readout notebook charged lateral skew. Its size is the point, because it is as large as the entire 50 mm allowance δ_{loc} that the stopping budget holds for localization along the direction of travel.

The comparison therefore concerns error scale rather than which allowance pays. The localization allowance carries small, validated residuals, such as the sub-millimeter travel during the clock-conversion bound that the observation contract absorbs (section 8.8). An extrinsic shift that consumes that entire budget represents a mechanical calibration failure; downstream consumers must detect and refuse such observations via calibration validity checks rather than absorb them. When combined with quadratic stereo depth dispersion, the total spatial error vector $\epsilon_{\text{spatial}}$ at standoff range is anisotropic, dominated by longitudinal depth along the optical axis and angular lever-arm effects orthogonal to it.

Every physical safety barrier operates by defending a geometric boundary around the machine envelope. For a spatial position error vector $\epsilon_{\text{spatial}}$, the triangle inequality gives a conservative relation between nominal and true clearance:

↪ How the localization allowance enters the base's kinetic barrier certificate is developed in section 12.5.1.

$$C_{\text{true}} \geq C_{\text{nominal}} - \|\epsilon_{\text{spatial}}\|$$

To ensure the true obstacle remains beyond the required safe physical clearance C_{safe} (such as the base's side clearance), the permission path enforces a clearance inset C_{inset} (equation 8.9):

$$C_{\text{inset}} = C_{\text{safe}} + \|\epsilon_{\text{spatial}}\|_{\text{p99}} \tag{8.9}$$

Here $\|\epsilon_{\text{spatial}}\|_{\text{p99}}$ is an empirically certified 99th-percentile quantile of the full spatial residual norm, incorporating optical noise, kinematic propagation, and uncalibrated mounting bias. The tempting shortcut replaces that quantile with one standard deviation from the stereo notebook. For a required clearance of $C_{\text{safe}} = 150$ mm, it would hold an inset of 162.5 mm at 2 m or 462.5 mm at 10 m. Neither number covers the Gaussian tail beyond one standard deviation or the mismatch outliers described earlier. The measured quantile targets 99 percent coverage under the declared calibration assumptions; it does not provide a hard bound on the remaining residual tail. Closing that residual tail requires a justified hard bound on the sensing error, a feasible stopping trajectory, and a safety filter that responds within the remaining latency margin.

Definition 8.2: Clearance inset

Clearance inset (C_{inset}) is the separation a consumer holds between an estimated obstacle position and the machine's envelope so that the true obstacle stays at least the required physical clearance away, except with a stated tail probability measured under the conditions of use.

1. **Significance**: The inset converts measured spatial error into clearance that the motion gives up (equation 8.9). Every millimeter of qualified error widens the region the permission path treats as occupied, so the planner must slow or route farther away. On the illustrative stereo rig, one standard deviation of depth error alone equals the base's 0.15 m side clearance at 6.9 m, so there the inset would double the clearance even if the residual tail were no wider than one standard deviation.
2. **Distinction**: A covariance describes the second moments of the error an estimator believes it has; the inset rests on residuals measured against ground truth, so it includes the bias and heavy tail that the covariance omits. A 99th-percentile inset is also not a hard bound. It leaves 1 percent of residuals outside, whose containment requires a justified sensing-error bound, a feasible response under that bound, and a timely independent permission path. A stop calculated from the same unsupported observation does not independently cover its residual tail.
3. **Common pitfall**: A frequent misconception is that a reported covariance, or a depth network's predicted spread, sets the inset. Neither is measured against ground truth, so neither contains the calibration bias and mismatch outliers that the residual campaign of section 8.6.2 captures.

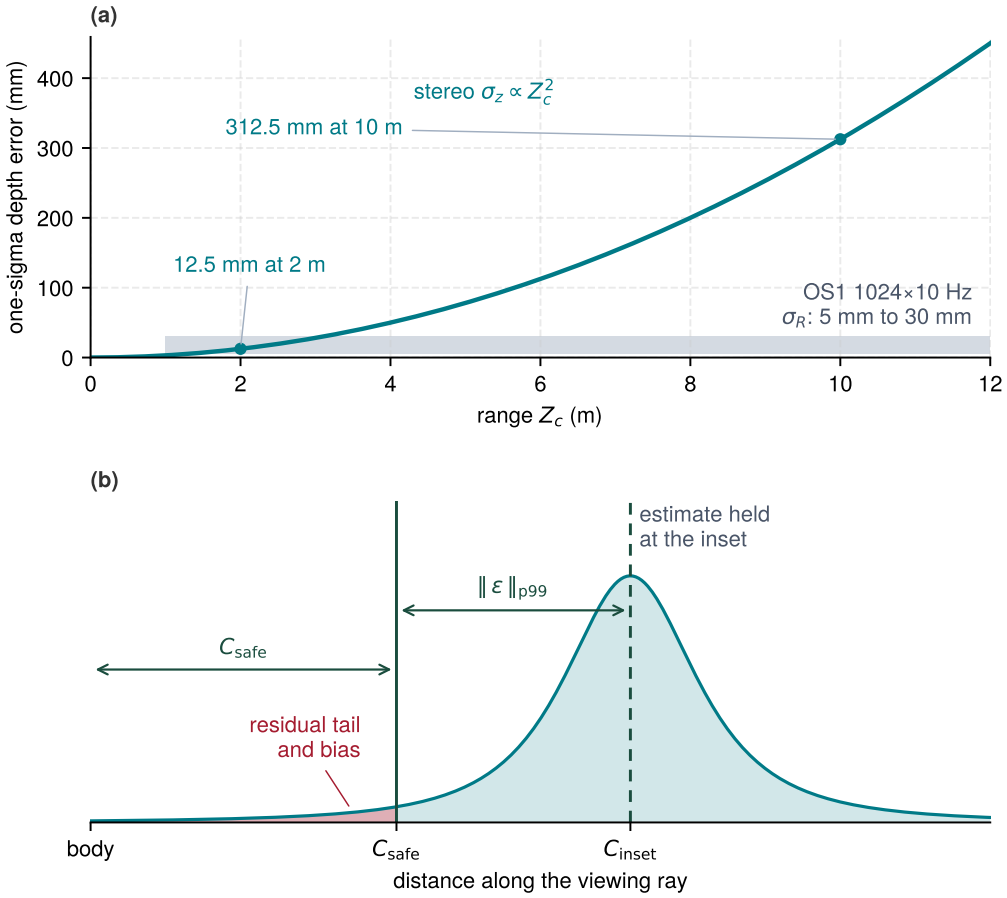


Figure 8.7: Depth error scale and clearance inset: (a) For the illustrative stereo rig, the one-standard-deviation depth scale grows with squared range, from 12.5 mm at 2 m to 312.5 mm at 10 m; the gray band is the OS1-64 datasheet range precision beyond 1 m in the specified 1024×10 Hz mode. Its transfer to the selected operating mode requires residual qualification. (b) A schematic error distribution along the viewing ray. Holding the estimate at $C_{\text{inset}} = C_{\text{safe}} + |\epsilon_{\text{spatial}}|_{\text{p99}}$ keeps the true surface beyond C_{safe} except in the shaded residual tail, which the quantile leaves and which bias can enlarge.

The two halves of the argument sit side by side in figure 8.7. In the upper panel, the stereo depth scale climbs quadratically past the LiDAR's flat datasheet precision for the specified 1024×10 Hz mode. In the lower panel, the inset holds the estimate far enough out that only the measured residual tail, which unmodeled bias can enlarge, falls inside C_{safe}.

Because clearance depends on propagated spatial error, downstream motion planners and safety arbitration layers cannot consume raw coordinate tuples. A covariance matrix $\Sigma_{\text{body}} \in \mathbb{R}^{3\times3}$ alone cannot determine whether a 10 mm or 500 mm clearance inset is justified; establishing that buffer requires an independently validated tail quantile or hard bound. When spatial error is qualified, the permission path can expand the clearance inset, trading speed or workspace for separation. Downstream deterministic safety filters, the per-tick checks that keep the machine inside a region from which it can still stop, hold it outside this expanded boundary C_{inset} and so preserve the clearance buffer against sensing and calibration error. Environmental hazards such as a textureless wall, solar glare, or lost calibration can invalidate that qualification without making a numerical covariance matrix literally infinite. The permission path must then refuse motion proposals that depend on the affected claim and select a feasible fallback.

↪ Safety filters, and the control barrier functions that formalize them, are developed in section 12.5.

On every frame, the producer builds a spatial claim in a fixed order, where any failed check halts the pipeline. It first converts the capture timestamp to the consumer's clock with a bounded

synchronization error and computes the observation age t_{age} at dispatch. If age plus clock uncertainty exceeds the dispatch threshold, it marks the observation stale, and proposals that need it are refused. At admission and across subsequent ticks, the permission path computes the current evidence age relative to capture time and compares it with a separate, later runtime staleness threshold (section 8.8). For a fresh observation, the producer unprojects each pixel measurement into optical coordinates with a sensor covariance.[12] It then carries point and covariance into the body frame by first-order SE(3) error propagation through the calibrated extrinsics at capture. A consumer that predicts forward must attach its motion-model uncertainty without altering the evidence epoch. Validated residuals, including bias, then set the inset radius C_{inset}, and when no valid bound remains, the affected motion is refused. What leaves perception is an error-qualified claim $(\mathbf{p}_{\text{body}}, \Sigma_{\text{body}}, C_{\text{inset}}, t_{\text{age}})$, never a bare coordinate.

That claim describes one measurement at one instant, and perception's responsibility ends with it. Keeping the rack-end range current between sweeps, fusing the LiDAR with a second sensor, joining detections into tracks, and applying a late measurement at its capture epoch are estimation over time. Chapter 9 takes them up, beginning with state estimation in section 9.2, and every one of them consumes the dated, framed, error-qualified claim built here. What perception must still supply is evidence that the claimed error was measured.

[12] **Covariance Propagation**: First-order propagation maps measurement covariance to $\Sigma_c = \mathbf{J}_{\text{unproj}} \Sigma_{\text{meas}} \mathbf{J}_{\text{unproj}}^\top$ in the optical frame and then to $\Sigma_{\text{body}} = \mathbf{R}_{bc} \Sigma_c \mathbf{R}_{bc}^\top + \Sigma_{\text{ext}}$ in the body frame, where the extrinsic term is what a mount shift adds. Its largest eigenvalue gives the principal variance scale, which for stereo points lies along the viewing ray; section C.12 derives the full propagation.

8.6.2 Qualifying the claimed error

Plugging a datasheet precision value or an unmeasured network clock offset into a clearance check leaves systematic mounting bias, heavy-tailed mismatch outliers, and asymmetric path delays uncovered. A physical obstacle can then sit inside the safety boundary while the permission check passes. Two numbers in the claim just built therefore cannot come from a model or a datasheet: the tail quantile that sets the clearance inset, and the clock-conversion bound that dates the claim on the permission path's clock. Each is fixed by a measurement campaign, and the observation contract of section 8.8 carries both. Whether a reported covariance matches empirical error is evaluated with consistency statistics that require an estimator's prediction; that test is developed alongside the estimator (section 9.2.1).

The clearance inset of equation 8.9 needs a 99th-percentile bound on the residual norm under intended operational conditions, not a theoretical covariance. The most direct procedure is empirical. Collect n_{cal} residual norms against ground truth, sort them, and select the k_ϵ-th smallest with $k_\epsilon = \lceil (n_{\text{cal}} + 1)(1 - \epsilon) \rceil$. This split-conformal rule guarantees that a future residual falls at or below the bound with probability at least $1 - \epsilon$, provided calibration and deployment residuals are exchangeable (Angelopoulos and Bates 2023). It is the inductive conformal construction that section 3.6.2 used to turn a policy's dispersion into a coverage guarantee, applied here to measured residual norms rather than to model scores. For $\epsilon = 1$ percent, the rule requires at least 99 residuals, returning the largest observed value when evaluated on that minimum set. With 1,000 residuals, it returns the 991st smallest value (the 10th largest). This guarantee holds marginally over the calibration distribution. A new floor finish, a lighting change, or a mechanical recalibration breaks exchangeability, requiring new residual campaigns sized by the per-claim sample-size rule of section 7.7.1. Because these residuals are measured directly against ground truth, they capture the sensor's physical bias, which nominal covariance models omit.

The clock-conversion bound ϵ_{sync} is likewise measured rather than assumed. The IEEE 1588 Precision Time Protocol (PTP) exchange that section 5.5.2.1 used to pair logged frames with actions estimates a device's clock offset by assuming that both directions of the path take equal time (IEEE 2020a). Section C.7 gives the message exchange and its servo. A path asymmetry Δt_{asym} shifts the estimated offset by $\Delta t_{\text{asym}}/2$ and leaves no symptom in the exchange. The exchange must therefore be timestamped in hardware at the network interface, where host scheduling cannot add delay to one direction and not the other. Between synchronization exchanges, the local oscillator drifts. The OS1-64's free-running clock is specified at 10 ppm (Ouster, Inc. 2025), which over a 1 s sync interval accumulates 10 µs of worst-case drift. Clock qualification records the measured tail of the servo's reported offset, the path-asymmetry allowance, and the drift between corrections. A sampled tail is statistical evidence, not a maximum-error guarantee. A contract that treats synchronization error as a hard bound also needs a justified limit on unobserved offset excursions and a detector that invalidates the mapping when its assumptions fail. For a hardware-triggered camera, this

bound is verified by timing the trigger edge against the IMU latch with a logic analyzer. Until those measurements exist, the clock-conversion bound in the navigation camera's record remains illustrative, and the LiDAR's datasheet guarantees only 1 ms. While empirical residual campaigns can qualify a stereo or LiDAR sensor whose physics directly measures depth, modern perception pipelines increasingly pair those metric sensors with neural networks that infer depth from a single image.

8.6.3 Learned depth as a measurement

A monocular depth network can predict plausible-looking meter values that err by meters on an unfamiliar floor texture or a life-sized photograph printed on a flat box, because a single camera physically measures only bearing and guesses scale from learned appearance priors. Learned models add two capabilities to metric perception: a semantic classification of spatial regions, and a depth estimate from a single camera. Lifting labeled detections into a persistent, object-centric scene graph carries state across frames, and section 9.6.2 develops the maintenance of that graph. Perception must settle a narrower systems question: whether a learned depth estimate may enter a safety clearance claim at all. The semantic layer identifies candidate objects and contacts; the metric layer must establish their physical geometry. Point clouds supply measured surface samples where pulses reflect, but missing returns never prove free space. Persistent representations that retain geometric evidence cannot alter an observation's capture timestamp or convert a learned model score into an error bound.

↪ The volumetric maps that retain this geometric evidence across frames are developed in section 9.6.1.

Lifting 2D pixel features into 3D metric space requires combining 2D token embeddings with per-pixel depth distributions. In deep monocular depth networks (such as Depth Anything, MiDaS, or metric depth transformers), models predict dense depth maps from monocular visual cues. However, single-view depth estimation is inherently ill-posed due to projective scale ambiguity: an infinite family of physical 3D objects with different scales and distances project to identical pixel arrays. Relative-depth models output scale- or affine-ambiguous predictions, whose conversion to metric depth requires external calibration, represented by $z_{\text{metric}} = s \cdot z_{\text{pred}} + t$ when the model uses that parameterization. Metric-trained heads directly predict depth in meters, but their units do not certify their error. Both model classes require residual validation and can fail silently on unusual geometries, novel textures, or optical illusions (such as a 2D photograph printed on a flat surface).

In bird's-eye-view (BEV) architectures such as Lift-Splat-Shoot (Philion and Fidler 2020), the network predicts a categorical probability distribution over discrete depth bins along each viewing ray. Each 2D feature token is cast outward along its optical sightline ray and 'splatted' into discrete 3D spatial voxel cells weighted by these predicted depth probabilities, transforming disembodied image embeddings into an explicit 3D volumetric representation. The resulting spatial uncertainty ellipsoid deforms non-linearly under perspective unprojection through the unprojection Jacobian $\mathbf{J}_{\text{unproj}} = \frac{\partial \mathbf{p}_c}{\partial [u,v,Z_c]^\top}$ (equation 8.10):

$$\Sigma_c = \mathbf{J}_{\text{unproj}} \Sigma_{\text{meas}} \mathbf{J}_{\text{unproj}}^\top \tag{8.10}$$

While transverse spatial standard deviation expands linearly with range ($\sigma_\perp \approx \frac{Z_c}{f}\sigma_u$), stereo radial depth standard deviation expands quadratically ($\sigma_z \approx \frac{Z_c^2}{fb}\sigma_d$). This perspective unprojection transforms near-field circular uncertainty disks into highly eccentric, needle-shaped ellipsoids oriented along the camera's sightline, with extreme radial dispersion at long ranges that must be bounded before downstream safety filters can certify clearance.

↪ The lift-splat projection of camera features into a metric bird's-eye-view grid is developed in section A.3.3.

Because the depth-bin distributions produced by learned lifting stages are uncalibrated model scores rather than certified metric error bounds, the clearance inset of equation 8.9 cannot rest on learned depth alone. Downstream safety enforcers require continuous validation against calibrated active ranging sensors or stereo disparity. This is the division of labor on the running machine. A learned head on the navigation camera may classify the worker and even estimate depth, but the rack-end range that enters the clearance check comes from the LiDAR. The split also keeps the check independent of the proposal it judges, because a checker that consumed the camera's own perception would share every blind spot of the proposer it exists to catch.

↪ The independence a monitor needs from the proposer across sensing, compute, and actuation is developed in section 12.8.

Systems Perspective 8.3: The metric veto invariant

Safety is an invariant of metric clearance, not semantic understanding. Suppose a slow 2 Hz vision-language foundation model classifies a pathway as "clear aisle" or dismisses an object as a harmless shadow. If the 20 Hz LiDAR, or the occupancy grid built from it, detects a physical obstacle return within the stopping envelope, the permission path must honor the qualified occupied-region evidence rather than let semantic confidence erase it. The permission path halts or slows the machine regardless of the semantic model's high confidence. Semantic models propose high-level task goals; qualified metric sensing supplies clearance evidence to the permission path. Neither sensor pipeline itself owns actuator authority.

Checkpoint 8.2: Spatial error and the clearance inset

A spatial claim is spent from the same clearance as its age, and its error must be measured before it is charged.

- ☐ **Quadratic depth error**: Can you explain why stereo depth error grows with the square of range while a pulsed LiDAR's range precision stays roughly flat?
- ☐ **Baseline estimate**: If the illustrative rig's 0.20 m baseline were halved, at what range would one standard deviation of depth error reach the 0.15 m side clearance, compared with 6.9 m now?
- ☐ **Covariance vs. clearance inset**: Can you explain why a residual quantile measured against ground truth, not a reported covariance, sets C_{inset}, and what that quantile still leaves uncovered?
- ☐ **Learned depth vs. metric evidence**: Can you explain why a depth network's predicted spread cannot enter a clearance claim until its residuals are validated, and why qualified metric evidence overrides a semantic label that calls a return a shadow?

8.7 Perception Failure Modes and Sensor Degradation

Every bound derived so far, whether metric, learned, or temporal, assumes that the sensor behaves as calibrated: propagation bounds the error of a sensor working as modeled, not one that has stopped working that way while still delivering frames at its nominal rate. A navigation camera can fail in two ways that look entirely different to downstream software. If its serializer link loses lock, the driver raises an error and the frame never arrives. If direct sunlight through an open dock door saturates the lens as the vehicle turns into an aisle, the camera delivers a complete frame at its nominal rate, with a shelving rack hidden under a patch of clipped white pixels. Perception failures divide along this boundary into two operational classes. **Detectable faults** occur when the physical sensor or communication transport asserts an explicit hardware or software error condition. Examples include a serializer-deserializer (SerDes) link losing clock synchronization, a cyclic redundancy check (CRC) detecting a corrupted payload, a DMA frame buffer overflowing, or a transport bus timing out. These failures are straightforward to handle. The hardware driver raises a fault flag at the ingestion boundary, downstream consumers drop the corrupted frame, and state estimators expand their uncertainty. Once the age of valid sensor evidence exceeds its configured freshness budget, the permission path rejects motion requests that depend on it and invokes a fallback qualified for the remaining state evidence, actuation authority, and stopping margin. In contrast, **silent failures** occur when the sensor hardware, firmware, and transport bus function without error, delivering a structurally valid tensor whose numerical values misrepresent the physical world.

Physical degradation of the optical channel is a frequent source of silent failure. When bright sunlight enters the aperture, incident photons overwhelm the full-well capacity of the CMOS photodiodes, clamping pixel values at their maximum quantization limit across large patches of the sensor array. This **dynamic range saturation** destroys local spatial gradients. Downstream feature extractors, optical flow estimators, and stereo disparity algorithms fail because numerical optimization over a uniform flat field yields zero directional gradient, even while the camera driver

delivers frames at the full nominal rate. Dimly lit environments trigger the opposite failure mode. When ambient photon flux drops, the discrete, stochastic arrival of photons (**photon shot noise**) and the thermal and electrical fluctuations of the readout circuitry (**sensor read noise**) dominate the signal. As the signal-to-noise ratio collapses, learned neural backbones begin extracting spurious geometric features from random noise patterns rather than physical obstacle boundaries. Contaminants on the protective lens or dome window, such as water droplets, dust, or grease smudges, act as irregular refractive elements and optical low-pass filters. They attenuate contrast, distort spatial geometry, and mask critical obstacles while the transport stack reports flawless operation.

Timing and transport anomalies can also corrupt an observation silently. If an unshielded physical interface experiences electromagnetic interference, deserializer bit slips (where the hardware drops or duplicates a bit, misaligning the subsequent serial data stream) can alter payload semantics without invalidating standard packet lengths. More dangerous than a dropped packet is an observation stamped with an incorrect capture epoch, because no transport monitor detects the error. If an image sensor captures photons at epoch t_0, but a late interrupt handler or an unsynchronized system clock timestamps the resulting memory buffer at $t_0 + \delta t$, the downstream state estimator integrates spatial features under an incorrect body pose. Consider a machine traveling with instantaneous velocity $\mathbf{v}$ and linear acceleration $\mathbf{a}$ along a given trajectory. When perception suffers an undetected timing desynchronization δt, the state estimator assigns the detected position of an obstacle to the body coordinates at $t_0 + \delta t$ rather than t_0. Over the unmodeled time interval δt, the physical state estimation error $\Delta\mathbf{p}$ between the asserted position and the true position is governed by the kinematic drift relation (equation 8.11):

$$\Delta\mathbf{p} = \mathbf{v} \cdot \delta t + \frac{1}{2}\mathbf{a} \cdot (\delta t)^2 \tag{8.11}$$

The arrival stamp discussed in section 8.3 represents a silent desynchronization of this exact type. At constant velocity, the acceleration term vanishes, leaving the kinematic offset $\mathbf{v}\,\Delta t_{\text{recv}}$ uncorrected while the driver reports nominal health. The asymmetry between a lost frame and a misdated one needs no estimator mechanics to see. An estimator that accepts a misdated frame as a correctly timed measurement can shrink its reported uncertainty around the wrong position, while a missing update can leave uncertainty to grow under its motion model. In this case, a dropped frame adds no information, so the reported spread grows and the evidence is honestly one frame period (16.7 ms) older. A misdated frame is accepted as information, so the spread shrinks around a position offset by $v\,\delta t$. On the running machine the arrival stamp alone places the obstacle 39.9 mm from where it stood, and the estimator reports that wrong position with more confidence than before. The motion planner is then sure that it has already cleared an obstacle it is about to strike. Chapter 9 develops the recursive estimator in which this happens, the Kalman filter.

Defending against silent failures requires dedicated runtime health monitors placed directly at the sensor ingestion boundary. A pixel-intensity histogram monitor inspects raw digitized frames immediately after DMA transfer, flagging overexposure when pixel counts concentrate at maximum bit depth, or flagging lens occlusion when spatial variance collapses below an empirical noise floor. A hardware watchdog timer tracks inter-arrival times across the DMA channel, flagging transport jitter when inter-frame intervals exceed $T_{\text{nominal}} + 3\sigma_{\text{jitter}}$. This empirical diagnostic heuristic does not replace the physically derived freshness deadline. Higher in the ingestion stack, an optical flow plausibility monitor compares calculated pixel displacement vectors against the body's physical velocity envelope, rejecting observations that imply accelerations beyond the chassis's mechanical limits. In multimodal configurations, cross-sensor consistency checks compare high-rate (1,000 Hz) inertial measurement unit (IMU) integrations against visual odometry. If visual odometry reports that the robot is stationary while the gravity-compensated IMU integration indicates sustained $2.0\ \text{m/s}^2$ linear acceleration, the monitor flags a cross-modal discrepancy once attitude, sensor bias, latency, and measurement uncertainties are reconciled.

Every runtime health monitor observes the physical world through the available transducer signals. Consequently, no single sensing channel can validate its own semantic interpretations. A camera assembly with pristine optics, optimal exposure, jitter-free transport, and sub-microsecond hardware timestamping can still present an image that causes a deep neural network to hallucinate a navigable path or fail to detect an obstacle. Because deep vision backbones map high-dimensional pixel arrays through non-linear manifolds, subtle visual anomalies (a sharp shadow across an

aisle, a life-sized person printed on a cardboard display, or specular glare off shrink-wrapped freight) produce valid pixel statistics, smooth optical flow fields, and misleadingly high prediction confidence. An ingestion monitor confirms that the raw data acquisition pipeline operated within nominal engineering limits, but it cannot confirm that downstream semantic inferences correspond to physical reality. Corroborating optical detections requires independent physical sensing modalities, such as lidar or millimeter-wave radar, whose coverage, beam geometry, and failure dependencies have been rigorously characterized. Even then, a validated permission path guarantees spatial clearance only within explicit operational and timing assumptions; no perception stack can guarantee unrestricted semantic truth. Understanding how the physical environment corrupts each sensing channel explains why single-modality checks fall short.

8.7.1 Fog, rain, glare, and specular surfaces

In an indoor warehouse, daylight flooding through an open loading-dock bay door or standing water on polished concrete can saturate cameras and deflect LiDAR beams into empty space, while fog and rain add atmospheric scattering for outdoor platforms that carry the same sensors. Each of these conditions degrades sensory transmission across optical, near-infrared, or radio channels without raising a hardware error flag. Optical cameras undergo severe degradation in the presence of atmospheric scattering and glare. Suspended airborne aerosol particles in fog, mist, and smoke (1 to 10 µm diameter) scatter visible wavelengths ($\lambda \approx 400$ to 700 nm) under Mie scattering physics. Scene radiance attenuates exponentially across distance according to Koschmieder's law:

$$C(d) = C_0\, e^{-\beta_{\text{atm}} d}$$

where C_0 is intrinsic object contrast, d is metric range, and β_{atm} is the atmospheric extinction coefficient. In dense fog ($\beta_{\text{atm}} \approx 0.05$ m^{-1}, an illustrative value), apparent contrast decays below the 0.05 perceptual detection threshold within 60 m. High-frequency edge gradients dissolve into uniform background luminance, preventing convolutional and transformer backbones from forming valid feature embeddings. Airborne rain introduces high-velocity streak noise across frames, while droplets impacting the protective lens act as irregular refractive microlenses. Each droplet deflects incoming rays, creating severe localized geometric distortion, optical blur, and false object silhouettes.

Rapid angular motion compounds this degradation through motion blur and modulation transfer function (MTF) collapse.[13] During a yaw rotation or manipulator sweep, a camera center at lever arm r travels a tangential distance set by angular rate ω and exposure duration:

$$\Delta x_{\text{rot}} = r \cdot \|\omega\| \cdot t_{\text{exp}}$$

For the machine's global-shutter wrist camera at its configured 5 ms exposure, swept at an illustrative $\omega = 3$ rad/s on an illustrative lever arm $r = 0.5$ m, this travel scale is $\Delta x_{\text{rot}} \approx 7.5$ mm. This metric displacement describes the physical travel of the optical center rather than image-plane blur in pixels. The resulting pixel displacement depends on both scene depth and focal length, while pure camera rotation shifts features across the image plane independently of depth. As motion blur smears sharp transitions across neighboring pixels, spatial gradients attenuate and feature trackers, visual odometry algorithms, and neural backbones lose tracking lock. Systems engineers must evaluate these effects across the full envelope of intended operational velocities and camera exposures.

[13] **Modulation Transfer Function (MTF)**: The fraction of scene contrast an imaging chain passes at each spatial frequency. A uniform blur of length L in the image multiplies it by a sinc that falls to zero at a period of L, so detail finer than the blur is erased rather than dimmed, and no network downstream can restore what the exposure removed.

Intra-frame illumination contrast introduces another challenging failure mode through dynamic range saturation and blooming. Standard auto-exposure algorithms adjust exposure time t_{exp} across consecutive frames to track gradual lighting changes, such as moving from a shaded warehouse aisle into an outdoor yard. However, auto-exposure cannot resolve extreme illumination differences within a single image. When a robot operating in a dim indoor aisle turns toward an open loading dock flooded with daylight, no single exposure setting suffices. An exposure long enough to resolve dark shelving units allows the intense photon flux from the dock to saturate the photodiodes, clipping those image regions to solid white. High dynamic range (HDR) sensors expand operational range by interleaving multiple exposures or employing dual-gain photodiode architectures. Yet staggered multi-exposure HDR introduces timing ambiguities that the observation contract must document. Because each synthesized exposure corresponds to a distinct temporal integration window, the metadata must specify which exposure midpoint dates the frame. When extreme overexposure occurs, excess photo-generated electrons spill over potential barrier implants into neighboring pixels

(**charge blooming**), washing out entire sensor columns into saturated values (255). Concurrently, internal reflections between lens elements generate veiling glare and lens flare streaks, eliminating the local spatial contrast essential for disparity matching and optical flow.

Active optical ranging encounters parallel limitations under degraded atmospheric conditions. Pulsed time-of-flight LiDAR, at silicon-band near-infrared wavelengths and at $1{,}550$ nm alike, suffers three distinct physical failure mechanisms in industrial and outdoor operation:

1. *Aerosol backscatter clutter*: Emitted laser pulses strike suspended fog droplets and dust particulates, scattering optical power back into the receiver during the initial nanoseconds of time-of-flight. This creates dense near-field point clutter, often appearing as a false obstacle wall within 0.5 to 3.0 m of the sensor aperture. Downstream spatial clustering algorithms misinterpret these backscatter returns as imminent collision hazards, triggering spurious emergency stops. Simultaneously, atmospheric extinction depletes forward pulse energy, significantly shortening maximum detection range. The magnitude of this range reduction depends on target reflectivity and the atmospheric extinction coefficient, requiring empirical calibration under the operational conditions for which the sensor is qualified.
2. *Retroreflector detector blooming and range walk*: High-visibility safety vests, barcode placards, and vehicle license plates incorporate retroreflective prismatic surfaces designed to return incident optical power directly along the emission axis at intensities orders of magnitude higher than diffuse surfaces. This strong return pulse triggers two distinct measurement errors. **Range walk** is a temporal distortion in the receiver's avalanche photodiodes (APDs) or single-photon avalanche diodes (SPADs). A simple leading-edge discriminator triggers when an analog pulse crosses a fixed voltage threshold, so a fast-rising, high-amplitude pulse trips the comparator earlier than a weak return and systematically underestimates the distance to the retroreflector. While intensity-based compensation curves can correct this offset under linear amplification, they fail once the analog front-end saturates. Concurrently, **blooming** creates a spatial distortion: optical scattering and electrical crosstalk within the detector array register false returns across adjacent detector channels, surrounding the retroreflector with a spherical halo of phantom points. Sensor manufacturers reflect these physical realities in their specifications; for example, the Ouster OS1 datasheet establishes distinct, wider accuracy tolerances for retroreflective targets compared to diffuse Lambertian surfaces (Ouster, Inc. 2025).
3. *Specular surfaces and non-Lambertian forward bounce*: Triangulation systems, structured-light projectors, and time-of-flight LiDAR all assume that surfaces produce diffuse Lambertian scattering, reflecting incident light uniformly across the hemisphere. Specular surfaces such as polished concrete floors, shrink-wrapped freight, painted metal panels, and architectural glass violate this assumption. Emitted laser beams undergo specular mirror reflection, bouncing away from the surface normal at an angle equal to the incidence angle ($\theta_{\text{refl}} = \theta_{\text{inc}}$) and directing optical energy away from the receiver. On wet or polished floors, this specular bounce results in complete signal loss, creating artificial zero-return dropouts ("puddle black holes"). Against glass walls or metal structures, multi-bounce reflections cause emitted pulses to travel indirect paths back to the receiver, generating phantom point clusters that appear meters behind physical walls or deep beneath the concrete floor.

Millimeter-wave radar provides complementary all-weather capability that overcomes many optical failure modes. Operating at 76 to 81 GHz, frequency-modulated continuous-wave (FMCW) radar uses a carrier wavelength of $\lambda \approx 3.9$ mm, roughly 4,000 times longer than near-infrared laser light and several orders of magnitude larger than fog droplets (1 to $10\,\mu$m). Scattering by such small airborne particles falls within the Rayleigh scattering regime, where the particle scattering cross-section σ_s scales inversely with the fourth power of wavelength:

$$\sigma_s \propto \frac{d_{\text{droplet}}^6}{\lambda^4}$$

Although this extreme wavelength dependence shields radar from the severe attenuation and backscatter that paralyze optical sensors in fog and dust, radar is not immune to environmental interference. Ground reflections produce multipath ghost detections, standing water films on

the radome attenuate radio-frequency signals, and low spatial resolution complicates boundary discrimination. A multimodal perception suite must therefore explicitly qualify radar coverage boundaries when primary optical streams degrade. Even when the physical channel is clear and the sensor hardware operates within specification, however, a neural backbone can still encounter scenes that lie outside its training distribution.

8.7.2 Out-of-distribution inputs at the sensor boundary

Even when a sensor is calibrated, unoccluded, and operating without transport faults, an unfamiliar scene (such as an overturned forklift, an unusual trailer profile, or a chemical vapor plume) can fall outside the operational distribution on which downstream models were qualified. Uncertainty in these observations stems from two distinct sources. **Aleatoric uncertainty** represents the irreducible physical noise of the transduction process itself, such as photon shot noise, thermal amplifier noise, or aerosol backscatter. The measurement's covariance model must quantify this uncertainty. In contrast, **epistemic uncertainty** stems from the model's lack of knowledge about scenarios omitted from its training distribution. Upgrading sensor fidelity cannot eliminate epistemic uncertainty. The limits of normalized softmax scores, calibrated uncertainty estimation, and the conversion of calibrated prediction sets into action refusals lie beyond perception's scope. Perception carries a narrower engineering responsibility. It must assess at the ingestion boundary whether an incoming observation appears outside the validated input support, and log that assessment directly in the observation contract.

Input-support monitors evaluate incoming sensor frames, or early feature embeddings from the backbone, against the support of the qualification dataset. Common implementations include computing a free-energy score over unnormalized logits (Liu et al. 2020), measuring the Mahalanobis distance to class-conditional feature centroids (Lee et al. 2018), or tracking the reconstruction error of an autoencoder trained strictly on nominal operational data. Each method requires an empirical acceptance threshold calibrated against expected anomalies. An in-bounds score means only that the monitor did not flag the input under its calibrated threshold; it guarantees neither membership in the qualification distribution nor physically accurate semantic inference.

↩ The limits of softmax confidence and the conformal calibration that bounds it are established in section 3.6.2.

When an input-support monitor detects an anomaly, the perception pipeline sets a `BIT_OOD_DETECTED` flag in the health bitmask that every observation carries, one of the record fields that section 8.8 assembles. The permission path monitors this bitmask to disallow high-speed motions, expand conservative clearance buffers, or trigger a deterministic supervisory fallback. In multimodal systems, the same bitmask arbitrates between sensors. On the running machine, if the navigation camera raises `BIT_OPTICAL_SATURATED` or `BIT_OOD_DETECTED` while the LiDAR's returns stay healthy, the pipeline demotes the camera's tokens and the rack-end claim rests on LiDAR range alone. This holds only if the LiDAR is independently validated to enforce spatial clearance under those operating conditions. Outdoor platforms apply the same arbitration with radar in the LiDAR's place.

↩ The input-support monitor these checks instantiate is established in section 7.9.

War Story 8.1: Silent perception omission (2016)

Context: A 2015 Tesla Model S traveling at about 74 mph with Traffic-Aware Cruise Control and Autosteer active struck a refrigerated semitrailer turning left across its path near Williston, Florida (National Transportation Safety Board 2017).

Mechanism: The crossing-path collision lay outside the front-to-rear crash modes for which the 2015 warning and automatic braking systems were designed. NHTSA reported that automatic braking required agreement between camera and radar; unusual vehicle shapes could impede camera classification (NHTSA ODI PE16-007).

Impact: The NTSB found no recorded indication that forward collision warning or automatic emergency braking detected an object, and no pre-impact braking occurred. The vehicle passed beneath the turning semitrailer, shearing off the car's roof; the paired investigation photographs in figure 8.8 document this physical outcome, highlighting collision scrape damage along the right underside of the trailer alongside the roofless passenger cabin.

Response: The NTSB examined operational design domain limits and driver engagement as well as the collision-avoidance systems.

Figure 8.8: Williston collision damage: This NTSB presentation slide shows damage on the right side of the semitrailer and the roofless Tesla after the 2016 crash. The crossing-path geometry and absence of pre-impact braking come from the NTSB accident report, not from the photographs alone. (Source: NTSB board-meeting presentation for report HAR-17/02; photographs courtesy of Florida Highway Patrol).

Systems lesson: An absent detection is not evidence that a crossing path is clear. A permission design must account for detection coverage and unsupported scenarios; a health flag cannot certify that every relevant object was perceived.

An observation contract can expose only the physical, temporal, and distributional faults that the ingestion layer is designed to measure. Detectable interface errors, transport jitter, and out-of-distribution feature shifts can be encoded into explicit health bitmasks. Silent semantic omissions, such as the missed detection at Williston, evade single-sensor health checks. Preventing catastrophic failures requires an architectural safety design: incorporating independent physical sensing modalities, enforcing conservative spatial permission envelopes, and never mistaking the absence of an error flag for confirmation of physical safety. Omission can also depend on who is in view: a detector qualified mostly on people standing upright can miss a kneeling worker or a child more often, so any detection rate a contract reports for people holds only for the groups it was measured on.

↪ How a detection gap between groups of people becomes a gap in stopping distance and impact energy, and how large each group's sample must be, is developed in section 17.5.

8.8 The Observation Contract

A downstream tracker, policy backbone, or permission path cannot reconstruct exposure timing, mounting calibration, or byte integrity from a raw tensor alone. The perception subsystem therefore wraps each sensory output in an **observation contract**, the sixth record in the book's sixteen-record chain. In closed-loop physical systems, an observation is unusable without an explicit capture epoch, an identified clock domain, a bounded conversion to the permission path's clock, and an extrinsic calibration operating within its qualified validity envelope. A safe consumer must reject any incoming record lacking these guarantees before inspecting a single payload byte. The system's shared clock domain and $\mathcal{H}_1$ age budget originate in the nervous-system handoff record of section 4.9; perception, in turn, provides the capture-side timestamps and uncertainty bounds that downstream consumers need to verify compliance.

↪ The sixteen-record chain, in which the observation contract is Record 6, is developed in section C.14.2.

Formally, the contract couples either a raw observation tensor or an extracted geometric bounding envelope with the validation metadata that downstream consumers require (equation 8.12):

$$\mathcal{O} = \langle t_{\text{capture}}, \text{clock_id}, \epsilon_{\text{sync}}, \text{frame_id}, \mathbf{T}_{\text{payload}}, \Sigma_{\text{body}}, C_{\text{inset}}, \text{mask}_{\text{health}}, \text{crc32} \rangle \tag{8.12}$$

In this tuple, t_{capture} records the exposure-midpoint timestamp registered on monotonic clock clock_id, ϵ_{sync} bounds the maximum synchronization error when converting to the clock of the

safety MCU that hosts the permission path, and frame_id identifies the calibrated sensor transform. The payload $\mathbf{T}_{\text{payload}}$ contains the raw sensor array or derived geometric bounding envelope, Σ_{body} characterizes its spatial covariance, and C_{inset} provides the qualified clearance inset. The health mask $\text{mask}_{\text{health}}$ conveys hardware and perceptual health status bits, and the checksum crc32 seals both header and payload against transport corruption. Spatial memory consumes this record to update its world model, while trajectory planning uses C_{inset} to inflate collision boundaries. Both modules evaluate evidence age, verify kinematic coordinate frames, and bound spatial uncertainty before allowing an observation to influence a control decision.

The tuple is the same object as the error-qualified claim $(\mathbf{p}_{\text{body}}, \Sigma_{\text{body}}, C_{\text{inset}}, t_{\text{age}})$ that section 8.6 assembled, now wrapped for transport. The claim's point travels in $\mathbf{T}_{\text{payload}}$, its covariance in Σ_{body}, and its inset in C_{inset}. Its age is deliberately not stored, because each consumer computes the current evidence age from t_{capture} and ϵ_{sync} on its own clock.

This contract does not replace binary serialization formats such as Protocol Buffers, FlatBuffers, or ROS 2 IDL; any of these serialization systems can transmit the underlying struct over shared memory or bus fabrics. While transport schemas standardize memory layout and data types, the observation contract establishes verifiable physical invariants: monotonic temporal progression, bounded clock skew, active calibration validity windows, and rigorous spatial uncertainty limits. Table 8.5 serializes the tuple as named fields, details each one alongside its validation rule, and populates the schema for the mobile manipulator's navigation camera. It splits t_{capture} and clock_id into `capture_timestamp_ns` and `capture_clock_id`, carries the calibration behind frame_id in `calibration_metadata`, and adds a `sequence_index` and a `provenance_digest` that the tuple leaves out.

Table 8.5: Observation contract schema: Compact fields needed to date and frame a claim, evaluate its uncertainty, bounding envelope, and health flags, and check the bytes and generating revision. The last column fills the fields this chapter computes for the mobile manipulator's navigation camera; its dispatch age and clock-conversion bound are illustrative. A keyed authenticator is a separate requirement if the threat model includes malicious modification.

Record field	Meaning	Consumer check	Navigation camera
`capture_timestamp_ns`, `capture_clock_id`	Exposure midpoint in one shared, monotonic capture clock	Convert to safety microcontroller (MCU) time with a valid bounded-skew mapping before checking age	Trigger edge plus $t_{\text{exp}}/2$ (top-row exposure midpoint) on clock `cam_nav`; dispatched 51.6 ms later (table 8.3)
`sync_error_ns`	Bound on capture-to-MCU clock conversion error	Add to worst-case age; refuse if missing or expired	0.2 ms, so the upper age at dispatch is 51.8 ms
`sequence_index`	Monotonic camera frame counter	Detect gaps and reordering	One count per frame at 60 Hz
`sensor_frame_id`	Transform-tree key and calibration revision	Select the valid extrinsic transform	`nav_cam` with its calibration revision
`tensor_payload`	Format, dimensions, length, and buffer	Validate bounds and record checksum before reading	Raw/debayered image tensor or point-cloud buffer
`bounding_envelope`	Bounding volume $[dx, dy, dz]$ or qualified clearance inset	Bound occupied volume and inflate safety sets (C_{inset})	Metric corridor bounds inflated by validated quantile
`spatial_covariance`	Positive-semidefinite spatial error scale	Use with separately calibrated bias and tail bounds	Point-wise or object-centric covariance matrix Σ_{body}
`calibration_metadata`	Intrinsics, extrinsics, coefficients, temperature, validity range	Reject calibration outside its validated region	Factory pinhole $\mathbf{K}$ and chassis extrinsic transform $\mathbf{T}_{bc}$
`provenance_digest`	SHA-256 of firmware and model revisions	Match the approved build; this is not payload integrity	Signed hash of vision backbone weights and firmware
`payload_crc32`	CRC over serialized header (excluding this field) and payload	Detect accidental record corruption; not authentication	32-bit cyclical redundancy check
`health_bitmask`	Hardware, degradation, and perception validity flags	Refuse claims with safety-critical faults or OOD flags	Sync-loss, link, saturation, rain/fog clutter, and OOD bits; input-support bits

The fields detailed in table 8.5 anchor each observation in physical time, geometric space, and software revision history. The capture timestamp t_{capture} must refer to a strictly monotonic hardware timer rather than wall-clock time (such as nanoseconds since the UNIX epoch), which remains vulnerable to stepping backward during network time adjustments. Because rolling-shutter sensors read out scan lines sequentially, any spatial claim derived from a rolling-shutter imager must explicitly identify the image row or region corresponding to that capture instant. The transport-level `sequence_index` counter detects frame drops and out-of-order deliveries directly on the bus, independently of clock readings. When the safety MCU operates in a separate clock domain from the camera host, an active synchronization daemon provides a versioned affine mapping $t_{\text{MCU}} = at_{\text{capture}} + b_{\text{clk}}$, an expiration window, and an empirical sync-error bound ϵ_{sync}, characterized as described in section 8.6.2.

Systems engineering demands precise conventions when accounting for sensor latency. The handoff matrix and the perception latency budget evaluate the sensor's latency contribution under different row conventions, and the observation contract must explicitly state which convention governs the record. The handoff matrix allots $\mathcal{H}_1$ one frame period (16.7 ms at 60 Hz) and references the entire frame by its middle row. Because rolling-shutter rows stagger their exposures at the exact rate they read out, the middle row finishes its own exposure halfway through the frame's readout window and waits only the remaining $t_{\text{readout}}/2$ for the bottom half of the array to clock off the die, so measuring from that middle row's exposure midpoint to the completion of sensor readout yields a sensor-side latency of $t_{\text{exp}}/2 + t_{\text{readout}}/2 = 16.3$ ms, which falls well within the handoff allotment. Conversely, the perception latency waterfall charges for the top row: $t_{\text{exp}}/2 + t_{\text{readout}} = 24.6$ ms. Because a physical hazard such as a warehouse rack upright can appear in the very first scan lines, a safety-certified stopping budget must charge for the oldest sensory evidence underpinning the spatial claim. Under this oldest-row convention, the navigation camera exceeds the handoff allotment by 7.9 ms. The two numbers answer different questions, and the stopping budget governs. The $\mathcal{H}_1$ allotment is a design budget for the sensing handoff, stated in the middle-row convention, and the camera meets it. The safety charge is row five, which uses this chapter's oldest-row waterfall. The 7.9 ms is already inside the 51.6 ms that row five charges, so nothing is missing from the stopping budget. What the mismatch does require is a record that says which convention dated it. The capture metadata therefore stamps the reference row index, so that a consumer checking $\mathcal{H}_1$ and a consumer checking clearance each read the age they need from the same field.

Upon dispatching an observation, the producer records an upper bound on its observation age at dispatch as $t_{\text{MCU,dispatch}} - t_{\text{MCU,capture}} + \epsilon_{\text{sync}}$. That metric reflects only the latency accumulated up to the producer's egress boundary. By the time the permission path admits the record, the evidence has aged further by the dispatch-to-admission transit delay Δ_{da}, and it ages further still before actuators execute a command. The permission path must evaluate freshness using its local monotonic clock against the original capture epoch; treating a static dispatch timestamp as if time had frozen violates basic physical causality. Submitting a new trajectory proposal derived from a previously buffered observation does not refresh the underlying sensory evidence.

For the navigation camera, the **dispatch-local** threshold equals the budgeted observation age 51.6 ms plus the 0.2 ms clock-conversion bound, yielding 51.8 ms. The threshold sits exactly at the budget because row five of the stopping budget charges exactly that age; admitting an older frame would spend travel that no row accounts for. A frame that meets every stage budget therefore reaches dispatch with zero spare margin, and any host contention, pipeline queuing, or batching beyond those budgets pushes it past the threshold. The stage values are allocations each stage must meet at its tail, not typical latencies, so a pipeline that meets them refuses only the frames that overrun them. In the vehicle's stopping budget, the 51.6 ms perception delay maps directly to physical travel distance at cruising velocity. The 0.3 mm displacement associated with the clock-conversion uncertainty bound is absorbed into the localization uncertainty parameter δ_{loc}. Neither accounting choice eliminates the ongoing physical aging that occurs after dispatch.

Admitting an observation into the motion-planning safety pipeline requires an empirically qualified current-age limit that accounts for the dispatch-to-admission bound Δ_{da} while reserving sufficient execution time for the active motion lease and physical braking response. Because this partial budget has not yet bounded Δ_{da}, the populated record in table 8.5 illustrates correct structural field construction rather than an admitted full-speed trajectory. Once engineers measure and bound

Δ_{da} across all inter-process channels, they can either close the stopping budget or reduce maximum vehicle velocity to restore safety margins. Latency accounting conserves time. Whether an engineer anchors the timeline at physical capture or measures from the admission gate by summing prior evidence age with the active lease, each elapsed interval appears exactly once in the stopping budget.

The transform identifier `sensor_frame_id` and its calibration revision key the observation into the robot's kinematic transform tree.[14] The provenance digest records the exact SHA-256 hash of the vision model weights and camera firmware, providing an auditable record of software configuration. Concurrently, `payload_crc32` guards against transmission glitches across shared-memory rings or serial buses. Data integrity is not semantic truth. Checksums and build digests detect accidental bit flips and firmware mismatches, but they cannot verify whether an image is optically uncorrupted, nor do they prevent adversarial tampering without a keyed cryptographic signature.

The `health_bitmask` structures failure reporting across three architectural layers. The lowest bits report hardware-level faults, such as clock synchronization loss, DMA ring buffer overruns, or physical link dropouts. The intermediate bits signal environmental degradation, including sensor saturation from direct sunlight, optical blooming, and aerosol backscatter from dust or fog. The upper bits represent perceptual validity concerns, such as severe field-of-view occlusion or out-of-distribution (OOD) sensory inputs that fall outside the training support tested during system evaluation. When any safety-critical bit is set, downstream motion planners and trackers must immediately reject spatial claims derived from that frame.

An explicit observation schema also creates a systematic interface for automated fault injection. Verification harnesses can deterministically alter capture timestamps, drop sequence numbers, artificially inflate covariance diagonals, or assert occlusion bits, confirming that downstream consumers reject or gracefully degrade unviable observations within their budgeted time limits. These software mutations demonstrate consumer responses for the tested corruptions under the tested budgets; evaluating resilience against physical phenomena such as optical flare, mounting deflection, and actuator dynamics requires hardware-in-the-loop testing regimes.

Learned policies require explicit contract metadata just as much as classical state estimators do. An end-to-end policy $\mathbf{a}_t = \pi(\mathbf{z}_{t_0})$ that receives only sensory pixels or point clouds cannot distinguish two identical images consumed under radically different pipeline latencies. Widely used vision-language-action (VLA) models do not receive these quantities. RT-2 and OpenVLA condition on visual tokens and a language prompt (Brohan, Brown, Carbajal, Chebotar, Chen, et al. 2023; Kim et al. 2024), and π_0 adds proprioceptive joint state (Black et al. 2024), but none of them is given capture age, extrinsic transforms, or measurement covariance as input. To integrate learned models safely into real-time control loops, this book presents an **observation tokenizer** that projects the full observation contract into the token space of a VLA policy or neural estimator. The sensory modality dictates the raw payload encoding (patch tokens from vision transformers, range tokens from lidar arrays, spike tokens from event cameras, or stress fields from tactile arrays), while the tokenizer interface preserves the capture epoch, geometric frame, and measurement uncertainty associated with that payload.

Under this architecture, the observation tokenizer pairs the sensory feature tokens $\mathbf{z}_{\text{sensor}}$ with continuous Fourier temporal embeddings ($\mathbf{e}_{\Delta t} = \text{Fourier}(t_{\text{current}} - t_0)$), coordinate frame prefix embeddings ($\mathbf{e}_{\text{frame}} = \text{MLP}(\mathbf{T}_{bc})$), and spatial covariance embeddings ($\mathbf{e}_{\Sigma} = \text{MLP}(\text{vec}(\Sigma_{\text{body}}))$) (equation 8.13):

$$\mathbf{z}_{\text{token}} = [\mathbf{z}_{\text{sensor}}, \mathbf{e}_{\Delta t}, \mathbf{e}_{\text{frame}}, \mathbf{e}_{\Sigma}] \tag{8.13}$$

A forward-propagated state token $\mathbf{e}_{\text{state}} = \text{MLP}(\hat{\mathbf{x}}_{t_{\text{current}}})$, generated by the state estimator that spatial memory maintains, can accompany these tokens so the policy conditions on the robot's predicted state at the instant of actuation rather than its historical configuration at sensor exposure. Because the observation contract preserves the exact capture epoch, delayed frames do not become worthless garbage. When network congestion or compute preemption delays delivery, a state estimator can ingest an out-of-order observation at the precise historical instant it captured and propagate corrections forward to the current state, a technique that spatial memory develops in section 9.2.3. While this embedding scheme exposes physical time, frame geometry, and uncertainty directly to transformer attention layers, engineers must verify that the model actually attends to these tokens in closed-loop operation. Demonstrating that a policy uses temporal embeddings requires rigorous ablation experiments that inject artificial latency into held-out evaluation trials and measure

[14] **Stereo Baseline Thermal Drift**: For a stereo baseline $b = 0.20$ m and an unmodeled change $|\delta b| = 0.1$ mm, first-order geometry gives $|\delta Z_c|/Z_c \approx |\delta b|/b$. At $Z_c = 20$ m, the corresponding depth bias is about 10 mm, assuming focal length and disparity are otherwise unchanged. Temperature compensation must be checked against the actual mount and calibration.

↪ Hardware-in-the-loop testing of physical phenomena is developed in section 15.8.

resulting closed-loop tracking error. Embedding metadata as neural tokens also does not substitute for deterministic safety gating. The permission path must continue to verify clock bounds, extrinsic calibration envelopes, innovation residuals (the gap between each measurement and the estimator's prediction of it), and health status bits before any network output is permitted to drive the physical actuators.

Checkpoint 8.3: Observation contract checks

A consumer can refuse only what the record lets it check, and it must check before it reads the payload.

- ☐ **Record triage**: Can you explain why a health bit, checksum, valid clock conversion, and freshness check must precede consumption of a spatial claim?
- ☐ **Timestamp corruption vs. dropped packets**: Can you describe why receiving a sensory frame with a desynchronized timestamp degrades spatial state estimation and policy grounding far more severely than dropping the packet entirely?
- ☐ **Deterministic fault injection**: Can you distinguish between physically perturbing optical sensors vs. deterministically mutating fields in the shared-memory observation contract during automated hardware-in-the-loop verification?
- ☐ **Age on the consumer's clock**: Can you explain why the permission path must recompute evidence age on its own monotonic clock from the capture epoch, rather than trusting the age stamped at dispatch, and why its 51.8 ms dispatch-local threshold is not the limit it applies at admission?

8.9 Fallacies and Pitfalls

Passing contract triage and computing state updates still does not make an observation semantically true in the physical world, and the most common perception errors come from treating a syntactically valid record as a statement about the present scene. Perception must describe the physical world within the strict temporal deadlines demanded by closed-loop control. In embodied systems, high semantic confidence and fine spatial resolution cannot compensate for pipelines that deliver stale observations, fuse asynchronous exposures, or treat average I/O bandwidth as a bound on single-frame latency.

Fallacy: *Accepting an observation because its semantic classification confidence is high, regardless of its age.*

Consider a mobile manipulator that receives an observation indicating with high semantic confidence that the rack end ahead is clear. If a scheduling stall in the vision pipeline delivers that observation several frames late, a warehouse worker who stepped into the aisle after the camera exposure will not appear in the image. The confidence score describes only the classifier's assessment of past sensory input, not current physical clearance. Treating an overdue packet as present state risks commanding actuators directly into occupied space. The perception interface must verify measurement age against its freshness limit (section 8.8) and reject observations that exceed the threshold. Furthermore, any state propagation that continues without fresh data must inflate kinematic uncertainty covariances, incorporating heavy-tailed residuals or reachability bounds on dynamic obstacles. This growth forces downstream controllers to contract their safety envelopes and slow the robot as sensory evidence ages. High softmax confidence reflects internal model certainty on an acquired image, but it guarantees neither temporal freshness nor true physical clearance.

Pitfall: *Fusing multi-sensor observations without a clock bound derived from the tolerated spatial error.*

Suppose two cameras on the mobile manipulator observe the same rack upright while the mobile base travels at its 1.5 m/s velocity limit, but their internal clocks differ by an uncorrected skew Δt_{skew}. If downstream fusion treats the two exposure times as simultaneous, the physical upright appears displaced by $v\,\Delta t_{\text{skew}}$ between the two sensor frames. Downstream track association can split this single physical obstacle into two conflicting tracks ("ghosting"), corrupting the world model. Spatial calibration cannot correct an uncharacterized temporal offset. Instead, the allowable clock synchronization error must follow directly from the tolerated spatial position error ϵ_{pos} and

the maximum operational velocity $v_{\max}$, yielding the relation $\Delta t_{\text{skew}} \leq \epsilon_{\text{pos}}/v_{\max}$. Hardware synchronization at exposure time makes that bound enforceable. Selecting a network timing technology such as the IEEE 1588 Precision Time Protocol (PTP) without first deriving this spatial error budget leaves the sensor fusion pipeline ungrounded.

Pitfall: *Inferring a critical read's deadline from average camera bandwidth.*

A comfortable average utilization figure says nothing about how long a critical read stalls behind synchronized sensor capture and inference bursts. On the mobile manipulator, safety permission checks execute on a dedicated real-time microcontroller reading from local memory, shielding the immediate control path from host bus contention. The danger instead appears on the application processor, where concurrent DMA transfers, memory bus saturation, and inference bursts delay the sensor ingestion pipeline (section 8.5). This contention inflates the capture-to-dispatch age of the perceptual observation and stretches the renewal interval between successive updates. System architects must verify worst-case capture-to-dispatch age and end-to-end renewal intervals under peak burst conditions rather than relying on average throughput metrics.

Fallacy: *Assuming an end-to-end Vision-Language-Action (VLA) policy implicitly learns to compensate for rolling shutter and sensor latency without explicit temporal tokenization.*

Deep imitation learning often assumes that large Vision-Language-Action (VLA) policies trained on extensive robot teleoperation datasets will automatically learn action corrections that compensate for sensor distortion and communication latency. In practice, demonstration datasets aggregate trajectories collected across fluctuating chassis velocities, camera frame rates, and host bus loads. If the model receives only raw pixel arrays without capture timestamps or row readout schedules, it cannot distinguish true physical obstacle geometry from rolling-shutter scanline shear or motion lag. Unresolved temporal ambiguity degrades closed-loop trajectory tracking and induces control oscillations. The quadratic compounding bound of equation 5.1 describes how per-step imitation error grows over a horizon, but it assumes a stationary Markov process rather than unmodeled phase lags and sensor dynamics. Providing explicit timing metadata, such as capture time deltas ($\Delta t = t_{\text{current}} - t_0$), readout offsets, and forward-propagated kinematic states, gives the network the causal context required to resolve these distortions. Even with temporal tokenization, empirical evaluation must verify closed-loop stability, and independent out-of-band safety permission checks remain mandatory.

Pitfall: *Treating neural depth network outputs as calibrated geometric covariances without empirical residual validation.*

Monocular depth estimation backbones and bird's-eye-view (BEV) lifting transformers output continuous depth fields or discrete depth-bin categorical distributions. Engineers often mistake these softmax spreads or secondary network confidence heads for calibrated geometric uncertainties (Σ_{body}), passing them directly into a state estimator such as an extended Kalman filter or a safety filter such as a control barrier function. In practice, raw neural confidence scores correlate poorly with true physical error distributions. When presented with unfamiliar textures, specular reflections, or occluding object silhouettes, depth networks produce gross multimodal outliers that deviate by tens of standard deviations from physical ground truth. Downstream clearance insets (C_{inset}) must never rely on raw neural variance. Safe execution requires empirical validation against heavy-tailed residual distributions and hard spatial bounds cross-verified by active ranging sensors such as LiDAR or radar.

Pitfall: *Relying exclusively on line-of-sight optical sensing for manipulation without tactile contact feedback.*

During reaches and grasps, the robot's own fingers, palm, and wrist occlude the contact interface. Optical cameras cannot observe local normal forces, shear stress distributions, or incipient micro-slip at the boundary between the gripper and the object. Relying exclusively on high-resolution visual perception to ensure grasp stability leads to dropped objects from undetected slipping or crushed workpieces from excessive actuator torque. Tasks that involve physical interaction and delicate object handling require direct contact feedback. Elastomeric tactile sensors and optical skin arrays can track surface shear and incipient micro-slip, while other applications may rely on wrist force-torque transducers, compliant passive mechanics, or fixtured tooling. Sensor selection must reflect the

physical contact dynamics of the manipulation task rather than defaulting to line-of-sight optical cameras.

Fallacy: *Assuming active LiDAR and depth sensors are immune to specular reflections and multipath interference in built environments.*

A common misconception is that active time-of-flight LiDAR and depth sensors are immune to optical artifacts because they project their own structured energy. In industrial facilities and built environments, surfaces routinely violate the diffuse Lambertian scattering assumption. Polished concrete floors, metallic shelving, architectural glass partitions, and shrink-wrapped pallet freight cause severe specular reflection. Emitted laser pulses deflect away from the receiver at shallow incidence angles, causing complete signal loss and creating artificial dropouts ("puddle black holes") on polished or wet floors. Conversely, multi-bounce reflections bounce pulses across multiple reflective surfaces before returning to the detector, generating phantom obstacles that appear meters behind solid walls or beneath the floor plane. The observation pipeline must validate return intensity distributions and cross-corroborate surface geometry against complementary inertial and radar channels.

8.10 Summary

A perception measurement is actionable only when its capture epoch, clock synchronization bound, coordinate frame, and spatial uncertainty match the kinematic requirements of the intended motion. Sensor selection begins with the physical quantity demanded by the control decision: photometric appearance, metric range, Doppler radial velocity, or contact deformation. Physical capture constraints then determine the exact temporal and geometric validity of that measurement. For rolling-shutter cameras, row-by-row readout creates geometric distortion that must be compensated before triangulation, while an optical bearing ray provides directional bearing but no distance until stereo disparity or active time-of-flight ranging resolves depth. Furthermore, calibration matrices remain valid only within the physical and environmental envelopes under which they were characterized. Latency between exposure and downstream dispatch directly consumes the vehicle's stopping budget. At the drive limit, the first five rows of that budget leave 187.1 mm of the 1.10 m clear distance, a remainder that must still absorb the dispatch-to-admission interval, the jerk-limited stop, and the tracking inset. Whether the machine may drive at that speed is therefore a question this chapter hands forward to section 13.6.2 and section 12.3, which close the budget. Table 12.1 lists every term with the chapter that prices it. Because an embodied system continues to travel while sensor data moves through serialization, transport, neural inference, and planner admission, unmeasured pipeline delays erode physical clearance margins just as severely as spatial measurement error.

Spatial error deducts from that same physical clearance budget. Stereo depth uncertainty scales quadratically with distance under fixed disparity noise, while angular extrinsic misalignment introduces lever-arm errors that widen linearly with range. System designers cannot rely on nominal datasheets or raw model outputs to establish safety bounds. Zero-mean covariance matrices frequently ignore systematic calibration biases, and classification confidences or learned depth logits do not represent calibrated tail probabilities. Establishing a rigorous 99th-percentile clearance inset requires empirical residual quantiles evaluated directly against ground-truth measurements across the operational domain. Perception delivers individual dated, localized, and qualified measurements; integrating these discrete observations into a coherent state estimate that remains reliable between sensor arrivals is the responsibility of spatial memory.

Silent failures present the most severe operational hazards in physical systems, precisely because dropped frames or overt hardware faults trigger immediate system alerts, whereas misdated frames, saturated detectors, or hallucinated traversable paths arrive without raising error flags. To guard against corrupted data, the perception pipeline enforces an explicit observation contract. Downstream consumers inspect and validate the capture timestamp, clock synchronization bound, reference frame, calibration identifier, error model, and hardware health flags before reading payload buffers. Even with rigorous contracts, confirming semantic truth requires corroboration across independent, complementary sensing modalities. Seven relations carry the chapter's quantitative argument, and table 8.6 records what each bounds or decides.

Table 8.6: Key equations of sensor perception: The relations that turn a sensor's timing and geometry into travel and spatial error, and set the clearance a consumer holds, with the place each is derived.

Equation	What it bounds or decides	Derived
$\Delta\mathbf{p} = \int_{t_{\text{capture}_0}}^{t_{\text{capture}_0}+t_{\text{age}}} \mathbf{v}(t)\,dt$	The travel an observation's age costs before any consumer can react; at constant speed, $v\,t_{\text{age}}$ enters the stopping budget	equation 8.5
$t_{\text{age}} = \frac{1}{2}t_{\text{exp}} + t_{\text{readout}} + \cdots + t_{\text{IPC}}$	The capture-to-dispatch age of serialized stages, and which stage dominates it; overlapping stages need a measured interval instead	equation 8.7
$\Delta\mathbf{x}(y) = \mathbf{v}\,y\,t_{\text{row}}$	The along-track shear a rolling shutter records, which must be removed before the estimator spends δ_{loc} on it	equation 8.1
$\lvert\delta Z_c\rvert \approx \frac{Z_c^2}{fb}\lvert\delta d\rvert$	How fast stereo depth error grows with range, and so the range beyond which one standard deviation consumes an allowance	equation 8.8
$C_{\text{inset}} = C_{\text{safe}} + \lVert\epsilon_{\text{spatial}}\rVert_{\text{p99}}$	The clearance a consumer holds so the true obstacle stays outside C_{safe} except with the measured tail probability	equation 8.9
$\Delta\mathbf{p} = \mathbf{v}\,\delta t + \frac{1}{2}\mathbf{a}\,(\delta t)^2$	The position error a misdated observation carries silently, the reason a wrong timestamp is worse than a lost frame	equation 8.11
$k_\epsilon = \lceil (n_{\text{cal}}+1)(1-\epsilon) \rceil$	Which sorted residual sets a clearance inset with coverage $1-\epsilon$, and the fewest residuals that can set one	section 8.6.2

Key Takeaways: Spatial perception and age of information

- **Observation age begins at capture and is paid in travel:** Hardware-latched exposure timestamps, row readout schedules, and bounded clock conversion enable downstream consumers to compute a qualified upper age bound. Every microsecond elapsed from photon arrival to actuator response translates directly into unobserved travel ($d_{\text{blind}} = v \cdot \tau_{\text{delay}}$) deducted from the physical clearance margin.
- **Choose the measurement for the decision:** Photometric appearance, metric range, Doppler radial velocity, high-rate edge transitions, and tactile contact deformation address distinct physical questions. Multi-sensor fusion improves system resilience only when sensor spatial coverage and correlated common-cause failure modes are rigorously qualified.
- **Fix the geometry before interpreting it:** Rolling-shutter readout shears geometric edges under vehicle motion ($\Delta x = v_{\text{base}} \cdot y \cdot t_{\text{row}}$), requiring per-row pose compensation prior to spatial triangulation. Mechanical vibration and thermal cycling also induce extrinsic calibration drift. An extrinsic shift of 0.005 rad at 10 m projects to 50 mm laterally, as large as the entire localization allowance δ_{loc}. Consequently, every calibration record must carry an explicit validity envelope that consumers verify prior to inference.
- **A wrong timestamp is worse than a lost frame:** A dropped frame is an overt failure that triggering systems can handle gracefully, whereas a plausible but misdated frame silently displaces an obstacle's reconstructed position while reporting deceptively narrow uncertainty. Hardware capture timestamps, clock synchronization error bounds, sequence continuity checks, and age validation must always precede payload interpretation.
- **Claimed error must be measured:** Softmax classification confidences and depth-bin logits do not characterize spatial tail risk, and zero-mean covariance matrices fail to capture systematic calibration bias. Bounding collision risk requires empirical residual quantiles evaluated against high-precision ground truth across operational conditions to establish defensible clearance insets.
- **The contract bounds what a consumer can refuse:** The observation contract packages capture epoch, clock conversion bounds, reference frame, calibration identity, error bounds,

and hardware health flags so the planning permission path can reject untrustworthy claims before reading payload data. Even a fully operational sensor can report a clear path that does not exist, and structured observation tokens do not guarantee that downstream policies compensate for transport latency. Establishing semantic truth requires independent cross-modal verification, and spatial memory must synthesize these dated snapshots into a coherent state that persists through occlusion.

Perception supplies the grounded evidence that physical action needs: detected obstacles, identified affordances, and measured range and velocity across complementary modalities. Its output is still a sequence of isolated measurements, each bound to a capture epoch and a sensor frame, and each qualified for the instant it was captured. A qualified measurement states where something was, how old that knowledge is, and how far to trust it. It never states where that thing is now, and when a worker steps behind a rack upright, direct perception falls silent.

The observation contract is where Part III's law, proposal is not permission, first takes physical form. A confident detection does not grant permission to move. The permission path admits motion only on evidence whose age, frame, and error it can check against the clearance that remains, and it refuses everything else before reading the payload. Every later stage in this part inherits that discipline, because each one consumes a dated claim that it did not produce and cannot refresh.

8.11 Historical Perspective and Further Reading

The geometric foundations of computer vision trace back to photogrammetry and geodesy, where surveyors established rigorous mathematical formulations for optical distortion and perspective projection long before digital processors or mobile robots existed. In the late 1980s, Tsai (1987) made accurate geometric calibration feasible on off-the-shelf industrial cameras and lenses by developing computationally efficient two-stage optimization algorithms. A decade later, Zhang (2000) democratized the process by demonstrating that a camera could recover its intrinsic parameters and radial distortion from a planar checkerboard pattern observed at several unconstrained orientations. This formulation transformed camera calibration from an exotic cleanroom procedure into a practical workshop routine. Concurrently, Hartley and Zisserman (2003) codified the multiple-view projective geometry that underpins stereo disparity, epipolar constraints, and triangulation error. As cameras mounted directly onto robotic manipulators, hand-eye calibration techniques (Shiu and Ahmad 1989; Tsai and Lenz 1989) resolved the rigid kinematic transformations relating camera frames to robot end-effectors. Furgale et al. (2013) generalized this problem to continuous-time systems by integrating temporal delay estimation directly into spatial extrinsics, demonstrating that camera-to-inertial sensor time offsets must be estimated as dynamic parameters rather than assumed to be zero. Together, these developments established that sensor calibration is never a static constant retrieved from an assembly drawing, but an evolving state estimate bounded by physical drift, mechanical compliance, and thermal expansion.

Sensor hardware diversified along a parallel trajectory as real-time autonomy demanded richer, faster environmental feedback. The autonomous driving competitions of the mid-2000s established scanning laser rangefinders as the primary metric sensor for navigation in unstructured environments (Thrun et al. 2006). Mechanically spinning multi-beam LiDAR systems delivered direct, dense depth measurements, yet their physical rotation introduced significant motion distortion across individual scan lines, which requires per-point timestamping and motion unwinding as detailed in section 8.4.2. To overcome the bandwidth and latency limits of synchronous frame-based sensing, neuromorphic engineering (Mead 1990) introduced event-based vision sensors featuring independent pixels that emit asynchronous signals only when local log-intensity changes exceed a threshold (Lichtsteiner et al. 2008). Over the subsequent decade, algorithmic frameworks for event cameras (Gallego et al. 2022) revealed their microsecond-level temporal resolution and high dynamic range. The same work exposed their central limitation, complete blindness to static scenes in the absence of relative motion. Operating several high-rate sensors of different types at once required rethinking temporal coordination. Clock synchronization had evolved as a classical problem in distributed computer systems (Lamport 1978), but physical embodiment demanded hardware-level precision. The IEEE 1588 Precision Time Protocol (IEEE 2002, 2020a) addressed this requirement by embedding

hardware timestamping directly into the network physical layer, enabling modern LiDARs, cameras, and compute nodes to align their measurement epochs to a shared master clock that real-time safety monitors can verify.

The third pillar of reliable physical perception is the formal qualification of error. Traditional robotic state estimation frequently assumed Gaussian noise models that systematically underestimated the probability of catastrophic tracking failures in complex environments. Conformal prediction (Vovk et al. 2005) addressed this vulnerability by proving that exchangeable calibration residuals yield distribution-free prediction regions with exact, non-asymptotic coverage guarantees. Angelopoulos and Bates (2023) made these theoretical foundations accessible to systems practitioners, establishing split-conformal methods as practical tools for safety-critical clearance verification. Observation contracts unite these three lineages. Each contract packages recent calibration revisions, formal network synchronization bounds, and empirical residual distributions. Downstream planning controllers and safety monitors can verify these empirical bounds explicitly rather than placing blind trust in raw transducer outputs.

For further reading, six foundational works elaborate on the geometric modeling, hardware timing, and statistical error qualification developed across this chapter:

- Hartley and Zisserman (2003) is the classic reference for projective geometry, epipolar constraints, and triangulation, providing the theoretical basis for the stereo depth uncertainty relations analyzed in section 8.6.
- Szeliski (2022) offers an exhaustive survey of computational image formation, camera calibration, and stereo correspondence from the computer vision perspective, detailing the optical aberrations and sensor transduction phenomena underlying section 8.2.
- Zhang (2000) presents the ubiquitous planar-pattern calibration method, outlining the closed-form solutions and nonlinear refinement procedures that generate the intrinsic calibration records used throughout production pipelines.
- Furgale et al. (2013) demonstrates continuous-time batch state estimation for multi-sensor suites, proving why temporal offsets between cameras and inertial measurement units must be modeled and optimized as explicit unknowns.
- Gallego et al. (2022) provides a thorough review of event-based sensing, tracing hardware architectures from analog pixel circuitry to contemporary tracking and SLAM algorithms while outlining the latency-bandwidth trade-offs relevant to high-speed robotic safety.
- Angelopoulos and Bates (2023) serves as a lucid, practical guide to conformal prediction and distribution-free risk control, clearly articulating the exchangeability conditions that physical distribution shifts such as floor wear, rain, or abrupt lighting changes can compromise in real-world deployment.

What's Next: From sensory photons to spatial memory

How long may a dated measurement keep authorizing motion after the scene that produced it goes out of view? Perception answers only for the instant of capture. When the mobile manipulator pivots past a rack upright, the cross aisle leaves the cameras' view, and a worker can step into the corridor that the last frame recorded as clear. Chapter 9 takes the observation contracts this chapter produced and fuses them, each at its own capture epoch, into a state estimate whose uncertainty grows while no new evidence arrives. That growth sets the deadline after which a remembered empty aisle can no longer support motion, and past that deadline the permission path refuses any proposal that relies on it.

Purpose

How long can a robot act on a remembered scene after it loses sight of it?

A person hidden behind a storage rack can keep moving while the robot's map still shows an empty aisle. Forgetting the person loses a constraint on motion; preserving the last position indefinitely turns old evidence into false certainty. The engineer must estimate the scene from measurements that arrive at different times with different errors, retain that estimate through brief sensing gaps, and limit how long it can support a decision. That limit depends on the motion the sensors cannot observe, the error already present, and the clearance the task can tolerate. A stored estimate must therefore carry both its physical age and the conditions under which its uncertainty remains bounded. The permission path needs that information in time to refuse motion whose evidence has expired. Spatial memory connects sensing to the causal boundary by preserving what an observation supports without extending its authority beyond the physical margin.

Learning Objectives

- Apply a state estimator's predict and update steps to dated measurements, including late ones at their capture epoch, and test whether its reported covariance matches its actual error
- Track objects across frames without withholding occupancy evidence until their identity is confirmed
- Specify a belief record that carries evidence age, uncertainty growth, and consumer query budgets
- Compose transform chains at a common epoch, and trace how localization drift and loop closure move remembered map cells without renewing their evidence
- Select a spatial representation for a clearance query from the query it answers, the memory reads it costs, and the storage it needs
- Design spatial updates that preserve evidence age and distinguish missing observations from verified free space
- Set belief expiry from bounded uncertainty growth and the task's physical tolerance
- Diagnose frozen transforms, phantom tracks, and unobservable drift that pass freshness and innovation checks

9.1 Spatial Belief Persistence and Expiry

On the warehouse mobile manipulator, intermittent observation becomes a hazard at every rack corner. As the robot pivots into a turn, structural uprights occlude the cross aisle from the navigation cameras, and whatever the vision backbone detected seconds earlier survives only in memory. A worker stepping around the corner can enter the corridor that memory still records as clear. Republishing the cached perception frame with a fresh software timestamp cannot replace the missing sensory evidence. The stopping budget assumes obstacles remain within declared clearances, and a person who arrives unseen violates that assumption. The open question is how long the remembered empty aisle may keep authorizing motion after the uprights hide it, and whether any amount of remembering can make the blind crossing safe.

Every physical AI system acts on a world it observes only intermittently. Perception delivers dated, calibrated observations, yet sensor frames arrive tens of milliseconds apart, a rack upright or a gripper finger can occlude a target surface for seconds, and the controller must keep issuing commands throughout those blind intervals. **Spatial memory** carries physical state across these perceptual gaps. In a conventional computing system, a value in memory remains valid indefinitely because external reality does not alter the digital state. In an embodied system, memory retains an exact representation of the past while the physical world continues to move. A cached state becomes stale not because bits decay, but because unobserved reality drifts away from the recorded value. The central operational question of spatial memory is how long a stored state may continue to authorize machine motion. The answer is a physical deadline rather than an arbitrary software timeout, determined by the initial measurement error, the rate at which unobserved dynamics can expand that error, and the clearance margins permitted by the task. Computing and enforcing that deadline requires five capabilities: an estimator that fuses dated measurements into a calibrated state distribution, a memory record that couples every geometric value to its capture epoch and an error-growth law, coordinate transforms and map structures that preserve those timestamps across aggregation, an invalidation mechanism derived directly from the growth model, and an accounting of unobservable environmental drift.

An embodied system cannot operate purely on instantaneous sensor frames, nor can it rely entirely on the implicit context cached inside a learned policy network. Instead, the architecture requires an explicit **belief**: an estimate of physical state projected forward from historical sensory evidence and paired with an explicit model of expanding uncertainty.[1]

↩ Observations dated by capture epoch and carrying calibrated spatial covariances are established in section 8.8.

1 **Belief State**: Åström (1965) showed that a controller that cannot observe its state directly loses nothing by acting on the conditional distribution of that state given everything observed so far, the formalization encountered in section 6.5.1 as a partially observable decision problem. However, an abstract mathematical distribution carries no native reference frame, evidence epoch, or error-growth model. A physical runtime requires all three to verify whether a clearance corridor remains valid during a sensor dropout.

Definition 9.1: Belief state

Belief state is an estimate of a physical quantity carried forward from dated sensor evidence, expressed within an explicit reference frame, accompanied by the evidence epoch t_0 of the most recent constraining measurement and a declared error-growth law $E(\Delta t)$ that models uncertainty expansion in the absence of new data.

1. **Significance**: A belief maps elapsed time into spatial uncertainty. The safety enforcement path permits motion only while $E(\Delta t)$ remains within the task's clearance envelope. Every belief therefore carries an invalidation horizon measured from t_0, beyond which the safety controller must reject any dependent trajectory.
2. **Distinction**: A sensor measurement captures evidence from a single discrete instant. A belief estimates state at later points in time through forward propagation, remaining valid only as long as its growth law accurately bounds physical drift.
3. **Common pitfall**: Mistaking publication recency for evidence freshness. Re-evaluating or republishing a belief updates software message timestamps, but only a new physical sensor measurement advances the evidence epoch t_0.

Spatial memory is the second of four proposal-side stages in Part III, positioned between perception and intent. Because it resides on the untrusted proposal side of the proposal boundary, spatial memory can shape proposed trajectories but cannot certify its own freshness. The permission path must independently evaluate the age of the underlying evidence against a local monotonic clock.

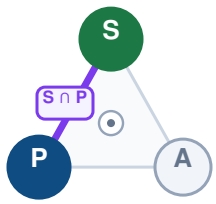
Learned policies maintain internal history through recurrent states or transformer attention buffers, but these mechanisms keep or drop tokens according to a capacity budget rather than physical persistence. A transformer's context window, and the key-value cache that stores it, holds a bounded number of tokens, so older tokens are evicted as new frames arrive (the streaming-window policies of section 9.6.3). When an obstacle steps behind a pallet rack, the tokens that recorded it can fall out of the window while newly observed features take their place, even though that obstacle continues to obstruct the physical corridor. An internal neural context window is therefore an unreliable sole record of physical state. Spatial memory decouples persistence from policy attention, explicitly preserving the entity, its last observed geometry, and an uncertainty volume that expands for as long as it remains occluded.

Externalizing physical state from the neural policy also cleanly decouples downstream consumers with divergent computational constraints. The motion planning policy queries a host-resident scene representation to extract a compact working set tailored to its candidate trajectory. In contrast, an isolated permission controller requires a strictly bounded local safety snapshot stored directly in its local memory to evaluate real-time clearance queries. This snapshot retains the raw evidence epochs, spatial uncertainties, geometric coverage bounds, and validity regions from the underlying beliefs. Replicating state across memory buses does not refresh its physical validity. The safety controller neither requires the complete global map nor waits for host queries to complete before deciding whether an ongoing motion remains admissible.

Internal software consistency does not guarantee physical geometric validity. To prevent an actuator from executing commands based on obsolete assumptions, an embodied memory system must elevate state expiration to an explicit interface event. Every stored belief carries an invalidation horizon, the deadline at which accumulated uncertainty consumes the task's clearance margin (section 9.7.2). When that deadline passes, the belief immediately ceases to authorize motion. The permission path rejects any proposal that relies on the expired state and selects a fallback qualified for the remaining evidence, actuation authority, and clearance, such as a controlled stop.

Every belief and its corresponding invalidation deadline originate in a state estimator. The perception front-end streams discrete, timestamped, coordinate-framed measurements annotated with calibrated sensor covariances. Transforming these intermittent observations into a continuous physical state, backed by uncertainty bounds that faithfully reflect unobserved drift, is the first job of spatial memory.

↩ The proposal boundary, above which learned components may only propose and below which the permission path alone admits commands, is established in section 1.7.



Belief carries sensing across the gap to planning.

9.2 Estimating State from Dated Measurements

A single LiDAR return or stereo match localizes the rack-end upright at one isolated instant. A physical safety permission path, however, requires a continuous range estimate that stays current between sweeps, fuses observations across heterogeneous sensors, and produces an uncertainty metric whose statistical confidence matches physical reality. A recursive **state estimator** satisfies all three demands by alternating two complementary operations: a prediction step that projects the state forward through a dynamic motion model, and an update step that incorporates each newly arrived, dated measurement. The discrete Kalman filter[2] (Rudolph Emil Kalman 1960) provides the classical formulation of this recursion, establishing the mathematical foundation for this chapter (Thrun et al. 2005, ch. 3; Bar-Shalom et al. 2001). Multi-object tracking and delayed-observation handling apply these two steps directly. The belief decay under occlusion examined in section 9.7 corresponds to the prediction step executing without measurement updates, while the observability limits of section 9.8 define the state dimensions that no update stream can reconstruct. The mechanics are clearest on a scalar, the remaining distance s from the mobile base to the rack-end upright, so the two operations are worked through on it before the notation extends to full state vectors.

[2] **Kalman Filter**: Stanley Schmidt's group at NASA Ames took up Kálmán's paper shortly after it appeared and, for circumlunar navigation studies, linearized the nonlinear measurement equations about the current estimate (Smith et al. 1962), the reformulation now called the extended Kalman filter. MIT's Instrumentation Laboratory then carried the filter into Apollo's on-board navigation in a square-root form suited to a computer with a short word length (McGee and Schmidt 1985). The recursion fit that computer because it keeps only the latest estimate and its covariance, never the measurement history, and the same property lets spatial memory hand a consumer one dated record instead of a log to replay.

The **predict** step advances the state estimate across time without incorporating new external evidence. Between two successive LiDAR sweeps separated by T_{nominal} = 50 ms, wheel odometry (section 9.5.1) indicates that the mobile base closed the distance by $v T_{\text{nominal}}$, yielding the prior prediction $\hat{s}^{-} = \hat{s} - v T_{\text{nominal}}$. Odometry, however, carries inherent uncertainty. An illustrative speed disturbance of 0.1 m/s (from minor wheel slip on polished concrete, for example) accumulates 5 mm of standard deviation over that single sweep interval. Because independent errors combine in quadrature, $\sigma_{-}^2 = \sigma^2 + \sigma_w^2$, an initial 20 mm uncertainty expands to 20.6 mm. Without new measurement constraints, prediction inevitably inflates state uncertainty.

The robot's inertial measurement unit (IMU) is the other source of high-rate data for the predict step, and its datasheet shows why dead reckoning cannot sustain an accurate estimate on its own. A sensor's noise density states how much random error it adds per square root of measurement bandwidth, so white noise of density N_{IMU} integrated for T seconds spreads by $N_{\text{IMU}}\sqrt{T}$, while a fixed offset integrates in proportion to T. The Bosch BMI088 gyroscope has a rate-noise density of $0.014\,^{\circ}/\text{s}/\sqrt{\text{Hz}}$ alongside an uncalibrated zero-rate bias of $1\,^{\circ}/\text{s}$. Its accelerometer has a noise density of 160 µg/$\sqrt{\text{Hz}}$ and an uncalibrated zero-g offset of 20 mg (Bosch Sensortec 2024). Integrating these sensor signals accumulates error, and stochastic noise compounds along a different trajectory than deterministic bias. Broadband white noise integrates in variance, causing orientation uncertainty to grow with the square root of time. Across 1 s without external range correction, it accumulates only 0.014°. In contrast, a constant bias integrates linearly, producing heading drift proportional to time that reaches 1° over that same second. At 1.10 m, this angular error projects into 19.2 mm of lateral displacement for the rack upright. Because acceleration undergoes double integration to give position, its bias scales quadratically with elapsed time ($\frac{1}{2} b_a T^2$). The bias generates 98.1 mm of drift after one second, about twice the 50 mm localization allowance. Integrated accelerometer white noise contributes only 0.9 mm (its position variance grows with the cube of time, a law derived in section 9.7). In this illustrative uncalibrated case, sensor offsets dominate broadband noise and limit how long the inertial system can coast uncorrected. Practical estimators therefore augment the state vector to estimate these biases online. This works only while the available measurements and executed motion constrain the relevant bias components (the observability condition of section 9.8). The estimators also use the underlying noise densities to parameterize the process noise, the matrix generalization of the odometry variance σ_w^2 that the general filter below writes as $\mathbf{Q}$. Because these offsets drift with temperature and vary across physical chips, operating parameters must be identified through in-situ stationary calibration on the physical platform rather than taken from static datasheet ratings.

The **update** step incorporates a fresh scalar measurement z characterized by variance σ_z^2. The updated posterior is a linear combination, $\hat{s} = (1-g)\,\hat{s}^{-} + g\,z$. Assuming the prior prediction error and measurement noise remain statistically independent, the posterior variance evaluates to $(1-g)^2\sigma_{-}^2 + g^2\sigma_z^2$. Minimizing this variance with respect to the blending weight g produces

the optimal Kalman gain, which balances each information source inversely against its relative uncertainty:

$$g = \frac{\sigma_-^2}{\sigma_-^2 + \sigma_z^2}, \qquad \hat{s} = \hat{s}^- + g\,(z - \hat{s}^-), \qquad \sigma^2 = (1-g)\,\sigma_-^2$$

The residual $z - \hat{s}^-$ constitutes the **innovation**, the new information supplied by the measurement that the forward projection did not capture. Given the Ouster OS1-64's worst-case datasheet range precision of 30 mm, the computed gain is 0.32. The estimator shifts approximately one-third of the way toward the raw LiDAR reading, contracting the posterior standard deviation to 17.0 mm, a modeled spread tighter than either input alone. Because published precision specifications typically reflect ideal calibration conditions rather than real-time operating modes, this sensor variance must be verified at the configured operational scan rate. Furthermore, the sensor's separate 25 mm systematic accuracy offset represents a structural bias that zero-mean Gaussian models cannot accommodate; offline calibration must eliminate this offset, or the downstream safety clearance margin must absorb it explicitly.

Fusing a second sensor executes as a sequential update step. The illustrative stereo camera rig analyzed in section 8.6 achieves $\sigma_z = 3.8$ mm at the 1.10 m rack-end distance. Fusing this measurement yields a stereo gain of 0.95, shrinking the final fused standard deviation to 3.7 mm. For statistically independent measurements captured at the same physical instant, update ordering is commutative: each observation contributes an information increment, and their underlying precision matrices (inverse variances) sum directly.

A misdated measurement breaks this estimation algebra silently. Suppose a stereo depth observation is tagged with its host arrival timestamp, which section 8.3 shows hides exposure, readout, and transport delay, rather than with its physical exposure epoch. The filter erroneously pairs this observation with a robot pose 39.9 mm further along the aisle than where the photons actually struck the sensor. Consequently, the measured range reads systematically long by that spatial displacement, causing the update to drag the state estimate 38.0 mm away from the physical obstacle while reporting the same deceptively tight 3.7 mm standard deviation. The resulting physical error spans approximately 10.3 reported standard deviations in the hazardous direction, yet the filter's covariance update detects nothing amiss because algebraic variance reduction depends entirely on modeled sensor noise rather than measurement residuals. Corrupt timestamps are therefore far more dangerous than dropped sensor frames. Dropping the stereo frame instead would leave the posterior uncertainty at 17.0 mm, imprecise but statistically honest.

Set side by side on one range-error scale (figure 9.1), the stages read as a single story. Prediction widens the bar from 20 mm to 20.6 mm, each update narrows it below both of its inputs to a final 3.7 mm, and the misdated column reports that same tight spread while its center sits 38.0 mm from the true range, the only bar that does not contain the truth.

The recursion generalizes from a scalar distance to an n-dimensional state vector $\hat{\mathbf{x}}$ with error covariance $\mathbf{P} \in \mathbb{R}^{n \times n}$. It parameterizes system dynamics through a state transition matrix $\mathbf{F}$, process noise covariance $\mathbf{Q}$, an observation matrix $\mathbf{H}$ projecting state space into measurement space, and measurement noise covariance Σ_{meas} (equation 9.1 and equation 9.2):

$$\hat{\mathbf{x}}_{k|k-1} = \mathbf{F}\hat{\mathbf{x}}_{k-1|k-1}, \qquad \mathbf{P}_{k|k-1} = \mathbf{F}\mathbf{P}_{k-1|k-1}\mathbf{F}^\top + \mathbf{Q} \tag{9.1}$$

$$\nu_k = \mathbf{y}_k - \mathbf{H}\hat{\mathbf{x}}_{k|k-1}, \quad \mathbf{S}_k = \mathbf{H}\mathbf{P}_{k|k-1}\mathbf{H}^\top + \Sigma_{\text{meas}}, \quad \mathbf{G}_k = \mathbf{P}_{k|k-1}\mathbf{H}^\top\mathbf{S}_k^{-1}, \quad \hat{\mathbf{x}}_{k|k} = \hat{\mathbf{x}}_{k|k-1} + \mathbf{G}_k\nu_k, \quad \mathbf{P}_{k|k} = (\mathbf{I} - \mathbf{G}_k\mathbf{H})\,\mathbf{P}_{k|k-1} \tag{9.2}$$

In this formulation, ν_k represents the innovation vector, $\mathbf{S}_k$ denotes innovation covariance, and $\mathbf{G}_k$ signifies the Kalman gain matrix (designated $\mathbf{G}_k$ to reserve $\mathbf{K}$ for camera intrinsic calibration matrices). The preceding scalar analysis corresponds to the degenerate setting $\mathbf{F} = \mathbf{H} = 1$, with the odometry displacement $-v\,T_{\text{nominal}}$ entering as a known control input. Equation 9.1 omits that input term for brevity, and the term shifts the mean without changing $\mathbf{P}$. Under linear dynamics and additive Gaussian noise, this closed-form update yields the provably optimal minimum-variance unbiased estimate. If nonlinearities or non-Gaussian noise corrupt the process, the update functions merely as an empirical linear estimator whose output covariance requires experimental validation.

Physical robotic sensors are inherently nonlinear functions of platform state. A LiDAR range measurement to the rack upright evaluates to $r = \|\mathbf{p}_{\text{upright}} - \mathbf{p}_{\text{base}}\|$, while a camera records target

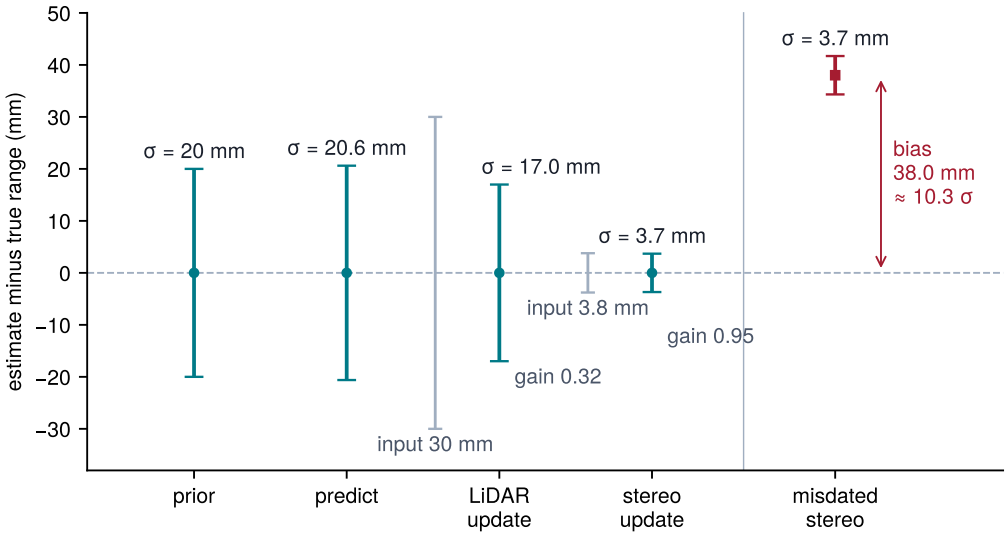


Figure 9.1: Predict and update on the rack-end range: Each bar spans one standard deviation of the range estimate. Prediction widens the bar from 20 mm to 20.6 mm; the LiDAR update (gain 0.32) and the stereo update (gain 0.95) each narrow it below both of their inputs, whose own spreads appear as gray bars. The misdated stereo update on the right reports the same 3.7 mm spread while sitting 38.0 mm from the true range, which the variance alone cannot reveal.

bearings through the nonlinear pinhole projection detailed in equation 8.2. The **extended Kalman filter (EKF)** (Smith et al. 1962) adapts equation 9.2 to nonlinear regimes by evaluating the measurement function $h(\hat{\mathbf{x}}_{k|k-1})$ directly and substituting the linear projection $\mathbf{H}$ with the measurement Jacobian $\nabla_{\mathbf{x}} h$ evaluated at the current state prediction. For a scalar range reading, this Jacobian with respect to platform base position reduces to the unit line-of-sight vector directed from the upright toward the base. This Taylor-series linearization is a first-order approximation. Substantial curvature across the prior distribution, common when estimating bearings to nearby obstacles or operating under broad initial uncertainty, can therefore cause the EKF to underestimate its true estimation error (Julier and Uhlmann 2004). This failure mode makes the empirical consistency evaluations of section 9.2.1 safety requirements rather than optional checks.

The **unscented Kalman filter (UKF)** developed by Julier and Uhlmann (1997) bypasses analytical Jacobians through deterministic sampling. For an n-dimensional state vector, the UKF instantiates $2n+1$ sigma points structured around the matrix square root of $\mathbf{P}$, propagates each sample point through the true nonlinear observation function, and reconstructs the transformed posterior mean and covariance (Julier and Uhlmann 2004). This transformation captures higher-order curvature effects on the mean that the EKF truncates, requiring $2n+1$ functional evaluations per cycle. The UKF nevertheless approximates the posterior as a unimodal Gaussian, leaving it subject to identical qualification and consistency standards.

Both filtering frameworks, and the multi-object tracking and out-of-sequence replay built on them, depend on every sensor measurement being indexed by its true capture epoch. The misdated stereo benchmark illustrates the breakdown when this assumption fails. While reported uncertainty remained artificially compressed, true physical error drifted across ten standard deviations. A reported covariance is therefore an engineering hypothesis that must be systematically validated against real-world data.

9.2.1 Testing whether the covariance is honest

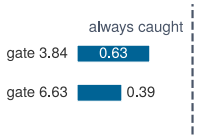
Catching an overconfident covariance like the misdated stereo filter's requires two complementary statistical tests: an offline qualification metric evaluated against ground truth before deployment, and an online runtime monitor evaluated directly against incoming measurement streams during operation. Both formulations use a zero-mean Gaussian error model with the correct nonsingular covariance. Whitening the error under these assumptions produces independent standard normal

coordinates; their squared norm, rather than the error vector itself, follows a chi-squared distribution. Matching covariance alone does not establish Gaussian tails.

A filter achieves statistical consistency when its reported covariance matches the dispersion of its actual state errors. When offline ground truth is accessible (a laser-tracker survey of the rack upright, say, with an optical motion-capture reference for the base pose), the normalized estimation error squared (NEES), $\epsilon_k = (\mathbf{x}_k - \hat{\mathbf{x}}_k)^\top \mathbf{P}_k^{-1} (\mathbf{x}_k - \hat{\mathbf{x}}_k)$, evaluates the system. Under that zero-mean Gaussian model with the correct nonsingular covariance, whitening the error of an n-dimensional state forms a vector of n independent standard normal variates. Their sum of squares follows a chi-squared distribution with n degrees of freedom and theoretical mean n. Evaluated across N statistically independent experimental trials, the scaled sample mean $N\bar{\epsilon}$ follows a chi-squared distribution with Nn degrees of freedom (Bar-Shalom et al. 2001). For the scalar rack-end distance over 50 experimental trials, the two-sided 95 percent acceptance interval for sample mean NEES $\bar{\epsilon}$ spans from 0.65 to 1.43. An empirical NEES above this band flags an overconfident filter, the safety-critical defect, because its reported uncertainty understates the error that clearance buffers must absorb. Conversely, an average falling below the lower bound indicates an underconfident filter whose inflated covariance unnecessarily throttles vehicle operating speed.

While absolute ground truth remains unavailable during live deployment, the estimator can continuously audit its measurement innovations. The normalized innovation squared (NIS), $\nu_k^\top \mathbf{S}_k^{-1} \nu_k$, follows a chi-squared distribution with m degrees of freedom for an m-dimensional measurement vector under valid model assumptions, so its expected value is m. The same statistic reappears below as the data-association gate. A bias b in the innovation adds b^2/S to that expectation, where S is the innovation variance. For the misdated stereo observation in figure 9.1, b is the 39.9 mm arrival-stamp travel, and the expected NIS rises from 1 to 6.25. A single misdated update's NIS then follows a noncentral chi-squared distribution, the bias setting its offset and the sensor noise its spread. One update therefore breaches the 95 percent validation gate of 3.84 with probability 0.63, and trips the 99 percent threshold of 6.63 only 0.39 of the time. Single-frame residual gating therefore admits a substantial fraction of corrupted measurements. Averaging independent innovations reduces sampling variation and can expose a persistent residual bias. For 50 independent scalar innovations under the valid model, the mean NIS has the same 0.65 to 1.43 acceptance band derived above for NEES. Independent repetitions of the worked misdated update average near 6.25, far above it. A sequential filter can instead absorb a systematic dating error into its state, reducing later innovations; correlated innovations also invalidate this nominal band. A runtime sliding-window NIS supervisor therefore detects dating errors that persist in the innovations, but cannot replace capture-epoch validation. Once an estimator's covariance and innovations are calibrated on a single landmark, the next challenge is maintaining separate filters across multiple moving objects without confusing their identities.

9.2.2 Multi-object tracking and data association



A per-update gate catches one misdated update only 0.63 or 0.39 of the time.

Maintaining separate filters across multiple moving objects adds an immediate architectural constraint: a perception pipeline cannot withhold an obstacle detection until a multi-frame tracker confirms its persistent identity, or a worker stepping into the aisle remains invisible to collision avoidance during the confirmation window. A fresh occupied-region claim must therefore constrain vehicle motion immediately, before perception systems identify the specific obstacle class or confirm a track. Persistent identity serves a distinct behavioral objective: correlating detections across frames allows the motion planner to estimate target velocity vectors and anticipate dynamic crossing events, while immediate spatial occupancy protects reactive clearance.

The software architecture therefore decouples immediate geometric spatial occupancy from the **tracking-by-detection** hypothesis. The tracking layer associates incoming detections, filters kinematic velocities, and tracks multi-dimensional uncertainty. Track retirement follows the lifecycle below, and how state persists when measurements stop is the subject of section 9.7. The state equations formulated below govern the kinematic information a confirmed track provides, rather than serving as a prerequisite for reactive collision avoidance.

Each active track i maintains an independent state filter tracking a kinematic state vector $\hat{\mathbf{x}}_t = [\hat{\mathbf{p}}_t^\top, \hat{\mathbf{v}}_t^\top]^\top$ with error covariance $\mathbf{P}_t \in \mathbb{R}^{6\times6}$. A discrete constant-velocity transition matrix $\mathbf{F}$ and process noise covariance $\mathbf{Q}$ advance this state between sensory frames through the prediction step

of equation 9.1, which carries the mean forward and grows the covariance by the process noise. When an incoming perception frame yields n_{det} candidate detections $\{\mathbf{y}_{t,j}\}_{j=1}^{n_{\text{det}}}$ (the frame index t plays the role of the step index k in equation 9.1), the tracker must resolve **data association**,[3] mapping candidate detections to established state tracks. To prevent spurious sensor noise or distant clutter from corrupting legitimate tracks, the tracker evaluates the squared Mahalanobis distance d_M^2 between detection $\mathbf{y}_{t,j}$ and the projected measurement $\mathbf{H}\hat{\mathbf{x}}_{t|t-1}$:

$$d_M^2 = (\mathbf{y}_{t,j} - \mathbf{H}\hat{\mathbf{x}}_{t|t-1})^\top \mathbf{S}_{ij}^{-1} (\mathbf{y}_{t,j} - \mathbf{H}\hat{\mathbf{x}}_{t|t-1}) \tag{9.3}$$

where $\mathbf{S}_{ij} = \mathbf{H}\mathbf{P}_{t|t-1}\mathbf{H}^\top + \Sigma_{\text{meas},j}$ defines the innovation covariance from equation 9.2 and $\Sigma_{\text{meas},j}$ specifies the measurement noise covariance; this validation metric is identical to the NIS metric defined in section 9.2.1. An ellipsoidal **validation gate** evaluates equation 9.3, rejecting any pairing where $d_M^2 > \gamma_{\text{gate}}$. The gating threshold $\chi_3^2(1-\alpha_{\text{sig}})$ possesses three degrees of freedom corresponding to three-dimensional Cartesian position measurements, retaining its theoretical significance only while residual Gaussian assumptions hold. For all candidate pairings satisfying the gate, the tracker builds an assignment cost matrix with entries $c_{ij} = d_M^2$ and computes the global minimum-cost one-to-one match. It uses either the Hungarian algorithm (Kuhn 1955), as the Simple Online and Realtime Tracking (SORT) baseline does (Bewley et al. 2016), or the Jonker-Volgenant shortest-augmenting-path solver (Jonker and Volgenant 1987). The match is optimal only for the costs it was given; it does not guarantee that each pairing is physically correct.

[3] **Data Association in Clutter**: Radar tracking met this problem first. Bar-Shalom and Tse (1975) showed that a filter which commits to the single nearest return inside its gate can follow clutter and lose the target, and they weighted every gated return by its probability of having come from the target instead. A tracker that commits to one assignment per frame, as this one does, reveals a wrong pairing only through inconsistent innovations, so a confirmed track's covariance must still pass the tests of section 9.2.1.

The tracking lifecycle organizes target hypotheses through three discrete states:

1. **Tentative state**: Unassociated detections instantiate tentative candidate tracks. Because sensor artifacts (specular reflections, dust particles, optical lens flare) generate transient false positives, candidate identities remain tentative until satisfying an M-of-N_{conf} frame confirmation policy (associated in at least M of the last N_{conf} frames). Raw geometric occupancy claims remain immediately accessible to vehicle collision-avoidance buffers throughout this confirmation window. If a downstream behavioral planner requires confirmed object identity or calibrated velocity, its latency allocation must account for this multi-frame confirmation interval rather than relying solely on the single-frame pipeline latency described in section 8.4.1.
2. **Confirmed state**: Upon passing confirmation criteria, the track registers as confirmed and publishes its complete kinematic state $(\text{ID}_i, \hat{\mathbf{p}}_i, \hat{\mathbf{v}}_i, \mathbf{P}_i)$ to planning and safety subsystems. Each newly associated measurement refines the track via equation 9.2, correcting the mean vector and contracting the error covariance matrix. Because this update achieves minimum variance only under linear-Gaussian assumptions, tracked covariances must continuously satisfy the consistency criteria established in section 9.2.1.
3. **Coasting state (occlusion)**: When an obstacle moves behind storage shelving or suffers transient occlusion by another vehicle, object detection fails. Rather than immediately dropping the entity, the tracker transitions the hypothesis into an unobserved coasting state. During coasting, state propagation proceeds strictly through kinematic motion model $\mathbf{F}$ in equation 9.1, while process noise $\mathbf{Q}$ progressively inflates state covariance in the absence of measurement constraints. Downstream path planners must compensate for this increasing uncertainty by applying progressively widening clearance margins. If no matching observation associates within timeout window T_{lost}, the active track terminates. Terminating a track reflects the loss of persistent identity rather than the clearance of physical space, so the spatial map must retain an appropriate unknown-space constraint (section 9.6). The rate at which coasting uncertainty degrades spatial traversability is the belief expiry problem formulated in section 9.7.

To support real-time planning under motion uncertainty, the tracker continuously serializes an auditable **dynamic track manifest** $[(\text{ID}_k, \hat{\mathbf{p}}_k, \hat{\mathbf{v}}_k, \mathbf{P}_k, t_{\text{last}}, \text{state})]$. The intent layer consumes these velocity vectors and covariance ellipses to bound the region each object could occupy over the planning horizon, while real-time safety enforcement systems compute certified stopping clearances against moving dynamic obstacles. Even when a detection associates cleanly with the right track, however, vision inference delay means that camera detections routinely arrive after newer LiDAR sweeps and IMU samples have already advanced the filter.

↪ The track manifest's velocities and covariances are developed as forward occupancy sets in section 10.6.1.

9.2.3 Applying a delayed observation

Fusing such a delayed visual detection directly into the estimator's current state pulls the position estimate backward toward where the obstacle stood at exposure time and corrupts the velocity vector. The physical capture epoch preserved by the observation contract enables the estimator to integrate these delayed measurements at their historical capture instant instead, provided the system maintains a calibrated state history and dynamic motion model. Rolling the filter back to that capture instant applies the update of equation 9.2 to the historical state estimate $\hat{\mathbf{x}}$, error covariance $\mathbf{P}$, observation model $\mathbf{H}$, and Kalman gain $\mathbf{G}_k$.

A delayed visual observation must correct the state at its true historical capture epoch before the estimator can project the correction forward to current wall-clock time. Robust systems implement this mechanism using an **out-of-sequence ring buffer**, a circular array whose slot k holds the prediction $\hat{\mathbf{x}}_{k|k-1}$ and covariance $\mathbf{P}_{k|k-1}$ for IMU sample k, the IMU input $\mathbf{u}_k$ that drove it, and that sample's capture time. The buffer needs $N_{\text{buffer}} = \lceil T_{\text{buffer}}/\Delta t_{\text{IMU}} \rceil$ slots, where Δt_{IMU} is the IMU sample period and the buffer horizon T_{buffer} is the oldest observation age the estimator will still accept. On the running machine, the IMU samples at 1 kHz ($\Delta t_{\text{IMU}} = 1$ ms), so covering the navigation camera's 51.6 ms observation age takes 52 slots. A consumer must either interpolate the buffered state to the observation's actual capture time or charge the bounded nearest-sample timing discrepancy to the error model. In the equations below, subscripts index IMU samples; t_0 and t_{recv} name the samples whose capture times are nearest the observation's capture epoch and its receipt. When an out-of-sequence observation $\mathbf{y}_{t_0}$ arrives at receipt sample t_{recv}, the estimator rolls back to sample t_0, retrieves the historical prediction $\hat{\mathbf{x}}_{t_0|t_0-1}$, computes the corresponding innovation and Kalman gain, and applies the update of equation 9.2 at that historical instant (equation 9.4):

$$\hat{\mathbf{x}}_{t_0|t_0} = \hat{\mathbf{x}}_{t_0|t_0-1} + \mathbf{G}_{t_0}(\mathbf{y}_{t_0} - \mathbf{H}_{t_0}\hat{\mathbf{x}}_{t_0|t_0-1}), \quad \mathbf{P}_{t_0|t_0} = (\mathbf{I} - \mathbf{G}_{t_0}\mathbf{H}_{t_0})\mathbf{P}_{t_0|t_0-1} \tag{9.4}$$

For the forward propagation pass that follows, consider first the baseline case with no intervening updates from other sensors; in general configurations, any intervening sensor updates within the interval must be sequentially re-applied in timestamp order. Because nonlinear motion models and their linearized transition matrices $\mathbf{F}_k$ depend on the state trajectory itself, the estimator cannot simply add the historical state shift to the current estimate, and instead executes a rapid replay sweep, re-integrating the buffered IMU inputs $\mathbf{u}_k$ from sample t_0 to sample t_{recv} through the continuous motion model $\mathbf{f}(\mathbf{x}, \mathbf{u})$, the state's rate of change under input $\mathbf{u}$, using the corrected state $\hat{\mathbf{x}}_{t_0|t_0}$ as its initial condition. This forward integration synchronizes current state estimate $\hat{\mathbf{x}}_{t_{\text{recv}}}$ with the newly arrived observation without introducing non-causal state discontinuities (equation 9.5):

$$\hat{\mathbf{x}}_{t_{\text{recv}}} = \hat{\mathbf{x}}_{t_0|t_0} + \sum_{k=t_0}^{t_{\text{recv}}-1} \mathbf{f}(\hat{\mathbf{x}}_k, \mathbf{u}_k)\Delta t_{\text{IMU}} \tag{9.5}$$

with covariance propagation across the replay interval governed by unrolling the single-step covariance recursion of equation 9.1 through the discrete transition matrix product $\Phi(t_{\text{recv}}, t_0) = \prod_{k=t_0}^{t_{\text{recv}}-1} \mathbf{F}_k$ to carry the newly contracted historical covariance $\mathbf{P}_{t_0|t_0}$ and each intermediate process-noise increment forward:

$$\mathbf{P}_{t_{\text{recv}}} = \Phi(t_{\text{recv}}, t_0)\mathbf{P}_{t_0|t_0}\Phi^\top(t_{\text{recv}}, t_0) + \sum_{k=t_0}^{t_{\text{recv}}-1} \Phi(t_{\text{recv}}, k+1)\mathbf{Q}_k\Phi^\top(t_{\text{recv}}, k+1) \tag{9.6}$$

The applicability of this rewind-and-replay routine (equation 9.6) is strictly limited by ring buffer horizon T_{buffer}. If scheduling jitter or memory bus contention delays an observation such that $t_{\text{age}} > T_{\text{buffer}}$, the circular buffer has already overwritten the slot for sample t_0. In this scenario, the estimator must reject the stale measurement, permit process noise covariance $\mathbf{Q}$ to grow the predictive covariance $\mathbf{P}$, and immediately notify downstream safety paths that external visual grounding has degraded.

End-to-end vision-language-action (VLA) policies confront this identical out-of-sequence dilemma when ingesting asynchronous visual frames without an explicit state-space ring buffer. The observation tokenizer developed in section 8.8 pairs each sensory token with its elapsed time since capture, leaving formal validation of the estimate and action-permission gating to dedicated safety monitors.

Checkpoint 9.1: The estimator behind every belief

Every belief the rest of the chapter ages is the output of this estimator. These items test whether you can run it and whether you can tell when its reported uncertainty is honest.

- ☐ **Predict vs. update**: In the worked scalar drift model, can you explain why a prediction step widens the reported variance, while an independent measurement update narrows it below both the prediction and the measurement?
- ☐ **Gain estimate**: If the stereo range's standard deviation doubled from 3.8 mm, with the LiDAR-updated 17.0 mm prior unchanged, what would the stereo gain and the fused standard deviation be, and which sensor would then dominate the fused estimate?
- ☐ **Estimator consistency**: Can you explain why a misdated update leaves the reported variance unchanged, when averaging independent innovations can expose a dating error that a per-update gate misses, and why this monitor cannot replace capture-epoch validation?
- ☐ **Occupancy vs. identity**: Can you explain why a tentative track's occupied region must reach clearance consumers before confirmation, and what a decision that needs confirmed velocity must add to its detection delay?
- ☐ **Late measurements**: Can you explain what the estimator must do with a measurement whose age exceeds its ring buffer's horizon, and why?

The state estimator outputs the core data record that persistent spatial memory maintains: a kinematic state vector, its verified covariance, the physical instant the state describes, and the capture epochs of the raw sensor observations that last constrained it. Forward prediction and rewind-replay passes maintain temporal currency across execution cycles, but only external sensor measurements inject genuine physical evidence, and neither mathematical projection advances the underlying evidence timestamps. Because downstream consumers must independently audit when a stored belief expires once an obstacle slips into occlusion, this state record must carry explicit temporal provenance alongside its numerical estimates. The handoff challenge is defining the exact contract a downstream consumer requires to evaluate stored spatial beliefs when direct line of sight is lost.

9.3 The Spatial Memory Handoff and State Invariants

A position vector arriving over an inter-process communication bus cannot identify the entity, physical quantity, or units it describes. The same sequence of floating-point values could denote a workpiece center in meters, a joint angle in radians, or a contact force in newtons. A consumer requires these distinctions before executing a control law; a confusion between meters and millimeters alone scales the interpreted displacement by a factor of one thousand. The belief record therefore explicitly packages entity identity, physical quantity, and measurement units at its foundation, rather than relying on conventions hidden in the producing model or transport wrapper.

Specifying the quantity and units remains incomplete without binding the value to a concrete reference frame. Identical spatial coordinates describe entirely different physical realities depending on the origin and orientation of the coordinate system. A Cartesian position $[0.142, -0.051, 0.812]$ m read in the robot base frame names a point about 0.8 m above the chassis origin, in open air over the base. Read in the tool flange frame, the same three numbers name a point 0.812 m out along the flange's approach axis, wherever the arm happens to point; with the gripper aimed at the cage door, that point lies inside the door rather than above the chassis. Because kinematic links flex, joints move, and coordinate transforms update at varying rates across distributed nodes, a belief record must carry an explicit frame identifier. Attaching the frame allows the receiving node to query the spatial transformation tree and project the stored geometry into the local frame required by the actuator, preventing the controller from acting on geometric misalignments caused by moving kinematic chains.

Geometry and identity describe physical state at a single moment, but spatial memory must also capture the temporal anchor of that state. The record carries the evidence epoch t_0 of the physical interaction or optical exposure that last constrained the estimate, the instant at which a

sensor transduced the evidence. In distributed machine architectures, intermediate nodes often republish data, execute Kalman filter prediction steps, or run forward kinematic propagations to maintain high-rate control streams; none of these computational steps adds physical evidence. Republishing and prediction must preserve the evidence epoch; a measurement update may renew only the components it physically constrains. Consumers therefore measure evidence age against the physical world rather than the scheduling frequency of the local computer.

At the boundary of the multi-sensor state estimator (section 9.2), downstream consumers do not need to rerun the filter recursion or repeat the consistency tests of section 9.2.1; they need only the resulting state, its justified error model, and the physical evidence that constrains each relevant component. Within that recursion, a prediction step advances the estimate epoch, the instant the propagated state describes (formalized in section 9.4), while its underlying physical evidence continues aging. A fresh measurement, by contrast, renews only the state dimensions it directly constrains. The spatial memory handoff therefore obliges the producer to expose bounded growth through occlusion and withdraw claims whose operating assumptions no longer hold.

Knowing the evidence epoch t_0 establishes elapsed time $\Delta t = t - t_0$, but elapsed time alone cannot determine whether a belief is valid for a given action. Two estimates of identical age diverge at different rates depending on physical constraints. A warehouse rack end bolted to the floor maintains a stationary position; its remembered boundary can remain useful while the machine's localization bound and the fixed-rack premise hold. In contrast, an occluded person hidden behind that rack can move at walking speed and close the narrow gap beside it before the next camera frame arrives.

The minimum record fields necessary for a consumer to evaluate a stored state can be derived directly from the requirement to bound current error. Let $E(\Delta t)$ represent the upper bound of the discrepancy between the stored value and true physical state after an elapsed time $\Delta t = t - t_0$. If an estimator establishes a state at time t_0 with an initial uncertainty bound e_0, and external disturbances or unmodeled velocities cause the true state to diverge at a maximum rate r, the upper bound on error at current time t obeys the linear expansion $E(\Delta t) = e_0 + r\,\Delta t$. At the rack end, the stored spatial claim asserts that no person stands near the machine. Here e_0 is the machine's localization error, r is the walking speed at which an occluded person can advance toward the vehicle, and the safety tolerance is the depth of observed free space beyond the machine's clearance envelope. Other disturbances grow error faster. A bounded unmodeled acceleration adds a quadratic term, and random acceleration noise, integrated twice, makes position variance grow with the cube of elapsed time, both derived in section 9.7. Omitting the initial bound or the dynamic growth terms leaves the consumer unable to compute $E(\Delta t)$, making an initial bound and an explicit expansion model structurally required fields of the record.

Expressing uncertainty through physical bounds and expansion rates distinguishes a physical AI belief from a probabilistic confidence score. An object detection network might output a class confidence of 0.94, but that softmax score is not calibrated evidence (section 3.6.2), and a downstream position controller cannot convert a unitless probability into a safe actuator displacement margin (that is, how far the arm can physically move before risking a collision). A confidence score of 0.94 provides no information about whether an obstacle boundary is uncertain by 2.0 mm or by 200 mm, nor does it indicate how rapidly that boundary uncertainty grows when occlusion occurs. A physical memory record must express its initial bound e_0 and expansion rate r in concrete physical dimensions such as meters, radians, or newtons per second. These rates are valid only within a declared validity region, such as a maximum assumed acceleration or a verified contact friction coefficient. If physical operating conditions leave that region, the expansion rate no longer holds, and the belief record must be treated as invalid.

At the spring-latched cage door, the gripper finger must enter a narrow latch-release slot that the finger itself hides from the wrist camera during the final approach. Before relying on the remembered slot pose, the consumer compares the belief's current error with the slot clearance. It converts the evidence epoch into its own clock domain, includes the clock-conversion bound, and evaluates the declared growth law at the time the state will be used. This check is a continuing obligation during execution, not a one-time path-generation check. A new motion proposal whose evidence fails the check is refused without automatically revoking a still-valid active command. If the active motion itself depends on expiring evidence, the controller must begin a feasible fallback maneuver

early enough that the mechanism halts within the available clearance. The machine must therefore remain inside its recoverable set, the states from which a qualified stop still fits within the remaining clearance, a boundary that section 12.3 derives from the finished stopping budget. The belief's expiry is a limit on supported motion, not a promise that an instantaneous stop is physically possible at that deadline.

The fields a consumer needs for this check travel together as the **belief record**, the seventh record in the record chain. At this stage, the record binds an identified physical quantity, with its unit, to a reference frame, an evidence epoch, an initial error bound, an uncertainty-growth law, and the validity region in which that law holds. The sections that follow add the fields each new problem demands (the estimate epoch and clock-conversion bound, a per-consumer query-work limit, the expiry deadline, provenance, and lifecycle status), and section 9.10 assembles the complete record. A classification score, a map publication time, or a transform value alone cannot supply that contract, because none couples physical units and evidence age to an error-growth law. The record makes the claims checkable; qualification must establish that they hold. A consumer cannot wait for an upstream publisher to announce expiry. If that publisher's thread hangs or its message stream stops, the consumer must still age the evidence autonomously and enforce its own safety deadline.

Evaluating the belief record depends on calculating the elapsed time $\Delta t = t_{\text{now}} - t_0$ against physical reality. If the consumer cannot verify the exact physical instant when energy transduction occurred, the calculated error bound $E(\Delta t)$ becomes an unanchored fiction, mistaking software compute cycles for physical evidence. Protecting that anchor is the job of the next two fields, the estimate epoch and the clock-conversion bound.

9.4 State Epochs and Temporal Anchoring

A bounding box or 3D Gaussian pose emitted by a neural object detector describes where an entity was when photons struck the camera CMOS sensor, not where it is when the inference tensor arrives in memory. Every spatial claim refers to a specific physical instant, its **epoch**, and any state crossing a physical AI pipeline carries three distinct epochs before an actuator can fire. The **acquisition epoch** (t_{acq}) anchors the observation contract to physical ground truth: the exposure midpoint for a camera frame, or the precise instant a hardware register latches an optical encoder count. Every observation carries its own acquisition epoch (the capture epoch of section 8.3). For each state component used by a consumer, the evidence epoch is the latest acquisition epoch of a measurement that constrained that component; for a belief built from one observation, the two coincide. A record combining differently constrained components must preserve those epochs separately, or use a conservative shared epoch and growth bound that supports every component the query needs. The rest of the chapter speaks of the evidence epoch whenever the belief, not a single observation, is meant. Downstream processing then introduces two subsequent epochs. The **estimate epoch** (t_{est}) marks the physical instant that the estimated state describes. A kinematic predictor or state observer can advance this temporal coordinate beyond the last observation without receiving fresh measurements; the instant computation completes is a separate scheduling detail. The **publication epoch** (t_{pub}) marks the instant the serialized state record is committed to the transport bus or shared-memory ring buffer for dispatch to downstream consumers.

↩ The hardware capture stamp this anti-pattern discards is established in section 8.3.

Collapsing these three timestamps into a single receipt or transmission timestamp destroys the physical anchor. This is the publish-timestamp anti-pattern of section 2.2, in which a wrapper stamps its output with the system wall clock after exposure, transport, inference, and postprocessing have already elapsed. What memory adds is a second way to commit it. A wrapper that stamps a propagated estimate with its publication epoch, or a filter that renews t_0 when it advances t_{est}, hides the evidence age just as surely as one that stamps a raw frame on arrival. Downstream receivers then ingest a message that appears freshly minted but wraps stale evidence. The age-as-displacement relation established in section 8.4 governs this entire pipeline. While publication epochs help diagnose pipeline latency and transport jitter, only the acquisition epoch enables a motion controller to compensate for physical movement that occurred while data were in flight.

Even when a system faithfully records acquisition epochs, physical AI architectures rely on distributed processing nodes whose local oscillator clocks drift independently. Connecting to a shared bus does not synchronize these time bases; the deployed clock-conversion protocol must establish an explicit error bound under realistic network loads and fault conditions.[4] That temporal

[4] **Clock Synchronization Bound**: Controller Area Network with Flexible Data-Rate (CAN FD) bit-phase synchronization aligns bit sampling within one frame; it does not align the distributed clocks that date physical observations. Precision Time Protocol and EtherCAT Distributed Clocks provide synchronization mechanisms, but their names alone do not establish the deployed error bound, which only a measurement under the stated load and fault conditions supplies.

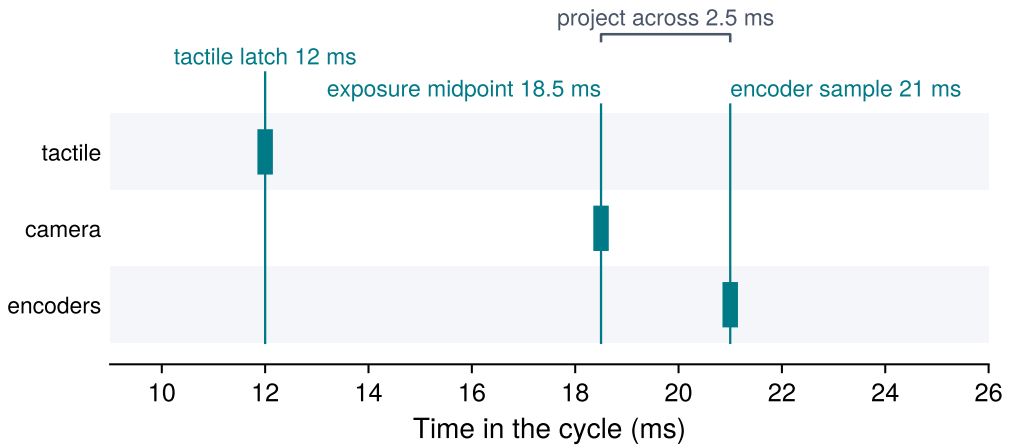


Figure 9.2: Three evidence epochs in one cycle: The tactile array, the camera's exposure midpoint, and the joint encoders each date their evidence on one clock, at 12 ms, 18.5 ms, and 21 ms in this illustrative cycle. A fused state dated to the encoder epoch must carry the camera's evidence across the 2.5 ms gap with a kinematic model and a bounded velocity; packing the three readings into one token sequence records none of these epochs.

uncertainty directly converts to spatial uncertainty scaled by the relative speed of the observed entity. The observation contract defined in section 8.8 carries this bound as its clock-conversion error, and any spatial belief derived from that observation preserves it. Every consumer adds the synchronization bound to the elapsed evidence age before judging freshness, incorporating the resulting positional uncertainty alongside sensor resolution limits and structural deflection. The permission path therefore treats this clock-synchronization uncertainty ϵ_{sync} as an irreducible temporal margin, expanding the required clearance by $d_{\text{sync}} = v_{\text{rel}}\epsilon_{\text{sync}}$ before granting motor torque authorization. With the observation contract's illustrative 0.2 ms bound and the base at its 1.5 m/s drive limit, that term is 0.3 mm, small beside the 50 mm localization bound but never zero. The bound matters most where it is loosest, on a link whose synchronization has not been measured under load.

Physical systems routinely combine asynchronously acquired signals, even when hardware triggers synchronize subsets of sensors. In an illustrative asynchronous cycle, a tactile array might latch normal force readings at $t_1 = 12$ ms, an optical tracking camera might have its exposure midpoint at $t_2 = 18.5$ ms, and joint optical encoders might sample angular positions at $t_3 = 21$ ms. These observations occur at different epochs and cannot be combined through direct tensor concatenation or naive algebraic operations. Multimodal foundation models and vision-language-action (VLA) backbones frequently pack visual patch tokens, proprioceptive vectors, and tactile embeddings into a single sequence under the implicit assumption that all tokens capture a simultaneous physical snapshot. However, nothing in that token serialization records that the camera frame came from t_2 and the encoder reading from t_3. As a result, representations inferred from unaligned inputs carry unquantified temporal mismatch errors. Fusing a camera observation at t_2 with an encoder observation at t_3 requires the consumer to project one state across the temporal gap $\Delta t = |t_3 - t_2| = 2.5$ ms. The projection uses explicit kinematic models and bounded velocities (for example, propagating the historical camera observation along the joint velocity vector to reconcile it with the instantaneous encoder reading). The gap is small in time but not in space; at the arm's 1.7 m/s Cartesian speed limit, the tool moves 4.25 mm in 2.5 ms, a millimeter-scale error that a fine insertion cannot absorb. Without the true acquisition epoch for each individual signal, the alignment calculation cannot determine the sign or magnitude of Δt, leaving uncorrected temporal offsets to compound geometric errors across every inference cycle. Placed on one shared timeline (figure 9.2), the three epochs fall at distinct instants, and the camera evidence must be carried across the 2.5 ms gap before it can be fused with the encoder state.

Equipped with these explicit epochs and the clock-synchronization bound carried in the record of section 9.3, downstream consumers can evaluate the elapsed duration between the evidence epoch and the execution deadline. They can then compute the worst-case expansion of the spatial error bound, and verify whether the state remains within task tolerances. Omitting the acquisition epoch leaves the consumer blind to transport delays and scheduling jitter, degrading deterministic closed-loop control into open-loop guesswork. Because physical geometry continuously evolves as bodies move through space, spatial transforms between reference frames are subject to the same temporal decay, carrying their own distinct evidence epochs and bounded uncertainties.

9.5 Coordinate Transform Expiry and Localization Drift

A coordinate frame binds a spatial representation to a physical body, but on an active robot that frame is continuously moving. Embodied architectures relate sensors, chassis links, and end-effectors through a transform tree, in which every frame has exactly one parent. A static drawing of this graph, however, conceals how rapidly its edges go stale. In the arm chain of figure 9.3, each edge stores a rigid-body pose parameterized by joint angles (Lynch and Park 2017; Craig 2005), describing the machine only at the instant its physical geometry was transduced. When an onboard computer chains transforms sampled at different timestamps, whether through neural inference latency, bus transport delays, asynchronous sensor clocks, or dropped packets, the resulting mathematical product yields a hybrid pose that the physical machine never occupied.

↪ Rigid-body transforms, their composition along a kinematic chain, and their rotation parameterizations are developed in section A.3.

Transform state also spans multiple machine words: three floating-point numbers for translation and four for rotation as a unit quaternion. A high-rate control reader racing an asynchronous perception writer can therefore tear a read, observing an old rotation paired with a new translation. The lock-free sequence lock (seqlock) mailbox established in section 4.3.2 resolves this concurrency race without blocking hard real-time control threads. Each reader makes a single bounded attempt per tick and never blocks. If the sequence count reveals a torn read, the thread discards the sample and lets the last validated transform age in place.

On the arm itself (figure 9.3, panel a), an effective lever arm r_{arm} separates the rotating wrist (joint 7) from the tool center point (`tool0`), so an angular lag $\Delta\theta_{\text{joint}} = \omega\,\Delta t$ sweeps the end-effector through an unmodeled arc $e_{\text{tool}} \approx r_{\text{arm}}\,\Delta\theta_{\text{joint}}$. The links (`link1` through `link7`) are connected by revolute joints whose optical encoders sample joint angles $q_i(t)$ continuously, so the arm's own edges can be updated frequently; the edge that ages is the wrist camera's estimate of the target.

Panel (b) shows the corresponding coordinate transform tree, maintained in robot middleware such as the Robot Operating System (ROS) library `tf2` (Foote 2013). Each directed edge represents a 4×4 homogeneous transformation matrix $\mathbf{T}_{AB}$ mapping points from child frame B into parent frame A. Because the arm's joint state arrives at its 1 kHz joint-control rate over a deterministic fieldbus while the wrist camera publishes detected object poses (`target_object`) at only 60 Hz over an asynchronous transport, the transform tree inevitably buffers edges with disparate timestamps. Properly designed transform libraries refuse to mix these epochs. A `tf2` lookup for a transform chain at query time t evaluates every edge at that exact timestamp t, interpolating each edge between its buffered samples. If t lies beyond the newest sample of any edge, the lookup raises an extrapolation error. Similarly, requesting the "latest" transform returns the chain at the newest timestamp common across all constituent edges, preserving a single consistent epoch (Foote 2013).

Unphysical hybrid poses arise when application code bypasses these library guarantees. If a node caches an edge, pairs a target pose from an asynchronous detection message with a live lookup of the arm at the current instant, or republishes an old edge under a refreshed timestamp, it multiplies the current forward kinematics $\mathbf{T}_{\text{base}\leftarrow\text{wrist}}(t)$ by a stale vision edge $\mathbf{T}_{\text{wrist}\leftarrow\text{object}}(t-\Delta t)$. This composition represents the **chimeric kinematic product anti-pattern**: an unphysical geometric artifact that corresponds to no configuration the physical robot ever occupied.

Enforcing a common timestamp leaves the application with an operational decision whenever a query timestamp lies ahead of the newest buffered sample. A lookup can fail immediately, or a non-critical consumer can block until new samples arrive subject to a timeout. In safety-critical execution paths, such as permission enforcement, lookups must remain strictly nonblocking and fail closed upon rejection. If an application instead attempts to predict a future transform, it must propagate a validated uncertainty bound; naive dead-reckoning extrapolation during an unannounced sensor stall rapidly accumulates lever-arm error $e_{\text{rot}} \approx r_{\text{arm}}\,\omega\,\Delta t$.

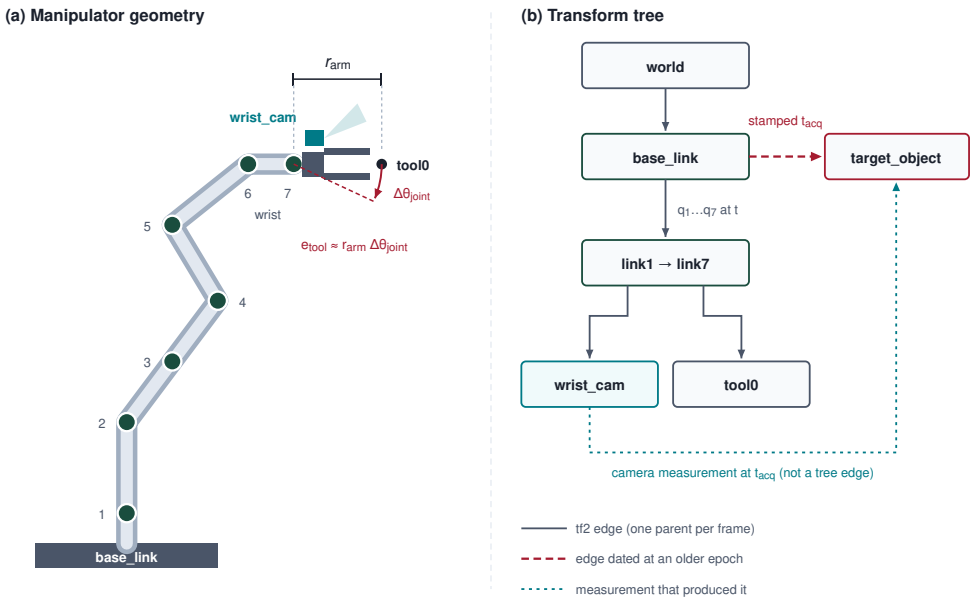

Figure 9.3: Manipulator kinematic frame tree and temporal dynamics: Articulated seven-joint manipulator geometry (a) and the corresponding coordinate transform tree in ROS `tf2` (b), in which every frame has exactly one parent. Each tree edge stores a homogeneous transformation matrix; articulated-arm edges depend on joint state, while mounting and localization edges have their own calibration or estimation premises. The target's pose hangs from the base frame, stamped with the epoch t_{acq} of the wrist-camera measurement that produced it, showing the capture-dated base-frame result. The error discussed here arises when application code instead retains the camera-relative measurement and composes it with current wrist kinematics; a wrist rotation $\Delta\theta_{\text{joint}}$ over the interval swings the tool center point by $e_{\text{tool}} \approx r_{\text{arm}}\,\Delta\theta_{\text{joint}}$ (adapted from Craig (2005) and Foote (2013)).

Transform expiration becomes spatial displacement at the plant interface. At the cage door the vision edge is the wrist camera's estimate of the latch-release slot (the `target_object` of figure 9.3), which the controller composes with the arm chain to place the finger relative to the slot. Composing that stale camera-to-slot edge with the current arm pose adds lateral drift $e_{\text{trans}} = v_{\text{drift}}\,\Delta t$, from motion of the base and door that no sensor reported during the interval, to the initial error e_0. It also adds a wrist lever-arm sweep $e_{\text{rot}} \approx r_{\text{arm}}\,\omega\,\Delta t$. The sum can carry the tool error e_{tool} outside the slot tolerance r_{tol} (figure 9.4). Applying the age-as-displacement principle to manipulator kinematics shows that uncompensated latency translates directly into geometric positioning error through the lever arm of downstream links.

The vulnerability of high-precision manipulation to transform staleness becomes clear when positioning an end-effector at a latch-release slot while the slot remains in direct view of the wrist camera. The wrist camera captures a new frame every 16.7 ms, renewing the observed slot pose and updating the camera-to-slot transform that guides fine alignment. To clear the opening, the fingertip must remain within a tight mechanical tolerance $r_{\text{tol}} = 1$ mm. To isolate the geometric penalty of a single missed frame, assume the camera observation is available at its capture epoch with zero ingestion delay, after which the transform edge ages by exactly one frame interval $\Delta t = 16.7$ ms. On a production machine, pipeline ingestion latency makes the edge older still; control loops must always charge the full capture-to-use latency, including neural inference, message serialization, and transport. Starting from an initial calibration error $e_0 = 0.1$ mm, lateral motion drifts by at most $e_{\text{trans}} = v_{\text{drift}}\,\Delta t = 0.20$ mm under an unobserved lateral velocity bound of $v_{\text{drift}} = 12$ mm/s.

The kinematic lever arm magnifies this displacement substantially. With the fingertip positioned at a distance $r_{\text{arm}} = 0.15$ m beyond the wrist joint, an alignment rotation at angular rate $\omega = 0.30$ rad/s sweeps the tip through an arc of $e_{\text{rot}} \approx r_{\text{arm}}\,\omega\,\Delta t = 0.75$ mm. The optical encoders register the wrist rotation correctly; the error comes from what the rotation is applied to. The cached camera-to-slot transform states where the slot sat relative to the camera at the previous frame, and the camera rides on the wrist. Application code that chains that cached transform with the current wrist pose

↪ The lever-arm kinematics behind this error propagation, built from the vector cross product, are developed in section B.6.4.

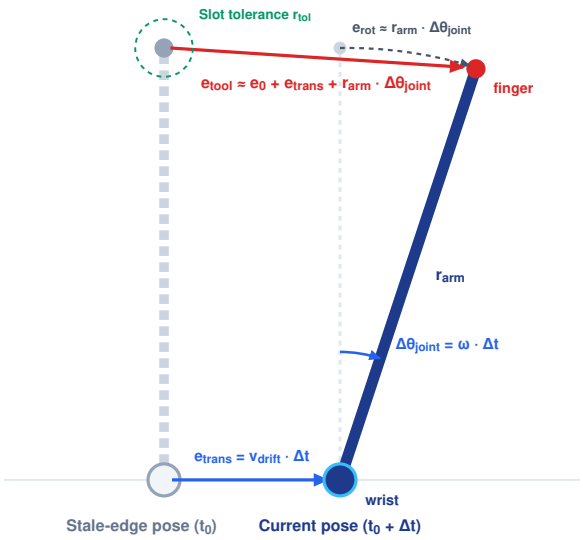

Figure 9.4: Transform staleness and lever-arm error at the latch-release slot: Illustrative finger error over one frame period, with zero ingestion delay assumed to isolate this contribution. A deployed calculation must use full capture-to-use age. The camera-to-slot edge ages by duration Δt. Lateral drift at the velocity bound v_{drift} moves the finger by $e_{\text{trans}} = v_{\text{drift}}\,\Delta t$, while the wrist turning at ω swings the fingertip, a lever arm r_{arm} beyond it, by $e_{\text{rot}} \approx r_{\text{arm}}\,\omega\,\Delta t$. Composing the stale edge with the current wrist pose adds both to the initial error e_0, so the finger error $e_{\text{tool}} \approx e_0 + e_{\text{trans}} + r_{\text{arm}}\,\Delta\theta_{\text{joint}}$ exceeds the slot tolerance r_{tol}.

therefore swings the computed slot along with the wrist, while the real slot, fixed in the door, stays where it was. The result is a hybrid pose that the arm never occupied. Correcting this error requires either querying the kinematic chain at the exact capture epoch of the camera frame or expiring the stale transform outright. Unchecked, the stale transform displaces the estimated finger position by $e_{\text{tool}} \approx e_0 + e_{\text{trans}} + e_{\text{rot}} = 1.05$ mm, which exceeds the mechanical tolerance by 5 percent. The lever arm contributes over three times as much error as translational drift alone. Because the matrix multiplications complete without raising a runtime exception, the control loop blindly aligns the tool to an invalid target, driving the finger into the surrounding strike plate.

The red error vector in figure 9.4 pierces the tolerance boundary even though every underlying matrix multiplication remains numerically valid. Because the dominant error originates in the kinematic lever arm rather than translational drift, a faster or more precise clock does not help; the stale chain is wrong at any timestamp resolution. Only composing every edge at the same epoch, or expiring the stale edge, removes the error, so systems software must enforce one or the other.

> **Systems Perspective 9.1: The lever arm of staleness**
>
> *A transform's admissible age is set at the point it serves, not at the joint it measures. The tool point drifts at roughly $v_{drift} + r_{arm}\omega$, so the longer the lever arm, the sooner an edge expires, and an edge still fresh enough to locate the wrist can be too old to locate the tool center point.*

9.5.1 Localization drift and map frames that jump

Unlike a manipulator arm bolted to a chassis with optical encoders on every joint, a wheeled mobile base has no mechanical anchor to the floor. Dead-reckoning odometry drifts past the stopping budget's localization bound within a single aisle, while map-based loop closures snap the pose back into alignment by jumping remembered obstacles across the map frame. Every map-anchored spatial belief in this chapter, and every allocation in the safety stopping budget, relies on that localization bound δ_{loc}, the guarantee that the robot estimates its position in the map within a bounded uncertainty radius. Maintaining that bound requires combining two distinct state

estimators with complementary failure modes, and spatial memory must account for how each estimator alters stored observations.

Odometry integrates high-rate incremental motion from wheel encoders, inertial measurement units (IMUs), or scan-to-scan lidar odometry. Odometric integration produces smooth, high-frequency pose updates with low latency, but because it measures only relative displacements, incremental integration errors accumulate without bound. Absolute position along the trajectory represents an unobservable subspace (section 9.8). Conversely, **map-based localization** matches real-time range scans against an authoritative pre-built map, bounding absolute drift at the expense of discrete, lower-frequency corrections. When an operating environment lacks a prior map, **simultaneous localization and mapping (SLAM)**[5] estimates the robot trajectory while constructing the map concurrently. Modern SLAM architectures formulate this estimation over a pose graph, a factor graph whose vertices represent historic robot poses and whose edges encode odometric and scan-matching constraints (Thrun et al. 2005; Cadena et al. 2016; Dellaert and Kaess 2017; Hess et al. 2016). When the robot revisits a previously mapped area, a **loop closure** introduces a cross-trajectory factor. Re-optimizing the nonlinear graph distributes the accumulated drift across historic poses, retroactively adjusting the estimated trajectory. While the underlying fusion filters follow the Bayesian prediction-correction mechanics detailed in section 9.2 and section 9.2.3, spatial memory systems must manage the distinct ways these estimators distort the age and coordinates of stored evidence.

[5] **SLAM**: Smith et al. (1990) showed that when a moving robot observes landmarks relative to itself, every landmark estimate inherits the common error in the robot's pose, so map error and pose error are correlated and must be estimated together. The acronym came later, in a survey presented at the 1995 International Symposium on Robotics Research (Durrant-Whyte and Bailey 2006). That correlation is why a loop closure moves remembered cells that no sensor has revisited.

How fast odometry spends that bound can be measured. The standard protocol for quantifying systematic odometry drift is Borenstein and Feng's University of Michigan Benchmark (UMBmark) (Borenstein and Feng 1996). A differential-drive robot traverses a 4 m square path covering 16 m of total travel, executing five runs clockwise and five runs counterclockwise. By comparing the odometric return pose against ground-truth external measurements, the benchmark calculates the average return error across both directions. Traversal in opposite directions isolates the two primary sources of systematic error, unequal wheel diameters and wheelbase uncertainty, which would otherwise partially mask one another on unidirectional trajectories.

On their experimental base, uncalibrated runs produced an average systematic return error of 317 mm. Calibrating the wheelbase and wheel-diameter ratio reduced this error to 21 mm, achieving a 15.1× precision gain. Normalized by path length, the systematic drift rate drops from 2.0 percent to 0.13 percent of distance traveled. At the uncalibrated rate, a mobile base exhausts an illustrative 50 mm localization bound after traversing only 2.5 m, equivalent to 1.9 s of operation at an aisle cruising speed of 1.3 m/s. Traversing a single 30 m aisle accumulates 594.4 mm of position drift, exceeding the bound by a factor of 11.9×. Even with careful calibration, pure odometry exhausts the 50 mm bound after 38.1 m (29.3 s), accumulating 39.4 mm across one aisle. Plotted against distance driven (figure 9.5), even the calibrated line crosses the bound only just past one 30 m aisle, which makes δ_{loc} a constraint on how often external map corrections arrive rather than an intrinsic property of the mobile base.

Three physical realities prevent this illustrative calibrated extrapolation from establishing an operational design margin. First, the laboratory benchmark operated at 0.2 m/s along straight segments to minimize wheel slip, stopping to pivot at each corner; production warehouse bases travel 6.5× faster under varying operational payloads. Second, kinematic calibration eliminates only deterministic systematic errors. Non-systematic stochastic errors (floor irregularities and micro-slip) produced a run-to-run standard deviation of approximately 25 mm, eclipsing the residual calibrated systematic error of 21 mm. Third, a constant per-meter error rate is merely a first-order linearization. An uncorrected heading error $\delta\theta_{\text{head}}$ produces lateral position displacement $\delta\theta_{\text{head}}\, d$ over a straight traverse of distance d. Because wheel-diameter mismatch causes heading error to accumulate linearly with distance ($\delta\theta_{\text{head}} \approx \kappa d$ for a constant heading curvature κ), the resulting lateral error grows quadratically, about $\frac{1}{2}\kappa d^2$, quadrupling each time the straight run doubles. Under this illustrative drift model, reserving localization margin requires external corrections at intervals shorter than the calculated crossing distance; the deployed interval must come from the machine's qualified drift envelope. In deployed systems, the site parameter δ_{loc} must be established empirically, by driving the robot past surveyed fiducials at nominal velocity and maximum payload across actual facility flooring, reporting drift rates at a defined operating percentile.

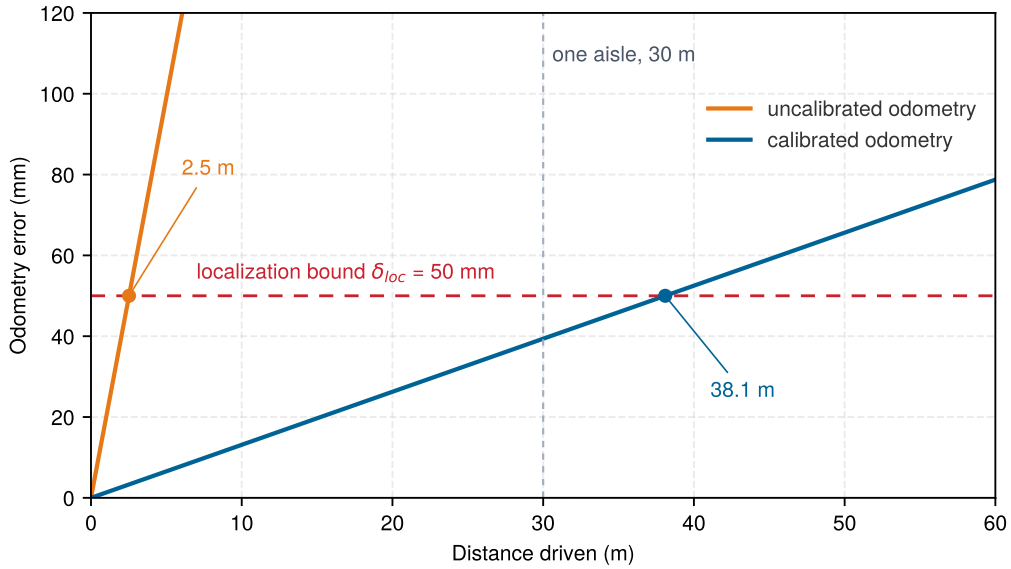

Figure 9.5: Odometry drift against the localization bound: The UMBmark return error, scaled per meter of path, grows linearly with distance driven. Uncalibrated, it spends the 50 mm localization bound after 2.5 m; calibrated, after 38.1 m, only just beyond one 30 m aisle. Both lines extrapolate return errors from a slow laboratory run; deployed correction spacing must be qualified against the machine's own drift envelope before δ_{loc} can be relied on.

The laboratory rates above isolate the systematic part of wheel-odometry error on a slow square path. Camera and lidar odometry are measured differently, by total error at road speed over long runs. A public driving benchmark scores each submitted method by its translation error averaged over every subsequence of 100 to 800 m in held-out sequences, in percent of distance traveled (Geiger et al. 2012). Figure 9.6 places every ranked method against the distance at which its drift rate would spend the machine's localization bound.

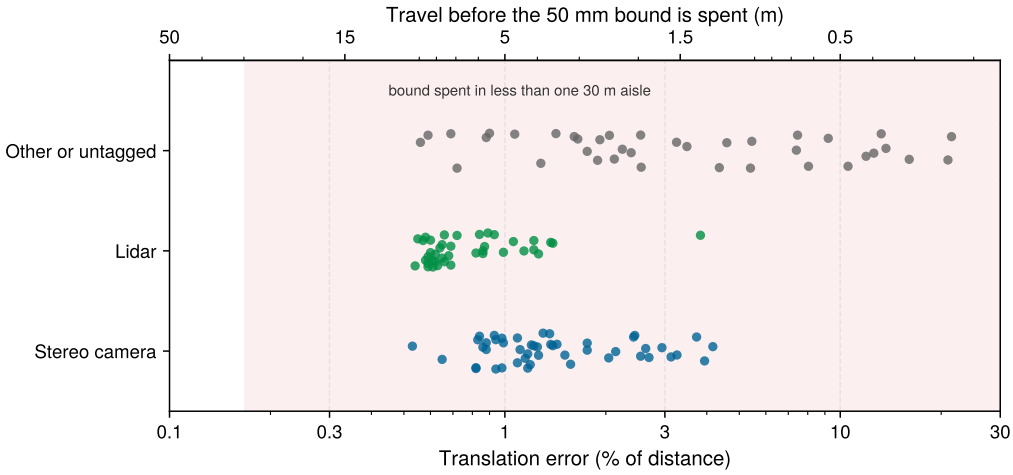

Figure 9.6: Even the best odometry needs a correction within one aisle: Each dot is one ranked method on a public odometry benchmark, placed by its translation error (percent of distance, averaged over 100 to 800 m subsequences) and grouped by sensor; methods without a stereo or lidar tag mix monocular, inertial, and event-camera inputs. The top axis converts error into the distance at which a constant drift rate spends the running machine's 50 mm localization bound, and the shaded region is shorter than one 30 m aisle. The benchmark is road driving, so it bounds what these methods achieve rather than predicting warehouse drift. Data from the benchmark leaderboard (Geiger et al. 2012).

The best of the 127 ranked methods drifts 0.53 percent of distance, and the median stereo and lidar methods drift 1.23 and 0.68 percent. At those rates the 50 mm bound lasts about 9 m for the best method, 7 m for the median lidar method, and 4 m for the median stereo method, all shorter than one 30 m aisle. These total-error rates sit above the calibrated laboratory figure of 0.13 percent, because they include the slip, vibration, and scene-dependent errors that UMBmark's calibration deliberately excludes. Read together, the two benchmarks bracket the problem rather than resolve it: the optimistic systematic rate stretches the bound just past one aisle, and the measured total rates of the best published methods spend it within a third of one. Every odometry source on the base is a bridge between external corrections, and the bound remains a requirement on how often those corrections arrive.

Loop closure introduces a consistency challenge that timestamp-based age tracking alone cannot resolve. An occupancy cell anchored in the global map frame retains its original capture epoch (the photons reflected from that obstacle are no newer), yet its spatial coordinates shift whenever the SLAM backend re-optimizes the underlying pose graph. Although the sensor evidence has not been refreshed, its spatial position changes discontinuously. Any local memory snapshot constructed prior to the loop closure now misplaces the obstacle by the magnitude of the graph correction, even while every timestamp within the snapshot passes validation. Robust spatial memory architectures must therefore tag spatial beliefs with the generation or revision identifier of the pose graph alongside individual cell epochs. When a loop closure shifts supporting trajectory poses, the system must either re-anchor dependent snapshots or invalidate them immediately.

The REP 105 frame convention met in table 8.2 already separates the two estimators (Meeussen 2010). Poses in `odom` are continuous but drift without bound. Poses in `map` stay globally bounded but jump whenever a scan-matching correction or loop closure resolves accumulated drift, and the localizer absorbs each correction by adjusting only the `map`-to-`odom` edge. What memory must decide is which frame its safety snapshot lives in. The permission controller builds its local collision-checking snapshots in the continuous `odom` frame, so a correction never moves an obstacle inside a snapshot that is in use. Over a snapshot's short lifespan (typically hundreds of milliseconds to several seconds), the drift that calibrated odometry accumulates is small and is charged against δ_{loc} in proportion to distance traversed; uncalibrated odometry, which spends the whole bound within 2.5 m, cannot rely on this. Anchoring safety snapshots in the `map` frame instead would make obstacle bounding hulls teleport discontinuously upon every map correction. Global mission planners, long-term semantic maps, and snapshot construction routines operate in `map`. When a major map correction occurs, the host invalidates and rebuilds the local snapshot rather than forcing real-time controllers to absorb discontinuous jumps. The `map`-to-`odom` edge remains subject to the same temporal expiration rules as any kinematic transform.

A stale transform displaces both the tool estimate and any observations mapped through it. The surrounding world ages too, but it has no joint encoders to report its motion. Memory must therefore record which surfaces and empty regions the sensors actually verified, as well as the frames in which those observations hold.

9.6 Certified Spatial Assertions in Scene Memory

When a mobile manipulator sweeps its range sensors down an aisle, spatial memory must partition the physical volume by what the sensors established: space observed to be occupied, space observed to be empty, and unobserved space. Only observed empty space can support a physical clearance claim, and only while that evidence remains temporally valid; once it lapses, the space becomes a fourth category, expired, which section 9.6.1 adds to the cell states. If a map representation merges unobserved space with free space, the permission path cannot detect occlusions, defeating evidence-freshness checks regardless of timestamp accuracy.

Distinct downstream consumers place competing demands on this spatial memory architecture. A learned manipulation policy requires object identities and local geometry to plan collision-free grasps or navigation trajectories. In contrast, the hard-real-time permission path requires bounded geometric queries whose supporting evidence can be verified before an execution deadline expires. To satisfy these disparate consumers, spatial memory organizes into a functional hierarchy. Metric maps compute geometric clearances and volumetric occupancy. 3D scene graphs structure those measurements into topological places and semantically labeled objects. Episodic memory retains

interaction histories needed to interpret operational context. While higher layers draw upon metric observations for geometric grounding, semantic labels and remembered events never possess the authority to certify physical clearance on their own.

9.6.1 Volumetric metric maps and distance fields

At the metric layer, a clearance query along a warehouse aisle demands a single, safety-critical quantity: the minimum distance from the robot's body hull (the simple solid that encloses the machine's body for collision checking) to the nearest region that is occupied, unobserved, or backed by expired evidence. In contrast, a neural or graphics rendering query estimates what a camera would observe from a specific vantage point. If the safety microcontroller had to scan thousands of occupancy voxels or chase pointer-linked octree nodes to find the nearest obstacle for each of the robot's body spheres, the clearance check would overrun its microsecond budget inside the permission tick. A spatial representation qualifies for the hard-real-time permission path only if it evaluates conservative physical clearance within the strict execution deadline of a permission tick, operating entirely within the memory footprint supported by the safety microcontroller. The design therefore allocates the query workload first, counts what each candidate representation must read from memory to answer it, and only then sizes the storage.

The clearance query inside the permission tick

The worked design allocates spatial collision checking within the machine's 1 kHz permission loop ($T_{\text{tick}} = 1{,}000$ µs). The required query returns conservative clearance at each body collision hull, where a hull is one of a set of spheres, the evaluation spheres, whose union covers the machine's body. Where the selected check also needs a clearance gradient, that work belongs in the same measured query. For an illustrative 20 to 50 evaluation spheres, the total work is:

$$T_{\text{query_total}} = \sum_{k=1}^{N_{\text{hulls}}} t_{\text{query}}(\mathbf{p}_k) \leq T_{\text{reflex_budget}} \tag{9.7}$$

To bound the total collision workload in equation 9.7, the worked $N_{\text{hulls}} = 50$ case reserves $T_{\text{reflex_budget}} = 100$ µs for local collision checking (the subscript names the reflexive, every-tick check, as opposed to planning). That allocation is part of the permission tick schedule of chapter 4 (figure 4.1), not an addition to it. The job declares a 250 µs WCET against a 400 µs deadline, and collision checking takes 40 percent of that WCET, leaving the rest for the other admission checks. Measured against the whole period instead, collision checking leaves 90 percent of the tick for everything else. This is an allocation to be tested on the deployed controller; full-map updates and trajectory optimization run outside this tick. Dividing the allocation among the hulls gives

$$t_{\text{query}} \leq \frac{T_{\text{reflex_budget}}}{N_{\text{hulls}}},$$

which for the worked case is 100 µs over 50 hulls, or 2 µs per query.

A latency allocation becomes a concrete architectural constraint only when translated into hardware resources: memory bus transactions and cache reads. The permission controller streams its local SRAM at 3.2 GB/s, so the 2 µs allocation covers at most 800 reads of an 8-byte cell per hull query, before any arithmetic, cache effect, or contention; qualification on the deployed controller must still measure the real bound. Against that ceiling, the candidate representations differ less in execution speed than in the physical question a single read answers (table 9.1). An **occupancy grid**[6] stores, per cell, whether that cell is occupied (Elfes 1989; Moravec and Elfes 1985). Certifying that a sphere hull of radius 0.25 m keeps its protective clearance means reading every cell within 0.35 m of its center, $\frac{4}{3}\pi\left((r_{\text{hull}} + \delta_{\text{margin}})/r\right)^3$ cells at pitch r. A hierarchical **octree** such as OctoMap (Hornung et al. 2013) answers the same point query after descending the tree, one dependent read per level, so near surfaces, where pruning cannot merge cells, the scan costs its cell count times the tree depth. A **truncated signed distance field (TSDF)** stores a projective distance to an observed surface along the sensor ray, clamped at a truncation distance of a few voxels (Curless and Levoy 1996). This ray-based construction does not give the nearest-obstacle distance in all directions, even within the truncation band; hull clearance requires a separately validated occupancy or Euclidean-distance

6 | **Occupancy Grid**: Moravec and Elfes built the first grids at Carnegie Mellon to fuse returns from wide-beam sonar, whose single echo cannot say where across its beam the reflector lies (Moravec and Elfes 1985). Each cell therefore holds accumulated evidence rather than geometry, and a cell no return has reached stays at its prior. The representation was designed for sensors too coarse to vouch for what they did not touch, which is why a permission-grade grid must keep unknown distinct from free.

conversion. A **Euclidean signed distance field (ESDF)** stores the straight-line distance to the nearest obstacle (Oleynikova et al. 2017; Millane et al. 2024), so one interpolated geometric lookup, 8 corner reads together with the snapshot validity checks developed below, supplies conservative clearance for an entire sphere. The hull passes when the distance at its center exceeds $r_{\text{hull}} + \delta_{\text{margin}}$ plus the geometric error. Rendering representations answer the second question. A 3D Gaussian splatting (3DGS) scene fits anisotropic Gaussians to a photometric loss (Kerbl et al. 2023), and a neural radiance field integrates learned density along camera rays. Neither stores a conservative distance, and collision checking on splats requires an added assumption that the fitted ellipsoids enclose the physical surface (Chen et al. 2025).

↪ The parameterization of a 3D Gaussian splatting scene is developed in section A.3.5.

Table 9.1: What one lookup answers, and what clearance costs: Reads for a sphere hull of radius 0.25 m plus the protective clearance, at a 5 cm pitch, against a budget of 800 reads per query on the permission controller. ESDF counts are geometric corner reads; fixed header checks also consume the allocation. The octree count is the worst case near surfaces, a tree depth of 8 levels per cell; pruning reduces it in open space.

Representation	Query one lookup answers	Reads per hull query at 5 cm	Can certify the hull's clearance?
Dense occupancy grid	Is this cell occupied?	1,437	Yes, by scanning every cell within reach
Octree occupancy	Is this cell occupied? (after a tree descent)	11,494	Yes, by the same scan, one descent per cell
TSDF	Is a surface within the truncation distance?	1	No general Euclidean hull guarantee from projective TSDF alone
ESDF	How far is the nearest obstacle?	8	Yes, under a validated conservative snapshot certificate
3DGS or radiance field	What would a camera at this pose see?	—	No; requires a separately qualified geometric conversion

Counted against the 800-read budget (figure 9.7), the representation families separate cleanly. A dense occupancy scan exceeds the budget at 2 cm and 5 cm and fits only at 10 cm, where spatial quantization error alone, up to half the voxel diagonal or 87 mm, consumes most of the protective clearance. A worst-case octree scan exceeds the budget at every pitch, because each cell lookup first descends a chain of dependent tree pointers. An ESDF needs exactly 8 geometric reads for one trilinear interpolation regardless of pitch, plus fixed snapshot-header validity checks. Both the metadata checks and the geometric lookup must fit inside the query allocation. The fixed geometric cost favors an ESDF for real-time safety snapshots, while memory capacity constrains the voxel pitch.

A dense ESDF snapshot of the stopping corridor, spanning the aisle width, the clear distance, and an illustrative 2 m manipulator reach height (2.86 m^3 in all), requires a voxel payload of 183 kB at 5 cm resolution, below the microcontroller's 1.05 MB SRAM capacity. The complete static allocation must also include the snapshot header and certificate, active buffers, controller binary, and validation workspace. At 2 cm pitch, the voxel payload alone swells to 2.86 MB, exhausting available SRAM. Adopting the 5 cm pitch introduces up to 43 mm of spatial quantization error into each lookup, an uncertainty that the collision filter must explicitly subtract from the reported clearance. A projective TSDF also cannot substitute for a Euclidean distance field simply because its point lookup is computationally inexpensive; a projective distance along a sensor ray fails to bound the distance to off-axis obstacles.

The host computer maintains the global reconstruction and extracts a bounded local snapshot enclosing the proposed robot trajectory and its emergency stopping corridor. The permission microcontroller admits a new snapshot only after validating its cryptographic provenance, spatial bounding box, per-voxel evidence timestamps, and geometric consistency against a qualified schema. Generating, transferring, and validating these snapshots introduces latency and bus traffic that must be scheduled and qualified independently from the inner-loop collision query. If the host pipeline stalls or drops frames, the active snapshot in microcontroller SRAM continues to age monotonically. The robot may sustain autonomous motion only as long as every cell the snapshot relies on remains within its invalidation horizon and the snapshot's geometric coverage encloses the vehicle's stopping envelope.

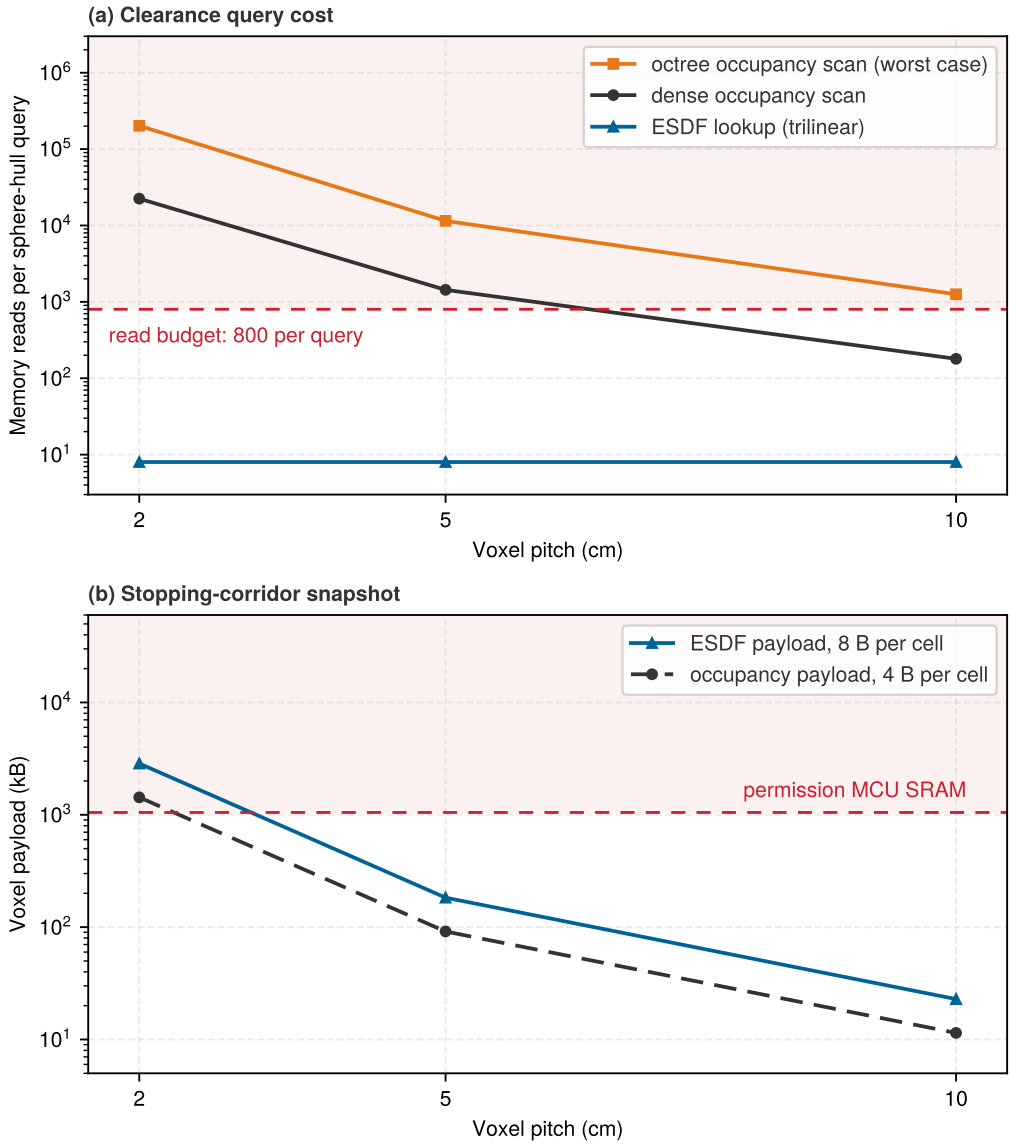

Figure 9.7: Clearance query cost and snapshot storage by representation family: (a) Memory reads to certify one sphere hull's clearance, computed from voxel pitch, hull radius plus protective clearance, and tree depth, against the per-query read budget that the 2 µs allocation and the permission controller's SRAM bandwidth allow. Occupancy scans grow with the cube of the inverse pitch and fit only at the coarsest pitch; an ESDF answers with one interpolated lookup at every pitch. (b) Voxel payload for a dense snapshot of the stopping corridor (aisle width by clear distance by a chosen 2 m height) against the controller's SRAM. Fixed header checks also consume the query allocation, and metadata, active buffers, binary, and validation workspace add to resident storage. Counts, not measured latencies; rendering representations are absent because they do not answer a clearance query.

Eight recent corner samples do not establish that the whole region behind a distance claim remains free. Although a trilinear lookup reads only eight local corner voxels around the hull center, the Euclidean distance value stored inside each corner vouches for the absence of obstacles across a surrounding sphere of voxels that the microcontroller never inspects at runtime, and if any distant voxel within that radius carries older evidence or borders an occlusion frontier from which an unseen hazard can advance, the local distance value becomes optimistic before the corner cell's own timestamp expires. The qualified construction path therefore selects an absolute support deadline

for the snapshot, fixing its frame and pose-graph revision, spatial coverage, clock mapping, and physical growth and entry-speed assumptions. Before building the frozen ESDF, it treats unknown and occupied regions as obstacles and removes from the observed free set every region whose evidence cannot support that set through the selected deadline. This conservative erosion reserves the entire declared interval, including the assumed entry and disturbance envelope. Independent validation must establish that the resulting field lower-bounds clearance throughout that interval; neither a producer's declaration nor its digest establishes the claim.

The local consumer checks the fixed header against its own upper-bounded clock, the declared frame revision, coverage, and validity conditions before reading the eight geometric corners. It refuses dependent proposals at the support deadline without a host callback or a map scan; a changed frame or physical assumption invalidates the certificate earlier. Header loads and checks belong inside the same per-query allocation, and motion admission must reserve a feasible response before expiry. The later per-hull erosion calculation can impose a shorter horizon. Because the frozen field already includes the declared interval's erosion, the consumer must not subtract that identical erosion a second time; hull motion and its stopping continuation still require complete swept coverage and qualified aggregate work.

Volumetric memory footprint scaling

↪ How host memory traffic would stall permission-path reads on a shared die, and why the selected placement confines it to evidence age, is developed in section 13.3.

The local snapshot decision leaves the host compute platform with capacity and update constraints. Keeping the chosen snapshot supplied requires sufficient memory capacity for the underlying map and sufficient memory bandwidth to integrate range observations before their physical evidence expires.

For the illustrative host-map sizing calculation, consider an operational workspace of physical volume $V_{\text{ws}} = L_x L_y L_z$. Discretizing this domain into cubic voxels of uniform pitch r requires memory proportional to workspace volume and to the inverse cube of voxel width:

$$M_{\text{dense}} = \left(\frac{V_{\text{ws}}}{r^3} \right) s_{\text{voxel}} \tag{9.8}$$

where s_{voxel} represents the storage footprint per voxel, here 8 bytes: 4 for a 32-bit distance, 2 for the observation weight, and 2 for the evidence epoch.

Obstacles occupy physical 2D surfaces embedded in 3D space rather than solid volumes, and a TSDF[7] requires stored values only near those surfaces. Truncating the distance field to a band $[-\mu_{\text{tsdf}}, +\mu_{\text{tsdf}}]$ around observed surfaces restricts storage to a shell $V_{\text{band}} \approx 2\mu_{\text{tsdf}} \cdot A_{\text{surface}}$, where A_{surface} is the total obstacle surface area. Partitioning space into blocks of n_{blk}^3 voxels with block pitch $L_{\text{blk}} = n_{\text{blk}} \cdot r$, and allocating a block only when it holds data, the sparse hashed footprint obeys:

$$M_{\text{hashed}} = N_{\text{blocks}} \left(n_{\text{blk}}^3 s_{\text{voxel}} + s_{\text{meta}} \right) + N_{\text{buckets}} s_{\text{entry}} \tag{9.9}$$

where $N_{\text{blocks}} \approx \lceil 2\mu_{\text{tsdf}} A_{\text{surface}} / (n_{\text{blk}} r)^3 \rceil$, s_{meta} is the block metadata (coordinates, allocation flags), and s_{entry} is the hash-table entry size.

Sparse volumetric storage requires an indexing mechanism that resolves 3D coordinates without the sequential pointer traversals of an octree. **Voxel block hashing** discretizes continuous world coordinates $\mathbf{p} = [x, y, z]^\top \in \mathbb{R}^3$ into an integer block coordinate vector $\mathbf{b} = [b_x, b_y, b_z]^\top \in \mathbb{Z}^3$:

$$\mathbf{b}(\mathbf{p}) = \left\lfloor \frac{\mathbf{p}}{n_{\text{blk}} \cdot r} \right\rfloor \tag{9.10}$$

A spatial hash function then maps the block index $\mathbf{b}$ from equation 9.10 to a specific hash table bucket index $h(\mathbf{b}) \in \{0, \ldots, N_{\text{buckets}} - 1\}$. The scheme comes from real-time surface reconstruction (Nießner et al. 2013), built on the spatial hashing of Teschner et al. (2003), and underlies the Voxblox and nvblox mapping frameworks (Oleynikova et al. 2017; Millane et al. 2024). In an architecture packing $8^3 = 512$ voxels per block with an 8-byte payload per voxel, each allocated block forms a contiguous 4,096 byte memory buffer. A single hash resolution loads an entire local 3D neighborhood into the processor cache. While average-case access time is $\mathcal{O}(1)$, worst-case retrieval latency depends on hash bucket collisions, probe sequence lengths, cache misses, and lock contention during concurrent sensor updates. Because hard-real-time safety guarantees require deterministic execution bounds

[7] **Truncated Signed Distance Field**: Curless and Levoy (1996) averaged many range scans into a signed distance stored only near the surface to build detailed models of real objects, and KinectFusion ran the same fusion in real time on a GPU from a handheld depth camera (Newcombe et al. 2011). Truncation bought both systems their memory savings. It makes the TSDF a representation for reconstructing surfaces, not for certifying the empty space between them.

rather than average-case performance, the local permission snapshot avoids pointer chasing and hashing overhead altogether by organizing its bounded stopping corridor as a dense, pre-allocated array in microcontroller SRAM. Notebook 9.1 applies both footprint equations to one warehouse workcell.

Napkin Math 9.1: The empty-air tax

Problem: A host map must cover a warehouse workcell of 10 m by 10 m by 3 m at the resolution manipulation needs, with an evidence epoch in every stored voxel so that each region's claim can expire. How much memory does a dense grid take, how much does a hashed band around the obstacle surfaces take, and what fraction of the dense grid describes empty air?

Variables:

- Workcell volume $V_{\text{ws}} = 300$ m³ (illustrative) at pitch $r = 1$ cm (chosen), with $s_{\text{voxel}} = 8$ B per voxel (illustrative).
- Obstacle surface $A_{\text{surface}} = 120$ m² (illustrative) and band half-width $\mu_{\text{tsdf}} = 4$ cm (chosen).
- Block edge $n_{\text{blk}} = 8$ voxels, the nvblox layout (datasheet).

Math: The dense grid, by equation 9.8:

$$M_{\text{dense}} = \frac{300\ \text{m}^3}{(0.01\ \text{m})^3} \times 8\ \text{B} = 3 \times 10^8 \times 8\ \text{B} = 2.4\ \text{GB}$$

The band and its voxel payload, by equation 9.9 without metadata or hash entries:

$$V_{\text{band}} = 2 \times 0.04\ \text{m} \times 120\ \text{m}^2 = 9.6\ \text{m}^3$$

$$N_{\text{blocks}} = \frac{9.6\ \text{m}^3}{(8 \times 0.01\ \text{m})^3} = 18{,}750, \qquad 18{,}750 \times 8^3 \times 8\ \text{B} = 76.8\ \text{MB}$$

Result: The dense grid needs 2.4 GB for 3 × 10⁸ voxels. The band is 3.2 percent of the workcell, so 96.8 percent of the dense grid describes space with no surface in it, and the hashed payload of 76.8 MB in 18,750 blocks is about 31 times smaller.

Systems insight: Obstacles are surfaces, not volumes, so a dense grid allocates the vast majority of its capacity to empty air. In an embedded robot computer, that multi-gigabyte memory footprint directly contends with memory pools required by vision foundation backbones and real-time motion controllers. The hashed calculation represents a theoretical lower bound: block metadata headers, hash table bucket arrays, and boundary fragmentation in partially occupied blocks increase this overhead in practice. This memory reduction applies strictly to the truncated surface representation. It also alters temporal bookkeeping: because the sparse map allocates memory only near detected surfaces, unallocated open space carries no explicit evidence timestamp. Unallocated space cannot vouch for its own clearance until the system explicitly logs a free-space ray-clearing observation.

This narrow-band scaling applies strictly to a TSDF, not to the full Euclidean distance field required by the permission snapshot. An ESDF stores metric clearance throughout the entire navigable volume where queries might occur. Its memory footprint therefore scales with the observed volume V_{obs}/r^3 rather than surface area A_{surface}. For a mobile warehouse manipulator, this observed volume corresponds to the spatial corridor reachable by the chassis and arm during stopping maneuvers, which dictates the snapshot dimensions evaluated above. Memory allocation semantics also dictate safety interpretation. In systems that perform volumetric free-space carving along sensor rays, unallocated blocks reliably represent unobserved, unknown space. In systems that allocate only narrow surface bands, however, an unallocated block could represent either confirmed open space or unobserved space hidden behind an occlusion. A safety-critical spatial memory system cannot conflate allocation status with occupancy state. Alongside observed occupied space, it must explicitly represent the three states that allocation cannot tell apart: observed free space backed by a valid evidence timestamp, unobserved space, and expired space where past observations have exceeded

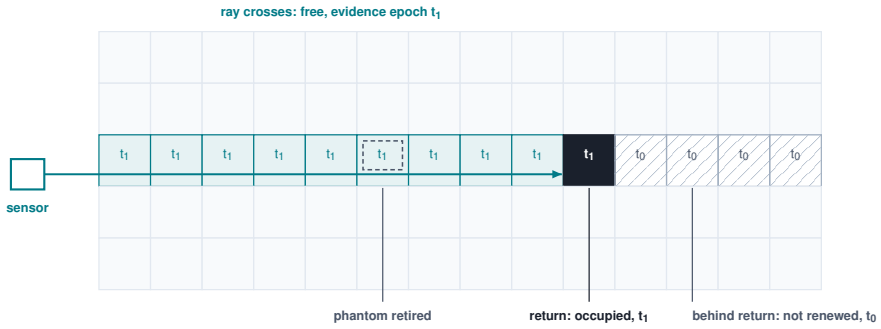

Figure 9.8: One range return updates only the cells it touched: Under the qualified coverage and geometric-error assumptions, the cells the ray crosses become free and take the capture epoch t_1 of the return, which also retires a phantom obstacle left on that line; the cell holding the return becomes occupied at t_1. Cells behind the return and every cell off the ray keep whatever epoch their own last evidence gave them, here t_0, so the map's publication time dates none of them.

their maximum validity horizon. Every cell therefore carries one of four states, occupied, free, unknown, or expired.

Ray-marching update traffic and negative evidence

When depth cameras stream range frames at framerate f_{cam} with $N_{\text{rays}} = W \times H$ pixels per frame, updating the volumetric map requires ray marching from the sensor origin to each observed surface point (Curless and Levoy 1996). Each ray traverses a line-of-sight distance d_{ray} at voxel stepping pitch r, requiring $N_{\text{steps}} = d_{\text{ray}}/r$ discrete cell evaluations. The raw DRAM update bandwidth consumed by naive ray marching is:

$$\text{BW}_{\text{DRAM}} = f_{\text{cam}} \cdot N_{\text{rays}} \cdot \left(\frac{d_{\text{ray}}}{r} \right) \cdot s_{\text{rw}} \tag{9.11}$$

where s_{rw} is the read-modify-write memory traffic per traversed voxel (8 to 16 bytes for reading the current occupancy or distance, updating running weights, and writing back).

For an illustrative VGA depth stream of 307,200 rays at 30 Hz, marched over 2 m at a 2 cm pitch (100 steps per ray) with 8 bytes per step, equation 9.11 gives 7.37 GB/s, 3.6 percent of the peak 204 GB/s of the host system-on-chip (SoC). This share of peak understates the actual performance impact, because these volumetric map updates share the memory interconnect with vision foundation models and motion controllers, and their throughput penalty stems from non-sequential access locality and memory bus contention rather than aggregate bandwidth alone. This update bandwidth represents a substantial baseline load that system architects must incorporate into hardware contention profiling, as memory bus saturation and cache thrashing degrade perception pipelines long before theoretical DRAM bandwidth is exhausted. Block hashing reduces this traffic by keeping active blocks in on-chip memory, and projective TSDF updates project voxels inside the viewing frustum onto the depth image instead of marching every ray. These methods reduce repeated memory traffic, but the reduction depends on scene coverage and update strategy. Sparse allocation still grows as the machine explores new regions; a bounded host store needs an explicit retention policy.

What a map can certify comes from how a range return updates it. Traversing the ray[8] from the sensor to the return (Amanatides and Woo 1987), the map records **negative evidence** along the traversed ray and positive evidence at its return. Treating an entire crossed voxel as free requires qualified beam coverage, resolution, and geometric error allowances. The ray alone does not observe every point in that voxel.[9] A valid empty ray can retire a phantom obstacle, but it says nothing about the volume behind a return, the hatched cells in figure 9.8 that keep their earlier epoch. A new scan down the aisle therefore cannot renew cells hidden behind the rack. Sparse allocation saves capacity without eliminating ray traversal, and any resulting processing delay adds to evidence age.

Because a return renews only the cells it touched, a map's global publication timestamp cannot certify the freshness of individual voxels. The manifest in table 9.2 therefore carries cell evidence

1 depth sample
100 voxel steps
× 307,200 rays
× 30 Hz × 8 B
= 7.37 GB/s

Marching turns each depth sample into 100 read-modify-writes, the per-ray factor that block hashing and projective updates reduce.

8 **Voxel Traversal**: Amanatides and Woo (1987) step a ray from one voxel boundary to the next by comparing the distances to the next crossing on each axis and adding one fixed increment, so each voxel visited costs a few comparisons and one addition. The work per ray is therefore proportional to the number of voxels it crosses, range divided by pitch, which is the d_{ray}/r factor of equation 9.11.

9 **Log-Odds**: Storing $\ell = \ln(p/(1-p))$ turns each Bayesian occupancy update into an addition, with an uninformed prior at $\ell = 0$. A cell no ray has touched and a cell that received as many hits as misses both read $\ell = 0$, so the value alone cannot separate never observed from observed and ambiguous. The manifest of table 9.2 therefore carries an explicit `cell_state`.

↪ The log-odds occupancy update and signed-distance fusion are developed in section A.3.6.

epochs alongside occupancy. For the worked local snapshot, construction and independent validation establish support for every admitted distance claim through the fixed support deadline. The local hull query checks that certificate's header and validity conditions within its allocated time, rather than scanning the supporting cells each tick. A freshly copied distance value without valid support cannot establish clearance. The manifest travels with the bounded snapshot as well as the host map; the isolated controller does not traverse the full host store.

Table 9.2: Volumetric belief manifest and cell evidence: The map header describes layout, pose-graph revision, query latency budget, and update time, while cell-local acquisition epochs and states support construction of a conservative local snapshot. Its fixed header carries the independently validated support deadline and scope checked by the local consumer. The consumer treats unobserved or expired cells as unknown unless a separately validated policy permits traversal.

Map field	Unit or type	Meaning and consumer check
`voxel_grid_origin`, `voxel_resolution_m`	m; m	Spatial anchor and pitch; match the active frame and calibration
`pose_graph_revision`	integer	Revision of the pose graph that placed the cells; a loop closure that changes it re-anchors or expires the snapshot
`map_update_epoch`	capture-clock ns	Last map publication/update; **not** freshness of every cell
`cell_evidence_epoch`	capture-clock ns per cell	Last physical observation for that cell; never refreshed by prediction or unrelated map updates
`free_space_sweep_epoch`	capture-clock ns per occupancy cell	Last valid observed free ray through that cell
`cell_state`	occupied, free, unknown, or expired per cell	Set explicitly, never inferred from allocation; unknown and expired read as obstacles
`clock_conversion`, `sync_error_ns`	mapping; ns	Convert capture epochs to the consumer's monotonic clock with bounded error
`support_deadline`, `validation_scope`	consumer-clock deadline; fixed certificate	Validated conservative interval, coverage, frame revision, and growth assumptions; refuse on expiry or scope violation
`query_latency_budget_us`	µs (at most 2 µs)	Bound collision and distance gradient query time to preserve the 1 kHz permission loop

Synthesizing these elements yields the primary metric the reactive permission path requires, the **free-space depth** d_{free}. To construct this bound, the qualified snapshot path generates and independently validates an ESDF wherein occupied, unobserved, expired, and insufficiently supported regions are obstacles throughout the declared support interval. Evaluating this field at the center of a spherical body hull and subtracting the hull radius yields d_{free}: the Euclidean distance from the hull surface to the nearest physical coordinate that lacks certified, fresh evidence of being empty. Under the validated coverage and entry-envelope assumptions, any dynamic hazard (a pedestrian stepping around a corner, a falling carton) remains within the regions treated as unobserved or uncertified, so d_{free} conservatively bounds the spatial margin available for vehicle motion within that interval. When evaluating a candidate trajectory segment down an aisle, the collision filter subtracts the composite geometric error (encompassing sensor calibration noise, localization covariance, and spatial voxel quantization) as well as the protective safety clearance δ_{margin} from d_{free}. The test is applied not at the hull's present pose alone but along every pose the admitted motion and its stopping trajectory will sweep, so the stopping distance of the stopping budget enters through the length of that swept path. The motion is permitted if and only if the remaining margin is strictly positive at every pose along it. If the robot approaches an occluded cross aisle, d_{free} contracts rapidly regardless of how quickly the microcontroller evaluates the memory lookup; computational throughput cannot compensate for physical occlusion. How rapidly this usable clearance margin decays under persistent occlusion is analyzed in section 9.7.

Forgetting, decay, and change

A dynamic physical environment requires spatial memory to evict stale data systematically. In a logistics facility, pallets move, access doors swing open, and workers cross aisles that range finders observed to be vacant moments earlier. An embodied system that preserves observations indefinitely accumulates both phantom obstacles (retaining records of objects that have moved away)

and phantom free space (assuming unobserved regions remain empty after hazards enter). Active negative evidence clears phantom obstacles whenever fresh sensor rays traverse previously occupied cells. However, detecting hazards that enter unobserved voids presents a different challenge, because no sensor returns exist to contradict the stale assumption of clearance.

Practical mapping systems handle unobserved space through varying assumptions (table 9.3). OctoMap clamps cell log-odds between fixed saturation limits, ensuring that a voxel reinforced by hundreds of historical returns can still be cleared rapidly by a small batch of contradicting observations (Hornung et al. 2013). Clamping accelerates adaptation upon re-observation, but it cannot alter belief in unvisited cells. Independent Markov chain occupancy grids assign each cell an explicit two-state transition model with online-learned transition rates, allowing an unobserved voxel's occupancy belief to relax gradually toward its historical steady-state prior (Saarinen et al. 2012). Modern GPU-accelerated mapping pipelines adapt these concepts to real-time volumetric streams. For example, the nvblox library periodically decays the occupancy probability of out-of-view voxels toward 0.5 (the uninformative state), discarding the assumption that the unobserved world is strictly static (Millane et al. 2024; NVIDIA 2026b). Dynablox identifies transient dynamic objects by maintaining an incremental model of high-confidence free space and flagging unexpected point returns that penetrate that volume (Schmid et al. 2023). Similarly, Khronos separates spatial dynamics across temporal scales, employing a fast tracking loop for short-term movements inside an active window alongside an asynchronous factor-graph optimizer for persistent architectural shifts (Schmid et al. 2024).

These approaches rely on statistical rate models. They parameterize the expected rate of environmental change based on past traffic patterns or heuristic tuning. While average-case models are well suited for high-level motion planning and route optimization, the permission path requires hard worst-case bounds. The deterministic expiration mechanism formulated in this chapter establishes that worst-case counterpart. Specifically, an observed free cell reverts to the unknown state no later than the minimum time required for an unobserved object, moving at the facility's maximum physical velocity bound, to traverse the distance from the nearest occlusion boundary into that cell. A heuristic decay model satisfies safety requirements only if its decay schedule transitions cells to unknown at or before this physical traversal deadline. Otherwise, statistical decay remains an optimization heuristic for path planners rather than a certifiable safety assertion for motion gating.

Table 9.3: Map maintenance mechanisms and what they certify, as of 2026: Rate models describe expected change and serve planning; only an expiry derived from a speed bound certifies that an unobserved cell is still free. The erosion deadline in the last row is derived in section 9.7. The named systems are point-in-time implementations of each mechanism.

Mechanism	What happens to a cell nobody observes	Representative system (as of 2026)	What it cannot certify
Clamped log-odds	Nothing; clamping only speeds change when the cell is seen again	OctoMap	Any change in cells no ray reaches
Per-cell transition model	Occupancy relaxes toward a learned long-run value	Independent Markov chain grids	A worst case; learned rates describe past traffic
Decay toward unknown	Occupancy relaxes toward 0.5 at a fixed rate once out of view	nvblox	Safety, unless the rate is set from a speed bound
Dynamic-object detection	Unchanged; returns inside confident free space are flagged as moving	Dynablox	Objects the sensors do not currently see
Spatio-temporal SLAM	Unchanged until revisited; change is detected on reobservation	Khronos	The interval between visits
Deterministic expiry (this chapter)	Free becomes unknown at the erosion deadline set by the speed bound	Worked design	Nothing past the deadline, by construction

Together, these volumetric grid and distance-field rules bound where the machine may move, but they stop at geometry. While a volumetric distance field certifies where free space ends, it treats every occupied cell as an anonymous obstacle and cannot tell the task planner which surface is the tote handle or the cage door.

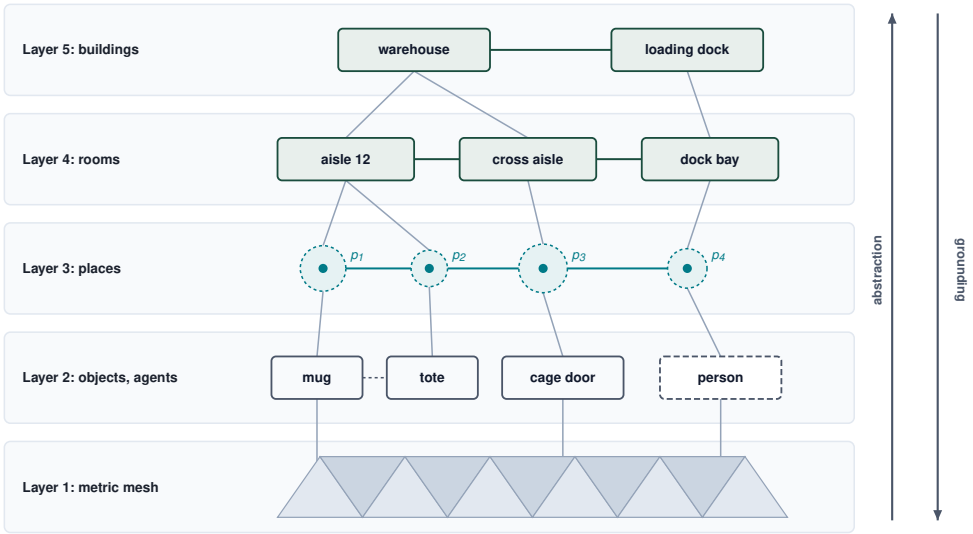

Figure 9.9: Hierarchical 3D dynamic scene graph architecture: Five-layer spatio-temporal memory organization bridging continuous 3D-indexed metric state stores to symbolic foundation reasoning. Drawn for the warehouse, Layer 1 captures triangular metric mesh geometry; Layer 2 extracts 3D objects and dynamic agents such as a walking person; Layer 3 models topological places via Voronoi freespace clearance spheres (p_i^{place}); Layer 4 structures architectural rooms and portals; and Layer 5 establishes global building mission topology. Vertical inter-layer edges coordinate upward abstraction (compressing metric surfaces into symbolic entities) and downward grounding (translating task tokens into metric coordinates) (adapted from Rosinol et al. (Rosinol et al. 2020, 2021) and Hughes et al. (Hughes et al. 2022)).

DRAFT

9.6.2 3D dynamic scene graphs

Supplying that identity is the job of semantic scene memory, which sits above the raw metric layer and inherits its physical constraints. Learned neural models infer what an object is, whereas the underlying metric mapping pipeline anchors where that object sits in physical space. Open-vocabulary scene memory bridges these domains using **3D vision foundation models**. A self-supervised visual backbone such as DINOv2 (Oquab et al. 2023) extracts dense patch feature representations. A promptable segmentation model such as the Segment Anything Model (SAM) (Kirillov et al. 2023) generates class-agnostic instance masks. Systems such as ConceptGraphs (Gu et al. 2024; Jatavallabhula et al. 2023) and Hydra (Hughes et al. 2022) lift those 2D masks and semantic features through calibrated depth, extrinsics, and visual odometry into an **object-centric 3D scene graph**. In this structured representation, each node represents an entity parameterized by a 3D centroid, a spatial covariance matrix, and a text-aligned multimodal embedding vector.

Drawn for the warehouse (figure 9.9), such a graph stacks five layers: a metric mesh, the objects and agents segmented from it (mugs, totes, the cage door, a walking person), topological places linked through free space, rooms such as aisles and dock bays, and the building itself. Edges between layers run both ways, compressing metric surfaces into symbols on the way up and grounding task tokens in metric coordinates on the way down.

Constructing and maintaining this semantic hierarchy consumes substantial compute and latency budgets. An illustrative vision foundation encoder requiring 3 TFLOP per frame at the navigation camera's full 60 Hz capture rate demands 180 TFLOP/s of sustained tensor throughput, even before accounting for image preprocessing, memory bandwidth, or post-processing clustering. By comparison, an edge application processor such as the NVIDIA Jetson AGX Orin achieves a manufacturer-specified peak of 43 dense FP16 TFLOP/s (as documented in its technical brief). This is a theoretical arithmetic ceiling that sustained neural workloads rarely approach, because memory bandwidth caps any kernel whose arithmetic per byte falls short of the processor's ratio of peak compute to peak bandwidth (Williams et al. 2009).

Because the illustrative foundation backbone exceeds this processor's peak throughput at full camera rate, the worked architecture implements a **multi-rate hierarchy**. In this decoupled design, lightweight metric processing pipelines running on the application processor consume raw frames delivered via direct memory access (DMA) to extract geometric obstacle points, update occupancy voxels, and track camera poses at the camera's full 60 Hz rate. Meanwhile, compute-intensive vision foundation backbones run asynchronously on selected keyframes at a reduced rate of 1 to 5 Hz, associating semantic embeddings and updating topological nodes. This multi-rate separation remains safe only because the high-frequency metric loop and the independent permission filter maintain certified physical stopping envelopes during the intervals between semantic updates.

↩ Each rate tier meets its own deadline across a non-blocking boundary, the decoupling established in section 4.3.

The vertical edges spanning the hierarchy in figure 9.9 enable dual-path reasoning. An agentic planner can query spatial relationships among objects and topological rooms without traversing millions of raw mesh vertices, while downstream manipulation requests (such as grasping a bin handle) resolve downward into precise Cartesian frames and localized geometry. From a systems memory perspective, each node encapsulates state elements that age at radically different physical rates:

1. *Geometric pose*: The spatial coordinates of an entity age according to the physical velocity bound of its category. A permanently anchored storage rack does not drift, whereas an unobserved cart or tote may displace at human walking speeds.
2. *Existence confidence*: The probability that an object remains present decays independently of its pose estimate. An unobserved tote may be removed entirely by a human worker; a narrow spatial covariance on an unobserved object provides false confidence if the entity itself is no longer present (section 9.11).
3. *Semantic classification*: Node category labels originate from learned visual embeddings. While semantic labels do not suffer physical drift over time, their validity is bounded by model calibration and out-of-distribution uncertainty, remaining uncorrected until the object is re-observed.

Contemporary frameworks update graph structures primarily upon re-observation: Hydra optimizes scene graph node poses when pose-graph loop closures update the underlying trajectory (Hughes et al. 2022), and Khronos registers object additions or removals when the robot revisits previously mapped areas (Schmid et al. 2024). Neither system explicitly tracks the temporal decay of unobserved entities using physical kinematic bounds. Tracking and enforcing these physical validity limits remains the responsibility of the belief record, and high-level symbolic abstractions can never refresh the evidence timestamps of the underlying metric cells. Beyond knowing where objects sit in the scene graph, a manipulation policy also needs to remember which physical actions it has already completed upon them.

9.6.3 Episodic memory and interaction history

When a transformer policy's sliding context window evicts older tokens as new camera frames stream in, the model can forget that it already unlatched the cage door or experienced a torque stall a hundred cycles ago. Metric representations and 3D scene graphs capture *where* surfaces, free space, and objects exist in the physical environment; **episodic memory** records *what happened*: the sequence of discrete contact transitions, grasping events, torque stalls, and human interventions that define a task execution history. By indexing physical events by their monotonic acquisition timestamps, episodic memory enables task planners to verify preconditions, for example confirming whether a mechanical latch was successfully unlatched or a transport tote was deposited into a fixture.

Learned policies frequently use attention mechanisms over past interaction tokens to infer task progress. However, maintaining unconstrained sequence histories is computationally intractable. A **streaming window** bounds transformer attention buffers by evicting historical tokens based on recency or attention sink criteria (Xiao et al. 2024). Such eviction policies operate independently of physical causality; an observation confirming that a container latch was secured a hundred navigation cycles ago is precisely the type of token dropped by a sliding context window. Consequently, the durable metric record and structured episodic state anchors must persist outside the transformer's transient attention buffer whenever their physical consequences continue to constrain manipulation. Retrieval augmentation supplies the policy with task context and relevant geometry, while the

underlying belief record carries the evidence epochs and error bounds that the permission path independently checks before admitting execution.

For reactive motion permission, any spatial assertion lacking an explicit evidence timestamp is treated as unverified, and any state estimate whose spatial uncertainty bound exceeds certified safety tolerances must be rejected before trajectory commands reach the hardware controller. Nevertheless, an embodied system cannot trigger emergency braking on every dropped sensor packet. Sustaining safe, fluid motion across transient sensor dropouts requires state estimators that propagate spatial belief forward in time under a declared error-growth law, with a deadline that governs execution until fresh observations either corroborate or correct the state.

9.7 Forward State Propagation and Occlusion Decay

When a sensor loses sight of a moving body, bringing the machine to a safe stop takes time and demands a usable state estimate throughout the deceleration interval. Forward propagation bridges this blind duration by projecting the most recent observation forward in time, whether the machine continues an authorized task or executes a protective fallback. A learned generative model can predict future trajectories autoregressively, and ensemble dispersion or Monte Carlo rollouts can quantify prediction variance. However, statistical spread alone does not constitute a certified upper bound on physical tracking error. In physical AI systems, forward state propagation must be anchored to explicit error-growth dynamics, whether implemented via the open-loop Kalman prediction step of equation 9.1, learned stochastic state observers, or expanding covariance ellipsoids.

Forward propagation updates the state estimate and expands its uncertainty envelope while preserving the original hardware capture timestamp. Across the unobserved interval, open-loop state estimation remains valid only so long as the growing error envelope remains within the task's geometric clearance. The rack end in the warehouse aisle shows where that boundary falls.

9.7.1 Bounded error growth and free-space erosion

At an aisle intersection, the gap between propagated prediction and live observation decides what the robot may safely execute. Where a storage rack ends, a worker may step abruptly into the clear distance $D_{\text{clear}} = 1.10$ m defended by the machine's stopping budget. Once the rack structure occludes the cross aisle, the central question becomes how long remembered free space can certify that the vehicle's path remains clear.

Every mathematical dynamics model simplifies physical reality, causing the discrepancy between the projected state and the physical world to compound continuously during sensor dropouts. This uncorrected drift is the open-loop prediction step of equation 9.1 running without measurement updates, the same widening seen over one sample step in figure 9.1, now compounded across the entire occlusion. In state estimation, this dispersion is called **occlusion covariance expansion**, the continuous widening of uncertainty while the sensors have no line of sight. Formalized by continuous Lyapunov or Riccati covariance propagation equations (section B.8), this propagation describes modeled dispersion before sensors regain visibility; hard divergence bounds require separately qualified disturbance limits.

In a deterministic bounded-disturbance framework, empirical sensor characterization and mechanical disturbance limits establish an initial position error bound e_0 at the instant of occlusion ($\Delta t = 0$). Two bounded physical terms subsequently degrade the state estimate. First, unmodeled kinematics introduce a drift velocity bounded by v_{drift}. Second, unmodeled forces and structural dynamics introduce a disturbance acceleration bounded by a_{dist}. Over an occlusion interval Δt, the worst-case position error bound $E(\Delta t)$ expands quadratically:

$$E(\Delta t) = e_0 + v_{\text{drift}}\Delta t + \frac{1}{2}a_{\text{dist}}(\Delta t)^2 \tag{9.12}$$

At the rack end, the stored belief is not the tracked position of an external object, but rather a spatial occupancy assertion: no person stands within the protective clearance margin δ_{margin} (100 mm) of the robot. The spatial map vouches for this claim out to the free-space depth d_{free} (section 9.6.1), defined as the distance from the vehicle hull to the nearest cell lacking active sensory evidence. Any obstacle hidden from the sensors lies across that occlusion boundary.

Two physical uncertainties consume this free-space buffer. First, onboard localization uncertainty introduces a bounded error δ_{loc} (50 mm), meaning the true physical clearance may already be smaller than the nominal map indicates. Second, an unobserved person can advance outward from behind the rack corner at an approach velocity bounded by $v_h = 1.6$ m/s, the standardized human walking speed mandated in safety standards (International Organization for Standardization 2024a).[10] Matching these physical parameters to the quadratic expansion in equation 9.12 yields an error growth $E(\Delta t) = \delta_{\text{loc}} + v_h\,\Delta t$ with zero acceleration disturbance ($a_{\text{dist}} = 0$). The allowable task tolerance is the uncommitted clearance $d_{\text{free}} - \delta_{\text{margin}}$. As a result, the certified free region erodes inward from the unobserved frontier at walking speed, causing the spatial claim to lapse at:

$$T_{\text{inv}} = \frac{d_{\text{free}} - \delta_{\text{loc}} - \delta_{\text{margin}}}{v_h} \tag{9.13}$$

This derivation starts from the observed free-space depth at capture. A frozen snapshot constructed with erosion already reserved through its support deadline must not apply that same erosion again; its fixed header still limits use to the validated interval. The safety pipeline evaluates this **free-space erosion** law across every swept volume that the admitted motion and its stopping trajectory will occupy. Any nonpositive result ($T_{\text{inv}} \le 0$) indicates that memory certifies no safe clearance along that path. This relationship formalizes the worst-case boundary of occlusion-aware reachable sets used in automated vehicle navigation, where the reachable volume of an occluded traffic participant expands outward from the visibility horizon (Orzechowski et al. 2018).

Two positions of the hull bracket the problem. Abreast of the rack end, the unobserved cross aisle begins immediately at the upright beam, so d_{free} equals the lateral clearance between the hull and the rack. Ahead of the vehicle along its current heading, the nearest unobserved boundary lies at the rack corner, D_{clear} away. In the top view of figure 9.10, a person hidden in the cross aisle can be anywhere inside a disc that grows at v_h from the rack end. In its time plot, the depth certified ahead of the hull falls to zero at 593.75 ms, while the depth abreast sits at zero from the instant of capture. Notebook 9.2 evaluates both cases numerically.

10 **Walking Approach Speed**: ISO 13855 positions a safeguard at $S = v_h\,T + C$ from a hazard, where T is the overall stopping time, C is an intrusion allowance, and v_h is the approach speed (1.6 m/s for a walking body) (International Organization for Standardization 2024a). v_h is a design convention the standard adopts, not a measured human maximum, and a person who runs exceeds it. The rack-end deadline therefore inherits a site premise, that nobody in the aisle moves faster, which the site must enforce or qualify.

Napkin Math 9.2: The erosion deadline

Problem: The navigation camera has just seen the aisle empty, and the rack uprights hide the cross aisle. For how long does that frame certify the space abreast of the rack end, and the space ahead of the hull, and how much of the second deadline is left when memory receives the frame?

Variables:

- Localization bound $\delta_{\text{loc}} = 50$ mm (illustrative) and protective clearance $\delta_{\text{margin}} = 100$ mm (chosen).
- Approach speed $v_h = 1.6$ m/s (datasheet: the ISO 13855 walking speed).
- Free-space depth abreast, the side clearance, $d_{\text{free}} = 150$ mm; ahead, $d_{\text{free}} = D_{\text{clear}} = 1.10$ m (both illustrative).
- Frame age at dispatch $t_{\text{age}} = 51.6$ ms (derived, section 8.4.1); navigation-camera frame period 16.7 ms (datasheet).

Math: Abreast of the rack end, equation 9.13 gives

$$T_{\text{inv}} = \frac{(0.15 - 0.05 - 0.10)\ \text{m}}{1.6\ \text{m/s}} = 0\ \text{ms}$$

Ahead of the hull it gives

$$T_{\text{inv}} = \frac{(1.10 - 0.05 - 0.10)\ \text{m}}{1.6\ \text{m/s}} = 593.75\ \text{ms}$$

and the frame's age at dispatch leaves

$$593.75 - 51.6 = 542.15\ \text{ms} \approx 33 \times 16.7\ \text{ms}$$

Result: Abreast of the rack end the frame certifies nothing, even at the instant of capture. Ahead of the hull it certifies 593.75 ms, of which the frame's age spends 82.6 mm of depth before memory receives it, leaving about 33 frame periods.

Systems insight: The deadline is set by the distance from the unobserved boundary, not by the frame rate or the speed of the lookup. Each millimeter of free depth beyond $\delta_{\text{loc}} + \delta_{\text{margin}}$ buys 0.625 ms, so no camera, however fast, gives the position beside the rack end any memory at all; only a sensor that sees the cross aisle can.

In the open aisle, spatial memory reliably bridges temporary camera frame drops. However, the notebook's deadline is computed for a hull standing at its current pose. A hull that drives toward the rack end at speed v closes on the occlusion boundary while the hidden person closes on it from the other side. The depth certified ahead therefore shrinks at $v + v_h$ rather than at v_h. Each successive swept volume along the planned path starts closer to the boundary, until the horizon reaches zero abreast of the rack uprights. The stopping budget makes the same point in distance. At the 1.5 m/s drive limit, the stopping-budget terms charged before memory enters already claim 912.9 mm of the 1.10 m clear distance before anyone moves in the cross aisle. The safety enforcement path must therefore evaluate equation 9.13 along the entire planned trajectory. The robot must bring itself to a controlled stop, or reacquire line-of-sight visibility into the cross aisle, before any point on the swept path breaches its invalidation deadline. The clear distance the sensors can still see caps the speed at which the hull may approach an occluded rack end, a ceiling that section 12.3.2 plots against clearance. Memory certifies clearance only to a depth governed by the physical distance to the occlusion boundary. At the rack corner, that geometric depth vanishes completely.

Nothing in the software data structures explicitly marks the moment a spatial record expires. The occupancy map may continue to report an empty cross aisle, and the state estimator may continue to publish syntactically valid ROS messages, yet the prediction has ceased to function as physical evidence. Cells within the erosion front revert to unobserved space, and the region beside the rack end becomes uncertified the instant the uprights obscure line of sight. The robot's stopping budget defends against a static obstacle at D_{clear}, such as a stationary worker or a dropped tote. Spatial memory adds a temporal deadline to that stopping budget without granting any additional physical braking clearance; the 912.9 mm partial stopping distance established in section 8.4.1 is the same with memory as without it.

A pedestrian actively walking toward the robot during a stopping maneuver alters the safety budget completely. In standardized safety calculations, an approaching human introduces an intrusion distance $v_h(\tau_{\text{delay}} + T_{\text{stop}})$, where walking speed acts across both the system reaction latency τ_{delay} and the mechanical braking time T_{stop} (International Organization for Standardization 2024a). At the 1.5 m/s drive limit, where a constant-deceleration stop requires $T_{\text{stop}} = v/a_{\text{brake}}$, this pedestrian displacement term alone consumes 1.41 m. This distance already includes the declared reaction latency and exceeds the entire 1.10 m clearance before adding the separately charged controller dispatch interval or the vehicle's own stopping travel. The walking-person speed ceiling this term imposes on a jerk-limited stop is derived in section 12.3.1.

Consequently, static clearance models cannot justify an unrestricted shared pedestrian crossing. Mitigating this risk requires engineered site controls, such as designated pedestrian crosswalks coupled with fixed infrastructure presence sensing at rack corners. Until detection coverage, sensor latency, and traffic protocols are qualified, site operations must retain this premise as an active operational constraint. Under no circumstances can stale spatial memory substitute for missing sensory evidence. Regardless of which traffic rules govern the facility, the robot's permission pipeline must reject any trajectory whose clearance margin relies on unobserved space past the belief's invalidation deadline.

↪ Unqualified environmental premises are enforced as operational restrictions in section 18.3.3.

9.7.2 The invalidation horizon

The two rack-end deadlines, for the aisle ahead and for the space abreast of the rack end, are instances of one physical quantity: the elapsed time at which a belief's growing error bound reaches the tolerance of the task it supports. Beyond that point, an extrapolated belief can no longer prevent a collision or a mechanical jam.

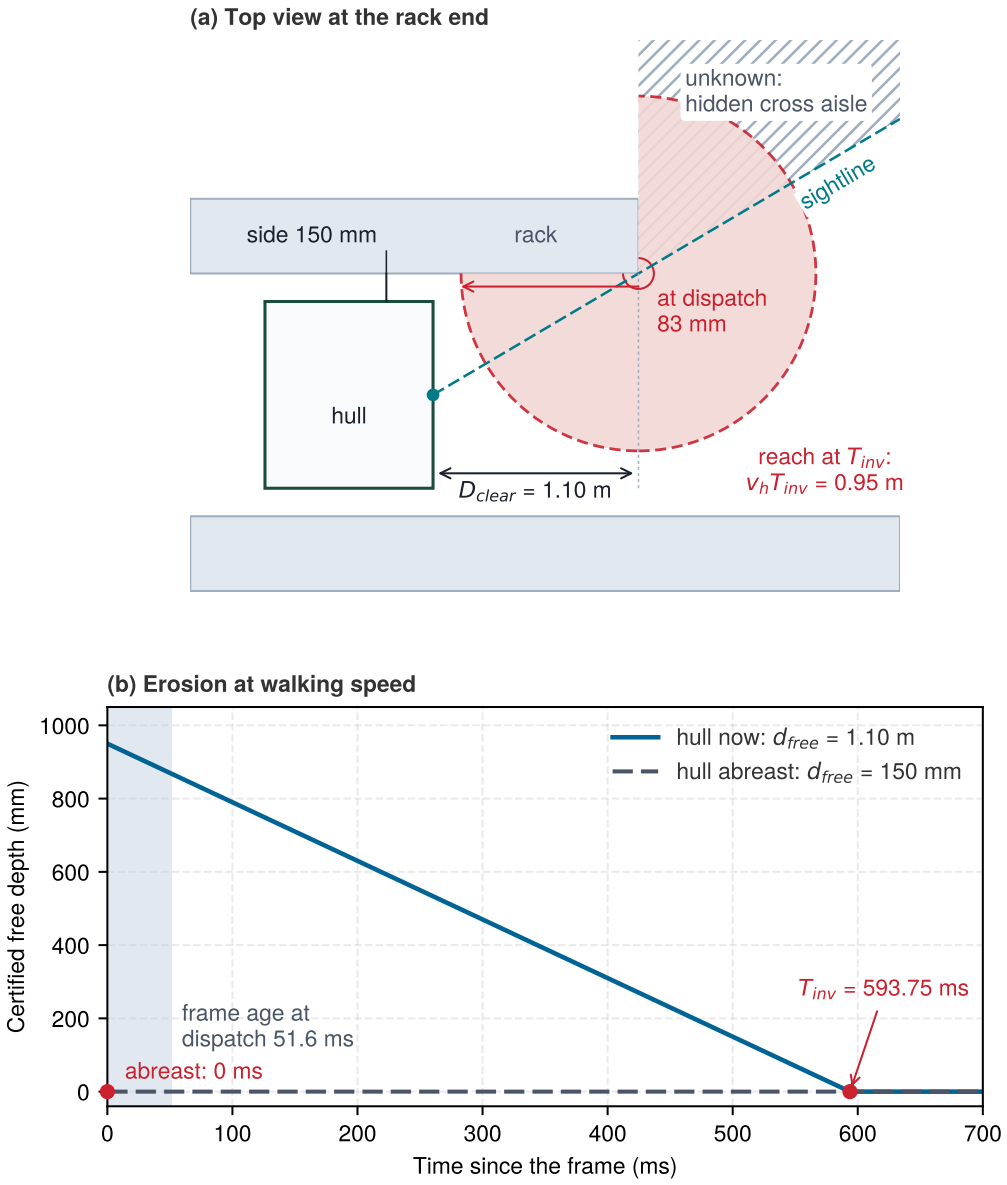

Figure 9.10: Free-space erosion at the rack end: (a) Top view. The navigation camera's sightline passes the rack end, so the cross aisle behind the rack is unknown from the moment of capture. A person hidden there can advance at v_h = 1.6 m/s; the dashed disc is the region that person may occupy when the claim lapses, which stops $\delta_{\text{loc}} + \delta_{\text{margin}}$ short of the hull's front. (b) The depth memory still certifies, $d_{\text{free}} - \delta_{\text{loc}} - \delta_{\text{margin}} - v_h t$. For the hull's current position it falls from the initial clear distance less localization error and protective clearance to zero at 593.75 ms, and the frame's 51.6 ms age at dispatch is spent before memory receives it; abreast of the rack end, the 150 mm side clearance certifies nothing even at capture.

Definition 9.2: Belief state invalidation horizon

Belief state invalidation horizon (T_{inv}) is the elapsed time since the last physical observation at which the belief's validated error bound $E(\Delta t)$ first reaches the tolerance r_{tol}:

$$T_{\text{inv}} = \inf\{\Delta t \geq 0 : E(\Delta t) \geq r_{\text{tol}}\} \tag{9.14}$$

where $E(\Delta t)$ is a bounded-disturbance growth law such as equation 9.12 or a calibrated error quantile, and a belief whose evidence epoch is t_0 stops supporting motion at $t_0 + T_{\text{inv}}$.

1. **Significance**: Marks the instant at which forward-propagated state estimation ceases to function as valid physical evidence, requiring the permission path to refuse dependent motion proposals before geometric clearance is breached. The same walking-speed bound gives the free space ahead of the hull 593.75 ms and the space abreast of the rack end 0 ms, so the horizon belongs to a belief and its tolerance, never to the machine as a whole.
2. **Distinction**: Unlike open-loop timeout watchdogs that monitor software process heartbeat intervals, the invalidation horizon is derived from continuous physical kinematics, bounded disturbance dynamics, and mechanical clearance constraints.
3. **Common pitfall**: Allowing a neural planner or Kalman filter to continuously extrapolate state estimates during extended sensor dropouts without bounding error expansion, mistaking smooth mathematical extrapolation for physical ground truth.

When the error growth law is linear, $E(\Delta t) = e_0 + r\,\Delta t$, the invalidation horizon simplifies to a direct closed form:

$$T_{\text{inv}} = \frac{r_{\text{tol}} - e_0}{r} \tag{9.15}$$

where a nonpositive result ($T_{\text{inv}} \leq 0$) indicates that the belief cannot support the task even at the instant of capture. The free-space erosion law of equation 9.13 instantiates this linear form with initial localization uncertainty $e_0 = \delta_{\text{loc}}$, approach speed $r = v_h$, and task clearance $r_{\text{tol}} = d_{\text{free}} - \delta_{\text{margin}}$. The moving mug-handle belief in section 9.10 applies this exact formulation using conveyor belt velocity. Computed for the evidence behind one action chunk, the root of equation 9.14 is the evidence horizon of section 3.5.2.

↪ The intent lease uses the invalidation horizon as the evidence horizon in its expiry; for an untracked conveyor target that horizon takes this linear form, as developed in section 10.5.

9.7.3 Accelerating error at the latch slot

In the rack-end scenario, a linear velocity bound set the erosion rate; at the cage door, the narrow opening of the latch-release slot sets the task tolerance r_{tol} while unmodeled accelerations compound quadratically over time. When the gripper finger enters the slot, the end-effector blocks the wrist camera's view, forcing the state estimator to integrate commanded joint torques through a nominal plant model without visual feedback. Because unmodeled forces and cable drag accelerate position error far faster than constant-velocity drift, an open-loop bridge that held across a dropped frame in the aisle can jam the finger against the slot wall in tens of milliseconds.

Throughout that blind insertion, the finger must remain aligned within 1 mm of the slot centerline, defining the mechanical task clearance r_{tol}. The other bounds carry over from the missed-frame scenario in section 9.5: an initial position error $e_0 \leq 0.1$ mm and an unobserved velocity drift $v_{\text{drift}} \leq 12$ mm/s. During occlusion, dynamic disturbances add an unmodeled acceleration bounded by $a_{\text{dist}} \leq 50$ mm/s². Under these bounds the error grows quadratically from e_0 and meets r_{tol} at the invalidation horizon $T_{\text{inv}} = 66$ ms (figure 9.11). A naive constant-velocity estimate rises more slowly and keeps admitting the belief out to 75 ms, after the bounded error has already breached the clearance.

Because the belief representation transforms the slot relative to the wrist pose at its exact capture epoch, which resolves the coordinate staleness analyzed in section 9.5, the growth law in equation 9.12 is freed from lever-arm rotational compounding. Position error expands solely through drift velocity and disturbance acceleration. Over a single 16.7 ms frame interval, this formulation limits position error to 0.31 mm, compared to 1.05 mm under an uncoordinated coordinate transform chain. Eliminating lever-arm extrapolation error allows the manipulation system to bridge brief sensor dropouts reliably where an unaligned pipeline would fail immediately.

Evaluating this bounded growth model with the scenario parameters yields $E(\Delta t) = 0.1 + 12\,\Delta t + 25\,(\Delta t)^2$, where elapsed time Δt is in seconds and error $E(\Delta t)$ is in millimeters. Setting $E(\Delta t) = r_{\text{tol}}$ produces the quadratic characteristic equation $25\,(\Delta t)^2 + 12\,\Delta t - 0.9 = 0$. The positive real root establishes an invalidation horizon of $T_{\text{inv}} = 66$ ms. Motion plans relying on this visual estimate must complete or transition to a qualified fallback before this deadline, with deceleration commands dispatched in advance.

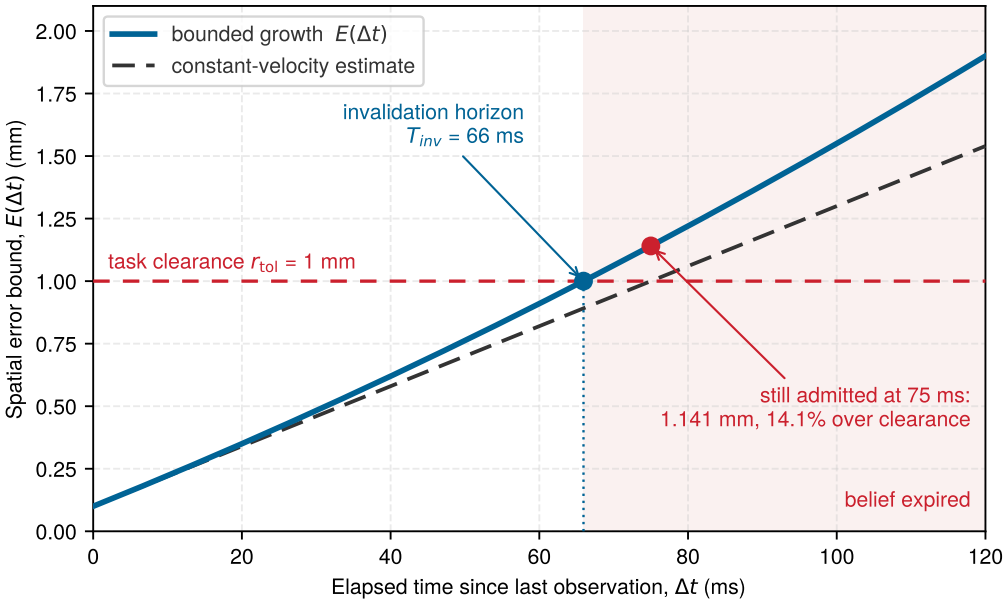

Figure 9.11: Belief uncertainty and invalidation horizon: Illustrative spatial error bound $E(\Delta t)$ of a gripper finger entering the cage door's latch-release slot, expanding quadratically under unobserved forward propagation until intersecting the slot clearance r_{tol} = 1 mm at invalidation horizon T_{inv} = 66 ms; the shaded region beyond it is elapsed time for which the belief no longer supports motion. A dashed constant-velocity estimate grows more slowly, and the red marker shows that estimate still admitting the belief at 75 ms, after the bounded error has passed the clearance. Belief has a shelf life governed by physical disturbance dynamics, and only qualified new evidence can renew the relevant state claim.

If the mechanical slot is machined to a tighter clearance of 0.30 mm, the invalidation horizon contracts sharply to 16.1 ms ($25\,(\Delta t)^2 + 12\,\Delta t - 0.2 = 0$). Tightening the mechanical clearance by a factor of 3.3× reduces the available prediction window by a factor of 4.1×, because the initial error consumes a larger share of the tighter tolerance. Subtracting the unchanged initial error leaves 0.9 mm in the original slot and 0.2 mm in the tighter one, so the usable-slack ratio exceeds the total-tolerance ratio. Acceleration separately shortens both horizons. In contrast, an estimator that naively assumes constant velocity ($a_{\text{dist}} = 0$) predicts an overly optimistic horizon of $(r_{\text{tol}} - e_0)/v_{\text{drift}} = 75$ ms. By that time, the bounded acceleration model permits error up to 1.141 mm, exceeding the allowable clearance by 14.1 percent. A controller operating on constant-velocity extrapolation would continue unguided insertion for 9 ms beyond safe physical bounds, risking mechanical jam or tool damage.

9.7.4 Covariance growth and probabilistic bounds

During a sensor dropout, double-integrating unmodeled acceleration noise causes position variance to grow with the cube of elapsed time, and feeding a raw variance directly into a geometric clearance check confuses statistical spread with a physical boundary. Both worked examples above bounded position error with deterministic limits. Inside a stochastic state estimator, variance propagation separates three distinct physical mechanisms that drive error growth during an occlusion. An unmeasured velocity error at the onset of occlusion causes position variance to expand quadratically as $\sigma_{v,0}^2(\Delta t)^2$. Unmodeled stochastic forces such as torque ripple or structural vibration, integrated twice across the dynamics, expand position variance cubically as $\frac{1}{3}q_c(\Delta t)^3$; these variance terms define the spread that calibrated confidence quantiles must absorb. In contrast, a persistent unmodeled force bounded by $|a_{\text{dist}}|$ (cable drag or sliding friction, for instance) deflects the body deterministically by at most $\frac{1}{2}a_{\text{dist}}(\Delta t)^2$, corresponding to the quadratic term in equation 9.12.[11]

These stochastic variance terms populate the estimator's internal **covariance matrix**, which quantifies the dispersion of a probabilistic error model rather than a hard physical clearance bound. Position variances carry squared length units (m^2), so their growth cannot be substituted directly

[11] **Non-Smooth Contact Dynamics**: Coulomb friction is set-valued at zero sliding speed, and a switch between stick and slip changes the contact dynamics. An impact can also change velocity abruptly. A smooth drift model qualified for one contact regime does not automatically bound these transitions. The belief record therefore treats a change of contact mode as leaving its validity region (section 9.10), not as one more bounded disturbance.

into geometric clearance checks. To examine how stochastic uncertainty expands during complete sensor dropouts, consider a kinematic body whose continuous translational acceleration is driven by unmodeled disturbance or actuator jitter modeled as zero-mean continuous Gaussian white noise. The acceleration obeys $\ddot{\mathbf{p}}(t) = \mathbf{w}(t)$, with $\mathbf{w}(t) \sim \mathcal{WN}(0, \mathbf{Q}_c)$, where $\mathbf{Q}_c = q_c\mathbf{I}$ represents the continuous power spectral density of acceleration noise with physical units $\mathrm{m}^2/\mathrm{s}^3$.

Integrating acceleration once yields velocity $\mathbf{v}(t) = \mathbf{v}(0) + \int_0^t \mathbf{w}(t')\,dt'$. Integrating a second time over elapsed duration t gives the physical position:

$$\mathbf{p}(t) = \mathbf{p}(0) + \mathbf{v}(0)t + \int_0^t (t-t')\mathbf{w}(t')\,dt'$$

To isolate the contribution of process noise, assume initial position and velocity are known precisely. During an occlusion interval where external measurement updates cease, the estimator projects state forward using its nominal transition model $\hat{\mathbf{p}}(t) = \hat{\mathbf{p}}(0) + \hat{\mathbf{v}}(0)t$. The unobserved position error covariance $\mathbf{P}_{pp}(t) = \mathbb{E}[(\mathbf{p}(t) - \hat{\mathbf{p}}(t))(\mathbf{p}(t) - \hat{\mathbf{p}}(t))^\top]$ accumulates continuous noise variance through double integration:

$$\mathbf{P}_{pp}(t) = \int_0^t (t-t')^2 q_c \mathbf{I}\,dt' = q_c\mathbf{I}\left[-\frac{(t-t')^3}{3}\right]_0^t = \frac{1}{3}q_c t^3\mathbf{I}$$

Double integration causes process-noise covariance to expand cubically with elapsed time ($\propto t^3$), the same $\sqrt{t^3/3}$ growth that set the BMI088 accelerometer's noise contribution in section 9.2. If initial state uncertainty is nonzero, the complete error covariance additionally incorporates propagated initial position variance, initial velocity variance, and their cross-covariance terms. Raw covariance represents stochastic dispersion rather than a guaranteed physical clearance boundary. To use this uncertainty in safety enforcement, the system must project covariance into a spatial safety margin through a calibrated coverage factor k (for instance, corresponding to a Chebyshev or Gaussian confidence bound), augmented by bounded systemic biases omitted by the noise model. For spherical or polyhedral bounding volumes, the nominal geometric hull can be inflated dynamically:

$$r_{\text{inflated}}(t) = r_{\text{hull}} + k\sqrt{\lambda_{\max}(\mathbf{P}_{pp}(t))}$$

where $\lambda_{\max}(\mathbf{P}_{pp}(t))$ denotes the principal eigenvalue of the position covariance matrix. The belief record must explicitly furnish these growth bounds and underlying assumptions before the permission path can rely on them to keep execution collision free.

A safety argument can rest on one of two distinct paradigms. In a **bounded-disturbance** framework, rigorous physical qualification establishes explicit limits on initial state errors, maximum drift velocities, disturbance accelerations, clock synchronization offsets, and contact mode transitions. Under these conditions, the 593.75 ms aisle-ahead horizon and the 66 ms latch-slot horizon represent deterministic, conditional worst-case deadlines within the qualified operating domain. Alternatively, in an empirical or data-driven regime, controlled sensor dropout trials benchmarked against high-precision ground truth can calibrate residual error quantiles (such as p99 or p99.9) across a representative operational distribution. This yields a probabilistic admission bound with a 1 percent or 0.1 percent tail risk, prior to unmodeled structural shifts. In both architectures, the spatial memory record and the consuming controller must explicitly declare the active validation regime, track operating domain invariants, and trigger a verified safe fallback if observations exceed the validity boundary.

↪ The barrier-function permission test that consumes such clearance margins is developed in section 12.5.

Both frameworks converge on one engineering invariant. The invalidation horizon (definition 9.2) marks the precise instant at which the propagated error bound intersects the allowable task tolerance, regardless of whether that bound stems from worst-case physics or calibrated statistical quantiles. Belief expiration is physical rather than computational. It is neither a generic network socket timeout nor an arbitrary 100 ms polling heuristic selected for scheduling convenience. Rather, T_{inv} is a deadline dictated by spatial clearance, machine kinematics, and disturbance dynamics. Beyond $t_0 + T_{\text{inv}}$, downstream controllers cannot assume the estimated pose satisfies the task's safety envelope.

9.7.5 Expiry across the machine's beliefs

A single global staleness timeout across the robot either admits a blind latch insertion long after the finger has drifted past the slot wall, or halts the mobile base in an open aisle while half a second of certified clearance remains. Because operating speed, carried payload, and contact state reshape disturbance bounds dynamically, the invalidation horizon in equation 9.14 cannot be reduced to a single global constant for the entire robot. Instead, the perception and memory interface must compute distinct expiry horizons for each operational regime. Transitions between regimes can alter validity instantaneously; for example, shifting from free flight to mechanical contact introduces impulsive impact dynamics within milliseconds, violating the continuity assumptions of smooth drift models.

Consequently, multiple spatial beliefs coexisting on the same physical platform expire along completely different timelines (table 9.4). A manipulator finger aligning with a latch slot is constrained by tight millimeter tolerances and compounding acceleration disturbances. Simultaneously, free-space claims around the mobile base and tracking estimates of a coworker near the arm share the same standardized human walking speed bound v_h. Even these human-centric beliefs, however, lapse at markedly different intervals, because each originates from a different initial localization uncertainty and must satisfy a distinct geometric tolerance. For volumetric free space, that tolerance is determined by the distance to the nearest occlusion frontier.

Table 9.4: Belief-expiry roots on the machine: Each root solves $E(t) = r_{\text{tol}}$ for that belief's error model and task limit. The two free-space rows are equation 9.13, with limits set by the depth to the nearest unobserved boundary less the protective clearance. The coworker's initial error is illustrative and its tolerance chosen, while its speed is the same walking-speed bound, so all three rows set by a person's motion grow linearly. The last column names the required disposition by that root; any physical response must begin early enough to remain feasible. The mug-handle belief, whose growth is set by the conveyor rather than a person, is worked in section 9.10.

Belief	Error bound $E(t)$ (mm; t in s)	Task limit (mm)	Root	Response at expiry
Free space abreast of the rack end	$50 + 1600t$	50	0 ms	Treat the cross aisle as unknown; refuse dependent advance
Free space to the rack end ahead	$50 + 1600t$	1000	593.75 ms	Refuse motion that relies on the claim; renew from the next frame
Latch-slot finger	$0.1 + 12t + 25t^2$	1	66 ms	Refuse the insertion; hold compliantly or reacquire the slot
Coworker beside the arm	$15 + 1600t$	150	84 ms	Revoke dependent arm motion; stop only if braking clearance remains

When an expiry deadline is reached, the motion permission system must refuse dependent actuation proposals until fresh sensory observations restore valid evidence. Even upon reacquisition, sensory updates renew state authority only under strict validation checks. Upon receiving new sensor data, the estimator computes the measurement innovation (section 9.2), the discrepancy between incoming physical measurements and predicted sensor observations. Incorporating this innovation requires verifying data association, sensor calibration, and physical feasibility constraints. A large innovation residual typically signals an unmodeled disturbance, an outlier measurement, or a tracking failure, which the estimation filter must isolate before granting motion permissions. Conversely, a state update must never trigger discontinuous step commands to low-level motor controllers; trajectory generation must preserve acceleration continuity. Furthermore, as the force-and-bias case of section 9.8 shows, a deceptively small innovation residual in observable dimensions provides no guarantee of accuracy along unobserved state dimensions.

Checkpoint 9.2: Deadlines, frames, and maps

Every deadline in table 9.4 comes from a growth law, a tolerance, and a map that preserved the evidence epochs behind them. These items test all three.

- ☐ **Expiry estimate**: If the coworker's tolerance tightened from 150 mm to 100 mm, with the same initial error and walking speed, what would its invalidation horizon be, and where would the row then fall relative to the latch-slot finger?
- ☐ **Horizon vs. timeout**: Can you explain why a single staleness timeout for every belief must over-admit some rows of the table and under-admit others?
- ☐ **Common-epoch composition**: Can you explain why the same finger misses the slot after one stale frame on a hand-composed chain yet stays within it for several frames when the slot is chained against the wrist pose of its own capture epoch?
- ☐ **Representation choice**: Can you explain why the local snapshot is a Euclidean distance field, and which resource, rather than lookup time, then limits its voxel pitch?
- ☐ **Map revisions**: Can you explain why a loop closure can misplace a remembered cell whose evidence epoch still passes every age check?

Every invalidation horizon is only as trustworthy as its error growth model. Such a model remains dependable only to the extent that the physical system can detect when its assumptions fail, whether through innovation monitoring upon reacquisition or systematic validation during sensor dropout trials. When unmodeled disturbances act along unobservable degrees of freedom, the system can drift far outside its tolerance without generating any detectable residual, which is why conservative geometric clearance and explicit physical bounds remain indispensable.

9.8 Observability Ceilings and Estimation Limits

A force sensor can report the exact same reading when mechanical contact force increases as when its analog conditioning circuit drifts thermally. Sampling that stream repeatedly cannot distinguish the two physical causes. The underlying question is observability, whether a system's available sensor outputs and known physical dynamics suffice to reconstruct the internal states required for control. Consider an instantaneous observation model $\mathbf{y} = h(\mathbf{x})$. When distinct physical states $\mathbf{x}_1 \neq \mathbf{x}_2$ yield identical measurements ($h(\mathbf{x}_1) = h(\mathbf{x}_2)$), the sensor mapping alone cannot separate them. In a combined force-and-bias state, equal and opposite shifts in contact force and sensor bias form an insensitive direction in the observation Jacobian $\mathbf{H} = \partial h / \partial \mathbf{x}$. Because this direction lies in the null space of $\mathbf{H}$, local state variations along it produce zero change in the measurement vector. The measurement likelihood therefore has zero directional derivative along this unconstrained direction, although it may still vary in directions that change the measured sum. Instantaneous ambiguity does not automatically imply unobservability across time; if subsequent motion or control actions induce dynamics that differentiate the states, temporal filtering can resolve the ambiguity. However, if the ambiguity persists along the entire operating trajectory, no amount of signal processing can recover the lost degrees of freedom. Scaling up neural network parameters or adding recurrent layers expands representational capacity, but computation cannot synthesize physical information that no sensor ever transduced.

Observability depends on both the sensor suite and the executed trajectory. When a physical disturbance drives a required state along an unobserved manifold, an estimator can fall into the **zero-innovation trap**. The innovation vanishes ($\nu = \mathbf{y} - \mathbf{H}\hat{\mathbf{x}} = \mathbf{0}$), so no measurement ever contradicts the model. The covariance update depends on the modeled noise and measurement geometry rather than the observed residual. It can contract uncertainty in measured or model-coupled directions without revealing omitted drift along an unobservable direction. A misspecified filter that treats bias as known can therefore contract its reported force uncertainty while the true force and omitted bias drift apart without changing the measured sum.

Consider an illustrative strain-gauge force sensor mounted at the mobile manipulator's wrist, delivering a steady reading of 5 N. Once an unknown bias is introduced, this single reading is compatible with an infinite continuum of true contact forces. An estimator or learned policy that

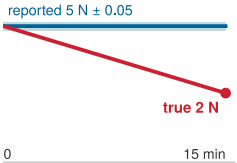
reports this contact force with narrow confidence bounds has not demonstrated that the state is **observable**.[12] When two distinct physical state histories map to the identical sequence of sensor observations, no downstream algorithm, whether an extended Kalman filter or a deep recurrent network, can deduce which trajectory the physical system followed. The digital computing substrate receives identical bitstreams across both realities.

[12] **Observability Rank Test**: For the force-plus-bias state with $\mathbf{H} = [1\ 1]$ and static dynamics $\mathbf{F} = \mathbf{I}$, Kalman's observability matrix stacks $\mathbf{H}$ and $\mathbf{HF}$. Because these two rows are identical, the matrix has rank one rather than two (Rudolf E. Kalman 1960). The unobservable direction corresponds to an equal increase in contact force and decrease in sensor bias, a mode that no number of scalar samples can resolve. Restoring full rank requires an independent sensing channel, an active excitation, or an external reference load.

> **Definition 9.3: Observability**
>
> ***Observability*** is the property that the history of a machine's sensor outputs over a finite time window, combined with its known control inputs and system dynamics, uniquely determines its initial state, ensuring that distinct physical trajectories produce distinct measurement sequences.
>
> 1. **Significance**: Observability defines the hard physical ceiling on state reconstruction, regardless of model architecture or parameter count. In the strain-gauge example below, a 3 N bias shift over 15 minutes alters the true contact force by 60 percent while the innovation remains zero, because the sensor records only their scalar sum.
> 2. **Distinction**: Observability is distinct from predictability. An estimator can project a future state with minimal covariance based entirely on prior dynamical assumptions; only measurements sensitive to that state can verify the prediction against reality.
> 3. **Common pitfall**: A vanishing innovation does not validate state accuracy. Along an unobservable manifold, the innovation residual can remain zero while tracking error grows. A misspecified filter can still contract its reported covariance under its model assumptions; the zero residual does not justify that contraction.

To trace the operational impact of this distinction, consider the wrist gripper regulating contact force against a rigid surface. Let $x(t)$ denote the true normal contact force, while the strain-gauge conditioning electronics introduce an unknown, slowly drifting bias $b(t)$. The raw measurement stream delivered to the estimator at each sample interval is $y(t) = x(t) + b(t)$. Suppose the sensor transmits a constant reading $y(t) = 5$ N. This measurement is satisfied by a true force $x(t) = 5$ N with zero bias $b(t) = 0$ N. However, it is equally satisfied by a true force $x(t) = 2$ N with a sensor bias $b(t) = 3$ N, or even by $x(t) = 0$ N with a bias $b(t) = 5$ N. For any arbitrary offset trajectory $\Delta(t)$, the paired state trajectory $(x(t) - \Delta(t), b(t) + \Delta(t))$ generates an identical measurement sequence $y(t)$. The difference between physical contact force and sensor bias lies within the **unobservable subspace** of the measurement model, the null space in which the two variations cancel exactly in the digitized signal.

Unable to distinguish physical load from electronic drift, an estimator must fall back on prior assumptions about state evolution. If a Kalman filter or recurrent estimator assumes that bias $b(t)$ remains static with near-zero process noise, it attributes all measurement variations in $y(t)$ directly to changes in contact force $x(t)$. As new samples arrive at 1,000 Hz, the estimator repeatedly folds the measurements into its belief state. Because the incoming stream aligns with the forward state propagation, the computed covariance contracts monotonically. The estimator then publishes an aggressively tight uncertainty bound of 5 N $\pm$ 0.05 N at p99. In reality, heat generated by nearby joint actuators warms the mechanical wrist bracket, inducing thermoelastic drift in the strain gauge. Sensor bias $b(t)$ creeps at 0.2 N/min. Over 15 min, this thermal drift shifts $b(t)$ by 3 N. True physical force on the workpiece drops from 5 N to 2 N, a 60 percent loss of grip force, even as the estimator reports high statistical certainty in its original value.



The reported force holds at 5 N while the true force slides to 2 N.

The downstream controller responds to this false certainty by regulating joint torques to maintain what it believes is an optimal 5 N clamping force. If the workpiece requires substantial friction to resist gravity, the actual 2 N contact load allows it to slip from the jaws, even as telemetry shows the grip force sitting exactly on target. Standard filter monitoring cannot catch this failure. The estimator evaluates its innovation sequence (the residual formulation of section 9.2), comparing each incoming measurement $y(t)$ against its predicted observation $\hat{y}(t)$. Throughout the entire drift sequence, the estimator predicts $\hat{y}(t) = \hat{x}(t) + \hat{b}(t) = 5$ N, which exactly matches the incoming sensor reading $y(t) = 5$ N. The innovation $\nu(t)$ evaluates to zero at every sample step. An innovation check tests only whether new sensor data conflicts with the model's forward projection; it cannot expose

errors aligned with an unobservable subspace where the sensor output remains entirely invariant to physical state drift.

Restoring observability requires system designers to introduce an external constraint that breaks the symmetry along the unobservable subspace. An engineering architecture accomplishes this in one of three ways. First, independent sensing can introduce a secondary measurement channel governed by distinct failure physics, such as monitoring joint motor drive currents or optical deflection sensors that do not share the strain gauge's thermoelastic drift. Second, the machine can execute deliberate physical excitation. After securing the workpiece with an external fixture, the arm commands the gripper to break contact briefly for 40 ms, establishing a known zero-force boundary condition ($x(t) = 0$ N) where the raw telemetry directly exposes the sensor bias $b(t)$. Third, the machine can rely on periodic external anchoring, bringing the end-effector into contact with a calibrated reference load cell during scheduled tool-change routines to zero the bias estimate. The mobile manipulator's base already depends on this third remedy. Wheel odometry leaves its longitudinal position along the aisle unobservable, and only the map-based corrections of section 9.5.1 supply the missing spatial constraint. When no admissible excitation separates two states that call for different responses before the machine must act, and no added channel is available, the states are observationally indistinguishable and no model on that channel can tell them apart. Section 18.3.4.1 develops this limit and the operating restrictions it forces.

When a physical state cannot be constrained through complementary sensing or active excitation, the estimation layer must treat that state as unobservable and refuse to publish unwarranted precision. The software interface must either mark the affected state dimensions as invalid or inflate their uncertainty bounds based on the hardware's worst-case physical drift rate, overriding the artificially contracted covariance generated by the filter. Formal observability analysis provides the mathematical foundation for identifying these blind spots. Classical linear state-space formulations originate with Rudolf E. Kalman (1960), while nonlinear extensions establish differential observability rank conditions on the Lie derivatives of the observation field (Hermann and Krener 1977). Systems engineers do not recompute these differential rank conditions in real-time control loops. Instead, the design task is to identify during system modeling which operating regimes lose observability rank, ensuring that runtime state estimators never claim statistical convergence along an unconstrained physical dimension.

Deterministic observability establishes whether system dynamics and sensor equations can distinguish trajectories over time, independent of stochastic noise assumptions. Nevertheless, practical estimator convergence and calibrated covariance bounds demand further conditions: accurately identified kinematic parameters, persistent trajectory excitation, and well-characterized sensor noise statistics. A manipulator trajectory can, for instance, leave a required state direction unconstrained by the available measurements; this estimator observability condition must be checked separately from the arm's kinematic singularities. Robust physical AI systems therefore deploy runtime monitors that track the validity conditions of each estimator. These watchdogs cross-check redundant sensing channels, track kinematic condition numbers, and enforce re-zeroing schedules. While runtime monitors cannot guarantee the truth of every modeling assumption, any detected violation must immediately invalidate the dependent state estimate. When an estimator explicitly revokes its own confidence, downstream controllers can transition cleanly to a validated fallback policy. An estimator that invalidates its own output fails safely and visibly; the dangerous failures in physical AI occur when an estimator reports tight confidence along an unobservable manifold, silently blinding the controller to physical reality.

↪ The Kalman and Hermann-Krener observability rank conditions are developed in section B.8.

9.9 Spatial Belief Failure Modes and Map Corruption

The failure modes of spatial memory rarely announce themselves with operating system exceptions or kernel panic logs. When a corrupted pointer or segmentation fault halts a process, the failure is loud and immediate, even if bringing the physical mechanism safely to rest requires dedicated fallback hardware. In contrast, spatial memory failures are quiet and deceptive. The memory subsystem continues publishing well-formed, syntactically valid data structures at high frequency, while the geometric coordinates inside those structures have parted ways with physical reality.

This divergence exposes the **middleware QoS mirage**, the memory-side counterpart of a limit section 4.3.2 established for transport, where no middleware setting could stand in for the chunk

lease. DDS-based robotics middleware, including ROS 2, provides Quality of Service (QoS) policies such as `Deadline` and `Liveliness`. These policies monitor declared message intervals and publisher liveliness assertions, not the physical truth of the payload. If an upstream camera driver deadlocks or an object tracker loses its target while a republisher continues sending its cached matrix and satisfying those communication contracts, the policies need not report a violation. Physical evidence validation must therefore accompany transport monitoring; otherwise frozen transforms, stale state-store entries, and phantom tracks can reach motor controllers as apparently healthy data.

Consider a camera that abruptly stops delivering frames while an intermediate transport node continuously republishes the last calculated transform under fresh timestamps. A downstream controller with a 5 ms publish-time freshness check accepts every message without protest. The scenario separates two kinds of failure in an embodied system. In a **loud failure**, a component crashes, halts execution, drops network packets, clears an output buffer, or asserts an explicit hardware error bit. Downstream consumers detect these faults through explicit validity flags or bounded stream timeouts. Avoiding harm then requires a qualified fallback (dynamic braking, position hold, or compliant impedance control) whose detection and response delays fit the remaining physical margin. In a **silent failure**, the spatial memory subsystem continues publishing structurally complete, numerically well-formed state records with valid status bits, low covariance flags, and monotonically increasing timestamps, even as the coordinates within those records drift away from the physical machine. Downstream control loops consume these corrupted records without raising an exception, closing feedback loops around phantom geometry. Physical actuators execute commands derived directly from these plausible yet false trajectories, such as driving an arm toward a target that now intersects a wall. Silent map corruption can therefore cross the causal boundary and inject destructive forces into the environment long before any software monitor registers an anomaly.

When an upstream sensor halts entirely, the timestamp anti-pattern of section 9.4 manifests as the **frozen transform**. This represents one of the most deceptive silent failures in embodied robotics because republishing a stale spatial snapshot with updated transport timestamps masks a dead sensor. In an illustrative timeline on the mobile manipulator, the wrist camera's tracking pipeline computes the target object's transform $\mathbf{T}_{\text{camera}}^{\text{object}}$ at timestamp $t_0 = 0$ ms. If the optical sensor subsequently disconnects, drops frames, or suffers thread starvation at $t = 10$ ms, the tracking algorithm ceases to produce new spatial evidence. If the message-passing middleware or an intermediate transport node retains that last computed matrix in an unexpired buffer and republishes it at 1,000 Hz, generating a synthetic transmission timestamp $t_k = t_0 + kT_{\text{rep}}$ with period $T_{\text{rep}} = 1$ ms, it erases the temporal provenance of the original measurement. A downstream tracking controller verifies freshness by computing data age as $\Delta t = t_{\text{current}} - t_{\text{msg}}$. Because the republisher stamped the message with the current system clock, Δt evaluates to less than 1 ms, satisfying the freshness threshold of $t_{\text{age,max}} = 5$ ms. The controller consumes the transform as current evidence. If the mug rides the pick-station conveyor at 0.20 m/s while the reported transform remains static, the controller accumulates 20 mm of spatial tracking error in 100 ms. This exceeds the 15 mm grasp tolerance, yet the estimator reports zero estimated tracking divergence.

Fresh stamps on a dead camera pass the age check while the error reaches 20 mm.

Phantom-object tracks arise when an estimator decouples the lifetime of spatial coordinates from the lifetime of existence evidence. Target tracking literature has long treated existence as an independent random variable alongside spatial kinematics: integrated probabilistic data association carries an explicit existence probability that updates with every sensor scan (Mušicki et al. 1994). Modern learned trackers implement this separation in different ways. ByteTrack pairs object detection with a Kalman motion model, maintaining unassociated tracks in a grace buffer across a fixed window of missed frames (Zhang et al. 2022); query-based architectures like MOTR persist learned object queries across successive video frames (Zeng et al. 2022). In either design, when an object is occluded or removed from the scene, the tracker enters the coasting state of section 9.2.2 and continues propagating its state vector $\mathbf{x} = [\mathbf{p}^\top, \mathbf{v}^\top]^\top$ under an open-loop motion model. If retention rules are overly generous, the estimator maintains a persistent phantom entity in the state store. The path planner routes the manipulator around empty space, or an automated grasping routine closes its fingers on vacuum. Conversely, evicting an occluded obstacle prematurely creates a severe collision hazard when the arm sweeps through the physical space. Resolving phantom tracks requires moving beyond passive measurement absence or arbitrary heuristic timeouts to active negative evidence

(section 9.6). When a line-of-sight sensor ray sweeps the candidate volume and encounters zero density, raymarching actively evicts the phantom obstacle from the 3D state store as soon as line of sight confirms clearance. In manipulation, unfulfilled contact expectations (such as zero load at a predicted contact boundary) immediately trigger physical hypothesis invalidation.

Coordinate frame misattributions divide along a similar boundary between syntax and semantics. A **schema-detectable frame mismatch** occurs when a publisher supplies a malformed frame identifier or a value outside a declared frame enumeration. Static schema enforcement can reject that packet at the serialization boundary. However, a well-formed identifier can still name an undefined link in the transformation tree graph. Resolving an otherwise well-formed identifier against the current transform tree requires a frame-aware validator or consumer; the transport schema alone does not establish that the named parent link exists. In contrast, a **semantically wrong frame assignment** occurs when an engineer or configuration file assigns a valid, type-correct frame identifier that represents the wrong physical link. For example, commanding the mobile manipulator's fingertip trajectory using the transform of the arm's bare mounting flange $\mathbf{T}_{\text{flange}}$ instead of the gripper's tool tip $\mathbf{T}_{\text{tool}}$ satisfies every schema validation check, type assertion, and tree traversal test. In an illustrative setup with a tool tip 150 mm beyond the flange along the tool z-axis, a flange-as-tip error shifts the intended contact point by that offset. Whether contact occurs depends on the fixture geometry and admitted path. Detecting a semantic frame error requires physical consistency checks, such as verifying measured motor torques against an analytical dynamic model of the arm, or cross-referencing multi-camera optical tracker observations against joint encoder kinematics.

When sensor updates drop out, an estimator relies entirely on its predictive forward model to advance state estimates across the blind interval. A well-formulated filter propagates the mean state estimate $\hat{\mathbf{x}}(t)$ and covariance $\mathbf{P}(t)$ under its stated dynamics and process-noise model. The worked drift model grows position uncertainty during the gap; general covariance propagation need not be monotonic in every direction. An **overconfident predictor** understates process variance $\mathbf{Q}$, holding $\mathbf{P}(t)$ artificially compact over an extended prediction duration, such as beyond an illustrative 200 ms. When fresh sensor measurements eventually arrive, the artificially small covariance causes the filter to discount incoming observations; it weights its internal dead-reckoning so heavily that it classifies valid measurements as statistical outliers and rejects them. Engineers identify overconfidence during system qualification by executing staged synthetic occlusions, dropping sensor frames for a range of intervals and evaluating the innovation ν at reacquisition against the covariance $\mathbf{S}$ the filter predicted for it. These are the NIS and NEES tests of section 9.2.1 applied at the end of a gap rather than in steady state. Averaged over the staged trials, the NIS at reacquisition, and the NEES against ground truth, must fall inside their chi-squared acceptance intervals (Bar-Shalom et al. 2001), and an average above the interval indicates an overly optimistic process noise model. Drift along an unobservable degree of freedom, such as workpiece slippage inside compliant gripper pads, produces no reacquisition residual at all (section 9.8). At vehicle scale, a terrain belief stands until the wheels themselves contradict it.

War Story 9.1: A rover trapped in sand (2009)

Context: By 2009 the *Spirit* rover had been driving for three years with an inoperative right-front wheel drive, dragging the dead wheel behind it as it drove backward on drives planned by operators on Earth. In the valley west of Home Plate, at a site the team named Troy, it drove onto soil that looked like the ground it had already crossed (Arvidson et al. 2010).

Mechanism: A thin sulfate-rich crust covered loose sulfate and basaltic sand. The surface's appearance, which is all that orbital and rover cameras observe, carried no information about the shear strength underneath. Climbing soil-covered slopes on five working wheels already produced high slip, and at Troy the wheels broke through the crust and excavated the sand beneath instead of advancing the chassis (Arvidson et al. 2010).

Impact: *Spirit* became embedded in late April and early May 2009. Months of extrication attempts, rehearsed on an Earth testbed, failed, and in January 2010 the mission redesignated the rover a stationary research platform.

Response: Slip detection already existed. Visual odometry, which compares the rover's tracked motion with its commanded wheel rotation, had been used on both rovers to measure slip and stop drives when it exceeded a limit (Maimone et al. 2007). That measurement bounded how deep each drive could dig once slip appeared, but it could not warn before the wheels broke through.

Systems lesson: Traversability inferred from appearance does not observe the property that matters, the soil's strength, so a stored traversability belief can be well formed and wrong. Slip is the physical residual that exposes it, and the belief must expire the moment that residual departs from its bound.

Frozen transforms, phantom tracks, misassigned frames, and overconfident predictors each demand distinct validation checks. The belief record of section 9.3 makes their provenance, age, frame, and growth assumptions available to consumers; independent physical checks still have to establish whether those claims hold. The filled record below collects those obligations for the latch-slot finger and the moving mug.

9.10 The Belief Record Schema

The belief record introduced in section 9.3, the seventh record in the record chain, binds each state estimate to its capture epoch, coordinate frame, and error-growth law so that downstream controllers can catch a frozen transform, a chimeric frame chain, or a prediction that has outlived its slot tolerance. This schema unifies discrete tracked entities and continuous volumetric representations (table 9.2) under one set of time and error rules, serving both trajectory planning on the host and bounded local permission checks on real-time microcontrollers. From the observation contracts established in section 8.8, the record inherits the raw sensor capture epoch, clock identifier, and hardware conversion bound. For differently constrained state components, it preserves separate evidence epochs or a conservative shared epoch and growth bound, as required by section 9.4. With these fields, the safety permission controller translates the sensor's capture timestamp into its own local monotonic clock with bounded synchronization error before evaluating evidence age. Persistent memory contributes five fields of its own. An estimate epoch dates the propagated state without renewing physical evidence. An uncertainty-growth bound projects error expansion across blind intervals. A validity region defines the operating envelope where that bound holds. The record also carries a physical invalidation deadline. Finally, a query-work allocation is set to at most 2 µs per local collision query in the reference design, and it becomes a justified execution bound only after qualification on the chosen hardware. Across its lifetime, each record moves through the four-state lifecycle of figure 9.12, whose guards enforce two rules. Only fresh evidence returns a record to `VALID`, and leaving `UNOBSERVABLE` also requires restoring the missing physical constraint.

The transitions enforce strict physical invariants across the spatial cache:

1. `VALID` → `DEGRADED`: Occurs upon sensor occlusion or field-of-view exit when direct measurement ceases, but the declared growth law still supports the task. Downstream consumers expand safety margins according to that law: stochastic models require calibrated coverage percentiles, whereas bounded-disturbance models enforce worst-case physical limits.
2. `DEGRADED` → `EXPIRED`: Occurs deterministically when projected uncertainty breaches task tolerance ($E(\Delta t) \geq r_{\text{tol}}$) or operating conditions leave the declared validity region. The entry immediately ceases to support dependent motion commands. Safety controllers must always reserve a feasible fallback trajectory in advance, because invalidating a software record cannot arrest physical momentum.
3. `ANY` → `UNOBSERVABLE`: Occurs immediately when physical observability rank collapses, such as unconstrained sensor bias drift under thermal changes or mechanical slippage along unmonitored degrees of freedom.
4. `ANY` → `VALID`: Requires fresh physical evidence ($t_0 = t_{\text{fresh}}$), innovation residuals passing gating checks, and revalidation of the dynamic model within the operating regime. Returning from `UNOBSERVABLE` additionally requires a restored physical constraint that resolves the rank deficiency; acquiring another ambiguous sample from the unconstrained sensor is insufficient.

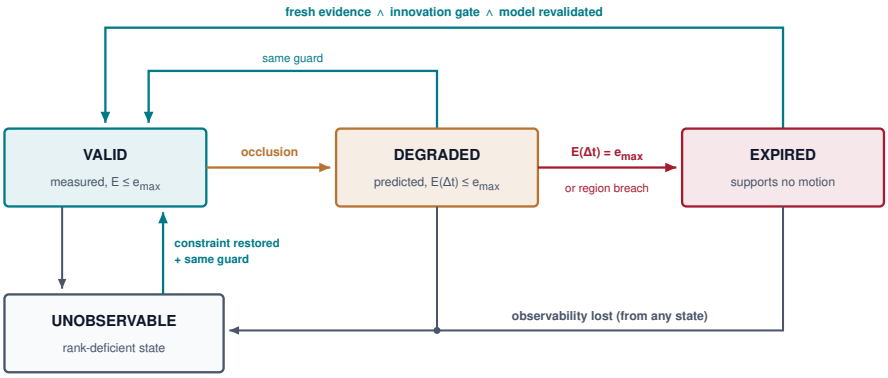


Figure 9.12: Spatial belief state machine and transition invariants: Each state carries its invariant inside the box and each edge its guard. Occlusion moves a record from VALID to DEGRADED, where the error bound grows under the declared law, and the bound reaching r_{tol} or a breach of the validity region moves it to EXPIRED. Every edge back to VALID passes the same evidence guard, so freshness alone cannot restore observability and extrapolation cannot renew validity; leaving UNOBSERVABLE also needs the missing constraint restored.

A belief record can never transition from `DEGRADED` or `EXPIRED` back to `VALID` through predictive extrapolation, autoregressive rollout, or software republishing.

Table 9.5 instantiates this schema for the latch-slot finger as a concrete bounded-disturbance belief record, and the prose that follows pairs it with the linear-drift record for the moving mug handle. Together, the two records show how the same fourteen fields accommodate both accelerating manipulation errors and constant-velocity transport bounds.

Field	Example record value	Consumer check

Table 9.5: Belief record: Value, unit, entity, frame, two epochs, clock conversion, error model, validity region, expiry, query latency budget, provenance, and lifecycle travel together as the seventh record in the record chain. A later estimate epoch dates the represented state, not a new measurement, and cannot extend expiry past $t_0 + T_{\text{inv}}$.

Field	Example record value	Consumer check
Entity and quantity	Gripper finger relative to the latch-release slot, lateral offset from the slot centerline	Match the target entity and task quantity
Value and SI unit	Lateral offset, stored in meters; the bounds below are shown in millimeters for reading	Decode as meters, not millimeters or force
Frame	`latch_slot` frame, with the transform revision of the wrist-camera calibration	Resolve a time-valid transform chain
Evidence epoch	t_0, the last wrist-camera capture before the finger occludes the slot, on the wrist camera's capture clock	Preserve across prediction and republishing
Estimate epoch	Latest propagation of the offset, on the same capture clock	Date the propagated estimate; do not renew evidence
Clock conversion	Versioned $t_{\text{MCU}} = a t_{\text{capture}} + b_{\text{clk}}$, error at most 0.2 ms	Refuse if conversion expires; add error to upper age
Initial error	e_0 = 0.1 mm	Check the initial bound against calibration
Growth law	$E(t) = 0.1\ \text{mm} + (12\ \text{mm/s})\,t + \frac{1}{2}(50\ \text{mm/s}^2)\,t^2$	Compare at evidence age with the slot tolerance
Validity region	Arm acceleration and contact mode unchanged since t_0; drift and disturbance bounds above validated within this region	Expire immediately on a mode or residual-bound violation
Expiry	t_0 + 66 ms, where the growth law reaches the 1 mm slot tolerance	Refuse dependent proposals at expiry; reserve time for an earlier physical response
Provenance	Wrist-camera observation ID, calibration revision, estimator build hash	Match approved sources; hash is version provenance, not payload integrity
Lifecycle	`VALID` at capture, `DEGRADED` once the finger occludes the slot, `EXPIRED` at t_0 + 66 ms	Never restore `VALID` without fresh physical evidence
Map cell evidence, when applicable	Not used by this record; a map belief such as the rack-end cross aisle carries a per-cell capture epoch and free/occupied/unknown state	Check a validated conservative snapshot certificate covering every supporting cell; unknown stays unknown
Collision query budget	$t_{\text{query}} \leq 2$ µs (qualified local clearance and required gradient lookup)	Qualify at most 2 µs per local query and the full collision workload within its allocation

The same schema governs the target belief consumed during grasping, the six-degree-of-freedom pose of a mug handle as the container advances along a takeaway conveyor toward the robotic manipulator. This record anchors its pose in the robot base frame, registers its evidence epoch to the wrist camera's final pre-occlusion capture, and synchronizes clocks under the same 0.2 ms conversion bound. At capture, calibration limits initial pose error to $e_0 = 3$ mm. Its error-growth law differs from that of the latch-slot finger. Because the conveyor belt advances at a bounded velocity of at most 0.20 m/s without independent acceleration, unobserved positional drift accumulates linearly over time according to equation 9.15, reaching the 15 mm grasp tolerance at $t_0 + 60$ ms. That is the freshness deadline section 2.2 derived for this same mug, from the same numbers; what memory adds is that the deadline now travels inside the record, beside the evidence epoch it is measured from. The validity region requires that the belt run forward within this rated speed and that the mug remain upright and seated. Any operational violation (a conveyor stall, a speed surge, or a shock that tips the mug) expires the record immediately regardless of elapsed time. In the worked tracked-evidence model, an active visual tracker compensates the nominal conveyor motion, leaving residual belt slip as the declared growth term. The tighter horizon requires qualification of the tracker's initial error, capture-to-use age, and residual dynamics; frame rate alone cannot establish it. This is the tracked evidence horizon met in section 3.5.2 and carried into the intent lease in section 10.5.

Downstream consumers evaluate either record through an invariant admission procedure. The controller converts the sensor capture epoch to its local clock, adds the synchronization uncertainty margin to the elapsed age, verifies the lifecycle status and validity region, and evaluates the growth law against the clearance budget of the proposed trajectory. Continuous-field representations follow an equivalent procedure, evaluating local signed-distance or occupancy snapshots against spatial clearance bounds within their qualified query allocations. Passing this admission check admits the belief to the **separate permission decision**; it does not command actuator motion. When an updated record fails admission or expires, an active motion command may continue only until the expiry of the record on which it was admitted. If that expiry arrives before a refreshed record does, the real-time controller must commit to a verified fallback maneuver before physical margins are exhausted. Notebook 9.3 walks through this admission evaluation for the mug-handle belief.

Napkin Math 9.3: The admission margin

Problem: A trajectory proposal requests closing the gripper on the mug handle 35 ms after the evidence epoch, measured on the consumer's local clock. Does the spatial belief remain admissible for the grasp at that instant, and how much validity margin remains?

Variables:

- Initial error $e_0 = 3$ mm and conveyor speed bound $v_{\text{conv}} = 0.20$ m/s (both illustrative); grasp tolerance $r_{\text{tol}} = 15$ mm (chosen); expiry $T_{\text{inv}} = 60$ ms (derived from equation 9.15).
- Clock-conversion bound $\epsilon_{\text{sync}} = 0.2$ ms (illustrative) and execution age 35 ms (illustrative).
- Lifecycle `DEGRADED`, with validity region intact: the belt advances forward within nominal limits and the mug remains seated.

Math: The consumer charges the clock synchronization bound to the elapsed age, evaluates the growth law at this upper bound, and computes the remaining belief lifetime:

$$\Delta t_{\text{upper}} = 35 + 0.2 = 35.2 \text{ ms}$$

$$E = 3 \text{ mm} + 0.2 \text{ mm/ms} \times 35.2 \text{ ms} = 10.04 \text{ mm} \leq 15 \text{ mm}$$

$$60 - 35.2 = 24.8 \text{ ms}$$

Result: The belief passes admission at the stated instant, retaining 4.96 mm of clearance margin and 24.8 ms of belief lifetime; the limiting evidence-use age is 59.8 ms after the evidence epoch.

Systems insight: Belief admission supplies a time-bounded input to the separate motion-permission decision. No grasp duration has been supplied, so the limiting evidence-use age is not a guaranteed completion time. The motion controller must establish a feasible completion or fallback before physical margins are exhausted within the remaining 24.8 ms. If an external disturbance knocks the mug loose, the record expires immediately despite valid timestamps, because the physical system has breached the validity region for which the growth bound was derived.

Checkpoint 9.3: Belief expiry and the memory record

These items close the chapter's body: the epochs a record carries, the deadline that ends it, the states no estimator can recover, and the lifecycle and admission check that govern all three.

- ☐ **Epoch classification**: Distinguish the evidence epoch (t_0) from the estimate epoch (t_{est}) and publication epoch (t_{pub}). Why does stamping an estimate with its publication time conceal the physical error accumulated since capture?
- ☐ **Admission margin**: For the mug-handle record, why does the consumer add the clock-conversion bound to the elapsed age before evaluating the growth law, and what must the controller do with the remaining lifetime once admission passes?

- ☐ **Unobservable manifold hazards**: Explain why vanishing innovation residuals ($y - \hat{y} = 0$) fail to reveal sensor bias drift (such as thermal expansion from nearby actuators) along unobservable degrees of freedom.
- ☐ **State lifecycle state machine**: Trace the deterministic transitions between `VALID`, `DEGRADED`, `EXPIRED`, and `UNOBSERVABLE`. Why does renewing a record require fresh physical evidence, and why does recovering from `UNOBSERVABLE` require restoring an underlying physical constraint?
- ☐ **Belief record**: Enumerate the required fields of the belief record (the seventh record in the book's architecture), including hardware capture epochs, qualified collision-query allocations, and task-space validity regions.

9.11 Fallacies and Pitfalls

Evaluating a spatial memory architecture requires auditing how separate state beliefs interact across time, coordinate frames, and physical occupancy. In physical AI, planning failures frequently occur when systems treat software records as static facts rather than time-decaying physical hypotheses. Two records can each be internally valid and fresh according to local timestamps, yet combining them without temporal reconciliation yields an inconsistent or hazardous model of the workspace. Before authorizing mechanical motion, a real-time controller must reconcile disparate sensor epochs, velocity bounds, and physical occlusion boundaries.

Pitfall: *Evaluating spatial clearance between moving bodies using asynchronous timestamps.*

In distributed robotics architectures and multi-sensor machine learning pipelines, visual perception introduces tens of milliseconds of latency across CMOS readout, PCIe DMA transfers, and neural forward passes. On the warehouse mobile manipulator, the chunk policy's inference pass alone, including the vision encoder, requires an illustrative 40 ms at p99, even before sensor capture and bus transport are counted. Concurrently, the base IMU streams at 1 kHz and the low-level drive controller updates at 100 Hz. When an autonomous base drives toward a rack end at its 1.5 m/s drive limit while a coworker walks toward the base at the 1.6 m/s walking-speed bound, their relative closing velocity reaches 3.1 m/s.

Consider a favorable case in which the visual detection record is only 20 ms old, less than the inference pass alone takes, while the drive controller's odometry is current at 0 ms. If both estimates fall within the 593.75 ms aisle-ahead expiry window, both pass individual freshness checks. Differencing their coordinates directly, however, conflates two incompatible physical epochs. For this separate illustrative comparison, stipulate 200 mm of available separation. Subtracting the 50 mm localization bound and the 100 mm protective reserve leaves 50 mm for temporal mismatch. Projecting both velocity bounds across the 20 ms gap gives a conservative common-time displacement envelope of 62 mm, exceeding that slack. The sum-of-speeds envelope deliberately reserves both motions; it is not the exact residual displacement when odometry is already current. Even this favorable record-age case therefore fails the chosen conservative check. Freshness tests verify only single-sensor recency; they cannot certify joint safety across moving reference frames. The controller must propagate every spatial estimate to a shared evaluation epoch using calibrated growth bounds, or enforce a strict timestamp skew limit derived from available clearance margins. **Individually fresh records measured at disparate epochs cannot establish joint clearance between moving bodies.**

Architect's countermeasure: Project all moving candidate bounds to a unified evaluation epoch using validated velocity bounds, or bound maximum allowable timestamp skew from worst-case closing velocities and available clearance margins.

Fallacy: *Bounded spatial covariance proves that a physical entity still exists in the workspace.*

When a coworker or moving obstacle passes behind an occlusion, such as a warehouse rack, downstream trackers frequently suffer from phantom track divergence. An autoregressive state predictor or Kalman filter continues extrapolating the entity's position along its last-observed velocity vector. If the filter configuration underestimates the process noise $\mathbf{Q}$, the predicted spatial covariance ellipse $\mathbf{P}_{pp}(t)$ remains deceptively compact and stays well below the track-pruning threshold. Motion

planners, interpreting this small covariance as a high-confidence localization, chart aggressive trajectories around the phantom track while treating the surrounding unmonitored space as fully accounted for.

This operational assumption conflates two orthogonal estimation metrics. The spatial covariance matrix $\mathbf{P}_{pp}(t)$ quantifies positional dispersion strictly conditioned on the hypothesis that the entity is present. It yields no guarantee regarding the marginal existence probability $\Pr(\text{exists} \mid \mathbf{y}_{1:k})$, which formal tracking theory formulates as an independent state variable (Mušicki et al. 1994). If the worker halts, reverses course, or leaves the aisle through a side doorway while occluded, the compact ellipse reflects only the open-loop momentum of the internal motion model. Spatial memory systems must explicitly decouple geometric state estimation from existence probability. Confirming or pruning occluded tracks demands active negative line-of-sight evidence, such as depth-sensor ray marching that shows an empty volume, or direct tactile feedback. **A compact spatial covariance ellipse reflects only conditional geometric dispersion under an assumed motion model, never the physical existence of an occluded entity.**

Architect's countermeasure: Decouple spatial state estimation from existence probability modeling, and require active negative line-of-sight raymarching or physical contact to confirm or retire occluded tracks.

Fallacy: *A voxel marked empty by a sensor ray remains traversable free space until an obstacle is observed.*

In 3D scene representations such as neural radiance fields (NeRFs), 3D Gaussian splatting, or static voxel occupancy grids, regions where rays encounter zero density or complete transmittance during an initial scan are frequently cached as permanently traversable free space. In dynamic warehouse and industrial environments, however, unobserved space is inherently non-static. Workers walk around blind corners, automated guided vehicles reverse into aisles, and access doors swing open without generating sensor returns in occluded sectors. Treating an unmonitored voxel as clear simply because a sensor ray traversed it seconds earlier is the **static world fallacy**.

Traversability represents a time-decaying physical hypothesis rather than an immutable geometric property. The certified safe depth within any unobserved region recedes continuously from its boundary, shrinking at the maximum velocity bound of dynamic agents that could enter it. The free-space erosion law in equation 9.13 establishes the precise operational lifetime of each clearance hull: $T_{\text{inv}} = (d_{\text{free}} - \delta_{\text{loc}} - \delta_{\text{margin}})/v_h$. Once this deadline passes, eroded voxels must revert to an unknown state, compelling motion planners and safety interlocks to treat them as potential hazards or bring the machine to a controlled stop. Beside the warehouse rack end, this validity deadline is 0 ms, so the claim lapses at the instant of capture. **Certified free space erodes continuously across occluded boundaries at the worst-case entry velocity of unobserved dynamic agents.**

Architect's countermeasure: Timestamp every free-space voxel with its `free_space_sweep_epoch`, build the conservative snapshot with unsupported space treated as obstacles through its independently validated support deadline, and enforce that deadline locally. Per-hull bounds from equation 9.13 may tighten use without charging an erosion already reserved in the field again.

9.12 Summary

Spatial memory begins with an estimator. In the worked drift model, prediction widens state uncertainty, while independent, synchronized measurement updates contract it. Fusing LiDAR returns with stereo depth estimates yields a tighter state estimate than either sensor can deliver in isolation, provided each measurement is registered at its true capture epoch. Applying a delayed measurement at the wrong epoch shifts the state mean while leaving its calculated variance artificially confident. In a real-time system, filter covariance represents a hypothesis about uncertainty rather than an empirical guarantee. Normalized estimation error squared (NEES) tests this claim offline against ground-truth trajectories, while windowed normalized innovation squared (NIS) tests monitor measurement-space consistency online under their independence and model assumptions. Innovation monitoring cannot replace capture-epoch validation or expose unobservable state error. Object tracking attaches identity and velocity to spatial clusters without delaying the raw occupancy evidence needed for emergency braking. When late measurements arrive, the estimator rewinds the filter to the capture epoch, incorporates the delayed correction, and replays state propagation back to the current execution cycle.

Spatial memory preserves the estimator's state across temporary sensing dropouts and occlusions, maintaining physical state independently of transient policy context. A complete belief record encapsulates the coordinate frame, evidence epoch (t_0), estimate epoch (t_{est}), error-growth law, and validity region required to evaluate remembered state. Kinematic forward models can propagate the represented state to a later estimate epoch (t_{est}), but the evidence epoch (t_0) remains anchored to the physical measurement that generated it. Coordinate transforms age like any other spatial belief. Composing a kinematic transform tree from edges sampled at mismatched epochs creates a synthetic pose the physical robot never occupied, with kinematic lever arms amplifying rotational skew into substantial position errors. Internal representations must directly match the queries executed on the critical path. A validated conservative Euclidean distance snapshot supplies a hull's clearance with eight geometric corner reads and fixed header checks at any pitch, which is why the permission controller's local snapshot is a distance grid. Rendering representations such as radiance fields and Gaussian splats can serve planning but cannot certify clearance. Downstream safety consumers must verify the supporting transform chain, validate cumulative error bounds, and check query execution budgets before admitting any remembered state into safety-critical gating decisions.

Belief expiry is governed by the task tolerance and a validated error-growth model. Free space erodes inward from unobserved boundaries at the maximum velocity of any hidden obstacle. Consequently, spatial memory certifies corridor clearance only to a depth dictated by those unobserved margins: 593.75 ms for the open aisle ahead, and zero usable clearance abreast of a blind rack corner, where the localization bound and the protective clearance consume the entire side gap. Odometry drift continuously widens positional uncertainty between map corrections, and pose-graph loop closures can shift the coordinates of remembered cells without renewing the physical evidence supporting them. Spatial memory introduces a hard deadline into the stopping budget, but it cannot synthesize missing distance; encountering an approaching pedestrian still requires qualified active-sensing crossing detectors or physical operational design constraints that eliminate blind encounters. On grid maps, only valid negative evidence, from direct and unoccluded line-of-sight rays, can substantiate a free-space claim. Neither a synthetic view rendered from a generative prior nor the periodic publication of an unchanged occupancy map can renew an occluded cell.

Superficially fresh data records can mask dangerous underlying staleness. A frozen transform node may broadcast at 1,000 Hz while repeating obsolete geometry, phantom tracks can mistake measurement variance for obstacle existence, and pipelining skews combine state vectors that never existed simultaneously in physical time. Worse, unobservable state drift evades innovation checks entirely when distinct physical configurations produce identical sensor returns. Under unobservable conditions, an estimator can drift silently while reporting zero residuals. Restoring system safety requires independent sensing modalities, deliberate motion excitation, or external spatial anchors before the filtered state can safely authorize machine action.

Across these stages, spatial memory turns dated sensor measurements into bounded, checkable claims about the surrounding world and retires each claim the moment its physical margin is spent. The chapter's estimation, representation, and expiry decisions rest on seven relations, which table 9.6 lists alongside the decision each settles and its derivation location.

Table 9.6: Key equations of spatial memory: The seven relations behind the chapter's estimation, representation, and expiry decisions, with the place each is derived.

Equation	What it bounds or decides	Derived
$\mathbf{P}_{k\|k-1} = \mathbf{F}\mathbf{P}_{k-1\|k-1}\mathbf{F}^\top + \mathbf{Q}$	How prediction propagates the estimate's uncertainty between measurements	equation 9.1
$\mathbf{G}_k = \mathbf{P}_{k\|k-1}\mathbf{H}^\top\mathbf{S}_k^{-1},\ \mathbf{P}_{k\|k} = (\mathbf{I}-\mathbf{G}_k\mathbf{H})\,\mathbf{P}_{k\|k-1}$	How much a dated measurement moves and narrows the estimate; valid only when the measurement is applied at its capture epoch	equation 9.2
$d_M^2 = \nu^\top\mathbf{S}^{-1}\nu \le \gamma_{\text{gate}}$	Whether a detection may be associated with a track; averaged over independent innovations, the same statistic tests measurement-space consistency	equation 9.3

Equation	What it bounds or decides	Derived
$\sum_{k=1}^{N_{\text{hulls}}} t_{\text{query}}(\mathbf{p}_k) \le T_{\text{reflex_budget}}$	The per-query time, including geometric reads and fixed validity checks, a clearance lookup may spend inside the permission tick	equation 9.7
$M_{\text{dense}} = (V_{\text{ws}}/r^3)\, s_{\text{voxel}}$	Voxel payload at a given pitch; full allocation also includes metadata, buffers, binary, and workspace	equation 9.8
$E(\Delta t) = e_0 + v_{\text{drift}}\Delta t + \frac{1}{2} a_{\text{dist}}(\Delta t)^2$	The bounded error of a belief propagated without new evidence	equation 9.12
$T_{\text{inv}} = \inf\{\Delta t \ge 0 : E(\Delta t) \ge r_{\text{tol}}\}$, free space: $T_{\text{inv}} = (d_{\text{free}} - \delta_{\text{loc}} - \delta_{\text{margin}})/v_h$	The deadline after which a belief supports no motion; for free space, how long remembered emptiness lasts at a given depth from the unobserved boundary	equation 9.14, equation 9.13

Key Takeaways: Evidence age and belief expiry

- **An estimator's covariance is a claim to test**: In the worked drift model, prediction widens state uncertainty while independent, synchronized measurement updates contract it. When updates arrive with misattributed timestamps, the filter contracts its covariance around an erroneous state. System architects validate filter consistency offline via normalized estimation error squared (NEES) against ground truth and monitor innovations online with windowed normalized innovation squared (NIS) tests under their independence and model assumptions. Innovation monitoring cannot replace capture-epoch validation or expose unobservable state error.
- **Occupancy precedes identity confirmation**: Reflex safety logic must act on raw occupied space immediately; an unconfirmed or tentative track must never suppress an underlying occupancy claim. When downstream decisions require confirmed semantic identity or velocity estimates, the system must account for multi-frame confirmation latency in its stopping budget. Deleting a lost track returns that volume to an unknown state rather than declaring it free space.
- **Prediction advances state, never evidence**: Kinematic extrapolation advances the state estimate (t_{est}) into the future, but the evidence epoch (t_0) remains frozen at the timestamp of the last physical sensor acquisition. Safety-critical physical claims must persist in explicit belief records with immutable evidence timestamps, even when higher-level neural policies evict their context tokens.
- **Representation follows the consumer's query**: Internal representations must align with the operational queries executed on the critical path. Validated metric distance snapshots support bounded collision clearance checks through geometric reads and fixed support-deadline, frame, and validity checks, topological scene graphs accelerate semantic target selection, and episodic logs enable task-level recovery. Storage footprint, cache update traffic, and worst-case query latency must all fit within the hardware tick budget.
- **Expiry follows the declared error model**: A spatial belief expires the moment its validated error bound $E(\Delta t)$ reaches the task tolerance r_{tol}. For continuous-time kinematic models, integrating acceleration white noise yields a variance term that grows cubically with elapsed time ($\sim \Delta t^3$). Translating this unbounded Gaussian dispersion into a probabilistic clearance margin requires calibrated coverage factors, whereas bounded disturbance models yield hard, conditional worst-case horizons.
- **Memory adds a deadline, not distance**: Free space erodes inward from unobserved boundaries at the maximum approach velocity of occluded obstacles. Consequently, memory certifies the clear corridor for 593.75 ms ahead of the platform, but offers zero usable clearance directly beside a blind corner, where the localization bound and the protective clearance consume the gap. When evidence expires, occluded voxels revert to an unknown state; only fresh line-of-sight sensor returns can renew a free-space claim.

- **Stale records look healthier than missing ones**: Stale data records frequently pass superficial health checks that outright message drops would fail: a frozen transform tree continues publishing, phantom tracks maintain low covariance, and unsynchronized consumers combine state vectors from divergent epochs. Uncompensated processing skew ($d_{\text{skew}} = v_{\text{close}} \Delta t_{\text{skew}}$) rapidly consumes physical safety margins unless every spatial input is projected to a common evaluation epoch before evaluation.
- **Unobservable error hides from innovation checks**: When sensor geometry leaves state dimensions unobservable, innovation residuals remain zero despite severe, unbounded physical drift. A misspecified filter that omits the ambiguous state can report shrinking uncertainty while the physical state diverges from its estimate. Restoring observability requires complementary sensor modalities, active persistent excitation, or external absolute anchors before the state estimate can safely authorize machine action.

The third law, proposal is not permission, requires the permission path to evaluate every proposed action against state data with an explicit, bounded age (principle 3). Spatial memory establishes this age. Elapsed time is measured from the evidence epoch t_0 of the raw physical measurement, never from the computational epoch t_{est} produced by kinematic extrapolation. Space that no valid ray has crossed has no evidence epoch at all, entering the permission pipeline as strictly unknown space. A verified age supports the safety argument only within a qualified error-growth model and feasible motion-response envelope; the permission path must reject the state at the exact deadline where that error bound breaches the task tolerance.

↪ The intent lease's expiry, which takes the belief record's expiry as its evidence term, is developed in section 10.8.

9.13 Historical Perspective and Further Reading

The state estimators at the foundation of modern spatial memory predate the mobile robots that rely on them. Rudolph Emil Kalman (1960) formulated the discrete-time recursive linear filter, establishing optimal estimation for linear systems subject to Gaussian noise. Within two years, Stanley Schmidt and his team at NASA Ames linearized the filtering equations about the running state trajectory to guide spacecraft navigation for the Apollo circumlunar mission (Smith et al. 1962), creating what is now known as the extended Kalman filter (EKF). Because Taylor-series linearizations introduce severe truncation errors when applied to highly nonlinear kinematics, Julier and Uhlmann (1997) developed the unscented transform, offering a derivative-free mechanism that propagates deterministic sigma points through the true nonlinear dynamics. In parallel, radar tracking research addressed measurement uncertainty in cluttered environments: Bar-Shalom and Tse (1975) introduced probabilistic data association (PDA) to resolve ambiguous target-to-observation assignments, while the statistical gating and consistency frameworks compiled by Bar-Shalom et al. (2001) provided rigorous methods to detect filter divergence. Control theory supplied the theoretical bridge to autonomy: Åström (1965) demonstrated that under linear-quadratic-Gaussian assumptions, a controller operating under partial observability can separate state estimation from control law computation and act directly on the conditional state distribution without loss of optimality. This separation principle justifies maintaining an explicit belief record in an embodied system.

Mobile robotics brought these recursive estimation techniques into unstructured environments. Moravec and Elfes (1985) and Elfes (1989) introduced occupancy grid mapping, projecting wide-beam sonar range returns into discrete spatial cells via probabilistic sensor models. While early robotic systems decoupled map building from self-localization, Smith et al. (1990) proved that errors in estimated robot pose and errors in stationary landmark coordinates are fundamentally correlated, formulating simultaneous localization and mapping (SLAM) as a single high-dimensional estimation problem. Over the following decades, surveyed extensively by Durrant-Whyte and Bailey (2006) and Cadena et al. (2016), SLAM matured from filtering frameworks into non-linear least-squares optimization over factor graphs (Dellaert and Kaess 2017), which decouple front-end feature tracking from back-end trajectory optimization. In parallel, volumetric surface representations migrated from computer graphics into physical AI pipelines. Curless and Levoy (1996) developed signed distance fields (SDFs) with weighted least-squares fusion to merge multiple range scans into coherent polygon meshes. With the arrival of commodity depth sensors, KinectFusion adapted this approach to run in real time on graphics hardware (Newcombe et al. 2011). Autonomous robotics then repurposed

these dense geometric structures for motion planning: OctoMap introduced hierarchically clamped octrees for compact volumetric occupancy (Hornung et al. 2013), Voxblox enabled incremental generation of Euclidean signed distance fields (ESDFs) directly from truncated signed distance fields (TSDFs) (Oleynikova et al. 2017), and nvblox ported these reconstructions to high-throughput embedded GPU architectures (Millane et al. 2024). To bridge geometric reconstruction and task-level semantic reasoning, 3D dynamic scene graphs now organize these dense metric representations into hierarchical abstractions spanning object instances, topological rooms, buildings, and moving agents (Armeni et al. 2019; Rosinol et al. 2020; Hughes et al. 2022).

Despite these mathematical and computational advances, classical mapping and estimation architectures leave one systems requirement unresolved, the explicit lifetime and epistemic boundaries of spatial information. Conventional estimators maintain state covariances, grid maps accumulate occupancy log-odds, and scene graphs categorize objects. Those ingredients must also be exposed and enforced as a consumer contract, coupling timestamped evidence, uncertainty growth under occlusion, and the temporal lease that limits each intended use. Downstream control processes, including trajectory generators, speed governors, and hardware safety monitors, require bounded guarantees on spatial validity. Automated driving systems approached this requirement by expanding reachable dynamic sets outward from the boundaries of sensor occlusion fields (Orzechowski et al. 2018). Spatial memory formalizes this coupling by binding evidence epochs, growth dynamics, and explicit validity leases directly to state estimates. By carrying its own temporal boundaries, a belief record enables hardware permission pipelines to revoke actuation authority before an expired belief causes an unsafe intervention or a physical collision.

The following foundational works provide detailed treatments of state estimation, map representations, and statistical consistency:

- Thrun et al. (2005) establishes Bayesian filtering, the Kalman and particle filter families, occupancy grid mapping, and SLAM within a unified probabilistic framework, serving as the foundational reference for recursive state estimation in section 9.2 and the volumetric map representations in this chapter.
- Bar-Shalom et al. (2001) serves as the definitive reference on target tracking and state estimation, establishing the mathematical foundations for statistical gating and the normalized estimation error squared (NEES) and normalized innovation squared (NIS) consistency tests deployed in section 9.2.1 and section 9.2.2.
- Julier and Uhlmann (2004) provides a rigorous mathematical derivation of sigma-point transformations, demonstrating why first-order Taylor series approximations cause extended Kalman filters to underestimate posterior covariance and become overconfident, which is the operational failure mode that filter consistency checks must catch.
- Cadena et al. (2016) surveys the evolution of SLAM systems as they transitioned from probabilistic filtering to factor graph optimization, detailing key open challenges in dynamic scene segmentation, semantic representations, and lifelong map maintenance summarized in table 9.3.
- Hornung et al. (2013) describes the OctoMap framework, formalizing a 3D probabilistic octree that pairs clamped log-odds updates with an explicit distinction between free and unobserved unknown space, a structural requirement for permission-grade spatial safety checks.
- Oleynikova et al. (2017) presents an incremental algorithm for constructing Euclidean signed distance fields directly from truncated signed distance fields on computationally constrained systems, providing the core representation adopted in this chapter for local metric snapshots.

What's Next: From valid beliefs to bounded goals

What may a valid belief authorize? Memory rules only on validity. It can say that a remembered object lies within a stated bound until a stated deadline, but it cannot say what the machine should do about that object. In the intent layer, a spoken request to take the mug from the conveyor must first be grounded to a feature the gripper can act on, the mug's handle, in the robot's own frame and units. Only then does it become an intent lease. The lease consumes the

belief record of that handle, carries that belief's evidence epoch forward as its own evidence time, and caps its expiry at that belief's horizon. It grants a bounded target with effort limits, never a path, for no longer than the evidence beneath it supports.

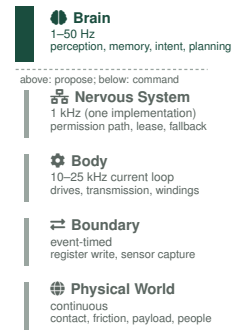
Purpose

Why is recognizing the right object insufficient to authorize a robot to reach for it?

A spoken request names an outcome, not a motion. Between the word and the grasp lie questions no label settles: which feature of the object to touch, where that feature sits in metric space, how hard to squeeze it, and how long the observation behind the answer stays true. A model can name the right object while misplacing its handle by more than the gripper tolerates, can locate it precisely a moment before a conveyor carries it away, or can report high confidence about the wrong object altogether. Once any of these answers becomes a coordinate it looks exactly like a correct one, and the drive that tracks it cannot tell the difference, so a machine that lets such a proposal command motion turns an error in meaning or timing into force against ceramic, glass, or a person. A learned target is safe to pursue only when it arrives bounded in space, effort, and time, with refusal available whenever the evidence cannot support it. Those bounds keep learned intent on the proposal side of the causal boundary, where a mistake can still be refused rather than delivered as motion that cannot be undone.



Learning Objectives

- Ground natural-language directives and symbolic task operators into metric affordance frames, continuous motion predicates, and verified geometric goal sets
- Emit the intent lease from parent belief records with explicit error envelopes, task tolerances, and effort ceilings
- Calculate intent lease expiry as the earliest of the evidence horizon, the administrative lease, and the stopping deadline
- Decide when grounding ambiguity or a wrong-object premise requires refusal rather than admission
- Evaluate terminal reachability within one evidence window, screen approach corridors against the forward occupancy of moving people, and select guarded, renewed stages for a longer approach
- Design hardware lease expiry that revokes motion authority even when the issuing process hangs or crashes

10.1 Grounded Affordances

An operator tells the warehouse mobile manipulator to "pick the red mug" from an active takeaway conveyor. The request names an outcome and leaves the grasp pose, approach velocity, contact force, and execution deadline unspecified. Spatial memory has already done its part by recording a belief about the mug's handle with an evidence epoch, an initial error of 3 mm, and a growth law. Under that law, the moving belt carries the handle outside the 15 mm grasp tolerance 60 ms after capture. Because that record says only where the handle is and how long the claim holds, it neither specifies what the machine may do with the handle nor authorizes actuator torque. **Intent** bridges this gap by binding the spoken request to an admissible, time-bounded physical goal that the motion planner can pursue.

↩ The belief record a lease consumes (evidence epoch, initial error, growth law) is established in section 9.10.

The reach does not stay inside the arm. On the running machine a slow intent model sits above a fast chunk policy that proposes base velocity and arm targets together in one whole-body stream (section 3.5.2). A wrong or stale mug target can steer the base as well as the wrist. What the permission path grants in answer to the request is therefore deliberately narrower than motion. It grants an intent lease (section 10.8), a record that names a target and effort ceilings but never a path. For the mug, the lease binds the parent belief record's digest and evidence epoch to a target pose in the handle's affordance frame, a goal region of spatial and angular tolerances around that pose, and ceilings on tool speed, acceleration, and contact wrench. Alongside those geometric and dynamic bounds, it records the motion predicates already validated, an expiration deadline on the safety controller's own clock, and the fallback that controller engages when the deadline passes.

Friction cones, force closure, and symbolic planners matter in this layer only because each supplies a field that the safety controller can check without re-running the upstream model: grasp mechanics fix the target pose, goal region, and wrench ceiling below; task operators (section 10.2) and open-vocabulary grounding (section 10.3) determine which predicates and error envelopes accompany a candidate target; and belief drift (section 10.5) paired with kinematic reachability (section 10.6) bounds the expiration deadline and dynamic limits.

This grounding step is where a learned model's output first turns into physical coordinates and contact limits that the robot can execute. Open-vocabulary object detectors, language models, and vision-language-action policies let operators specify manipulation tasks in plain words rather than through hard-coded skill libraries. What those neural networks emit, however, is only a statistical hypothesis, such as a bounding box, a semantic token, an uncalibrated point coordinate, or a chunk of normalized actions. An objective function that knows nothing of metric clearance, actuator torque limits, or physical time produced it. On the running machine, the division of responsibility is therefore strict: the learned Brain proposes candidate actions, and the deterministic permission path checks and admits them before any drive receives current.

↩ The proposal boundary and the permission path are established in section 1.7.

Before the permission path admits a proposed target for planning and execution, the target must satisfy three physical requirements:

1. *Metric physicality*: The target cannot remain a symbolic label; it must resolve to an explicit geometric feature carrying a six-degree-of-freedom pose, a gripper aperture, and a bounded contact wrench profile.
2. *Bounded error*: The proposal must include a certified spatial error envelope that fits strictly within the task tolerances and mechanical effort limits of both the manipulator and the workpiece.
3. *Temporal expiration*: Every target must carry an explicit evidence epoch, bounding its valid lifespan as target objects shift and sensory observations grow stale during compute cycles.

Every request traverses an explicit pipeline to meet these three requirements. Sensory perception resolves symbolic task operators into measurable physical predicates, and calibration transforms image regions into metric poses. The permission path then evaluates effort limits, evidence age, kinematic reachability, and dynamic obstacle clearances before committing the target to the motion planner. A vision-language-action (VLA) model (Brohan, Brown, Carbajal, Chebotar, Chen, et al. 2023) can propose the mug's target directly, but its deliberative inference loop is slow. The running machine's intent model executes at 2 Hz and requires 336 ms (derived in section 3.4.1) to autoregressively decode 7 target values. These values are a 3D position, a three-value orientation (which the producer converts to the quaternion the wire format carries), and an open-close gripper command. The machine therefore splits proposal across two speeds (section 3.5.2). The intent model names the target, and a smaller chunk policy streams motion toward it between intent inferences.

That split keeps the joints supplied with setpoints, but it does not keep the target true. If the conveyor moves while one intent inference runs, every chunk aims at where the mug was when the model's frame was captured. One inference outlasts the handle's 60 ms evidence window more than five times over. When target evidence expires between model inferences, the system must either switch to a high-rate local visual tracker or arrest motion entirely. Section 10.5 quantifies these expiration dynamics. Safe physical agency demands dated geometric evidence, explicit capability limits, and an autonomous permission path capable of revoking execution authority whenever the neural model lags or stalls.
